The VSM computes the vertical velocity profile based on the assumption of quasi-steady flow and the assumption that the flow is locally uniform in the horizontal plane. These assumptions follow from the different time and length scales in the nearshore zone. The time and length scales in the vertical plane are much smaller than the time and length scales for the horizontal pattern. Hence, the vertical profile will adjust much faster to changes in external conditions than the horizontal flow pattern.

Primary and secondary current

The description of the primary and secondary current is based on the concept of de Vriend and Stive (1987). Their approach will be outlined in short below.

The current can be split into a primary and a secondary current, according to the definition:

$$u = u_p + u_s \quad \text{with} \quad u_p = \bar{u}(x, y, t) f_p \left(\frac{z - z_b}{h} \right), \quad \bar{u}_s = 0 \quad (1)$$

with a similar expression for the velocity in y-direction. The suffix p denotes the primary

current, the suffix *s* the secondary current. From this definition it follows that the depth-averaged flow is determined entirely by the primary current.

After substitution of the definitions for the primary and secondary current into the Reynolds equations for turbulence-averaged flow and integration from the bottom to a point above the highest water surface elevation the primary current can be defined such that:

$$\frac{\partial}{\partial z} \left(\nu_t \frac{\partial u_p}{\partial z} \right) + \frac{\tau_{bpx}}{\rho_w h} = 0 \quad (2)$$

Here ν_t is the turbulence viscosity, τ_{bpx} is the bottom shear stress related to the primary flow, ρ_w is the mass density of water and *h* is the water depth.

For the secondary current a more complicated expression was found with contributions of different sources. For practical reasons only the secondary flow resulting from the vertical non-uniformity of the wave-induced forces is taken into account. To describe this wave-induced secondary current the water column is divided into three layers:

1. Surface layer, above the wave trough level
2. Middle layer
3. Bottom boundary layer

Next step in their approach was to reduce the description of the surface layer to its effects on the middle and bottom layer. The effects which should be accounted for are wave breaking and mass flux.

The effect of the wave breaking is taken into account by imposing an effective shear stress at the wave trough level. This representing the transfer of momentum across the wave trough level into the flow. This stress is given by:

$$\tau_{wave} = \frac{D_b}{c} \quad (3)$$

in which:

τ_{wave}	=	shear stress at wave trough level representing wave breaking
D_b	=	dissipation due to wave breaking
<i>c</i>	=	wave propagation speed

Non-breaking progressing waves cause an onshore mass flux above the wave trough level in the direction of wave propagation. Since there is no net flux this has to be compensated by an averaged velocity at lower levels that is opposite to the wave direction (undertow). The mass flux follows from:

$$m = \frac{E}{c} \quad (4)$$

in which:

<i>m</i>	=	mass flux
<i>E</i>	=	wave energy
<i>c</i>	=	wave propagation velocity

The equation for the wave-induced secondary flow could now be derived from the momentum equation for the middle layer and the expression of the primary flow. After some reduction the equation for the secondary flow in the relatively shallow breaker zone yields:

$$\frac{\partial}{\partial z} \left(v_t \frac{\partial u_s}{\partial z} \right) = \frac{\tau_{sxx} - \tau_{bxx}}{\rho_w (z_t - z_b)} \quad (5)$$

In which τ_{sxx} is the effective shear stress at the wave trough level, τ_{bxx} is the bottom shear stress related to the secondary flow, z_t the wave trough level and z_b the bottom level. Equation 5 can be solved with the integral condition of continuity which yields that the mass flux in the surface layer must be compensated by a return flow in the lower layers:

$$\int_{z_b}^{z_t} u dz = -\frac{m}{\rho_w} \quad (6)$$

Eddy viscosity model

Within DELFT3D the mean current profile in the remaining two layers is computed using an eddy viscosity model according to van Rijn et al. (1995). The viscosity is written as the product of a scale factor and a shape function. The distribution of the eddy viscosity is assumed to be parabolic in both layers and zero at $z = 0$.

Since there are different sources which contribute to the turbulence viscosity the VSM distinguished three limit cases for which the combined viscosity must reduce. These cases are:

1. Turbulence viscosity for purely slope-driven currents. In this case the distribution of the eddy viscosity is parabolic and zero at the bottom level and the water surface.
2. Turbulence viscosity for purely wind-driven currents. In this case a maximum is expected near the surface, so the eddy viscosity distribution is taken half-parabolic.
3. Turbulence viscosity generated by wave breaking. The distribution of in this case is assumed to be similar to that induced by wind stress.

Near-bed orbital velocity

The model of the time-variation of the near-bed velocity (orbital motion) is based on the concept described in Roelvink and Stive (1989). They suggested to split this oscillatory part of the near bottom flow, \bar{u} into a component varying on the time scale of the wave groups, u_1 and a component varying on the time scale of the individual waves, u_2 .

Assuming that $u_1 \ll u_2$, two contributions can be distinguished which contribute to the time-varying flow; non-linear short waves and long waves/short wave interaction. The contribution due to non-linear short waves is computed using Rienacker and Fenton's method (1981) for monochromatic waves while the contribution due to bound long waves is based on Sand (1982), and an empirical relationship for the phase of the bound wave relative to the short wave envelope.

In the transport model of van Rijn/Ribberink a complete representative time-series of the near-bed velocity is made. This time-series has the same characteristics of asymmetry, long waves and amplitude modulation. The method followed is outlined in DELFT HYDRAULICS (1995).

Continuity correction

Based on the concept outlined above the test case was applied to the Q3D model. From the first runs it appeared that a lot of sediment was transported by the secondary current in

offshore direction, creating a huge bar (see also left part of Figure 8). This was caused by the return flow which remains constant and at the same location in between full hydrodynamic runs (branch A in the model scheme). Since this enormous bar seems quite unrealistic the number of sediment transport steps was decreased which lead to better results. However, this results in higher computational costs since more hydrodynamic runs has to be carried out. Therefore it was suggested to update the undertow by the continuity corrections.

The secondary current is determined by eq. 5. From this equation it can be seen that the wave breaking-induced shear stress τ_{tsx} at the wave trough level is a very important parameter in the driving of the undertow. This parameter is defined by:

$$\tau_{tsx} = \tau_{wind} + \frac{D_b}{c} \tag{7}$$

with τ_{wind} is the shear stress at the wave trough level due to wind.

The effect of the decreasing water depth on the undertow can be taken into account by updating the wave energy dissipation D_b after each transport and bottom step. The wave energy dissipation is determined from the dissipation model of Battjes and Janssen (1978):

$$D_b = \frac{1}{4} \rho_w g Q_b \frac{H_{max}}{T_m} \tag{8}$$

with:

- H_{max} = maximum wave height according to Miche criterion
- T_m = mean wave period
- Q_b = fraction of breaking waves

Updating the wave energy dissipation improves the simulation of the waves breaking on the generated bar and result in a stronger undertow at these particular locations. When the wave action and the undertow are strong enough this will cause the bar to travel further downward the cross-shore profile and reduces the amount of sediment deposited at the same location. The resulting profile development with the improved model is shown in the right part of Figure 8.

It should be noticed that the wave height during the transport and bottom steps still remains constant. Since the wave height is needed to determine the fraction of breaking waves Q_b , the dissipation is still not updated completely.

Figure 8 Left: Profile development without updating return flow; right: Profile development with updating return flow.

6. Q3D results

Normal incident waves

Since the hydrodynamic results are the same for both the 2DH and Q3D model here the attention is focused on the sediment transport and bottom changes.

The initial sediment transport pattern is presented in the left part of Figure 9. Sediment is transported by the return flow in offshore direction, while the gyres in the lee of the breakwater transport sediment towards the centre line of the sheltered area. The resulting bathymetry after 100 hours of wave action is shown in the right part of Figure 9. A double salient is generated at the moment while the bottom profile in the exposed area is changed in a similar way as shown in Figure 8. The resulting bathymetry contains very irregular contour lines which affect the progress of the computation (disturbing effect on the flow pattern).

Figure 9 Left: Initial sediment transport pattern; right: Bathymetry after 100 hours.

Oblique incident waves

The initial sediment transport and resulting bathymetry after 100 hours is shown in Figure 9. The sediment transport pattern shows that the cross-shore sediment transport is still dominating over the longshore sediment transport. This seems to be one of the causes of the same irregularities occurring in the bottom contour lines.

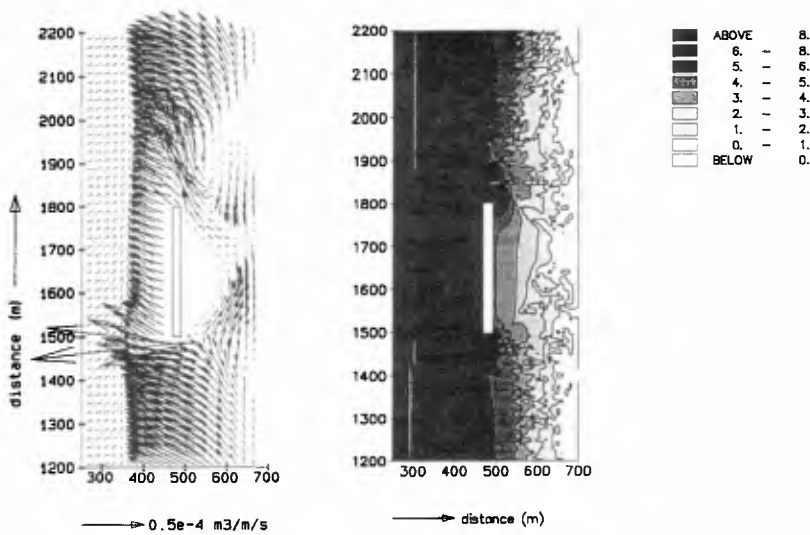

Figure 10 Left: Initial sediment transport pattern; right: Bathymetry after 100 hours.

5. Discussion

In Table 1 criteria for the formation of salients and tombolos, derived from laboratory and field data are given. From this table it can be concluded that most criteria pointed to the formation of a tombolo for the simulated test case. Based on these criteria it can be concluded that the 2DH model results show good qualitative agreement. With this model the equilibrium situation can approximately be simulated.

Reference	Criterion	Present case
Gourlay (1981)	$L_b/X_b \geq 0.67$ Tombolo	$L_b/X_b = 1.36$ Tombolo
Dally and Pope (1986)	$L_b/X_b \leq 0.5$ Salient $L_b/X_b \geq 1.5$ Tombolo	$L_b/X_b = 1.36$ Salient/Tombolo
Harris and Herbich (1986)	$L_b/X_b < 1$ Salient $L_b/X_b > 1$ Tombolo	$L_b/X_b = 1.36$ Tombolo
Suh and Dalrymple (1987)	$L_b/X_b > 1$ Tombolo	$L_b/X_b = 1.36$ Tombolo
Hanson and Kraus (1990)	$L_b/\lambda_b \leq 48(1-K_t)H_0/h_b$ Salient $L_b/\lambda_b \leq 11(1-K_t)H_0/h_b$ Tombolo	$\frac{L_b/\lambda_b}{(1-K_t)H_0/h_b} = 1$ Salient
Hsu and Silvester (1990)	$L_b/X_b > 1.33$ Tombolo	$L_b/X_b = 1.36$ Tombolo

Table 1 Criteria for the formation of salients and tombolos (L_b =breakwater length, X_b =breakwater axis-to-shore distance, K_t =transmission of the breakwater, H_0 =deep water wave height and λ_b =wave length at the breakwater)

The 2DH results with normal incident waves were also compared with other model results by Nicholson et al. (1996). From this comparison it was concluded that the area models are able to reproduce the major morphological features associated with offshore breakwaters. However, it also became clear that the choice of the sediment transport formula had a pronounced influence on the resulting morphology. This is also shown within this study by comparison between the sediment transport rates computed with the formula of Bijker and the formula of van Rijn/Ribberink.

Within this study the Q3D model has been improved so that the breakwater test case can be reproduced. From the results it is shown that the sediment transport by the undertow is a dominating feature in the initial state. However, since the prediction of the bathymetry contains very irregular contour lines, the equilibrium state can not be simulated until now.

CHAPTER 158

Evaluation of beach modelling techniques behind detached breakwaters

Philip Axe¹, Suzana Ilic¹ and Andrew Chadwick²

1 Abstract

This paper presents an evaluation of current design formulae for beach response to multiple breakwaters, comparing the predictions of the design guidelines with observations of beach response made during the large scale field experiment carried out at Elmer, on the UK south coast. The introduction describes typical shoreline response to breakwaters, the forcing mechanisms responsible and the characteristics of macro-tidal beaches. The remainder of the paper presents the empirical design tools, and the results of the evaluation.

2 Introduction

Detached breakwaters have been used for coastal protection throughout this century. Experience of the effects of such structures on macro-tidal beaches is limited however, and little information is available to design engineers on the response of coarse grained beaches to detached breakwaters. Salient and tombolo formation has been observed behind both natural and man-made coastal structures. Circulatory gyres in the lee of these structures, responsible for this planshape development, have long been observed (e.g. Sauvage *et al*, 1954). The forcing mechanisms responsible for these gyres have been identified as due to longshore currents set up by oblique breaking of diffracted waves, and also due to differences in set-up at the shoreline, due to longshore differences in wave height, again due to diffraction.

2.1 Shoreline response to single units

Shoreline response to single offshore breakwaters is dominated by the ratio of breakwater length to offshore distance. The influence of this ratio can be seen in the data collated in Hsu and Silvester's (1990) paper. This data is plotted in figure 1 as

¹ Researchers, ² Reader, School of Civil and Structural Engineering, University of Plymouth, PL4 8AA, United Kingdom

Figure 1. Ratio of breakwater length to breakwater-salient tip distance, plotted against breakwater length to offshore distance, collated by Hsu and Silvester, 1990

the ratio of breakwater length (L_s) to breakwater-salient tip distance ($X-S$), against the ratio of breakwater length to offshore distance (X). (A schematic diagram showing the meaning of the various dimensions is shown in the appendix. The data has been replotted in this way to illustrate clearly both the clarity of the relation, and also the spread of data, especially at higher values of L_s/X . This variability is not apparent in the original graph, where the data is fitted to a $1/x$ type curve.). This data is obtained from a variety of prototype schemes, physical models and a set of numerical tests (Perlin, 1979).

The importance of the ratio of L_s/X has been observed by many researchers, and forms the basis of several empirical prediction schemes. The exact shoreline response to a particular value of L_s/X is not definable, but in the literature, the onset of tombolo formation has been observed for values of L_s/X between 0.67 and 2.5, while salients begin to form for values between 0.5 and 1.5. No shoreline response is observed for values of L_s/X less than 0.5. Chasten *et al* (1993) presents a good review of the literature.

The uncertainty in predictions of shoreline response to single units is due to the combined influence of other factors, such as the size and availability of sediment, structural properties (such as the porosity- determined by armour and core sizes, and packing and freeboard, which control wave transmission) of the breakwater, and wave conditions (such as the directional spread of the incident wave energy).

2.2 Multiple breakwaters

For multiple detached breakwaters, the task of predicting shoreline response is more complex. In addition to the parameters controlling beach response described previously, the breakwater gap width has a major effect on the final beach plan shape. The gap width controls the amount of energy reaching the shoreline and thus available to drive longshore currents. The relative gap width (that is, the ratio of the gap width to the incident wavelength) also controls the way in which incident waves are diffracted, which in turn affects the currents responsible for the beach planform development. Where the gap is large compared to the incident wavelength, wave diffraction is considered to occur at the breakwater tip, and the breakwater may be considered to behave as an individual structure. Where the gap width is small, the diffraction appears to be from the centre of the gap, and the shoreline response to the two breakwaters can be considered to be governed by both breakwaters.

Previously, experience of detached breakwater design has been concentrated in micro- and meso-tidal regimes, such as Japan (see, for e.g., Seiji *et al*, 1987) the Italian Adriatic (Liberatore, 1992), the Spanish Mediterranean (Berenguer and Enriquez, 1988), or the Great Lakes (e.g. Pope and Rowen, 1983). The UK south coast is a strongly macro-tidal environment, and this has implications for detached breakwater design.

Current design guidance gives predictions of the still water shoreline position. In a macro-tidal regime, in order to maintain a suitable berm width under storm conditions, the design engineer is interested in knowing the high water shoreline position. Figure 2 highlights the problem, showing a 3D surface of a section of the Elmer frontage, with the shoreline positions at low water, mid tide and mean high water marked. It can be seen from this figure that at low tide, the breakwaters are above the water line, and only operate as the tide rises. The tidal rise increases the offshore distance of the breakwaters.

In addition to the varying geometry of the system, the changing water levels also affect the incoming waves. At lower tidal levels, waves are more likely to be depth limited, and the breakwaters lie within the surf zone. This condition is favourable to tombolo formation (Gourlay, 1987). At high water, the breakwaters are well offshore, and waves break straight onto the beach. The wavelength of an incoming wave is reduced at low water, which changes the relative gap width, which in turn is responsible for controlling whether the breakwater acts as a single unit, or as part of an array. The question that we want to answer is this:

'Is an equilibrium beach planform reached for every tidal level (in which case it would be simple to map the 3D morphology of the beach), or does the beach only come into equilibrium at the high and low water stands (where the rate of change in water depth is a minimum)?'

Figure 2 Positions of low water, mid tide and high water shorelines (solid black lines) at Elmer. All dimensions are in metres

2.3 Field Study

A field experiment, to study the shoreline response to a new set of breakwaters was devised and carried out at Elmer, between 1993 and 1995. Elmer lies on the UK south coast, 15 km from the western boundary of the Selsey Bill - Thames estuary coastal cell. The predominant drift direction along this coast is from west to east. The study site is the most seaward protrusion along an otherwise straight stretch of coastline, and has thus behaved as a headland area. In the winter of 1989, severe storms led to flooding of the residential hinterland. Works were planned, and constructed between 1992 and '93. These consisted of a 239,000 m³ beach fill along 2 km of frontage, stabilised by eight shore-parallel offshore breakwaters and a terminal rock groyne (described in Holland and Coughlan, 1993). A plan of the scheme is shown in figure 3.

The field work program provided wave data recorded simultaneously at the shoreline and offshore. Data was processed using common spectral and directional analysis routines. Beach surveys were taken concurrently with the wave data collection. Data was collected for at least one year, to avoid seasonal bias.

One wave recorder (a pressure transducer array described in Bird, 1993) was deployed 650 metres offshore, towards the western end of the scheme. This provided the incident wave conditions. At the shoreline, the Inshore Wave Climate Monitor (IWCM- described in Chadwick, Borges, Pope and Ilic, 1995) was deployed to provide directional wave conditions after the waves had been diffracted through the gap between breakwaters three and four.

Figure 3. Elmer frontage, showing numbering scheme for breakwaters, and levels of highest (solid line) spring, mid (dotted line) and lowest spring (dashed line) tides

Photogrammetric surveys of the beach were commissioned in collaboration with the local coastal protection authority. Aerial surveys provided overlapping colour prints, at a contact scale of 1:3000, of the coastline up to 2 kilometres east of the scheme, and 1 kilometre west. Profile data was provided along profile lines set in discussion with the local coastal protection authority. This gave 65 cross shore profile lines, and 4 longshore lines. Within the scheme, profile line spacing was 30 metres, with the exception of the instrumented area, where a line spacing of 10 metres was provided. Beyond the limits of the scheme, line spacing was 50 metres. The first survey was produced on completion of the scheme (September '93), and then on the following dates: 2 February '94; 29 May '94; 16 September '94; 29 January '95 and 16 May '95. Below the low tide limit, bathymetric data was obtained by an echo sounder survey. A summary of data collected is presented in table 1, and monthly averages of wave conditions are shown in figure 4.

Parameter measured	Method	Start date	End date	Data availability
Directional wave conditions (offshore)	Sub-surface pressure transducers	23 September 1993	14 January 1995	2776
Directional wave conditions (inshore)	Direct measurement by resistance staffs	5 October 1993	13 December 1994	1550
Wave induced currents	Electromagnetic current meters, float tracking	18 April 1994	24 April 1994	24
Beach profiles	Aerial survey	September 1993	May 1995	6 surveys
Beach samples	Direct sampling	April 1994	June 1995	22 samples

Figure 4. Monthly averaged wave conditions (offshore)

1 Evaluation of empirical models

Four models were selected for evaluation. These were : Pope and Dean (1986); Suh and Dalrymple (1987); Ahrens and Cox (1990); and McCormick (1993). Of these, Suh and Dalrymple and McCormick’s models provide values of salient length (Suh and Dalrymple) or of shoreline position (McCormick), whereas the Pope and Dean, and Ahrens and Cox models both describe the beach response in general terms.

The Suh and Dalrymple model is based on a set of physical model tests carried out in a spiral wave basin, and on prototype and model tests described in the literature. The equation presented to fit this data is:

$$S^* = 14.8 \left(\frac{G_B^*}{L_B^*} \right) \exp \left[-2.83 \left(\frac{G_B^*}{L_B^*} \right)^{\frac{1}{2}} \right] \tag{Equation 1}$$

where X_s is the salient length, G_B is the gap width, and L_B is the breakwater length. Characters marked with an asterisk represent values non-dimensionalized with respect to the offshore distance of the structure.

The McCormick (1993) model is based on the observation that bays formed behind detached breakwaters tend to be ellipsoid. This observation was based on aerial photographs, and on selected physical model data of Shinohara and Tsubaki (1966) and of Rosen and Vajda (1982). Validation for the model was carried out on four breakwaters within the ‘Bay Ridge’ prototype scheme in Chesapeake Bay. This model is more complex than the others studied. It is still based primarily on the ratio of offshore distance to breakwater length, but also includes the effects of wave steepness, direction and beach slope. These values are used to predict the size and locations of the ellipses that define the shoreline position. For the purposes of this

evaluation, the predictions of salient length were extracted from this information. The reader is recommended to read McCormick's original paper for details of the application of this model.

Pope and Dean (1986) proposed a system of classifying the effect of breakwater schemes in terms of their shoreline response. Beach response was divided into five bands, ranging from 'no sinuosity' through 'subdued salients', 'well developed salients', and 'periodic tombolos' to 'permanent tombolos'. The classification is based on the degree of protection afforded to a coastline (in terms of the ratio of breakwater length to gap length) plotted against the ratio of offshore distance to water depth at the structure. Preliminary results of a validation of this method were presented for low to moderate wave climates.

Ahrens and Cox (1990) followed the classification scheme proposed by Pope and Dean, defining a beach response index I_s . The index is defined below, in equation 2.

$$I_s = e^{\left(1.72 - 0.41 \frac{L_s}{X}\right)} \quad \text{Equation 2}$$

Values of I_s less than 1 predict permanent tombolo formation, while values greater than 5 predict no sinuosity. The method is based purely on the breakwater length and offshore distance, and therefore ignores any effects of variable gap width.

To apply these models to the Elmer site, the profile data and construction plans were analysed to provide information on the scheme geometry. Because of the interest in the ability of these schemes to predict beach response at varying tidal levels, measured salient lengths, offshore distances, beach slopes and water depths were extracted at 0.3 metre intervals, from the mid tide level up to mean high water springs (2.4 metres higher). This information was then used to drive the models, and the predictions were compared with the observed findings. Offshore distances of the breakwaters are presented in Table 2, while measured salient lengths are presented in Table 3.

Water level (over mean water level)	Break water 1	Break water 2	Break water 3	Break water 4	Break water 5	Break water 6	Break water 7	Break water 8

Figure 7. Elmer breakwaters plotted according to the classification scheme of Pope and Dean (1986)

Figure 8. Variation in breakwater index with tidal level, according to the classification scheme of Ahrens and Cox (1990)

4 Results

The model predictions from Suh and Dalrymple (1987) shown in figure 5, show excellent agreement between observed and predicted salient lengths at the lower levels- when tombolos occur. As the tide rises, this model predicts steadily increasing salient lengths. This is counter to the observed salient behaviour, but in line with the observations reported in Chasten *et al* (1993). The response predicted by McCormick's model (shown in figure 6) differs from this. Similar tombolo formation was predicted at the lower tidal levels. Salient length was predicted to decrease behind breakwaters 1,2,6 and 7, and predicted to increase behind breakwaters 3,4 and 8. In the case of breakwaters 1 and 2, this decrease in salient length improved the quality of the predictions, but for the other breakwaters, the predictions worsened at the higher tidal levels.

Figure 7 shows the predictions according to Pope and Dean's classification. Tombolo formation is only predicted to occur behind breakwaters 3 and 4, although the prediction of the limit between salient and tombolo for breakwater 3 is perfect. The limited shoreline response behind breakwaters 1 and 2 at high tide is also represented well, but tombolo formation at low water is not predicted. Figure 8 shows the effect of varying water depth on Ahrens and Cox's beach response index. Tombolo formation is predicted at mid tide behind breakwater 3,4,5,7 and 8. A tombolo does

not form behind breakwater 5 however, and the tombolos behind breakwaters 1 and 2 were not predicted to occur. As the water depth is increased, the transition from tombolo to salient is reasonably well described.

5 Discussion

From these results, it appears that the methods of Suh & Dalrymple, and of McCormick, work very well for describing tombolo formation, but do not appear to be as reliable when modelling salient formation. This may be due to a tendency to over predict salient lengths, which is a characteristic that would be masked when comparing these models with field tombolos. This tendency has been observed previously and reported in Chasten *et al* (1993). As a counter to this however, both models described the lower salient and tombolo formation behind breakwater 4.

The Suh and Dalrymple model was developed from physical model tests and prototype data where the gap widths between breakwaters was constant, and the beach response averaged across a scheme was evaluated. Where the gap widths are variable, as at Elmer, and individual salient lengths are required, the limits of applicability of this model may have been exceeded. Additionally, the study site is characterised by the bimodal nature of the beach. In the updrift west of the scheme, the tombolos are formed of sand, while the upper beach is gravel. In the (downdrift) east of the scheme, where the gap widths are wider, the tombolos are predominantly gravel. The formation of tombolos from finer material to the remainder of the beach leads to a difference in beach slope in the bays and on the tombolos. This in turn affects the rate at which parameters (non-dimensionalized against offshore distance) vary with depth. In the east of the scheme, this problem is less pronounced, due to the more uniform nature of the beach.

The more general predictors, of Pope and Dean, and Ahrens and Cox, were more successful in predicting beach response- due in part to the fact that as they only give general descriptions of a likely response. To illustrate this, it is clear that in figure 7, tombolos were not predicted to occur behind breakwaters 7 or 8. The observed response, shown in figure 3, is that tombolos formed. The response predicted by this method does however lie close to the limit of salient tombolo formation presented by Pope and Dean. Thus the predictions are reasonable. The prediction of the response to 3 and 4 was excellent. The method failed in the predictions of 1 and 2. As mentioned previously, the net drift direction at Elmer was from west to east, and this has led to an increased accumulation of material behind the first two breakwaters, that has not (yet?) been passed through the system. It may be supposed therefore that the Pope and Dean predictions are best used where longshore transport into a system is not significant, such as in a pocket bay, or indeed in the middle of a scheme of breakwaters. This failure to predict the beach response to breakwaters 1 and 2 also occurs with Ahrens and Cox's technique, although this method does succeed in predicting the tombolos behind breakwater 8 (and less well) breakwater 7.

6 Conclusions

From the comparison of the predicted and observed salient lengths during this exercise, three of the predictive schemes (Ahrens and Cox, McCormick, and Pope and Dean) were unable to predict the behaviour of the updrift breakwaters. This suggests that these techniques are not suitable for use where there is significant longshore transport into a scheme, which restrict their use to the design of pocket beaches, or to the central portions of multiple breakwater schemes, where net longshore transport is expected to be low. The robustness of the simplest technique (Ahrens and Cox) is surprising, suggesting that even in multiple breakwater schemes, the ratio of breakwater length to offshore distance is still paramount in determining shoreline response. This would seem to be contrary to other research (such as, for example, Hanson, Kraus and Nakashima, 1989), which suggested that wave transmission, for example, was an important parameter in determining shoreline response. The findings in this work are most likely to be a result of this evaluation being well within the range of applicability of the Ahrens and Cox method.

The inability of these methods to predict shoreline positions behind detached breakwaters does make them of less use to design engineers. To improve our design capability, physically based numerical process models, validated against field measurements, are needed before we can confidently develop 'rules of thumb' to simplify design.

7 Acknowledgements

The authors would like to express their thanks to Arun District Council and to the Hydraulics Engineering Research Unit of the University of Brighton for their help in this project. They would also like to thank Dr. P.A.D. Bird for his assistance in preparing equipment for the fieldwork stages of the project. The fieldwork was supported by the UK Engineering and Physical Sciences Research Council Grants GR/H 82969 and GR/H 74360. Data processing and analysis was financially supported by Arun District Council and SCOPAC, the Standing Conference on Problems Associated with the Coastline.

CHAPTER 159

Numerical Modelling of Bed Evolution Behind a Detached Breakwater

Philippe P  chon¹ and Charles Teisson¹

Abstract

The sedimentological impact of waves on a sandy beach with a detached breakwater is simulated using a compound system of models. The results are satisfying since a salient could be generated behind the structure. They are in agreement with bed evolutions surveyed in experimental facilities and in nature. A quantitative analysis of the results performed in the framework of the working group 'Coastal Area Modelling' of the project MAST G8M shows that the volume of accretion computed here is in good agreement with the volumes obtained by other models and empirical formula.

Introduction

A numerical system has been developed for simulating bed evolution due to breaking waves. Wave, current, sediment, transport and bed evolution are computed successively. Since the wave field is affected by sea bed changes, hydrodynamic phenomena are up-dated when bed evolution is significant. The system of models is illustrated on figure 1.

The three numerical models belong to the library TELEMAC based on finite element technic. They are coupled within an automatic procedure.

Comparisons of the numerical results with measurements in flume cases were carried out in the past. They gave satisfying results (Broker Hedegaard et al 1992, P  chon 1994), undertow as well as bed evolution were well predicted. Standard parameters were used for these simulations except for the sediment transport formula where the suspended load was increased in the surf zone to account for breaking effect.

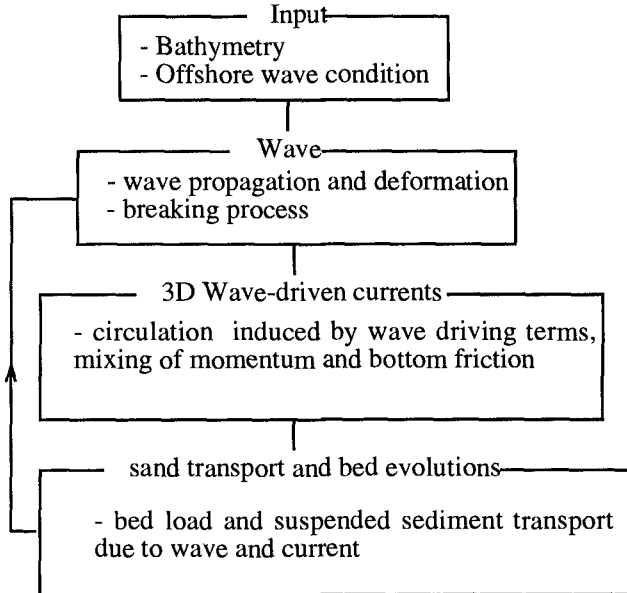

Fig.1 Structure of models

The present article deals with the application of the models on a three-dimensional case ; the impact of a detached breakwater built along a rectilinear beach is investigated. In a previous study (Péchon et al., 1995) the good agreement of computed currents with measurements collected in a basin (Mory and Hamm, 1995) was exhibited on the same but reduced scaled structure. Accurate data of seabed movement and wave climate are not available for the present full scaled test. However the effect of breakwaters is qualitatively known according to surveys in coastal zones, and the ability of models to reproduce realistic morphological changes can be checked. Moreover an intercomparison exercise with other modellers was performed (Nicholson et al 1995) in the framework of the European program MAST2 G8M.

The numerical models

The wave model

The model ARTEMIS V1.0 solves the complete mild-slope equations :

$$\text{div} (C C_G \vec{\text{grad}}\varphi) + \omega \frac{C_G}{C} \varphi = 0$$

with $C = w / k$ C : phase celerity

$C_G = \frac{1}{2} (1 + \frac{2kh}{sh 2kh}) C$ C_G : wave group celerity

φ : complex horizontal part of the potential

$$\varnothing (x, y, z, t) = Z(z) \varphi(x, y) e^{-i\omega t}$$

where $Z(z) = \frac{ch(k(h+z))}{ch(kh)}$

According to the rather schematised bathymetry tested here, the wave height decay in the surf-zone is given by the formula $H_b = 0.8 h$ where H_b is the breaking wave height and h the still water depth.

The radiation stress can be calculated knowing the wave potential. However this leads to a very irregular radiation stress field which has to be smoothen. So it is preferred here to express the driving terms in function of the dissipation of breaking waves.

The computed instantaneous wave velocity follows an ellipse, therefore there is not a simple incidence. In the following current and transport models, the required incidence is supposed to be given by the large axis of the ellipse.

The time-averaged current model

The model TELEMAC-3D V3.0 solves the time-averaged three-dimensional equations accounting for the vertical variability of the forces due to breaking waves and especially roller effect (Péchon 1994). They read, in the case of a flume for clarity :

$$\frac{\partial U^2}{\partial x} + \frac{\partial UW}{\partial z} + \frac{\partial(\overline{u_w^2} - \overline{w_w^2})}{\partial x} + \frac{\partial \overline{u_w w_w}}{\partial z} = -g \frac{\partial \xi}{\partial x} - \frac{\partial \overline{u'w'}}{\partial z} + t$$

$$\frac{\partial U}{\partial x} + \frac{\partial W}{\partial z} = 0$$

with U, W : time-averaged current due to breaking waves
 u_w, w_w : instantaneous wave velocity
 u', w' : turbulent fluctuations of velocity
 x : free surface level
 t : contribution of the roller of breaking waves

The overbar indicates time-averaged quantities.

The following closures are taken :

$$\frac{\partial(\overline{u_w^2} - \overline{w_w^2})}{\partial x} = \frac{1}{\rho h} \frac{D}{C} \quad \text{with}$$

$$\frac{\partial \overline{u_w w_w}}{\partial z} = \frac{1}{2\rho h} \frac{D}{C} \quad \begin{array}{l} D : \text{energy dissipation} \\ C : \text{wave celerity} \\ h : \text{mean water depth} \end{array}$$

$$\overline{u'w'} = -v_t \frac{\partial U}{\partial z} \quad v_t = Mh \left(\frac{D}{\rho}\right)^{1/3}, \text{ constant } M = 0.4$$

$$t = \frac{14}{\rho} \frac{D}{g HT} \quad \begin{array}{l} T : \text{wave period} \\ H : \text{wave height} \end{array}$$

The sediment transport model

The sediment transport is calculated by a satellite version of the numerical model TSEF V3.0 using Bailard formula (1981) in terms of the near-bed velocity field resulting from the previous model. The bed load and suspended load transport rates are expressed as :

$$\vec{q}_b = \frac{f_{cw} \epsilon_b}{\Delta g \operatorname{tg} \phi} \left[\langle |\vec{u}|^2 \vec{u} \rangle - \frac{\operatorname{tg} \theta}{\operatorname{tg} \phi} \langle |\vec{u}|^3 \vec{i} \rangle \right]$$

$$\vec{q}_s = \frac{f_{cw} \epsilon_s}{\Delta g W_s} \left[\langle |\vec{u}|^3 \vec{u} \rangle - \frac{\epsilon_s}{W_s} \operatorname{tg} \theta \langle |\vec{u}|^5 \vec{i} \rangle \right]$$

in which

\vec{q}_b bed-load transport rate m²/s

\vec{q}_s suspended load transport rate

f_{cw} friction factor wave+current

ϵ_b efficiency factor for bed-load transport $\epsilon_b = 0.13$

ϵ_s efficiency factor for suspended load transport $\epsilon_s = 0.024$

\vec{i} unit vector directed downslope

ϕ internal angle of friction of the sediment

W_s fall velocity

Δ apparent density

\vec{u} instantaneous nearbed velocity vector

$\operatorname{tg} \theta$ bed slope

$\langle \cdot \rangle$ time-averaged quantity

This formula is expected to give the transport rate inside and outside the surf-zone. The friction factor is adopted for the wave alone :

$$f_w = \exp \left(-6. + 5.2 \left(\frac{A_w}{k_s} \right)^{-0.19} \right)$$

with $A_w = \frac{H}{2 \sin kh}$ orbital excursion

$k_w = \frac{3}{D_s}$ roughness coefficient

D_s grain size diameter

In the present model the velocity \vec{u} is the summation of the time-averaged velocity and the instantaneous orbital wave velocity near the bed.

At the present state of knowledge, sediment transport formulae have broad correlation between predicted and observed values. Soulsby et al (1995) compared Bailard formula with data and they showed that only 57% of the predicted transport rate lay within a factor of 5 of the data. In the following application, it has been observed that the original formula overestimates the transport rate. So it is divided by 10 here, which is equivalent to increase the time scale.

Bed evolution model

The mass conservation of sand is also computed by the previous model which solves the equation for mass conservation of sediment.

Wave and current fields are updated when the bed evolution is greater than 0.5 time the water depth at 3 nodes of the mesh or 0.3 time at 10 nodes. In the following application this criteria occurs about every 30 hours.

Application

Description of the case

The domain of computation is presented on figure 2. At the initial time the bottom slope is 1:50 nearshore and the bed is horizontal offshore where the bottom level is -7.4 m.

The four lateral boundaries are closed for current and sediment transport. Only the offshore boundary is open for waves.

The generated wave at the offshore boundary is perpendicular to the shoreline. In the present model the wave is supposed to be regular, with a period of 8.0 s. The wave height is 1.2 m. The median grain size is 250 μ .

The mesh grid for wave computation contains 10500 nodes. It is refined in order to have at least 10 nodes per wave length. The horizontal mesh grid for current and sediment transport (fig 3) has 1450 nodes and each vertical profile has 9 nodes in the three-dimensional computation of currents.

Results

For the initial bottom, along a current cross-shore profile the wave height increases and reaches 1.6 m at the distance of the structure $y = -110$ m where the still water depth is -2.0 m (fig. 4), then it breaks. Wave pattern diffracts behind the structure.

In spite of the account for three-dimensional effects, the velocity field is nearly homogeneous over the water depth. In fact in this case the currents are mainly generated by alongshore gradient of surface elevation because the wave direction is nearly normal to the shoreline, and this gradient is constant over the vertical. The 3D effect would be stronger with oblique wave direction because the current would be also generated directly by driving terms with non-uniform vertical profile.

The near-bed velocity field displays a large eddy behind the breakwater (fig. 5). In the shallower part the intensity reaches 1.0 m/s whereas it is less along the structure in deeper part. In the open area the velocity field is very irregular because of variations of wave height. A cell takes place in the right hand side of the beach because of the closed boundaries at this corner. 2DV undertows are not

generated. The irregularities of the velocity field near the breaking line are due to the variation of the wave height in the longshore direction (fig. 4).

The resulting sand transport pattern displays very strong rate of $0.013 \text{ m}^2/\text{s}$ behind the breakwater in shallower water (fig. 6). Out of this area, the transport rate is very small except locally such as on the right hand side of the beach.

After 10 days of cumulative wave action, the accretion behind the breakwater is very strong, often greater than 2.0 m, creating a salient (fig. 7). The thickness of erosion in the bordering area is generally smaller, less than 1.5 m .

The wave, current and sediment transport patterns calculated with this new bathymetry are modified (fig. 8, 9 and 10). The wave field is more irregular. The velocities and transport rates behind the breakwater are more intense because of the reduction of the water depth. The cell seen initially on the right hand side of the beach creates disturbances which extends along the beach. The choice of constant wave conditions is probably responsible for this situation ; in prototype situation the variation of wave incidence for instance contributes to smooth bathymetry and avoid extension of such phenomenum.

Comparison with other models and available data

In a literature review reported by Moreno (1995), a similar case was mentioned. The shoreline evolution behind a detached breakwater with a normal wave was investigated in a wave tank (Rosen and Vajda 1982). The beach was built of coarse bakelite. In the computation, the offshore steepness H_0/L_0 is equal to 0.012 which is close to the experimental condition 0.015. The ratio of structure length on the distance from shoreline is 1.4 in the computation, 1.0 and 2.0 in tests 6 and 7 of the experiments.

In the experiments a salient is created behind the breakwater with one prominence in test 6 and two symmetrical prominences in test 7. Regarding the computed bed evolution after 10 days (fig. 7), the numerical modelling leads to formation of two salients (or one in the half-domain) as in test 7. However the immersed area was not measured in the basin, so it is not possible to go further in the comparison. Moreover the numerical modelling does not reproduce the stirring up of sand in the emerged part.

Watanabe et al (1986) also tested a detached breakwater in a experimental basin with movable bed. The beach was made of sand of 0.2 mm. In this test the wave breaks in deeper water than in the numerical simulation, roughly at the same distance offshore than the breakwater. According to the different conditions the numerical and experimental results cannot be superimposed. However it is seen that in intermediate water, the contourlines -3.0 m in the field case (fig. 7) and -6 cm in the basin for instance have the same curvature. In shallow water a prominence is created in both tests but the shoreline moves offshore just out of the lee of the structure in the basin whereas it is eroded in the same area in the field test.

After 15 days the volume of accretion behind the structure is equal to $23\ 000 \text{ m}^3$ according to the readjusted transport formula. This value is in good

agreement with other models of DHI, Uni. Liverpool, HR and STCPMVN developed in the project MAST2 G8M where it ranges from 21 000 to 29 000 m³ (Nicholson et al 1995).

It is noted that these two tests in experimental basins were not chosen for the present simulation because on one hand the transport formula of Bailard was elaborated for real life conditions and would not be appropriate for a reduced scale simulation. On the other hand the hydrodynamic results of the present simulation was already validated in a wave tank with fixed bed (Péchon et al 1995).

Conclusion

A compound system of models of the library TELEMAC have been developed in order to reproduce the refined evolution of the sea-bed in the surf-zone. In order to facilitate its use in practical applications, the codes have been coupled in an automatic procedure.

The sedimentological impact of waves on a sandy beach with a detached breakwater have been reproduced. The results are qualitatively satisfying since a salient have been generated behind the structure. They are in agreement with bed evolutions surveyed in experimental facilities and in nature. A quantitative analysis of the results performed in the framework of the working group 'Coastal Area Modelling' of the project MAST G8M shows that the volume of accretion computed here was in good agreement with the values obtained by other models.

Improvement of the models can be expected in the future by calculating instantaneous wave velocity field solving Boussinesq equations which include non-linear effects. Moreover Soulsby et al (1995) showed deficiencies of the transport formula compared with measurements. So further work is required for having a more reliable one.

Additional applications have to be done with this system of models in order to get experience and to appraise its limitations. More complex situations have to be investigated, for instance by accounting for tidal range.

CHAPTER 160

COMBINED DIFFRACTION AND TRANSMISSION OF WATER WAVES AROUND A POROUS BREAKWATER GAP

Xiping Yu¹ *and* Hiroyoshi Togashi²

ABSTRACT

An analytic method for the combined diffraction and transmission around a porous breakwater gap is presented. The method can be summarized as follows. First of all, it is necessary to decompose the incident wave into two components, according to the incidence angle and the permeability of the two breakwaters that form the gap. Then, let the breakwaters be completely transparent to the relevant component of the incident wave and ascertain the transmission field. Next, treat the breakwaters as solid to the other component of the incident wave and solve the diffraction field. Finally, superpose the transmission and the diffraction to give the objective wave motion. The available analytic methods for the diffraction by an aperture on solid wall are comparatively studied since they play the central role in working out the final solution of a real problem with combined diffraction and transmission. Sample computations are carried out for typical cases with both regular and irregular incidence. The computational results show that the phase effects of the porosity of the breakwaters on a combined wave field can be significant.

INTRODUCTION

Being constructed with rocks or concrete blocks in most of the engineering practices, segmented offshore breakwaters for the purpose of shore protection are usually of greater or lesser permeability. For this reason, it has long been a keen

¹Assoc. Prof., Dept. of Civ. Eng., Nagasaki Univ., 1-14, Bunkyo-Machi, Nagasaki City, Nagasaki 852, Japan.

²Prof., ditto.

interest of not only the scientific researchers but also the practicing engineers to have a good understanding on the effects of the permeability of a porous breakwater on the pertinent wave motion.

There exist possibly a few very different approaches to water wave problems with porous breakwaters involved. The one appeared to be relatively dogmatic is to isolate the region occupied by the porous skeleton and consider the details of the flow within the porous medium, which is in general of a complex picture and needs to be treated as viscous and turbulent. A solution of such configured problem also requires the relevant exterior flow to be matched with the flow inside the pores. Since both a straightforward look at the pore water flow and the matching procedure are extremely sophisticated, studies in the past decades, instead of dealing with Navier-Stokes flows, have been directed to modeling the effects of the porous skeleton on the fluid motion. There have been a few effective models based on such consideration established. The one by Sollitt and Cross (1972) and Madsen (1974), which includes both the resistance and the inertia forces exerted on the fluid by the porous skeleton, has indeed been applied to many practical problems.

Even with modeling, treatment of the flow inside a porous medium is still not easy at all. Practical solutions can only be obtained under very simplified conditions. This situation has motivated a more pragmatic approach that is to treat the surface of the porous structure as an absorptive or partial reflective boundary of the problem concerned. With this consideration, however, prescription of the amplitude and phase of the reflected wave relative to the approaching wave is necessary (Chen, 1986; Isaacson and Qu, 1989). Extension of the applicability of this approach thus requires continued efforts to establish highly accurate empirical formulas for the reflection coefficient and the phase trapping property of a structure with given porosity and known hydraulic conditions behind the structure.

The approach adopted in the present study is yet another one. It was originally proposed by Yu and Chwang (1994) and Yu (1995). As a porous breakwater is thin when compared to the local wavelength, the normal component of the seepage velocity through the porous body was noted to be proportional to the difference of the wave function at both sides of the breakwater. The proportionality coefficient is a function of the physical thickness, the porosity as well as the other properties of the porous medium and the wave.

The primary objective of the present study is to provide an analytic method for the combined diffraction and transmission around a porous breakwater gap. We shall try to find a method that takes advantage of the well established techniques for diffraction by a solid aperture. Emphasis will also be paid on the phase effects of the porosity of breakwaters.

Fig. 1. Definition sketch of a porous breakwater gap.

THORRY

Formulation

The physical problem is sketched in Fig. 1. Outside the porous breakwaters we adopt the conventional assumptions that the fluid is inviscid and incompressible, and moreover, the fluid motion is irrotational. The three dimensional wave field can then be represented by a scalar velocity potential ϕ that satisfies the Laplace equation. Let the waves of interest be sinusoidal with respect to time and be of small amplitude. Hence, we can express the velocity potential in the following form with the time and the vertical coordinate separated:

$$\phi(x, y, z, t) = F(x, y) \cosh k(h + z)e^{i\sigma t} \tag{1}$$

where σ is the angular frequency of the wave motion, k is the wave number, h is the water depth, x and y are the horizontal coordinates, z is the vertical coordinate, and t is the time. F , usually called the wave function, is complex-valued with its modulus proportional to the amplitude and its argument equal to the relative phase of the surface oscillation. It can be readily confirmed that Eq. (1) satisfies the impermeable bottom condition and also the free surface condition as far as σ , k and h are related to each other through the dispersion equation:

$$\sigma^2 = gk \tanh kh \tag{2}$$

where g is the gravitational acceleration. By substituting Eq. (1) into the Laplace equation for ϕ we can show that $F(x, y)$ is governed by the following Helmholtz equation:

$$\nabla^2 F + k^2 F = 0 \tag{3}$$

where ∇ is the horizontal gradient operator.

For the problem concerned in the present study the boundary conditions include the incidence condition, the radiation condition at infinity and a partial

transmission condition along the permeable breakwaters. The incident wave, long-crested and propagating in the direction that forms an angle α with the positive x -axis, can be described by

$$F_0 = A_0 e^{ik(x \cos \alpha + y \sin \alpha)} \quad (4)$$

where $A_0 = gH/2\sigma \cosh kh$ and H is the incident wave height. The partial transmission condition at the porous breakwaters can be written as:

$$\left. \frac{\partial F}{\partial y} \right|_{y=0+} = \left. \frac{\partial F}{\partial y} \right|_{y=0-} = -ikG(F|_{y=0+} - F|_{y=0-}) \quad (5)$$

where $G = \gamma/k\delta\{f - i[1 + C_m(1 - \gamma)/\gamma]\}$ represents the permeability of the breakwaters while, δ is the physical thickness of the breakwaters (geometrically, the thickness of the breakwaters is considered to be zero) and, γ , f and C_m are the porosity, the linearized resistance coefficient and the added-mass coefficient of the porous medium, respectively. $y = 0+$ and $y = 0-$ indicate respectively the downwave and the upwave side of the breakwaters. As the ratio of the physical thickness of the breakwaters to the local wavelength is less than about 0.2, which is right in most of the practical situations, Eq. (5) has been shown to be in good agreement with experimental data (Yu, 1995). Since the wave function and its gradient are proportional to the dynamic pressure and the velocity of the fluid, respectively, in a linear wave theory, Eq. (5) is apparently identical to the Darcy's law which states that the velocity of the fluid flow in a porous medium is directly proportional to the pressure gradient. The actual difference between Eq. (5) and the Darcy's law is that we allowed a phase lag between the velocity and the pressure gradient to represent the inertia effects of the porous flow. This is trivial if the porous medium is closely-packed and the resistance dominates the flow. But it might be important if the porosity of the breakwaters is relatively large.

Reflection and Transmission

Consider the special case where the opening of the porous breakwater gap described in Fig. 1 approaches zero, or the two semi-infinite breakwaters are connected to become a continuous one extending to infinity at both ends. On this particular occasion, we are able to derive an explicit solution for both the reflected and transmitted waves under arbitrary incidence conditions.

Let the reflection and transmission coefficients of an infinite breakwater be defined as the ratios of the amplitudes of the reflected and the transmitted wave to the incident wave. Denoting the reflection and the transmission coefficient by K_r and K_t , respectively, we can formally express the wave field in the reflection region and that in the transmission region by

$$F_r = F_0 + K_r A_0 e^{ik(x \cos \alpha - y \sin \alpha)} \tag{6}$$

$$F_t = K_t A_0 e^{ik(x \cos \alpha + y \sin \alpha)} \tag{7}$$

Both K_r and K_t are assumed to be complex-valued so that information on not only the magnitude but also the phase of the reflected and transmitted waves is included. To satisfy the partial transmission condition (5) at the porous breakwater, we attain the following relations:

$$K_t \sin \alpha = (1 - K_r) \sin \alpha = G(1 + K_r - K_t) \tag{8}$$

which yields

$$K_r = \frac{\sin \alpha}{2G + \sin \alpha} \tag{9}$$

$$K_t = \frac{2G}{2G + \sin \alpha} \tag{10}$$

Back substitution of Eqs. (9) and (10) into Eqs. (6) and (7) gives rise to the final solution of the simple reflection-transmission problem. It must be pointed out that verification of Eqs. (9) and (10) by measured data under general conditions has not been carried out. It is because they were demonstrated to be in satisfactory agreement with laboratory experiments at $\alpha = \pi/2$ or under the normal incidence conditions we give credence to these equations in the present study.

Diffraction

In both the reflection and transmission regions we decompose the wave function F into two parts: the transmitted wave F_t and the diffracted wave F_d . That is, we let

$$F = F_t + F_d \tag{11}$$

where F_t is given by Eq. (7) with K_t defined by Eq. (10). For F_t is known we need only to fix F_d to finally determine F .

Since both F and F_t satisfy the Helmholtz equation, which is linear and homogeneous, F_d should do likewise to ensure Eq. (11). That is,

$$\nabla^2 F_d + k^2 F_d = 0 \tag{12}$$

At $x \rightarrow \pm\infty$, the effects of the breakwater gap on the wave field die off and, therefore, F approaches the relevant solution for a continuous breakwater. This can be written as

$$F_d \rightarrow 2K_r A_0 e^{ikx \cos \alpha} \cos(ky \sin \alpha) \quad \text{at } y \leq 0 \text{ and } x \rightarrow \pm\infty \tag{13}$$

$$F_d \rightarrow 0 \quad \text{at } y \geq 0 \text{ and } x \rightarrow \pm\infty \quad (14)$$

Along the porous breakwater, Eq. (5) leads to

$$\frac{\partial F_d}{\partial y} = 0 \quad \text{at } y = 0 \text{ and } |x| > \frac{b}{2} \quad (15)$$

Eqs. (12), (13), (14) and (15) are in fact the formulation for diffraction by an impermeable breakwater gap provided the incident wave is given by

$$F_2 = K_r A_0 e^{ik(x \cos \alpha + y \sin \alpha)} \quad (16)$$

which is the original incident wave expressed by Eq. (4) with a phase shift (since K_r is complex-valued) and an amplitude reduction (since $|K_r| < 1$).

It becomes now very obvious that the wave field around a porous breakwater gap can be treated as the superposition of a transmission and a diffraction by impermeable structures. Namely, we can split the incident wave (F_0) into two component waves ($F_1 = K_t A_0 e^{ik(x \cos \alpha + y \sin \alpha)}$ and $F_2 = K_r A_0 e^{ik(x \cos \alpha + y \sin \alpha)}$). To one of these components (F_1) the breakwater is completely transparent and transmission of wave into the region behind the breakwater is totally free. To the other component wave (F_2), on the other hand, the breakwater works like a solid wall. A complete reflection in front of it will occur and transmission of the wave energy into the region behind the breakwater is only by the diffraction process. Since both K_r and K_t are complex-valued in general, it should be emphasized that split of the incident wave is not simply a proportional division of the incident wave energy or amplitude. The phase effects of the porosity of the breakwater must be correctly considered.

A different way to view the combined diffraction and transmission around a porous breakwater gap can be explained as follows. Instead of Eq. (11) we let

$$F = K_r F_0 + K_t F_{0d} \quad (17)$$

where F_0 is interpreted as the wave field due to transparent breakwaters and F_{0d} as the wave field due to solid breakwaters (the relevant incidence is F_0 in either case). Considering the fact

$$K_r + K_t = 1 \quad (18)$$

we can treat a porous breakwater as the proportional combination of a transparent one and a solid one. The resulted wave field associated with the porous breakwater can also be interpreted as the similarly proportioned combination of the relevant wave field as the breakwater is transparent and solid. Again, it is important to notice that the proportional factors are complex-valued, so disintegration of breakwaters depends on not only the porosity of the breakwaters but also the properties of the wave.

ANALYTIC METHODS FOR DIFFRACTION

By the concept described in the previous section, the solution of wave motion around a porous breakwater gap can be obtained as long as the principle for decomposition of the incident wave or disintegration of the breakwaters in addition to an effective solution method for the diffraction by solid breakwater gaps are available. The theoretical elements which underlie the decomposition and disintegration course for given incidence condition and the porous properties of breakwaters has been discussed in details. In the following we shall give a brief summary of the useful methods for the diffraction by solid breakwater gaps with emphasis on their limitations when recently available numerical recipes are employed.

Water wave diffraction by solid breakwater gaps is one of the most classical subjects of coastal and harbor hydrodynamics. The problem has its analogy in both acoustics and electromagnetics. A large number of studies, analytical and numerical, have been carried out in the past half century. Exact solutions of the problem can be obtained by separation of variables in the elliptic coordinates. This elegant method is usually attributed to Morse and Rubenstein (1938) who gave the first outline of application for the diffraction of sound and electromagnetic waves by a slit in the infinite plane. Its effectiveness in solving the relevant water wave problems was widely recognized after Carr and Stelzriede's work (1952). The method is essentially straightforward but it does involve substantial efforts if numerical results are necessitated. The difficulty is owing to the appearance of the unusual Mathieu functions, for which advanced computational programs do not seem to have been readily available until this manuscript is to be finalized (although no sign showed they are more accurate than the present development, the routines in the recent book by Zhang and Jin (1996) are valuable). Even the excellent work by Sobey and Jonsson (1986) still had to partially rely on tables for some characteristic values. In principle, Morse and Rubenstein's method is valid with no restriction. However, accurate evaluation of the modified Mathieu functions of the third kind, which are involved in the solution, is rather difficult if the breakwater gap is wide. Owing to this fact, the exact solution method has not been recommended if the ratio of the opening of the breakwater gap to the local wavelength is larger than 3 (Carr and Stelzriede, 1952). Whether this suggested limit is still reasonable at present and how accurate is Morse and Rubenstein's solution near this limit are, however, not known.

The standard method for the diffraction by a solid breakwater gap with relatively large opening is attributed to Penney and Price (1952). The method is based on the Sommerfeld solution for the diffraction around the tip of a semi-infinite wall. It was widely promoted in the coastal engineering society (CERE, 1984), because of its relative simplicity from the numerical point of view when

Fig. 2. Computed wave height at $x = 0$ and $y = L$ for varying opening of breakwater gap. Morse and Rubenstein's solution, Penney and Price's solution and Mei's solution are compared.

compared to Morse and Rubenstein's method. One needs only to evaluate the Fresnel integrals for determining the wave motion. Penney and Price's solution is not exact because it assumed that the scattered waves due to one breakwater arm produce no transverse flow at the position of the other arm and this assumption is approximately valid only when the opening of the breakwater gap is larger than a few wave length depending on the accuracy requirement.

Approximate solution for the diffraction by a breakwater gap with small opening is also available (Mei, 1989). This is called Mei's method and is based on matched asymptotic expressions. It assumed that the gap is equivalent to a singularity to a far-field observer. In the near-field, on the other hand, general representation of the wave field can be derived by conformal mapping. Mei's solution is concise but it can not be applied to cases with large ratio of the opening of the breakwater gap to the local wavelength. The limit for given accuracy is yet open to question.

Owing to the fact that practical problems in coastal and harbor engineering may not always fall inside the limits of the approximate solutions for large and small gaps, we developed a highly accurate numerical method for evaluating Morse and Rubenstein's solution in the present study. The characteristic values of the Mathieu functions in the method are determined through finding the eigenvalues of real-symmetric tridiagonal metrics with elements differing widely in order of magnitude. The relevant eigenvalue problems are solved by the QL method with implicit shifts (Press et al., 1989) in double precision. The computer codes were strictly checked by the tables given in Abramowitz and Stegun (1972). The Bessel functions of the various kinds involved in the expansions of the Mathieu functions are also evaluated in double precision, following the

Fig. 3. Computed wave height at $x = L$ and $y = L$ for varying opening of breakwater gap. Morse and Rubenstein's solution, Penney and Price's solution and Mei's solution are compared.

schemes given by Watanabe et al. (1989).

Figs. 2 and 3 are the plots of the relative wave height β (= the ratio of the local wave height to the incident wave height) against the relative opening of the breakwater gap (= the ratio of the opening b to the wavelength L) at two different positions. It can be noticed that the agreement between Morse and Rubenstein's solution and Penney and Price's solution is fairly good if b/L is larger than about

Fig. 5. Comparison of the wave height distribution around the breakwater gap. The left half is Mei's solution. The right half Morse and Rubenstein's solution. $b/L = 0.1$.

0.5. At the other end, Morse and Rubenstein's solution almost coincides with Mei's solution if b/L is less than about 0.1. Accurate evaluation of Morse and Rubenstein's solution has been successfully done for b/L up to more than 10, which is much larger than the number reported previously.

Figs. 4 and 5 also compare Morse and Rubenstein's solution with Penney and Price's solution and Mei's solution. The comparisons are made for the wave height distribution around the breakwater gap at $b/L = 0.5$ and $b/L = 0.1$, respectively. The selected ratios of the opening of the breakwater gap to the wavelength can actually be viewed as the limits of the approximate solutions. The agreement, as can be seen, is fairly good from the engineering point of view.

COMBINED DIFFRACTION AND TRANSMISSION

Hereinbelow we examine the combined diffraction and transmission around a porous breakwater gap with numerical examples. The first case under consideration is of an oblique incidence with $\alpha = \pi/4$. The relative opening of the gap is 1.0. For reference, the diffracted wave height distribution as the breakwaters are solid, which can also be treated as a limiting case of the combined diffraction and transmission at $G = 0$, is shown in Fig. 6. The wave pattern we can have is evidently a typical one for pure diffraction which represents the dynamic

Fig. 6. Wave height distribution around a solid breakwater gap. $b/L = 1.0$ and $\alpha = \pi/4$.

processes of essentially radial waves.

The combined diffraction and transmission around the gap formed by breakwaters with any permeability can be readily assembled from a unidirectional wave and the diffracted wave as depicted in Fig. 6. Fig. 7 presents an example for $G = 0.25 + 0.25i$, that is, $K_r = 0.500 - 0.207i$ and $K_t = 0.500 + 0.207i$. What we can recognize from this figure is that the wave pattern for combined diffraction and transmission is very different from the one for a pure diffraction. This may have to be explained by the phase interactions between the diffraction (an essentially radial wave) and the transmission (a unidirectional wave).

To understand the combined diffraction and transmission of random waves, we turn to a case with normal incidence of the Bretschneider-type spectrum:

$$S(f) = 0.430\bar{H}^2\bar{T}(\bar{T}f)^{-5} \exp[-0.675(\bar{T}f)^{-4}] \tag{19}$$

where \bar{H} is the mean wave height, \bar{T} is the mean wave period and $f = \sigma/2\pi$ is the frequency. Fig. 8 is a comparison of the energy-spectrum of the wave at $x = \bar{L}$ and $y = \bar{L}$ (\bar{L} is the mean wavelength) under various conditions of the porosity of the breakwaters. In the computations, the mean wave period is 10 s and the still water depth is considered to be 5 m. The opening of the breakwater gap equals to the mean wavelength. The permeability of the breakwaters in terms of the mean wavelength is assumed to take different values representing structures with different porosity ($G = 0$ is for solid breakwaters; $G = 0.1$ for densely-packed and resistance dominated breakwaters; and $G = 0.25(1 + i)$ for loosely-packed and

Fig. 7. Wave height distribution around a porous breakwater gap with combined diffraction and transmission. $b/L = 1.0$, $\alpha = \pi/4$ and $G = 0.25(1 + i)$.

Fig. 8. Spectrum of the combined diffraction and transmission at $x = \bar{L}$ and $y = \bar{L}$ with various permeability of the breakwaters. Incidence is of the Bretschneider-type. $b/\bar{L} = 1.0$.

moderately dissipative breakwaters). The important information included in the figure is that the wave spectrum behind the breakwater undergoes significantly different transformation for different properties of the breakwaters. When the breakwaters are impermeable, the spectrum is of only one peak, like the incident wave. When they are porous, however, the spectrum shows at least two peaks. This implies that the performance of the breakwaters depends closely on the

Fig. 9. Comparison of the wave height distribution for regular and irregular waves. Normal incidence is considered. $b/L = 1.0$ and $G = 0.25(1 + i)$.

wavelength. It should also be noted that as the permeability increases, wave energy behind the breakwater increases, as it should be. But, the increase of the energy related to long waves is particularly remarkable. This indicates that a porous breakwater is less effective to long waves.

Fig. 9 compares the wave height distribution around the porous breakwater gap with $G = 0.25(1 + i)$ when the incident wave is regular and irregular. We are able to observe totally different wave patterns for monochromatic and spectral waves. This is again explained by the effects of phase interactions between diffracted and transmitted waves.

SUMMARY AND CONCLUSIONS

We presented an useful method for the combined diffraction and transmission around porous breakwater gaps. The method can be summarized as follows: (1) we need to decompose the incident wave into two components, according to the incidence angle and the permeability of the breakwaters which form the gap; (2) we assume the breakwaters to be completely transparent to the relevant component of the incident wave and ascertain the transmission field; (3) we treat the breakwaters as solid to the other component of the incident wave and solve the diffraction field; (4) we superpose the transmission and the diffraction to obtain the objective wave. Since they play the central role in working out the final solution of a real problem with combined diffraction and transmission, methods for the diffraction by solid breakwater gaps were comparatively stud-

ied. Limitations of the approximate solutions for large and small breakwater gaps were demonstrated. Sample computations were done for typical cases with combined diffraction and transmission. The computational results showed that the effects of phase interactions between diffracted and transmitted waves, which result from the porosity of the breakwaters, are not insignificant.

CHAPTER 161

PREDICTION OF WAVE REFLECTION FROM ROCK STRUCTURES: AN INTEGRATION OF FIELD & LABORATORY DATA.

Mark A. Davidson¹, Paul A.D. Bird², David A. Huntley¹, and Geoff N. Bullock².

ABSTRACT: An empirical predictive scheme for wave reflection from rock island breakwaters is derived from a multiple regression analysis of a large data set (780 data points) which includes both laboratory and full-scale measurements. The large parameter space embraced due to the inclusion of both laboratory and field data leads to a robust solution for the prediction of wave reflection. The resulting equation expresses the reflection coefficient as a function of a number of dimensionless parameters which can be identified with specific physical processes. These include wave breaking, dissipation due to friction and turbulence induced by structural roughness, and transmission into and through the breakwater.

SYMBOLS

d_t	Depth at the toe of the structure relative to the still water level.
D	Significant armour diameter $= (W_{50}/\rho)^{1/3}$
H_i	Significant wave height
K_r	Frequency averaged reflection coefficient $= \sqrt{\int S_r df / \int S_i df}$
f	Frequency
L_o	Deep water wavelength
P	Notional permeability (Van der Meer, 1988)
r	Multiple regression correlation coefficient
R	Reflection number $= \frac{L_o^2 d_t \tan \beta}{H_i D^2}$, (Davidson <i>et al.</i> , 1996)
S_i, S_r	Incident and reflected spectral estimates
W_{50}	Median mass of rock armour
β	Average structure slope
ρ	Density of rock armour
σ	Standard error in multiple regression analysis
ξ	Iribarren number $= \tan \beta / \sqrt{H_i / L_o}$

INTRODUCTION

Much attention has been focused on the prediction of wave reflection from rubble mound structures (e.g. Seelig and Ahrens 1981, Postma 1989, Van der Meer 1992, Allsop and Channell 1989, Hughes 1995, Davidson *et al.* 1994.). A recent review can be found in Davidson *et al.*, 1996. Most predictive schemes for wave reflection have been based on empirical relationships involving the Iribarren number derived from laboratory experiments. Whilst the Iribarren number describes well the form of breaking waves (Battjes, 1974) and hence dissipation due to breaking, the processes of turbulent dissipation due to the roughness of the structure and transmission into and through the structure are not obviously related to the Iribarren number and have normally been accounted for through additional empirical coefficients. The combined effects of the empirical nature of these equations and the inevitable limited parameter space have meant that these solutions are rarely universal particularly at full-scale. This problem is compounded by potential scale effects and inconsistencies in the method of analysing wave reflection.

Davidson *et al.*, 1996, collected full-scale data seawards of a rock island breakwater both before and after the addition of more armour to the seawards face of the structure. This modification was designed to reduce the slope of the structure hence enhancing structural stability and ameliorating wave reflection. Conventional plots of reflection coefficient versus Iribarren number showed the pre- and post- modification data sets as two distinct populations. The failure of the Iribarren number to condense both data sets on to a single curve severely limits the accuracy of predictive schemes which express wave reflection as some function of ξ .

For these full-scale data an improved parameterization of wave reflection was derived in terms of a dimensionless reflection number R where:

$$R = \frac{L_o^2 d_t \tan \beta}{H_t D^2} = \xi \left(\frac{L^{3/2} d_t}{H^{1/2} D^2} \right) \quad (1)$$

and;

$$K_r = \frac{0.635 \sqrt{R}}{41.2 + \sqrt{R}} \quad \text{or} \quad K_r = 0.151 R^{0.11} \quad (2)$$

It can be seen from Equation 1 that R revises the relative weighting of wave height and wavelength in the Iribarren number and includes other physically significant parameters such as the depth at the toe and the characteristic armour diameter.

Whilst equations based on R provide an excellent prediction of wave reflection ($r=0.87$, $\sigma=0.055$) for these full-scale data (within the parameter space of the measurements) poor predictions were found for laboratory data. These inconsistencies can be explained in part due to the potential scale effects which may significantly contribute to differences between the field and laboratory data (up to 10%, Shimada *et al.*, 1986), but more significantly to the empirical nature of Equations 1 and 2 and the limited parameter space of the data from which they were derived.

This contribution aims to minimise problems associated with limited parameter space by integrating both laboratory and field investigations. The advantage of this approach is that although it is empirical the resulting predictive scheme is remarkably robust over a broad range of scale and incident wave conditions.

The problem of predicting wave reflection is essentially the solution to the energy balance equation including the processes of wave reflection, dissipation (due to breaking, turbulence and friction) and transmission (both through and over the structure). Therefore an accurate solution for the reflection coefficient intuitively should include parameters which relate (even if only empirically) to each of the most significant processes involved (Figure 1). Thus, solutions based on a single parameter like the Iribarren number which only obviously relate to the process of dissipation due to breaking are only likely to provide a ubiquitous solution for wave reflection where breaking is the dominant process.

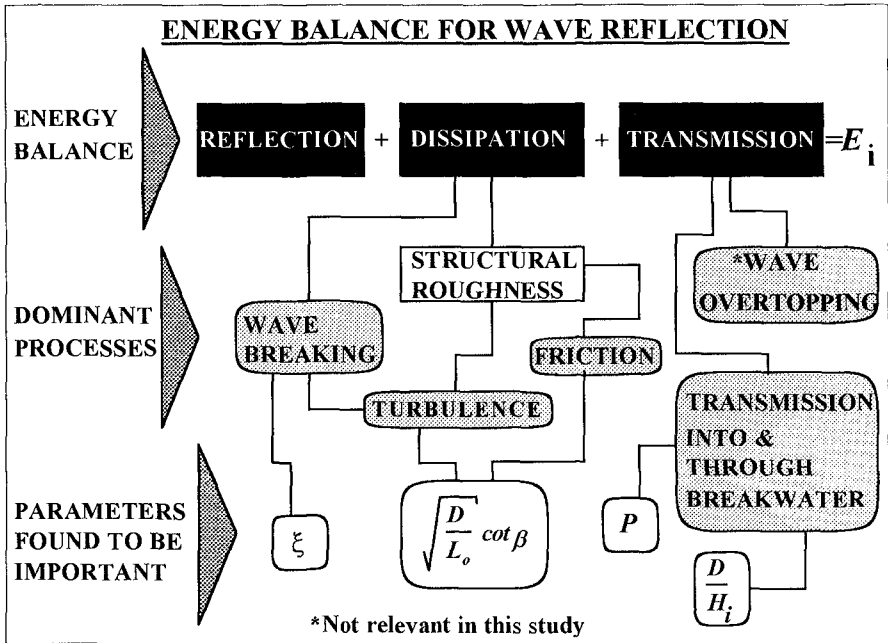

Figure 1: Schematic diagram illustrating the dominant processes affecting wave reflection and some of the parameters associated with them. Here E_i is the incident wave energy.

DATA BASE

Data analysed here includes laboratory tests from Seelig and Ahrens (1981), Allsop and Channell (1989), Postma (1989), and field data from a natural rock island breakwater, both before and after a modification of the seawards slope of the structure (Davidson *et al.*, 1996). The reader is referred to the original references for details of these experiments. A summary of each of these experiments including the ranges of specific dimensionless variables have been summarised in Table 1. All available information from each experiment was entered into a data base. For each experiment information was available on; wave height, deep/shallow water

wavelength, structure slope, armour diameter, permeability, the number of armour layers and depth at the toe of the structure. In all cases wave overtopping was not significant.

Table 1: A summary of the data sets, parameter space and analysis techniques used in this study.

RESULTS

A multiple regression analysis technique was used in order to determine the relationship between the frequency averaged reflection coefficient and various non-dimensional variables which are identifiable with of specific physical processes affecting wave reflection. The results of this analysis are summarised in Table 2. A number of parameters were tested, and the impact of each parameter on the wave reflection was assessed through the correlation coefficient (r) and standard error (σ). If the addition of a parameter led to a reduction in the standard error and an increase in the correlation coefficient then the parameter was assessed as being significant and left in the equation for further analysis. If however, the addition of a parameter lead to an increase or no significant change in the standard error (or rise in correlation coefficient) it was neglected in subsequent tests.

Parameters which were found to significantly improve predictions of wave reflection are shown in Figure 1 and listed below:

- 1) The Iribarren number which characterises the form of the breaking waves and hence relates to the dissipation of wave energy due to breaking.
- 2) A relative diameter term (D/H_b , referred to here as the transmission parameter) which Van der Meer, 1992 has shown empirically to be related to wave transmission.
- 3) A roughness parameter ($\sqrt{\frac{D}{L}} \cot \beta$, Seelig & Ahrens, 1981). The effective roughness of the structure increases both as the armour diameter increases relative to the wavelength of the waves, and as the slope of the structure is reduced. Gentler slopes give rise to increased energy dissipation due to the effect of turbulence and viscosity of water close to the sea bed.

4) Van der Meer's Permeability parameter (Van der Meer, 1988).

5) The relative toe depth $\left(\frac{d}{L_o}\right)$. The exact physical significance of this parameter in the process of wave reflection is not clear. The effect of decreasing the depth at the toe will ultimately lead to breaking offshore of the structure, thus reducing reflection. Conversely, in the case of a fully permeable breakwater transmission of wave energy through the structure may increase (reducing wave reflection) with increasing d_t as the width of the breakwater (at mean water level) is reduced.

The relationship between K_r and some of the variables tested was non-linear and an improved correlation could be obtained if the logarithm of the variable was taken prior to carrying out the regression analysis. This is true if the effect of a given variable on wave reflection diminishes as the value of that variable increases. The Iribarren number provides a good example of this. When waves are steep enough to break (low Iribarren numbers, $\xi < 4$) wave reflection increases proportionately with the Iribarren number through the continuum of breakers from the extremes of spilling to surging. However, when waves cease to break further increase in wave reflection produces no change in the reflection coefficient.

Table 2: Multiple regression analysis statistics showing parameter coefficients, correlation coefficients and standard errors. Note that * sign indicates that the logarithm of the variable has been taken prior to the regression analysis.

Table 2 gives a number of predictive equations for wave reflection based on these data. The number of parameters and the accuracy of the equations increasing towards the bottom of the table. Also given are the linear, multiple regression coefficients. The best predictor of wave reflection is given at the bottom of this table (in bold type) and yields the following equation:

$$K_r = 0.298 \log(\xi) - 0.011 \left(\frac{D}{H_i}\right) - 0.321 \log\left(\sqrt{\frac{D}{L_o}} \cot \beta\right) - 0.191P - 0.358 \left(\frac{d_t}{L_o}\right) - 0.049 \quad (3)$$

Predicted and observed reflection coefficients from Equation 3 are shown in Figure 2.

Figure 2: Predicted and measured reflection coefficients for both field and laboratory data.

DISCUSSION

Inspection of Table 2 shows that the accuracy of the predictive scheme for wave reflection is significantly improved (as indicated by the correlation coefficient and standard error statistics) through the addition of each of the 5 variables. It should be noted that several other combinations of variables (not shown here) were tested and shown not to significantly improve (or even worsen) predictions of K_r . Equation 3 provides a remarkably robust solution for wave reflection given the exceedingly broad parameter space covered by the 780 data points. The equation includes parameters which have physical significance in the processes of wave dissipation due to breaking (ξ), turbulence /friction induced by structural roughness ($\sqrt{\frac{D}{L_o} \cot \beta}$), and transmission through and into the breakwater ($\frac{D}{H_i}$ & P) (see Figure 1). The relative toe depth (d/L_o) is also seen to significantly improve reflection estimates although the physical significance of this parameter is less clear.

The excellent correlation between observed and predicted reflection coefficient for these data is shown in Figure 2. The correlation coefficient and standard error for the data shown in Figure 2 are 0.943 and 0.0521 respectively. A conservative estimate of K_r for which 98% of the data does not exceed is given by adding two times the standard error ($=0.1042$) to Equation 3.

Inspection of Figure 2 shows that there is evidence of some systematic deviation of the reflection estimates for low measured values of K_r (<0.18). These discrepancies probably arise due to errors in analysis techniques which are sensitive to bias due to signal noise for low

reflection conditions. However, these deviations are of little significance since reflected wave energy is less than 4% of the incident value in this area of the graph.

Correlation coefficients and standard errors associated with field data alone ($r=0.815$) are poorer than those associated with the laboratory data ($r=0.962$). This is perhaps to be expected to some extent since there are a greater number of variables associated with the field situation. For example, non-uniformities in the wave field, oblique wave approach and irregularities in the structure may all contribute to uncertainties in K_r . However, Davidson *et al.*, (1996) conducted numerical tests indicated that errors in estimates of K_r due to oblique wave approach and low signal coherence between sensor pairs are generally low (error in $K_r < \pm 0.09$) for these data. It is valid therefore to consider other potential reasons for the increased scatter in the predictions associated with the field data.

Table 1 shows that the field data embraces a considerably broader range of Iribarren numbers. In particular the field data extends to much higher Iribarren numbers where waves of low steepness surge (un-broken) against the structure. In this regime dissipation due to wave breaking is of little importance and the processes of transmission and dissipation due to turbulence and friction promoted by the roughness of the structure most significantly affect the energy balance (Figure 1). It is under these highly reflective conditions that there is considerably more scatter in the estimates of reflection coefficient (Figure 2). This may indicate that the processes of transmission, and dissipation due to structural roughness are less well represented by Equation 3 than those associated with wave breaking. This hypothesis is supported by the fact that the data from the second deployment which has the reduced slope ($\tan \beta = 1/1.55$) and lower Iribarren numbers shows less scatter than the data collected in more reflective conditions in the first deployment ($\tan \beta = 1/0.82$).

It should also be noted that Equation 3 is some what biased towards the model scale tests since the ratio of laboratory to field data analysis here is of the order 3:1. Hence if the solution given by Equation 3 is more suited to the laboratory data, scale effects may significantly contribute to the scatter in the field data. More field data is required to clarify this issue.

Although Equation 3 provides a good and versatile estimate of wave reflection within a very broad parameter space, an improved prediction of wave reflection ($r=0.87$, $\sigma=0.055$) at full-scale is given by Equations 1 and 2 within the range of field measurements summarised in Table 1.

Figure 3 shows a series of plots illustrating the relative impact of each of the terms in Equation 3 on the overall estimate of reflection across the measured parameter space. In these figures the range of the value of each term in the field and laboratory is represented by lines joined by open circles and crosses respectively. Also shown are the 95% confidence intervals for each parameter. Inspection of Figure 3 shows that the dissipation, transmission and roughness parameters have a first order effect on wave reflection with relatively small contributions ($\Delta K_r < 0.15$) from the permeability and relative depth terms.

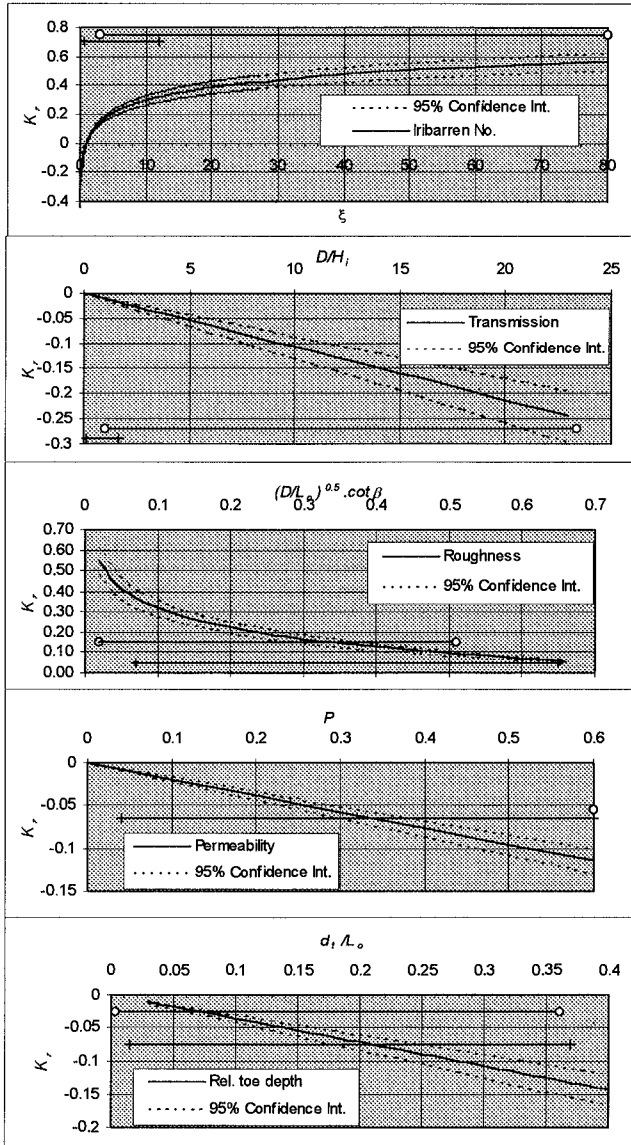

Figure 3: Figure showing the relative influence of each of the five terms in Equation 3 on the reflection coefficient estimate over the field and laboratory parameter space. Note that the field and laboratory range for each variable are indicated by lines joining open circles and crosses respectively.

The relative impact of each term in Equation 3 on the reflection estimate is in some cases very different for the field and laboratory data. For example the Iribarren number is very significant across the full range of the laboratory data but has little impact on K_r for much of the field data which corresponds to high Iribarren numbers and non-breaking waves. Conversely, the transmission parameter has a much more significant effect on K_r for the field data. Table 2 (line 3) shows that the addition of the transmission parameter to the equation significantly increases the correlation coefficient ($r=0.622 \rightarrow 0.828$). Plots of predictions based on the Iribarren number alone (not included here) show the field and laboratory data as two distinct series. Inclusion of the transmission term effectively brings together the field and laboratory data. This emphasises the importance of the effects of wave transmission which perhaps have not been fully appreciated previously from laboratory experiments which have a much more limited range in Iribarren number.

It should also be mentioned that there may be several other parameters which are significant in the process of wave reflection which have not been considered in Equation 3. In particular, Van der Meer (1992) sites the relative crest freeboard height R_c/H_i as being an important factor influencing wave transmission. Unfortunately statistics for R_c (height of the structure crest above mean sea level) were not available for all data and therefore the effect of R_c/H_i could not be tested here. Other significant factors might include the effective breakwater width corresponding to the still water level and wave frequency. Thornton and Calhoun (1972) found also that wave transmission was a frequency dependent process with lower frequency wave propagating more readily through the structure. The effect of wave overtopping and strongly oblique wave approach are also not accounted by Equation 3.

CONCLUSIONS

Multiple regression analysis of this large data base (780 data points) including both field and laboratory data provides a robust predictive scheme for wave reflection and an insight into the relative importance of parameters affecting this process. The results of this study can be summarised as follows:

- 1) An accurate prediction of wave reflection ($r=0.943$, $\sigma=0.0521$) over the sampled parameter space (Table 1) is given by:

$$K_r = 0.298 \log(\xi) - 0.011 \left(\frac{D}{H_i} \right) - 0.321 \log \left(\sqrt{\frac{D}{L_o}} \cot \beta \right) - 0.191P - 0.358 \left(\frac{d_i}{L_o} \right) - 0.049 \quad (3)$$

A conservative estimates which of wave reflection not exceeded by 98% of data is given by addition of two times the standard error (0.1042) to this equation. Equation 3 is valid for normally incident waves and no overtopping.

- 2) Equation 3 includes parameters which are physically significant in the processes of wave dissipation through breaking (ξ), turbulence and friction induced by structural roughness $\left(\sqrt{\frac{D}{L_o}} \cot \beta \right)$ and transmission into and through the breakwater (P , D/H_i).
- 3) In Equation 3 the Iribarren number (relating to dissipation through breaking), transmission and roughness parameters exert a first order effect on wave reflection estimates with smaller contributions ($\Delta K_r < 0.15$) from the permeability and relative depth terms.

- 4) More field data is required in order to test the validity of Equation 3 at full-scale and the potential importance of scale effects.
- 5) For conditions corresponding to the parameter space covered in the field experiment (Davidson *et al.*, 1996, see Table 1) Equations 1 and 2 are recommended for the prediction of wave reflection.

ACKNOWLEDGEMENTS

The authors would like to extend their thanks to the Engineering and Physical Sciences Research Council (EPSRC, Grant no. GR/H17183) and MAST (Grant no. MAS2-CT92-0030) for funding this research. We would also like to acknowledge the technician support in the School of Civil & Structural Engineering and Arun District Council for their co-operation in the field.

CHAPTER 162

PERFORMANCE EVALUATION OF BUOY-MEMBRANE WAVE BARRIERS

M.H. Kim¹, B.L. Edge², S.T. Kee³, and L. Zhang⁴
Department of Civil Engineering
Texas A&M University
College Station, TX 77843, USA

ABSTRACT

The interaction of water waves with a tensioned, inextensible, vertical flexible membrane hinged at the sea floor and attached to a solid cylindrical buoy at its top, was investigated in the context of two-dimensional linear wave-body interaction theory. A two-domain boundary element program was developed based on a discrete-membrane dynamic model and simple-source distribution over the entire fluid boundaries. To verify the numerical results, a series of experiments were conducted with two different models in the two-dimensional wave tank. For each model, both surface-piercing and submerged cases were tested. The numerical prediction was generally in good agreement with experimental results except resonance regions. The comparison was improved after including viscous or material damping effects. It is shown that the buoy/membrane system can be a very effective wave barrier if it is properly designed.

INTRODUCTION

A flexible membrane can be used as a portable and sacrificial breakwater, containment boom, underwater screen (Huygens et al., 1994), and silt curtain (Sawaragi et al., 1989). It has the advantage of being lightweight, inexpensive, reusable, and rapidly deployable. Since it can be easily removed, we expect minimum environmental impacts on various coastal processes. Using inflatable buoy, it can be air-dropped and self-erected. Its shape and mass can be easily controlled by filling with air or water optimized for various sea conditions (e.g. Ohyama et al., 1989; Broderick & Jenkins, 1993; Zhao, 1994). In this paper, we will particularly focus on the use of floating or submerged buoy/membrane as a breakwater (Thompson et al., 1992).

Most floating breakwaters proposed so far (e.g. Seymour & Hanes, 1979; Sollitt et al., 1986; Isaacson et al., 1994) have been relatively transparent to the incident wave field especially in the long wave regime. In order to improve the performance in long waves, it is necessary for the structure to occupy a major fraction of the water column. In view of this, numerous flap-type or elastic-beam breakwaters have been investigated but they were not greatly successful primarily due to the motion-induced waves in the lee side. The effectiveness of this kind of vertical breakwaters was improved by tuning structural responses (Sollitt et al, 1986; Evans & Linton, 1991; Abul Azm, 1994) or by adjusting structural flexibility (Lee & Chen, 1990; Williams et al., 1991,1992) and porosity (Wang & Ren, 1993).

In Kim & Kee (1996), the wave interaction with a tensioned vertical flexible membrane hinged or elastically supported at the seabed and the mean free surface was considered. Both analytic and numerical solutions were developed and used to assess the performance with varying various parameters such as membrane tension, length, mass, and mooring stiffness. It was found that almost complete reflection was possible despite large vertically-sinusoidal membrane motions which tended to generate only exponentially decaying local (evanescent) waves in the lee side. Consequently, the efficiency was in general higher than conventional floating breakwaters. The overall performance, however, depended on the magnitude of membrane tension and types of boundary conditions.

In Kee & Kim (1997), more practical buoy-membrane systems were considered. A special two-domain boundary element method was developed to solve the interaction of a rigid buoy and flexible membrane with regular waves. It was observed that diffracted and radiated waves by a buoy tended to diminish the efficiency of the membrane-alone case. However, it was shown that the practical system with a floating buoy can still be highly efficient if it is properly designed.

To validate the numerical results of Kee & Kim (1997), a series of experiments were conducted in a 35-m long, glass-walled two-dimensional wave tank at Texas A&M University. Two different models were tested both in regular and irregular waves. Reasonable agreement was observed between theory and experiment. The representative results of this experimental study are reported in this paper.

Key Words: flexible membrane, floating breakwater, submerged breakwater, potential theory, hydroelasticity, two-domain BEM, performance evaluation, model experiment

THEORY AND NUMERICAL METHOD

The interaction of a buoy/membrane wave barrier with long-crested monochromatic waves is solved in the context of potential theory. Buoy and membrane motions are assumed to be uniform in the longitudinal direction thus allowing two-dimensional analysis. It is also assumed that wave and membrane motions are small so that linear theory may be applicable. For analysis, the Cartesian coordinate system with the origin on the mean free surface and the y axis positive upward is used. Assuming ideal fluid and harmonic motion of frequency ω , the velocity potential can be written as $\Phi(x, y, t) = \text{Re}[\phi(x, y)e^{-i\omega t}]$. The velocity potential of a monochromatic incident wave of amplitude A and wavenumber k , propagating in the positive x direction is given by

$$\phi_0 = \frac{-igA \cosh k(y+h)}{\omega \cosh kh} e^{ikx} \quad (1)$$

where $\omega^2 = kg \tanh kh$ with g and h being the gravitational acceleration and water depth, respectively. The complex disturbance velocity potentials, ϕ_1 and ϕ_2 , in two fluid domains I and II (see Figure 1) satisfy Laplace equation $\nabla^2 \phi_l = 0, (l = 1, 2)$ and the following linearized free-surface (Γ_f), bottom (Γ_b), and radiation conditions:

$$-\omega^2 \phi_l + g \frac{\partial \phi_l}{\partial y} = 0 \quad (\text{on } \Gamma_f) \quad (2)$$

$$\frac{\partial \phi}{\partial n} = 0 \quad (\text{on } \Gamma_b) \tag{3}$$

$$\lim_{|x| \rightarrow \infty} \left(\frac{\partial}{\partial x} \pm ik \right) \begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix} = 0 \quad (\text{on } \Gamma_c) \tag{4}$$

where $\mathbf{n} = (n_x, n_y)$ is the unit outward normal vector.

Figure 1. Computational domain.

Under large initial tension, we assume, for simplicity, that the membrane is inextensible and the heave motion of the buoy is negligible. Then the boundary condition on the buoy is

$$\frac{\partial \phi}{\partial n} + i\omega \{ \eta_h n_x + \eta_b n_y \} + \delta_{11} \frac{\partial \phi_b}{\partial n} = 0 \quad (\text{on } \Gamma_b) \tag{5}$$

where δ is the Kronecker delta function, and $n_\theta = xn_y - yn_x$. The symbols η_h and η_b represent complex sway and roll responses respectively. In addition, the disturbance potentials must satisfy the following linearized kinematic and dynamic boundary conditions on the membrane surface:

$$\frac{\partial(\phi_1 + \phi_b)}{\partial x} = \frac{\partial \phi_2}{\partial x} = -i\omega \xi \tag{6}$$

$$\frac{d^2 \xi}{dy^2} + \lambda^2 \xi = \frac{\rho i \omega}{T} (\phi_2 - \phi_1 - \phi_b) \quad (\text{on } \Gamma_m) \tag{7}$$

in which $\lambda = \omega \sqrt{m/T}$ with T and m being the membrane tension and mass per unit length, respectively. In (6) and (7), ρ is the fluid density, and the harmonic membrane motion $\Xi(y, t) = \text{Re}[\xi(y)e^{-i\omega t}]$. The dynamics of the tensioned membrane is modeled as that of the tensioned string which satisfies one-dimensional wave equation. Unlike rigid body hydrodynamics, the body boundary condition on the flexible membrane is not known in advance. Therefore, the

membrane motions and velocity potentials need to be solved simultaneously. If buoy is submerged, the continuity of pressure and normal velocity must be satisfied along the fictitious vertical centerline above buoy:

$$\phi_1 = \phi_2, \quad \frac{\partial \phi_1}{\partial n} = -\frac{\partial \phi_2}{\partial n} \quad \text{at } \Gamma_f \quad (8)$$

To solve the above boundary value problem, a two-domain boundary element method using simple sources along the entire boundary is developed. The details are given in Kee & Kim (1997). Two auxiliary vertical boundaries (Γ_{e1}) and (Γ_{e2}) are located sufficiently far from the membrane such that the radiation condition (4) is valid. The discrete membrane equation is given in the following form:

$$\rho i \omega (\phi_{0j} + \phi_{1j} - \phi_{2j}) l_j - T_j \left(\frac{\partial \xi}{\partial \zeta} \right)_j + T_{j+1} \left(\frac{\partial \xi}{\partial \zeta} \right)_{j+1} = -m l_j \omega^2 \xi_j \quad (9)$$

where

$$\left(\frac{\partial \xi}{\partial \zeta} \right)_j = (\xi_j - \xi_{j-1}) / \Delta \zeta_j$$

The symbol l_j is the length of the j -th segment, and $\Delta \zeta_j = \frac{l_j + l_{j+1}}{2}$. The geometric boundary conditions at the seabed and the top connection point $(0, -R)$ are

$$\xi = 0 \quad \text{at } z = -h, \quad \xi = \eta_h + R\eta_b \quad \text{at } z = -R \quad (10)$$

The equation (9) can in principle be solved for variable tensions. In the present study, however, we assume that the initial tension T is much greater than membrane weight or dynamic tension thus can be regarded as constant. The sway-roll coupled equation of buoy motion is given by

$$M(-\omega^2)X = F_p - (K_{HS} + K_m)X - F_T + F_D \quad (11)$$

where $X = [\eta_h \ \eta_b]^T$, M =buoy mass matrix, K_{HS} =hydrostatic restoring coefficients, K_m =mooring stiffness, F_p =potential force, F_D =linearized drag force, and F_T =force at the connection point. The force F_T caused by membrane tension can be either restoring force or excitation. The detailed expression of these variables is given in Kee & Kim (1997).

EXPERIMENT

In order to validate the theory and numerical procedure developed in the preceding section, we conducted a series of experiments using a two dimensional wave tank (37-m long, 0.91-m wide, and 1.22m deep) equipped with a dry-back, hinged flap wave maker capable of producing regular and irregular waves (see Figure 2). The wave elevation was measured with a resistance wave gauge having an accuracy of ± 0.1 cm. A probe measuring incident and reflected wave heights and another probe measuring the transmitted wave heights are placed at 9.14m and 24.38m from the wavemaker, respectively. The wave barrier model was placed at 18.29m from the wavemaker between the two probes. Regular waves were generated by a user-defined time-voltage input to the wave maker. The wave period range used in our experiments was from 0.7 to 2.5. The wave heights used in the experiments range from 3cm to 6cm.

Figure 2. Wave tank and experimental set-up.

A sinusoidal regular wave was generated with the beginning and end of the series attenuated in amplitude. Two models were constructed for the present study. The buoy of model I is relatively small and heavy and made of PVC pipe. The buoy of model II is relatively large and light and made of foam wrapped by plastic sheet. The models consisted of a flexible membrane suspended from a cylindrical buoy and hinged at the sea floor. The flexible membrane was made of a thin stretching-resistant plastic material resembling a plastic tarpaulin. The total length of the buoy with side caps was 86cm. The membrane was attached to the bottom by clamping it between two angle irons which were fastened to the bottom. Four (type 1) or eight (type 3) taut mooring (two at each end) lines are used and they consist of unstretchable steelon-nylon wire that can resist up to 534N and a spring near the bottom connection. When mooring type 3 is used, two taut cables having the same anchoring point are connected to the side and bottom of a buoy, respectively. The stiffness of each spring was measured by applying static loads. The stiffness per length was found to be piece-wise linear as displacement increases. To avoid being slack, each mooring line is slightly pre-tensioned. Table 1 and 2 summarize the principal characteristics of the model I and II used in the experiment. The signal of the incident wave train was obtained (see Figure 3a,b) as it passed the probe toward the membrane breakwater. Then, the reflected wave train was recorded as the reflected waves pass the probe again in the opposite direction. After averaging the wave heights for the incident and reflected, and transmitted wave trains, the reflection coefficient R_f and transmission coefficient T_f can be calculated from the ratio of the averaged reflected and transmitted wave height to the averaged incident wave height.

Reflected and transmitted waves were repeatedly reflected from the wave maker and beach as time goes on. In order to minimize the effects of multiple reflection, the fixed single probe method was adopted in favor of moving single probe method and three-probe method (Isaacson, 1991). It is shown in Hagen (1994) that the present method is more reliable than the moving or three-probe methods when nonlinear phenomena or multiple reflections exist. In most of our surface-piercing-buoy experiments, the errors estimated from the energy relation were kept within 10%. The difference can be attributed to viscous, gap, and nonlinear effects, and mooring/material damping etc.

RESULTS AND DISCUSSION

The boundary element program developed as described in the preceding section was used to predict the performance of surface-piercing or submerged buoy-membrane wave barriers. The computational domain is defined as in Figure 1. The error was calculated from the energy conservation relation $R_f^2 + T_f^2 = 1$. It is seen that the errors uniformly decrease as the number of segments is increased.

Figure 3. (a) Incident and reflected, and (b) transmitted wave packet for wave period 1.08 sec.

Figure 4 shows comparison between the numerical results and measurements for a surface-piercing buoy/membrane breakwater (model I) without mooring lines. In this experiment, both small and large amplitude waves were used to see the sensitivity to wave heights. As can be seen in the figure, experimental data agree well with the present numerical results. As expected, smaller-amplitude waves correlate better with the linear wave-body-interaction theory. The discrepancy for large-amplitude waves can mainly be attributed to nonlinear effects since it is more pronounced in the high-frequency region. The experimental results satisfied the energy conservation with less than 8% error in the whole frequency range. To account for viscous and material damping effects, 2.5% of the sway and roll critical damping of the cylinder as well as 0%, 2.5%, and 5% of membrane critical damping was included in the cylinder and membrane equations of motions. The results are also plotted in Figure 4. As can be seen in this figure, its effect is not significant in the wave frequency range considered, which is not surprising because the relevant Keulegan-Carpenter (KC) number is smaller than 1.

Figure 5 shows the result of the same case (model I, surface piercing) except that the buoy is moored by a pair of weakly pre-tensioned springs (type 1) located at both ends of the cylinder. As mentioned earlier, the spring exhibited piece-wise nonlinear behavior, and thus the averaged stiffness was used in this computation. The computed results correlate well with the measured data except for the resonance region characterized by the sharp increase of the reflection coefficient. The discrepancy near resonance can mainly be attributed to the increased viscous and nonlinear effects. Actually in this case, we observed large buoy and membrane motions in the experiment. To assess the effects of increased damping due to viscosity and mooring lines, the same damping parameters as in Figure 4 were used in the motion calculation and the results are also shown in Figure 5. It is seen that viscous effects are increased near the resonance region.

In Figure 6, the experimental results for a moored (type 1), submerged wave barrier (model I) are compared with numerical prediction. The overall correlation of the potential theory with experiment is somewhat worse than the surface-piercing cases, indicating that viscous or material damping effects play a more important role for submerged breakwaters. The experimental results do not accurately satisfy the energy relation because of the increased viscous and nonlinear effects. In addition, we observed, especially for short waves (or large kh), mild wave breaking above the buoy surface, which can also contribute to energy loss. To see the viscous effects more clearly, we first included the sway drag force on the cylinder through Morison's formula as explained in the preceding section with 5% roll damping ratio. We can see in the figure that its effect is small. To have further insight, we also presented the cases in which the sway and roll damping ratios of the cylinder are 5%, and membrane damping ratio is increased from 0% to 5%. It tends to lower both reflection and transmission coefficients except near $kh \approx 2.8$, where reflection increases. The new results with viscosity tend to correlate better with measured data.

Since the buoy of model I is relatively small and heavy, its wave-blocking performance is not very impressive. For comparison, the performance of a similar system with larger and lighter buoy (model II) was also tested and compared with numerical prediction. Figure 7 shows the performance of the model II without mooring for various kh values. Figure 8 shows the performance of the same system with type 3 mooring lines. In both cases, the predicted results agree well with measured data except the resonance region, where nonlinear effects can be significant. It is also seen that the efficiency in long waves can be significantly enhanced by adding mooring lines. The efficiency for $kh > 3$ is very high regardless of the presence of mooring lines.

Figure 9 shows the performance of the submerged system (model II) with type-3 mooring in regular waves. Compared to the surface-piercing case, the efficiency in long waves is greatly enhanced, while that in short waves becomes poor. The predicted results again correlate reasonably with measured data. The results of Figure 8 and 9 indicate that high performance can be achieved for a variety of wave conditions if the submerged and surface-piercing systems are combined. Finally, In Figure 10a, the performance of the surface-piercing model II in irregular waves is shown. As a typical operational condition in a partly protected sea, a two-parameter Pierson-Moskowitz spectrum with significant wave height=1.5m and peak period=6.5s was selected. We can see that the transmitted wave spectrum is greatly less than the incident wave spectrum. In this experiment, due to the accumulated multiple reflection from both wave maker and beach, the duration of the time series cannot be long. Therefore, five different time series of 180-s duration were generated and the averaged spectra were presented in Figure 10a. Figures 11a,b show the typical time series of wave elevation recorded by wave probes 1 and 3. Figure 10b shows the performance of the submerged system in irregular waves. For this plot, four different time series are averaged. One of such time series is shown in Figure 11c,d.

CONCLUDING REMARKS

The interaction of waves with a tensioned, inextensible, vertical flexible membrane hinged at the sea floor and attached to a rigid cylindrical buoy at its top, was solved in the context of two-dimensional linear wave-body interaction theory. Both submerged and surface-piercing buoy/membrane system were considered. A boundary element program was developed based on a discrete-membrane dynamic model and simple-source distribution over the entire fluid boundaries. A two-domain BEM was employed since the membrane is infinitely thin. Membrane motions and velocity potentials were solved simultaneously because the body-boundary condition on the membrane is not known in advance. The accuracy and convergence of the developed program were verified through comparison with analytic solutions.

To verify the numerical results, a series of experiments were conducted with two different models, in the two-dimensional wave tank. For each model, both surface-piercing and submerged cases were tested. The model I with a small buoy was efficient only for limited wave frequency bands, while the model II with larger and lighter buoy performed well for a wider range of wave conditions. The model II successfully reduced the sea state 3-4 to sea state 2. It was also found that submerged systems can be effective in blocking long waves, while surface-piercing systems are more effective for larger kh values. The numerical prediction was generally in good agreement with experimental results except resonance regions. The comparison was improved after including viscous or material damping effects.

CHAPTER 163

An Improved Design Method for the Riprap of Earthfill Dams of Large Reservoirs

Jean-Pierre Tournier¹, Pierre Dupuis¹, Raymond Arès²

Abstract

Since impounding of the various reservoirs of the La Grande Complex in northern Québec, the riprap of several dams and dykes suffered some damage during the fifteen-year period which followed. A mandate was given to the Société d'énergie de la Baie James (SEBJ) in January 1992 to review the riprap design and evaluate the necessary repairs. The paper focuses on this work. An improved design method, for the riprap of earthfill dams of large reservoirs, is proposed based on four years of intensive studies and fifteen years of field data. Large scale model tests with irregular waves completed the studies.

Introduction

The construction of the various structures on the La Grande Complex (Phase 1), in northern Québec (figure 1), was done over a period of twelve (12) years between May 1973 and December 1985.

The project required the building of 215 embankment dams and dykes along with three powerhouses producing 10 000 megawatts and had a total cost of 13,7 billion dollars (Canadian). Since the filling of the reservoirs, which took place between 1978 and 1983, the upstream protection of some structures underwent damage and had to be repaired. Until 1992, a total of 19 structures required work varying from minor repairs to repeated dumping of rockfill on the upstream slopes.

In January 1992, La Société d'énergie de la Baie James (SEBJ) was mandated by Hydro-Québec to review the overall design of riprap, taking into account the actual condition of the dams and dykes on the Complex and to estimate the work to be done using existing techniques. To fulfill its mandate, SEBJ conducted extensive field measurements, including wind and wave measurements on four reservoirs and large scale model tests of various repair schemes using irregular waves. This paper focuses on riprap design and repair. Reevaluation of the design wave with a revised wave hindcast formula is presented by Dupuis et al. (1996), while large scale model testing of the repairs is described by Mansard et al. (1996).

Figure 1. La Grande Hydroelectric Complex

Original riprap performance

The results of extensive studies indicate that the riprap of most of the embankments has performed satisfactory since reservoir filling. In general, the most important damage was caused by the presence of fine material in the riprap. In a few cases, when systematic repairs were required, the riprap was undersized because the wave height was underestimated in the original design or the riprap specifications were sometimes relaxed during construction. Experience has shown that the use of graded riprap evaluated with the median mass M_{50} increases the risk of having local areas of undersized riprap. Of the 215 earth structures, seventeen needed general repairs.

According to the findings, coarser riprap with a narrow gradation was specified for repairs with a strict control on the minimum size to eliminate any contamination by fine material.

Repair work

The decision to do repair work on a given structure is based on the present condition of the structure, the historical performance of the riprap and on the requirement that the in-place riprap meets the dimensions required. Dams and dykes with steep slopes, in general, were treated with special attention due to their importance and the fact that the mode of failure of the riprap was more severe and rapid and could cause sliding or sloughing of the crest. Damage observed on structures with flatter slopes and adequate protection was generally limited and

evolved slowly.

Structures which had adequate protection but had minor local damage associate with weak zones needed maintenance or local repairs. The local repairs consisted essentially of repairing the damaged or weak zones by rearranging the existing stones and adding stones of appropriate size. In cases where the structures had generalized damage and the riprap was, in whole or in part, undersized, systematic repairs were done. The design and repair techniques were verified and optimized with large scale model tests at the National Research Council of Canada (NRC) that reproduced the natural conditions found on the reservoirs.

Figure 2. Typical systematic repairs (1)

Figure 3. Typical systematic repairs (2)

The method retained for systematic repairs consisted of dumping the riprap from the crest (figure 2) or on the slope, one meter above the maximum water level (figure 3), depending on the required quantity and the width of the berm.

This berm was then cut back with a backhoe and the rockfill rearranged down to 1 meter below the maximum water level. When required, the freeboard was heightened by adding a layer of rock to form a cap-like protection (figure 4).

Figure 4. Systematic repairs at the Dam KA-03 with heightened freeboard.

At the end of 1997, more than two million tons of riprap will be placed on some fifty embankment dams and dykes, ranging from minor to systematic repairs. The know-how acquired during the execution of this mandate enabled new concepts to be elaborated regarding riprap design. This new approach was also verified in the field and lab, with tests on large scale models.

Design considerations

The following well-known Hudson formula is used to evaluate the mass that should resist a certain wave height for specific conditions such as embankment slope and rockfill characteristics:

$$M = \frac{\rho_r H_s^3}{K(S_r - 1)^3 \cot \alpha} \quad [1]$$

with M the rockfill mass in kg, ρ_r the rockfill mass density in kg/m^3 , S_r the rockfill specific density, $\cot \alpha$ the slope, H_s the significant wave height and K the stability coefficient.

Recently, Van der Meer (1988) proposed elaborate equations for irregular wave

climates with various types of wave attack (spilling, plunging or surging). However, for the worst wave conditions these equations can be reduced to the same form as the Hudson formula. Along with the required parameters (slope of fill, mass and density of the rockfill), the formula which gives the mass as a function of the wave height contains a stability coefficient K which takes into account all other factors and corresponds to a safety factor. In the literature, this coefficient is known as K_d or K_r according to different conditions. If all the physical and geometrical parameters are fixed, the calculated resisting mass corresponds to a value for the stability coefficient.

For a given test, if the mass is "unique", that is, if all the blocks are identical (as was the case for Hudson's tests) the definition of this coefficient is straightforward and unique (K_d). On the other hand, when mass variation is allowed within the riprap, it is common practice to define this coefficient (K_r) for the average mass M_{50} . However, if all other parameters are constant, each mass can be considered to be associated to a given value of the stability coefficient. Therefore a variation in mass, in effect, translates into a variation in the stability coefficient which is inversely proportional to the mass (figure 5).

Figure 5. Schematic representation of the relation between M and K

By using this approach, the variations in the mass according to the different methods can be represented in terms of the variations in the stability coefficient equivalent (figure 6). It can be noted that a wide range in the variation of the mass, as in the case for well graded riprap, implies that a large portion of the rockfill has a stability coefficient above 5,0, and can reach 9, 10 or even 17,6 depending on the case and corresponds to the fine part of the riprap. This confirms the results of our

studies that the damage was due mainly to the presence of fines and to our approach of using graded or uniform riprap.

Figure 6. Effect of gradation on the equivalent *K* coefficient

Therefore, for the design, we should determine an acceptable lower limit of the mass, that is an upper limit to the stability coefficient which will resist a given wave height with an acceptable damage index value. In common practice, the damage index *S* is defined as follows:

$$S = \frac{A}{D_{n,50}^2} \quad M_{50} = \rho_r D_{n,50}^3 \quad [2]$$

where *A* is the eroded cross-section area and *D_n* the nominal stone diameter.

For the evaluation of this upper value of the stability coefficient, a new damage index is proposed, based on the minimum mass:

$$\hat{S} = \frac{A}{D_{n,\min}^2} \quad M_{\min} = \rho_r D_{n,\min}^3 \quad [3]$$

The ratio of damage between the two indexes, for a given area of damage, is:

$$\frac{\hat{S}}{S} = \sqrt[3]{\left(\frac{M_{50}}{M_{\min}}\right)^2} \quad [4]$$

Practically, a value of \hat{S} equal to 2,5 is considered as the beginning of damage while a value of 5 is defined as tolerable damage. The results indicate that beyond values of 7 or 8, the damage rate tends to accelerate and can lead to major damage. It should be noted that the condition $\hat{S} = 2,5$ or $5,0$ is more severe than the condition $S=2,0$ or $4,0$ generally used.

Tests conditions

SEBJ designed test cases for riprap that could withstand events with a significant wave height of 2,5 m with an accepted degree of damage ($\hat{S} = 5$). Large scale tests (15:1) were performed by the NRC for two different slopes with irregular waves. In the first phase, irregular wave trains were generated with spectral characteristics similar to those measured in the reservoirs and tests were conducted to check if observed damage could be reproduced. As can be seen on figure 7, similar damage zones indicate that the tests were conclusive.

Preliminary large scale model tests allowed a stability coefficient value of 3,5 to be used by SEBJ. Typical wave trains were generated following analysis of wave records gathered at the site. For both steep (1,8:1) and flat (2,25:1) slopes the minimum rock mass was calculated using formula [1]. The rock mass gradation was specified with a ratio, between maximum and minimum mass equal to 2,5.

Dyke TA-13

Scale Model

Figure 7. Comparison of damage

The riprap layer thickness is given by:

$$d_c = 2D_{50} \quad D_{50} = \sqrt[3]{\frac{M_{50}}{C_f \rho_r}} \quad [5]$$

with d_c the depth of cover and C_f a form factor taken to be 0,6. Gradations of 2,4 and 2,9 were realized respectively for steep (CTR) and flat (CTD) slope tests. There were three different levels of attack. The riprap thickness (d_c) was taken as the average thickness of the riprap within the zone of influence, that is 5 meters above and below the level of attack which was 2 times the target design wave height. Other tests (CTRU, CTDU) were performed with uniform blocks ($M_{max}/M_{min} < 1,2$) to confirm that the minimum mass was a key parameter for graded riprap design. Finally, some tests were conducted to verify the influence of a greater ratio between M_{max} and M_{min} (up to about 9 which could occasionally occur in the field) on the performance of riprap designed according to this new approach.

Results

As a first step, SEBJ designed tests with a stability coefficient $K=3,5$ applied to the minimum mass for an accepted degree of damage ($\hat{S} = 5$). A graded material (M_{max}/M_{min} around 2,5 to 3,0) was specified for the riprap and two different slopes were tested. The data, obtained from the tests, was as follows:

Test	Slope [H:V]	M_{min} [kg]	M_{50} [kg]	M_{max} [kg]	M_{max}/M_{min}	$d_c/D_{n,min}^{(*)}$	$d_c/D_{n,50}^{(*)}$
CTR	1,80	1515	2585	3686	2,43	2,6	2,2
CTD	2,25	1023	2052	3007	2,94	3,1	2,5

(*) Mean value at intermediate level.

The rockfill mass density is 2710 kg/m^3 and the theoretical values of H_s , according to equation [1] are respectively 2,60 and 2,46 for steep and flat slopes. The results, as shown on figure 8, represent the variations in the equivalent coefficient K obtained as a function of the damage index after 4 cycles of waves for a given H_s applied to the intermediate level for steep and flat slopes. After 4 cycles, or about 5000 waves, the level of equilibrium was obtained, at least, up to a damage index $S=4$ or $\hat{S} = 6$. For these conditions, a linear variation in the equivalent coefficient K can be noted for the same reference mass (minimum, median or maximum) as a function of the damage index. Similar results are obtained for different attack levels.

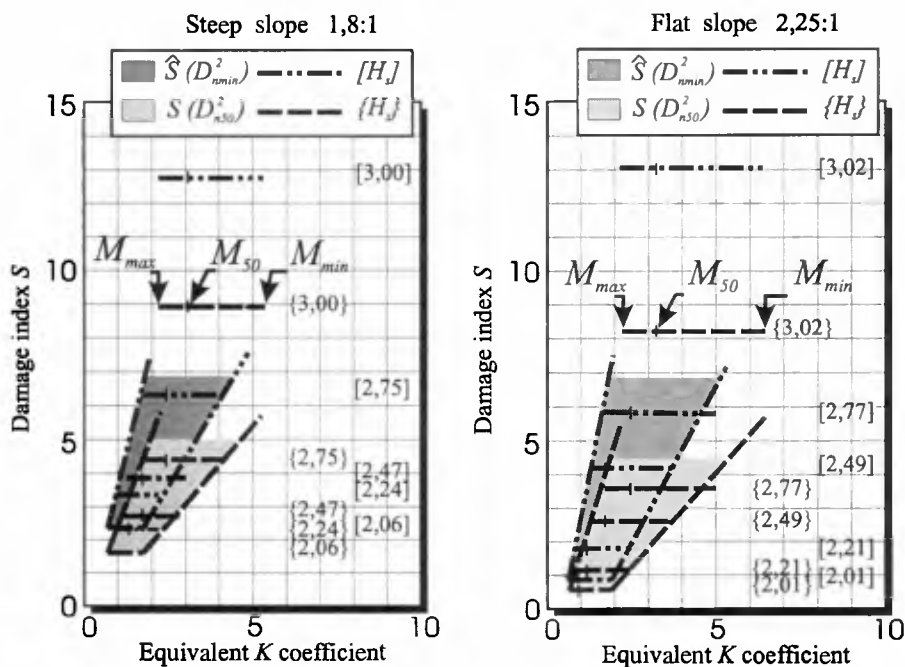

Figure 8. Relation between K and S

These results were obtained using a graded riprap with a tolerance for the rockfill of $M_{max}/M_{min} = 2,4$ and $2,9$. In order to verify if this tolerance had an influence on the upper limit obtained for the coefficient K, similar tests with uniform rock equal to the minimum mass were performed. The data, obtained for the tests, was as follows:

Test	Slope [H:V]	M_{min} [kg]	M_{50} [kg]	M_{max} [kg]	M_{max}/M_{min}	$d_c/D_{n,min}^{(*)}$	$d_c/D_{n,50}^{(*)}$
CTRU	1,80	1499	1596	1681	1,12	2,6	2,6
CTRUM	1,80	1499	1596	1681	1,12	2,1	2,0
CTRU5	1,80	2342	2552	2913	1,24	2,2	2,1
CTDU	2,25	1154	1252	1340	1,16	3,0	2,9
CTDUM	2,25	1154	1252	1340	1,16	2,1	2,0

(*) Mean value at intermediate level.

Figure 9 shows the variation in the equivalent coefficient K obtained as a function of the damage index after 4 wave cycles for tests with uniform material and the equivalent test with graded material.

Figure 9. Comparison between graded and uniform material

The values obtained for K with tests on material with a uniform mass are comparable to the corresponding values for the minimum mass for tests with graded material or slightly superior for low values of the damage index and a steep slope. These results indicate that the minimum mass controls the resistance of the riprap for these gradations. It can be noted that a uniform material test (CTR5), on a steep slope, with a larger minimum mass (2342 kg in comparison to 1499 or 1515 kg) shows the same trend. In the same way, the apparent discrepancy of test CTDUM on a flat slope is explained by the influence of the riprap thickness ($d_c/D_{n,min} = 2,1$ in comparison to 3,0 or 3,1). The results confirm that a thicker riprap is more resistant.

Finally, in the field, it is difficult to keep a ratio M_{max}/M_{min} lower or equal to 3,0 as specified. Experience has shown that a ratio between 4 to 6 can be readily obtained. So tests on steep slopes were conducted to verify the influence of such a ratio on the performance of riprap.

The data, as obtained for these tests, was as follow:

Test	Slope [H:V]	M_{min} [kg]	M_{50} [kg]	M_{max} [kg]	M_{max}/M_{min}	$d_c/D_{n,min}^{(*)}$	$d_c/D_{n,50}^{(*)}$
CTR3	1,80	854	2498	4323	5,06	3,1	2,2
CTR4	1,80	543	2606	4725	8,70	3,6	2,1

(*) Mean value at intermediate level.

The results of these tests (CTR3 and CTR4) are shown on figure 10, along with the results of the other tests on steep slopes, as a function of equivalent coefficient K obtained with minimum mass to damage index \hat{S} also according to a minimum nominal diameter. The K values obtained from tests with a ratio M_{max}/M_{min} up to 5,1 are almost identical, and superior for CTR4 test with a ratio equal to 8,7. The higher value is due partly to a relative larger thickness ($d_c/D_{n,min} = 3,6$ in comparison with a mean value of 2,6) and also due to the more severe conditions imposed on a well graded material using minimum mass. In fact, back calculations indicate that the performance of CTR4 corresponds approximately to the resistance of M_{10} . So the use of a minimum mass approach is a conservative approach and finer material of at least 10% can be tolerated without much effect on the required resistance.

Figure 10. Relation of K versus \hat{S} for all tests (steep slope)

performance of CTR4 corresponds approximately to the resistance of M_{10} . So the use of a minimum mass approach is a conservative approach and finer material of at least 10% can be tolerated without much effect on the required resistance.

It is generally accepted that a damage index, based on the median mass, of 2 or 3 is considered as no damage and that a value of 4 or 5 is a level of acceptable damage. Using the minimum mass approach, a damage index value of 2,5 and 5 respectively is recommended to define the limits of no damage and acceptable damage, which, in terms of median mass, translates into values less than to 2 and 4.

Figure 10 represents the variation of the stability coefficient as a function of the damage index using the minimum mass approach for all the tests done on a steep slope with a minimum acceptable riprap thickness of two layers. The upper limit obtained for the coefficient K , which allows for the calculation of the minimum mass, is 3,50 (as predicted) for tolerable damage and 1,75 for no damage. The test results on flat slopes are quite similar and confirm the values for the coefficient K .

To sum up, the riprap design for the tests was based on the coefficient $K = 3,5$ for the minimum mass with a tolerance in the variation of mass $M_{max}/M_{min} = 2,4$ to 2,9 and an acceptable damage ($\hat{S} = 5$). The results are:

Tests	H_s	
	Design	Observed
Steep slope (1,80:1)	2,60	2,61
Flat slope (2,25:1)	2,46	2,59

and confirm that these parameters are justified.

In terms of design, the choice of the damage index should be related to the selected period of occurrence of the maximum wave attack. We recommend the tolerable damage for a return period of 1000 years and no damage for a period of 100 years.

Conclusion

Tests results show good behaviour of the riprap layer designed according to the approach based on the minimum mass and even some reserve for flat slopes. Tests have indicated that protection should extend to 2 times the design wave height below the attack level.

Uniform riprap is at least as resistant as graded riprap and for these gradations, stability is controlled by the minimum mass.

Results of tests and performance of riprap are more easily explained in terms of the minimum mass concept. Using this concept, values of 2,5 and 5 are proposed for the damage index respectively for the start of damage and acceptable damage. Within these boundaries, evolution of the damage index is linear with respect to the stability coefficient.

In accordance with Hudson's original work, the studies showed that a relatively uniform riprap performs best, so a ratio of 3,0 between the maximum and minimum mass is used for design purposes. In the field, however, it is difficult to preserve such a ratio. Experience has shown that a ratio between 4 and 6 can be readily obtained and is acceptable. The Hudson formula is used to obtain the minimum

mass of the rock. For the design, the significant wave height is used with a return period of 1:1000 years and a stability coefficient equal to 3,5. These values correspond approximately to the no damage condition with a 100 year return period and a stability coefficient of 1,75.

Resistance to wave action is a combination of both rock mass and permeability of the riprap. Sufficient void volume within the riprap allows for efficient wave energy dissipation. Rocks uniformly sized and uniformly graded with sufficient thickness achieve this objective.

CHAPTER 164

GEOTEXTILE SYSTEMS IN COASTAL ENGINEERING- an overview -

Krystian W. Pilarczyk, M.Sc.¹

Abstract

Geosystems has gained popularity in recent years because of their simplicity in placement and constructability, cost effectiveness and their minimum impact on the environment. An overview is given on application of the existing geosynthetic systems in hydraulic and coastal engineering.

Introduction

Various structures/systems can be of use in coastal engineering, from traditional rubble or concrete systems to more novel methods as geosystems and others. There is a growing interest both in developed and in developing countries in low cost or novel methods of shoreline protection particularly as the capital cost of defence works and their maintenance continues to rise. The shortage of natural rock in certain geographical regions can also be a reason for looking to other materials.

The geotextile systems as bags, mattresses, tubes and containers filled with sand or mortar, and artificial seaweed and geotextile curtains, can be a good and mostly cheaper alternative for more traditional materials/systems as rock, concrete units or asphalt. These new systems were applied successfully in number of countries and they deserve to be applied on a larger scale. Because of the lower price and easier execution these systems can be a good alternative for coastal protection and coastal structures in developing countries. The main obstacle in their application is however the lack of proper design criteria. An overview is given on application of the

Manager R&D, Rijkswaterstaat, Hydraulic Engineering Division, P.O. Box 5044, 2600 GA, Delft, The Netherlands, Fax +31-15-2611361

existing geosystems and reference is made to the design criteria.

Systems and applications

Geotextile systems utilize a high strengt synthetic fabric as a form for casting large units by filling by sand or mortar, or as curtains collecting sand. At this moment there is a relative large number of products of this type on the markt provided by some specialistic companies all over the world.

The following types and applications of geosynthetic systems can be distinguished:

1. Closed forms/units filled with sand, gravel or mortar: bags, mattresses, tubes, containers
2. Open-matting bags filled with stone or asphalt
3. Geotextile forms/moulds sand-filled structures
4. Geosynthetic sheets for dune reinforcement
5. Geotextile curtains for shore erosion control
6. Artificial seaweed mainly for scour prevention
7. Silt fences with various applications (pollution)
8. Geocells for surface (slope) erosion control
9. Geocomposite mats for drainage/erosion control
10. Traditional applications as geotextile filters
11. Water- or air-filled dams
12. Other (unclassified) systems (bearer for blockmats, temporary slope protection, landfill covers, cabling, pins, pipes, connections).

More informations on these systems can be found in (Pilarczyk, 1995, Pilarczyk & Zeidler, 1996) and in references.

Geosynthetic forms

Mattresses are mainly applied as slope and bed protection. Bags are also suitable for slope protection and retaining walls or toe protection but the main application is construction of groynes, perched beaches and offshore breakwaters. The tubes and containers are mainly applicable for construction of groynes, perched beaches and offshore breakwaters.

Figure 1. Application of bags

They can form an individual structure conform some functional requirements for the project but also they can be

used complementary with the artificial beach nourishment to increase its lifetime. Especially for creating the perched beaches the sand bags and /or sand tubes can be an ideal (often low-cost) solution for constructing the submerged sill (with a low wave loading).

Some coastal engineering concepts are shown in Figure 2. Underwater breakwaters and sills (perched beaches) are not easy to construct with traditional materials. In this respect (sand)tubes, although based on the same principle, are more advanced even by comparison with sandbags, which are only 1.0 to 5.0 m³ in capacity and are time-consuming as concerns both manufacturing and installation while hydraulic filling of tubes provides a few hundreds m³ of sand in few hours.

The sand-filled bags and /or tubes can be of use for constructing of groynes. Up till now there is no reliable design methods concerning the functioning of groynes. When the groyne will work satisfactorily such groyne can be strengthened additionally (if necessary) to get a permanent function. If not, the groyne can be easily demolished. In general, the sand-filled structure can be used as a temporary structures to learn the natural interactions/ responses, or as the permanent structures

Figure 2. Coastal applications of geotubes/containers

at locations with relatively low wave attack ($H < 1.5\text{m}$), or as submerged structures where direct wave forces are reduced by submergence. The units (if necessary) can be interconnected by bars or by creating a special interlocking shape.

These systems can also be applied in hydraulic/river engineering for constructing of spur dikes, guide dams, revetments, bottom groins, bottom protection, etc.. As other possible applications can be mentioned: containment dikes for storage of (contaminated) dredged material, dike or dune reinforcement, moulds for artificial sand structures, etc.

The main advantages of these systems in comparison with more traditional methods (rock, prefabricated concrete units, blockmats, asphalt, etc.) are: a reduction in work volume, a reduction in execution time, a reduction in cost, a use of local materials, a low-skilled labour and (mostly) locally available equipment.

That means that in most, not too extreme cases/conditions the work can be done by a local contractor under supervision of the specialistic experts/company.

Geocurtains

There are a number of various applications of geocurtains, i.e. silt- and/or pollution curtains, guiding screens for sediment control in rivers and harbours, fences for surface erosion control, etc.

Information on these systems can be found in references.

An interesting application for shore erosion control is the geocurtain known under the name **BEROSIN** (Fig. 3).

Figure 3. Application of geocurtains (**BEROSIN**)

The **BEROSIN** curtain is a flexible structure made of various woven geotextiles which after placing by divers near the shore and anchoring to the bed catches the sand transported by currents and waves providing accretion on a shore and preventing the erosion. The horizontal curtain (sheet) can be easily spread (at proper sea conditions) by a small workboat and two divers. The upper (shore-side) edge, equipped with some depth-compensated floaters, should be properly anchored at the projected line. The sea-side edge is kept in position by the workboat. By ballasting some of the outside pockets at the lower edge with sand or other

materials and with help of divers, the lower edge is sinking to the required position. The proper choice of permeability of geotextile creates the proper conditions for sedimentation of suspended sediment in front/or under the curtain and at the same time allowing the water to flow out without creating too high forces on the curtain and thus, on the anchors. In case of coast of Vlieland (NL), some of the horizontal curtains placed in the intertidal zone have provided a growth of a beach/foreshore of 0.5 to 1.0 m within a week while others within a few weeks. It was also recognized that the sheets (curtains) can be easily damaged in vicinity of rock due to abrasion (one curtain was connected to the existing rock groyne). On the other hand, the heads of the existing groynes were badly damaged and the beach between the groynes was eroded during the storms while the area protected by the curtains remained in proper condition.

It seems that this system can provide a low-cost measure for steering of the morfological processes. However, more prototype experiments in various wave climate are needed before the final conclusions on the effectiveness and durability of this system in various design conditions can be drawn.

The most recent development concerns the application of a number of (anchored) floating screens (grids), placed in a certain pattern along the sea bed (Huygens et al, 1995). However, the first in site experiment has failed because of high wave induced forces and resulting anchorage problems.

Artificial seaweed

The field observations provided that in some coastal areas the natural seaweed plays an important role in retaining sand along the coastlines due to the reduction of the shear stresses exerted by currents and waves on the seabed. This fact was the base of the idea to produce and apply the artificial seaweed for erosion control. The first users of artificial fibres for erosion control and/or to prevent marine scouring date back to the 60-ies (England, Denmark, Netherlands). The artificial seaweed was composed on polypropylene tape (having a specific gravity of less than one), 3 to 10 mm wide, connected edge to edge to form a continuous serrated sheet. In some cases dozens of tapes were bundled together to form individual tufts of seaweed. Fronds varied from 1 to 2 m in length. In the Netherlands, research on artificial seaweed has been conducted in cooperation with the Shell Plastics Laboratory, Nicolon Geotextiles Company and the Rijkswaterstaat (Dutch Public Works), (Bakker et al, 1972) The improper anchorage was the main reason of the failures with this system .

The experience from US and European projects indicate

that the artificial seaweed can be successfully applied for scour prevention around the legs of offshore platforms and around offshore pipelines when the anchorage is designed properly. Applications of artificial seaweed to beach erosion control were till now less successful. There were often no discernable differences between the shoreline protected with artificial seaweed and adjacent unprotected shorelines. The materials appear to be inadequate to survive moderate to high wave activity. One of the main reason for that was again the problem with anchoring (Rogers, 1987). Due to the high forces of breaking waves in a surf zone the necessary anchorage needs special expensive measures which makes this system less competitive with more conventional solutions.

The past experience with the artificial seaweed indicates that the most promising application for this product is prevention of localized scour at offshore structures (platforms, pipelines, etc.). The wave induced currents are there of a limited strength (less problems with proper anchorage), because of larger depths no problem with UV-resistance, and less problems with effect of fouling and debris. That also explains why the recent developments and applications are related (limited) to that area.

The product which actually successfully operates on the markt for offshore applications has a form of a underwater artificial sea grass field/mats (developed in 80-ies), and is known as Seabed Scour Control System (SSCS, 1995). Based on the artificial seaweed concept of "arrested sedimentation" SSCS system (mat) suffers none of the drawbacks of similar previous systems. It has superb positional stability, it is not prone to phylloplankton colonisation, it requires no special tools or skills for installation and it actually serves to enhance its own effectiveness and that of other conventional sea defence forms.

The functioning principles are straight-forward; buoyant fronds floating upright from the seabed act to reduce seabed and near-seabed current velocities, encouraging the deposition of transported (eroded) seabed material. In conjunction with this action, at relatively shallow water the fronds also interfere with wave-induced orbital forces, effectively causing waves to break early and thus reducing the impact on threatend shorelines, breakwaters, etc.

This technique employs chemically inert materials to create a flexible barrier to retard the flow of water. The SSCS scour control mats are retained on the seabed by anchors hydraulically driven to a depth of 1 m. The system has been designed and tested for stability in current velocities in excess of 10 knots (> 0.5 m/s). The flexible fronds-mat can also be incorporated into flexible concrete block mats to provide added effectiveness in

stability and in wave dissipation. The main applications are in protecting fixed offshore platforms, mobile rigs and pipelines from the effects of scour.

Stability of geosystems

The main obstacle in application of geosystems is the lack of proper design criteria. However, from the literature review it is possible to formulate some stability criteria based on small scale experiments. It can be concluded that the stability of the coastal structures composed of geosystems (bags, mattresses, geotubes) can mostly be expressed in the similar way as for rock, namely in term of $H_s/\Delta D$ parameter.

* Sand and mortar filled bags

For the time being it can be concluded that the stability of sandbags with the width-length ratio not larger than 1 to 3 and properly filled (> 70%), can be computed in the similar way as riprap. It is recommended to calculate the stability acc. to Pilarczyk's formula (Pilarczyk, 1990) with stability coefficient $c = 2.5$, nl.:

$$H_s/\Delta D = c \cos\alpha \xi^{-1/2} \quad \text{for } \xi \leq 3 ,$$

(for $\xi > 3$, the values calculated for $\xi = 3$ can be used),

where: H_s = significant wave height, Δ = relative density of the bags, $(\rho_s - \rho_w)/\rho_w$, D = average thickness of bags, c = stability coefficient defined at $\xi = 1$, $\cos\alpha$ = slope angle (it can be neglected for slopes milder than 1 on 3), ξ = surf-similarity parameter equal to $\tan\alpha/(H_s/L_o)^{1/2}$, and L_o = wave length. The density of bags (ρ_s) can be assumed 2000 and 2300 kg/m³ resp. for sand and concrete (Δ resp. 1 and 1.3).

Note: Sand-filled units exposed to direct wave attack are applicable till $H_s = 1.5$ m (max. 2 m).

* Stability of foreshore protection mattresses incl. sand-sausage mattresses (ProFix-mats)

For the first approximation of stability of sand- or mortar-filled mattresses (i.e. ProFix or Fabriform mats) of more or less uniform thickness the formula proposed by Pilarczyk (1990) can be used:

$$H_s/\Delta D_{eq.} = c \cos\alpha \xi^{-2/3} \quad \text{for } \xi \leq 3$$

(for $\xi > 3$, the values calculated for $\xi = 3$ can be used) where: Δ = relative density of the mattress, $D_{eq.}$ = equivalent (average) thickness of mattress, c = stability coefficient defined at $\xi = 1$ (definition of other parameters is the same as above).

The value of coefficient 'c' depends on the failure

mechanism and the ratio between the permeability of the mattress and the permeability of the subsoil, k_m/k_s :

$c = 3$ to 4 when $k_m/k_s < 1$ with the uplift of mattress and deformation of subsoil as main failure mechanism, and

$c = 4$ to 6 when $k_m/k_s \geq 1$ with the deformation of subsoil as the main failure mechanism.

The range of c -values follows from the research projects of Delft Hydraulics with placed block revetments/block-mats and different type of mattresses. It should be noted that the uplift can already start at $c = 2$, but it is so small and of such short duration that it will no result in a serious damage to the mattress protection. Therefore $c = 3$ to 4 can be treated as a design value.

In special cases as large mattresses of temporary use and/or when some deformation of the subsoil can be accepted or the subsoil is more resistant to deformation (i.e. clay) the higher values of ' c ' can be chosen (max. 6). The research described in (Delft Hydraulics, 1975; large mattresses on circular island) can be illustration of such case. Using these high c -values the structure should be controlled on sliding, and in most cases it will require a special anchoring of mattresses.

Sand-filled units applicable till $H_s \leq 1.5$ m.

* General stability criteria for geotubes filled with sand or mortar (Wouters, 1995)

Based on small scale investigations by Delft Hydraulics (Breakwater of concrete filled hoses, M 1085, 1973) and other literature informations, the following stability criteria for geotubes can be formulated:

- tubes on the crest (at S.W.L. or submerged) lying parallelly to the axis of breakwater

$$H_s/\Delta B = 1$$

where B is the width (horizontal ovality measure) of a tube; one may roughly assume $B = 1.1 D$ (original diameter of a tube).

Note: when the crest layer is composed of two tubes connected artificially to each other (i.e. re-bars) the equivalent width is equal to $2B$.

- when the tube is placed perpendicularly to the axis of a breakwater the stability can be approximated by

$$H_s/\Delta L = 1$$

where L is the length of a tube.

Sand-filled units are applicable till $H_s = 1.5$ m (max. 2m).

Due to the absence of reinforcement in the mortar filled units it is very likely that for long tubes (say longer than 3D) also cracks will occur; some reinforcement should be recommended or an equivalent length should be taken equal to $L < (3 \text{ to } 4) D$.

Conclusions

The geotextile systems can be a good and mostly cheaper alternative for more traditional materials/systems. These new systems were applied successfully in number of countries and they deserve to be applied on a larger scale.

In the past the design of these systems was mostly based on rather vague experience than on the general valid calculation methods. Actually, more proper design rules have been established based on some scale investigations and experience from realized projects. However, more research, especially concerning the large scale tests and evaluation of performance of already realized projects, is still needed.

The technologies related to geotextile systems have been utilized extensively in Europe, Northern America, Mexico, Japan and Australia, producing often successful installations but only few technical details. Some manufacturers and contractors are inclined to protect know-how to preserve market advantages. Therefore, to effectively commercialize these technologies it is necessary to uncover the technical details. Technically the methodologies have shown to be feasible but there are design and constructibility uncertainties that still must be addressed.

A number of weak points of above reviewed systems can be omitted when the actual knowledge/experience will be applied in the design and technological improving of these systems including such aspects as fabric choice, fabric coating, filling method, installation techniques, stability criteria, and life-time.

The intention of this literature search is to uncover, as far as possible, the technical informations on these systems and make them available for the potential users. It will help to make a proper choice for specific problems/projects and it will stimulate the further developments in this field.

There are more applications of geosynthetic (geotextile) systems in coastal engineering than those mentioned above. It is going too far in the scope of this paper to review all of them. However, the main other applications can be found in the references.

There is a rapid development in the field of geotextiles and geotextile systems and there is always a certain time gap between new developments and publishing that in specialistic books. Therefore, it is recommended to follow the professional literature on this subject (Jour-

nal of Geotextiles and Geomembranes, Geotextiles Congresses, Coastal Engineering Congresses, etc.) and manufacturer's brochures for updating the present knowledge.

CHAPTER 165

Groynes on the East Frisian islands: History and experiences

Hans Kunz ¹

Abstract

Groynes can be a valuable shore-protection structure. An example for this fact are the 'Strombuhnen' ('stream groynes') which have been constructed on most of the East Frisian islands throughout the last hundred years. These groynes are integrated in an engineering coastal protection system, which includes seawalls, dune revetments, 'Strandbuhnen' ('beach groynes') and artificial beach-restoration. The modern approach of society in Germany (and many other countries) towards nature preservation and integrated management of the coastal zone discourages use of 'hard' constructions. However, there are several demands of society, for which we have to concede, that properly designed 'stream groynes' can function effectively and economically; under certain conditions; this can also be the case for 'beach groynes'. According to the stated demands, these constructions have, more or less, the target to govern natural processes; hence they are principally objectable from an environmental point of view.

Introduction

The seven East Frisian islands extend along the North Sea in the western part of Germany (Fig. 1). The chain of barrier-islands is broken by inlets and separated from the mainland by a tidal flat system (Fig. 2). The semi-diurnal tides and wave action generate a net littoral drift from West to East. With respect to hydrodynamical boundary conditions and sediment transport, the islands experience both, erosion and accretion. The processes at the spits of the islands are governed by the tidal inlet, associated with the sediment transport processes in the ebb delta-shoals and the tidal

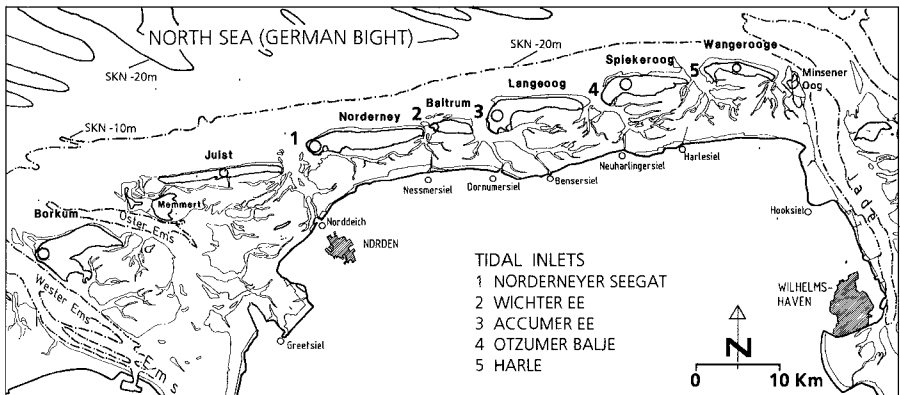

Fig. 2: The East Frisian islands and tidal inlets.

basin. The inlets are the most active part of the system; in the past they permanently changed their location as a reaction on structural changes within the sea/inlet/basin-system (naturally or man made). A migrating inlet can lead to erosion of an island, by the strong currents in the tidal channel and by effects on the ebb-delta shoals ('reef bow') which decrease the sand supply from the littoral system (negativ sand budget). The morphological development of the East Frisian islands is well recorded since 1650 (e.g. Homeier, 1962).

Groynes on the East-Frisian islands

Groynes are shore-perpendicular (normal) constructions. Professional terms in German literature distinguish 'Strandbuhnen' ('beach groynes') and 'Strombuhnen'

Fig. 3: Groyne-types (left). Stream-groyne (right).

('stream groynes') - see Fig. 3. The definition of 'beach groynes' has stated the purpose, quite similar to SPM (1984), as trapping littoral drift, building a beach, defending the removal of sand from the beach. 'Stream groynes' are structures to withstand and to govern the eroding forces (currents) of migrating tidal channels - e.g. KFKI (1993), TAW (1995).

The first solid construction (groynes, revetments) on the East Frisian islands were directed against dune and beach erosion. They failed in the beginning, because they could not stop migration of the inlets and they did not trap sand. The effects of scouring in front of the revetment and lee-erosion, prompted the extension of the protection means (expansion, displacement of the problems). Later on, the functional purposes of the groynes had been focused on the stabilization of the tidal inlet, leading to controversial discussions on the extension of groynes into deep water. The extreme high expenses for these 'Strombuhnen' finally had been justified by different targets (e.g. Witte, 1970):

- protection of the settlements (residential, recreational, commercial purposes).
- Preservation of the existing coastal protection constructions.
- Stabilization of the Ems- and Jade-waterway (Borkum- and Wangerooge-island).
- Stabilization of the tidal inlets and by this maintenance of the wadden-waterways to small harbors and of drainage channels.
- Protection of the mainland (dikes, foreland) against the impact of stormfloods.

The construction of 'stream groynes' started around 1900 and had been carried out on the western spits of four East Frisian islands. In every case these groynes had been constructed by extending existing 'beach groynes' into the deep water of the channel (response to the fact that the implemented groynes failed to stop erosion). Hence, these groynes are a combination of both types, depending on the crest-height; the lower part is addressed as 'underwater-groynes'. Since 1951/52 the technique of beach restoration has frequently applied to compensate sand losses by maintaining beaches within the groyne fields, which are high enough to protect the structures against failure caused by stormfloods.

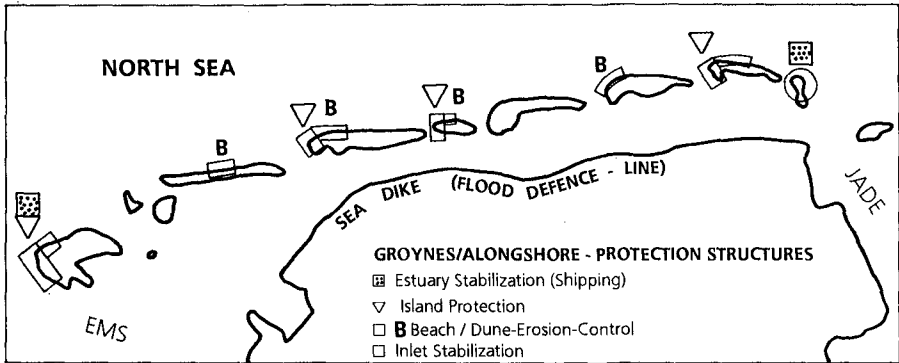

Fig. 4: Groynes on the East Frisian islands and their different targets.

The development of the groynes as part of the engineering coastal protection systems on the East Frisian islands is well known and described (e.g. Fülischer (1905), Gaye & Walther (1929), Kurzack et al. (1950), Witte (1970)).

Fig. 4 displays the groynes of the East Frisian islands (124); all are incorporated in protection structures (about 20 km length in total) which include shoreparallel constructions (seawalls, revetments). The different main targets with respect to the island/inlet are marked by signatures. The islands, tidal flats, forelands (saltmarshes), sea dikes (flood defence line) form one unit; hence the areas behind the islands benefit from the island protection means. The construction of groynes has rather based on a 'guidance on functional design', (e.g. Kraus et al., 1994) than on 'roles of thumb'; adaptations derived from 'lessons learnt from experience' and from changing hydrographic and morphological boundary conditions. The effects of groynes had been studied in physical models, especially for Norderney-island (hydrodynamical preinvestigations go back to the end of the last century; in the forties of this century they had been combined with morphodynamics (movable bed using amber grains) - Pr. Versuchsanstalt, 1940.

Examples

Fig. 5 shows, as an example, the actual situation of Baltrum-island: the western spit is totally armored, the inlet (Wichter Ee) has been fixed by 'stream groynes', the shoals (littoral drift) feed only areas eastward of the exposed spit. This situation is comparable with Norderney-island (e.g. Fig. 2 in Kunz, 1993a) and the problems are principally the same (e.g. Luck 1976, Kunz 1987).

The migration-history of the Wichter Ee inlet is shown on Fig. 6 by the development of: the Wichter Ee itself (ΔW), the watersheds of the Wichter Ee tidal basin (to the West (ΔN) and to the East (ΔB)), the shore-line of Baltrum West. The definition of the terms is illustrated on Fig. 7. The construction of 'beach-groynes' started earlier on Norderney than on Baltrum (see (N) and (B) on Fig. 6); the exten-

sion of the existing beach groynes into the tidal inlet (conversion into 'stream groynes') is marked by (N/B). The stabilization-effects are obvious: the system lost it's dynamic behavior and became static. This happened to the East Frisian islands as a whole, as three more inlets (see Fig. 4) had been stabilized (e.g. Luck 1976). Society

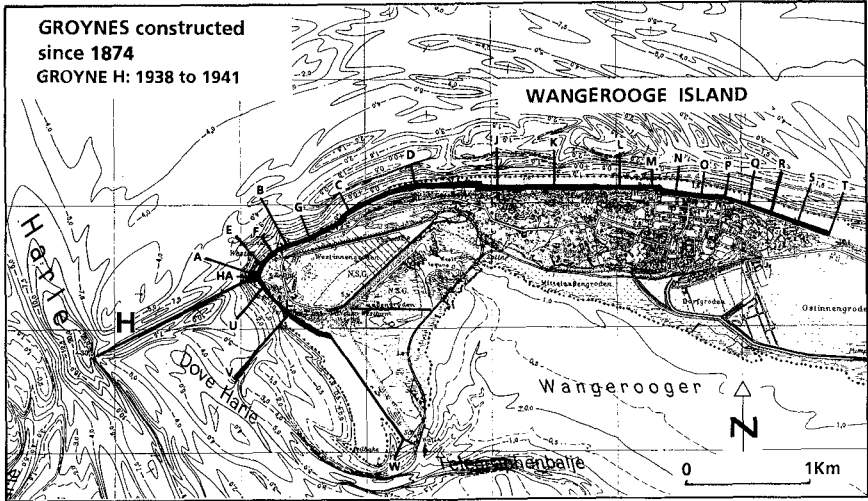

Fig. 8: Groynes on Wangerooge-island. Forschungsstelle (1980).

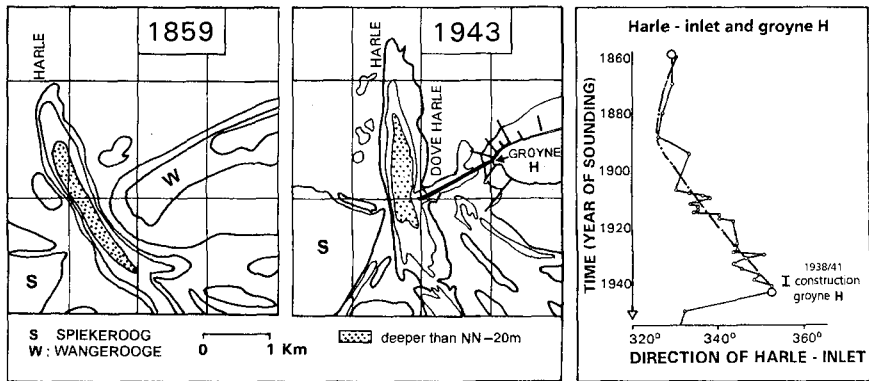

Fig. 9 : Harle inlet and Wangerooge island in 1859 and 1943. Turning of the Harle-inlet-direction before and after the construction of groyne H - Lüders (1952).

valued this result as a success; nowadays there are complains arising from the new targets of nature conservation, which society has more and more agreed on throughout the last decades (e.g. Kunz, 1993b).

The western spit of Wangerooge-island and additionally about four more kilometers of the shoreline to the East are protected by groynes (Fig. 8). The history of the island-protection is closely associated with the Jade-waterway and the harbor of Wilhelmshaven (e.g. Krüger 1911, Witte 1970). The Harle-inlet migrated to the East and turned clockwise (Fig. 9), a trend which can be explained by natural and by man made reductions of the attached catchment area 'Harle tidal basin' - Homeier (1973).

Fig. 10: Development of the protection on Norderney west (1857 to 1877).

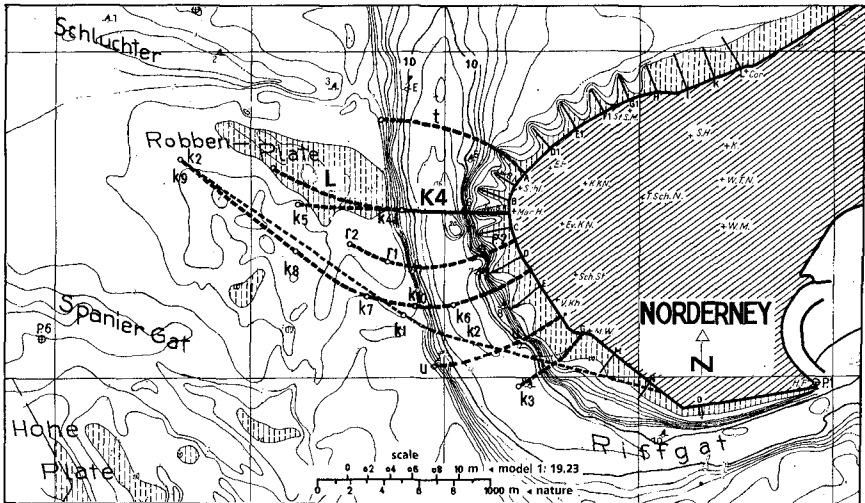

Fig. 11: Proposed groyne-extensions and training dams into the Norderney-inlet: physical model with movable bed (Pr. Versuchsanstalt, 1940).

The western spit of Wangerooge-island and additionally about four more kilometers of the shoreline to the East are protected by groynes (Fig. 8). The history of the island-protection is closely associated with the Jade-waterway and the harbor of Wilhelmshaven (e.g. Krüger 1911, Witte 1970). The Harle-inlet migrated to the East and turned clockwise (Fig. 9), a trend which can be explained by natural and by man made reductions of the attached catchment area 'Harle tidal basin' - Homeier (1973). By the extension of groyne H from 290 m to 1460 m with a crest height of about MLW it was possible to close the secondary channel 'Dove Harle' and to restore a morphodynamic situation almost similar to the middle of the last century by returning the direction of the Harle-inlet (Fig. 9, right), which has been more favorable for the island with respect to the island stabilization-targets (Lüders 1952).

The groynes and shore-parallel structures on the East Frisian islands have been implemented 'step by step' since the middle of the last century. In each case the first

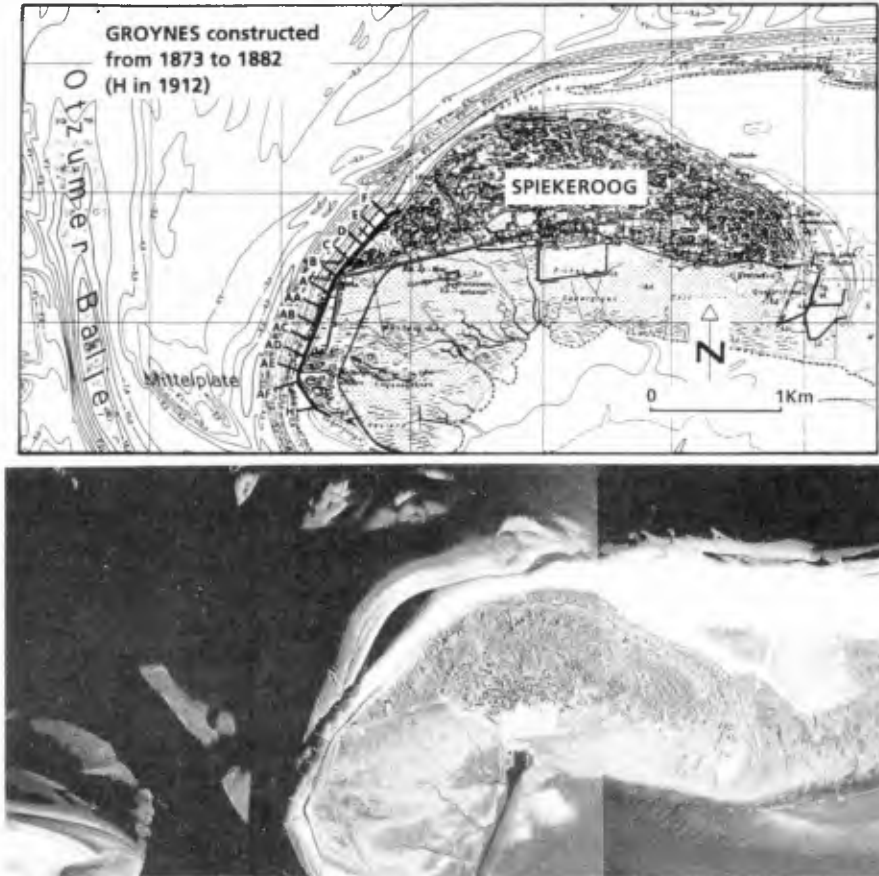

Fig. 12: Spielerog West. Above: groynes and dune revetment. Below: Aerial view, May 1989, shortly before landing of an accumulated shoals.

step had been a technical response to the respective problem: short stretch of dune revetment against dune-losses; a few short 'beach groynes' against beach-scouring; extensions against effects of lee-erosion etc.. Thus, the first 'voluntary step' had been followed by further steps which had been determined by the natural processes in interaction with the coastal defence-constructions (man made boundary conditions). This history is especially well documented for Norderney (e.g. Fülischer (1905), Gaye & Walther (1929), Kurzack et al. (1950), Peper (1956), Witte (1970)). Fig. 10 describes this history for the first two decades after a short solid seawall had been constructed in 1957/58 (still in place!). Under the existing conditions (tidal channel is migrating towards the island, lack of sand supply by cross-shore transport, unfavorable balance between net and gross longshore transport, bypassing) the construction had to be adapted or given up. The adaptation by 'stream groynes' stopped the inlet movement, but it didn't solve the erosion-problems. Therefore the question had been investigated, how the morphological and hydrographical boundary condi-

Fig. 13: Time-Distance-Lines for profiles on Juist island. Profile 52: construction of groynes with seawall from 1913 to 1922. Data: Archive CRS, Norderney.

had been investigated, how the morphological and hydrographical boundary conditions could be changed by groynes and training dams in such a way, that a new tidal inlet (displacement to the West, anticlockwise turning of the direction up to 45°) could be established and maintained - Pr. Versuchsanstalt (1940), Kurzack et al. (1950). Fig. 11 gives an idea about the enormous dimensions of the discussed plans. Fortunately an especially established expert-group worked out an alternative (Küstenausschuß, 1952) and the decisionmakers followed their recommendations. Subsequently the first large scale beach nourishment in Europe (1.25 Mio m^3) had been carried out on Norderney-island in 1951/52 (see Fig. 14).

The morphological development of Spiekeroog-island since the Middle Ages had been substantially affected by natural sedimentation in the related tidal basin (Harle-bay) and by land reclamation means (poldering): persevering recession of the coastline in the West, accretion in the East - Homeier (1961). This led to a break through of the foredunes in 1832. The following construction of dikes (embankments) failed; consequently a solid construction work (groynes and dune revetment) had been implemented between 1873 and 1884, with supplements in 1912 and 1936/37 (Fig. 12, above). The construction works were successful; the large scale morphological features fluctuated around a generally stable stage and, in average, the natural sand supply from the 'reef bow' (merging shoals) has been sufficient. Critical situations occur when approaching shoals accumulate in front of the shore line, creating a shore-parallel channel (last phase before merging). In this phase the groynes combine more or less stabilization functions of beach- and stream-groynes (Fig. 12, below).

Fig. 14: Combined coastal protection system on Norderney-island.

The last groyne-seawall system on the East Frisian islands had been constructed on Juist between 1913 and 1922. Fig. 13 demonstrates long term trends of shore line developments: erosion in the West (prof. 15), accretion in the East (prof. 70), intermediate stages inbetween (prof. 25 & 52). The general trends are overlapped by short term variations. The displayed trends can not be extrapolated without taking into account the possibility, that there may be a kind of cycle with a very long time-period (see prof. 52). Unfortunately we have only a few records on profile mapping available, which reach far enough back into the past, to work on this question. On Juist the settlement seemed to be endangered by dune-erosion in the first decade of this century. The construction of the protection-system coincided with the transition from an erosive to an accretional trend (see prof. 52). Subsequently the groyne and the seawall had been buried under sand (up to 10 meters).

Groyne as part of a coastal defence strategy

The groyne on the East Frisian islands are incorporated into an engineering coastal defence system. This system has been successful in stopping the migration of tidal inlets and it preserved endangered parts of the island. The groyne were not effective in reducing beach erosion; but they can stabilize artificially restored beaches, if appropriately designed. Beach restoration is carried out as part of the maintenance. Fig. 14 demonstrates the strategy by the Norderney-example:

- Stream Groyne to stop the eastward directed migration tendency of the tidal inlet.
- Beach Groyne to stabilize the beaches in front of the shore-parallel structures.
- Shore-parallel Structures to protect the foredunes against erosive forces.
- Artificial beach nourishment of groyne fields to protect the existing structures against damage during storm floods.

Fig. 15: Crib groyne No. 33 on Borkum island. Aster et. al. (1989), KFKI (1993).

The groynes need to be maintained and restored. A restoration-example is shown on Fig. 15 to give an idea about the dimensions - e.g. Aster et al. (1989), KFKI (1993).

The existing coastal defence systems on the East Frisian islands demonstrate, that they are sound tools to fix the shoreline. On the other hand they show, how expensive these systems are and how strongly they interfere with nature. There is an increasing demand by the island population to defend shoreline retreat with the 'hard' technique which has been proven as successful in the past. Fig. 16 deals with actual problems on Borkum-island. The western spit has been protected since the middle of the last century - e.g. Witte (1970), Aster et al. (1989). The north-eastern part of the island reacts (erosion, accretion) on structural developments of tidal channels and the foreshore (e.g. Kunz et al. 1996). The existing erosional trend and the expected development in future (szenario 2045) makes it understandable, that protection demands arise. However, if we take into account the aspects of an integrated coastal zone management, we should learn from history, that society has to take into account the problem as a whole, including the large scale processes (time & space). She also has to remember the fact, that an armoring of the existing intermediate stage is not favorable. The displayed hydro-morphological situation explains, together with the other examples, why proposed 'head-land' solutions (e.g. Silvester, 1978) provide no realistic alternatives for the East Frisian islands.

Fig. 16: Development (1874 to 1994) of the flood- and ebb-stream channels which impact the northern part of Borkum-island. "Szenario 2045" for erosion. Existing groyne-sea-wall system around the western spit.

Conclusions

Man started to protect the islands against erosion by solid structures since the middle of the last century. Groynes had been proven as an essential part of the coastal protection systems. The groynes are incorporated into a system which consists of different types of groynes, seawalls & dune-revetments and of artificial beach/foreshore-nourishment. The system had been successful in stopping the migration of tidal inlets and it preserved endangered western parts of the islands. The groynes were not effective in reducing beach erosion - but the existing groynes can stabilize artificially restored beaches, if the restoration is appropriately designed.

The existing groynes have to be maintained and enhanced, as far as they are essential to protect the historically developed situation. Beach groynes may be given up, instead of being reconstructed. This has to be investigated sitespecifically.

If we combine the lessons learned from the groyne-history with the recently developed demands of society (environmental issues & cost-benefit-ratio) we can not recommend to continue with the strategy of the past. Future strategies for the coastal-protection of the East Frisian barrier-islands should not include the construction of groynes, except in special cases, where no shore-line-retreat is acceptable and no solutions are possible, which are less static.

CHAPTER 166

PERMEABLE PILE GROINS

Thomas Trampenau¹, Frank Göricke², Arved J. Raudkivi³

ABSTRACT: Permeable pile groins have been built on the southern shores of the Baltic Sea in large numbers for the past century and a half, yet no detailed literature has been written on how these structures function. The study of the groin system at Warnemünde, has shown that this type of groin causes a reduction of the littoral current and elimination of the local rip currents. This, in turn, causes underwater profiles to raise, a widening of the beach and a seaward movement of the shoreline.

INTRODUCTION

Groins are one of the oldest forms of coastal protection structures used in a multitude of forms and types of material the world over. Their expected effects, however, are still only loosely predictable. Groins are generally solid structures extending from the shoreline into the surf zone. These may be short or long, high or low groins, where the latter are frequently overtopped by waves. There are also groins that slope from the beach or revetment down to the sea bed at the seaward end. Groins may also be classified by the type of construction and materials used. Rubble-mound, concrete, steel or wood are examples of materials used in construction. Many groins are permeable, but mainly as a result of leakage rather than intention. For example, rubble-mound groins may become less pervious as sand and slit block the voids.

The following discussion is restricted permeable pile groins. These are pervious by nature and built using piles rammed with predetermined spacing that may vary along the groin. Such a groin is illustrated in Fig. 1.

Figure 1. A permeable pile groin field in the test area Warnemünde during low water (caused by wind set-down)

The use of pile groins has been primarily confined to the southern coast of the almost tideless Baltic Sea, where over 900 pile groins have been built along the German coastline since 1843 (Weiss 1991) and about 950 along the Polish shores (Basinski 1963; Onoszko 1984). The permeabilities (the ratio of the pile diameter to the pile spacing) vary up to about 50%.

Frequently, the food of the groin has been rammed tight (permeability = 0%). The groins typically protrude 0.5 m above the sea level. Unlike non-permeable groin fields which cause a saw-tooth shoreline to form, permeable pile groins fields retain a continuous, straight shoreline (Fig. 2).

Consequently, the explanations of performance of groin, as expounded in literature, are not directly applicable to permeable pile groins. A discussion of the functioning of the permeable pile groins was published by Raudkivi (1996). The primary effect of permeable pile groins is the slowing down of wave induced longshore current in the groin fields and an elimination of rip currents along the groins (Fig. 3). This results in the raising of the profile within the reach of groin field and the development of a terrace. The following is a representation of field data from the groin system Warnemünde near Rostock, Germany.

Figure 2. Typical shoreline alignment of a permeable groin field at low water

Figure 3. Schematic beach profile and wave-induced longshore current distribution with and without permeable pile groins

THE TEST AREA

The coastline of the test area faces northward. The predominant wind direction is from west to northwest that leads to a net eastward component of annual energy flux. An aerial view of the groin system is shown in Fig. 4.

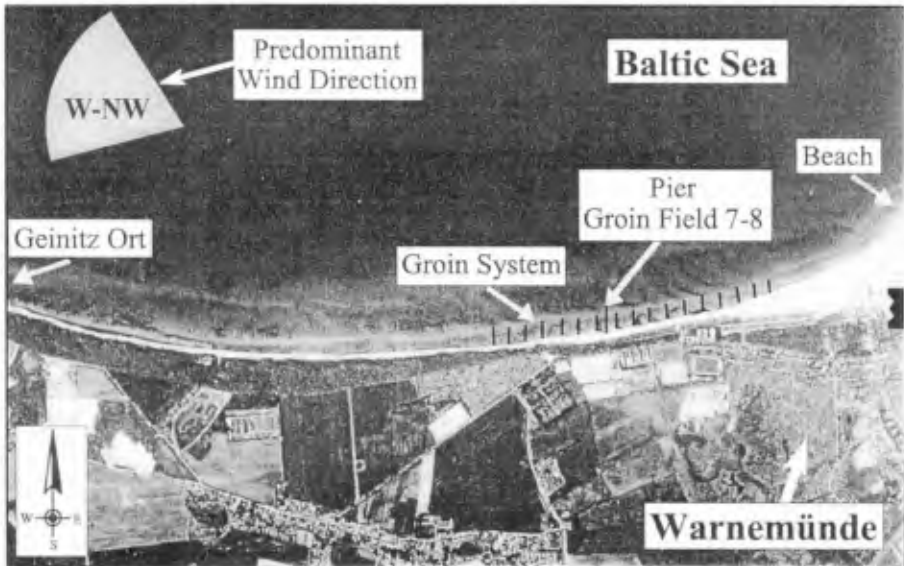

Figure 4. Aerial view of the groin system at Warnemünde

Although typical fluctuation of the water level due to wind setup/setdown is less than ± 0.5 m, storm tides up to 2.8 m above MSL have been recorded. Severe storm tides are associated with weather systems of lows in the North Atlantic or Mediterranean that move to the Baltic area and meet with Northern European high pressure systems. This leads to severe winds from the northeast. These have a mean return period of about 6 years. The frequency of significant wave heights H_S higher than 1.0 m is approximately 5%. The predominantly fine-grained sediment of the coastline has a narrow swash zone, followed by an upward concave slope (terrace) that ends with a steeper slope down to the trough landward of the first shore-parallel bar. The term "first bar" is used because in the tideless Baltic Sea frequently more than one shore-parallel bar is present (Fig. 5).

Temporary bar-trough features (inner bar) occur on the nearshore slope due to local breaking of waves. In the swash zone the middle and coarse fractions of the local sand dominate. On the terrace about 90% are finer than 0.2 mm. The sand grain diameters increase down to the trough (0.35-0.63 mm). On the bar, though, about 90% of the sand is finer than 0.2 mm.

Figure 5. Typical shoreline profile in the test area

Field data has been collected from the Warnemünde test area since 1989. 17 pile groins were installed during 1991-92 and extend 120 m seaward from a baseline that is about 20 m landward from the water's edge. They are spaced 80 m apart. The top of the piles are 0.5 m above mean sea level. The groin system Warnemünde is shown in Fig 6.

The permeability (P) of the groins varies. The groins in the centre of the groin system are rammed tight for the first 80 m of their seaward reach. The permeability of the remaining 40 m displays an increase of spacing between the piles. The permeability of the groins also decreases between groins in the field. The groins furthest east and west exhibit the lowest mean permeabilities. Groin 8 and 9 have the highest permeabilities. The dotted area on Fig. 6 delineates the area where the groins are rammed tight. Groins 2 and 3 have pile spacings up to 0.25 m compared with pile diameter of 0.22 m. Permeability increases from 30% up to 55% with a mean over the groin length of 40%. The groins 5 and 6 have permeabilities from nominal zero up to 40% with an average of 20%, and groins 7 and 8 have permeabilities up to 40% with a mean of 13%. To verify the efficacy of the permeable groin field after construction, a profile 140 m westward of the first groin was used for reference. Regular surveying along this profile as well as within the groin fields between groins 2-3, 5-6 and 7-8 have been carried out since 1991.

RESULTS

The bands of annual wave-induced profile variations at the groinless reference station are shown in Fig. 7 for the year 1990/91 superimposed onto the bands of the years 1992 up to 1995. Other years depict an essentially identical picture of small profile changes dependent on sea conditions. Changes between the underwater profile in the groin field 2-3, (of relatively high permeability) from that before the installation of groins, is illustrated in Fig. 8.

Figure 6. Aerial photo of the test area Warnemünde (enlargement)

A time span of almost two years past before a change of the profile become noticeable. In 1995 a significant widening of the beach and development of an underwater terrace is apparent. It is also noticeable that the terrace now extends beyond the end of the groins. The underwater profile development in the groin field 5-6 is shown in Fig. 9. Also to be noted is the seaward shortening of the terrace, a rise of the underwater profile near the shoreline and a widening of the beach about 20 m in seaward direction.

The changes of underwater profile in the permeable groin field 7-8, with the lowest permeability ($P=13\%$) over their entire length, is shown in Fig. 10. The comparison of the annual profile bands, before and after groin installation, were is informativ. The differences in band variation (1990 and 1991) before groin installation are relatively small and comparable with those at the reference station that shows no trends. After installation of the groins in autumn 1991, 1) the shoreline has moved steadily in seaward direction, 2) the terrace has narrowed considerably, 3) the beach level has been raised, 4) the underwater profile in the groin field has lifted 0.5 m and 5) its slope at the groin toe has become steeper.

At the reference profile (groinless coast) only small profile changes have been recorded. The results show that permeable groins with relatively high permeability over their entire length lead to a shift of the shoreline seaward (note groin field 2-3). A further reduction in permeability and a tighter inshore segment lead to a raising and seaward shift of the underwater profile, as seen in groin fields 5-6 and 7-8.

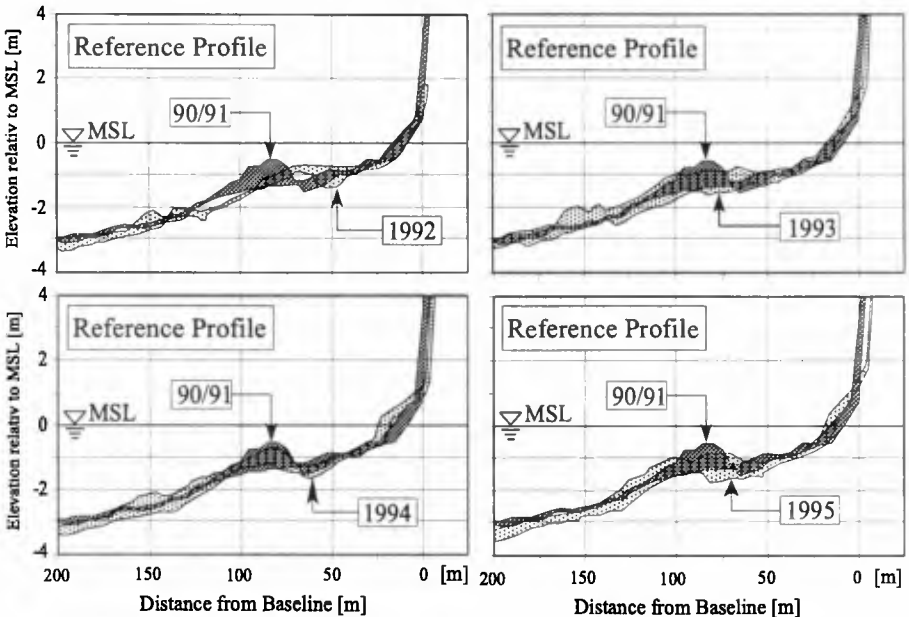

Figure 7. Bands of profile movements at reference station from 1992 up to 1995 compared with the band from 1990/91

Figure 8. Bands of profile movements in groin field 2-3 from 1992 up to 1995 compared with the band from 1990/91 before groin installation

Figure 9. Bands of profile movements in groin field 5-6 from 1992 up to 1995 compared with the band from 1990/91 before groin installation

Figure 10. Bands of profile movements in groin field 7-8 from 1991 up to 1995 compared with the band from 1990 before groin installation

Significantly low permeability at the seaward end appears to concentrate the longshore current and erode the slope as seen from comparison of profiles of groin field 7-8.

The development of the shoreline over the time is illustrated in Fig. 11. No changes in the location of the depth contours are indicated at the reference location (Fig. 11 A) since 1990. No trends are recognizable in the groin fields before construction of the groin field.

Response to groin construction was slow in groin field of relatively high permeability (e.g. 2-3). However, a slow movement of the shoreline and the -2 m contour line is apparent after installation of the groins (Fig. 11 B). In groin fields 5-6 (Fig. 11 C) and 7-8 (Fig. 11 D) the shoreline and the -1 m contour line started moving steadily seaward soon after installation of the groins, whereas at 7-8 the -2 m contour line moved landward.

Tests with tracer sands showed that sand placed at the edge of the seaward limit of the terrace moved predominantly along the slope to the trough. A small amount of the sand was carried in the direction of wind into the groin field. Tracer sand placed in the swash zone was transported partly into the corner of the groin field. However, the sand suspended in the swash zone was transported in a narrow band seaward normal to the beach. The width and alignment of this transport path indicate that the sand was transported in suspension by the return current.

DISCUSSION

It is apparent from the field data that pile groins have reduced the wave-induced longshore current without creating rip currents. This has led to two beneficial effects:

- widening of the beach, and
- raising the level of the terrace.

The more gradual slope of the underwater profile and the shallower water over the terrace distributes the conversion of wave energy over a broader area and reduces the energy loading per unit area. This leads to a reduction of the erosion potential of the shoreline breakers and hence increases the stability of the beach. Groins with insufficient permeability, cause increased velocities past the ends of the groins and erosion of the seaward slope from the terrace to the trough. The groins should, therefore, be accordingly permeable (even in the swash zone) to eliminate local rip currents.

CHAPTER 167

THE EFFECT OF GROUNDWATER ON SCOUR NEAR STRUCTURES

John H Loveless¹, Geoffrey T Grant² and Robert I Karlsson²

ABSTRACT

A previously unreported mechanism which is believed to be a key process in the formation of shingle beaches is identified. It is proposed that this mechanism be called "winnowing".

Several new considerations relating to the selection of appropriate model sediments for shingle beach models are discussed. It is shown that lightweight sediments are subject to a significant scale effect and a compromise solution is suggested.

The results of some experiments, never previously performed, of beach scour in front of sea walls resulting from various combinations of wave attack and groundwater flow in the beach are presented. These show that the presence of groundwater flow in the beach has a significant impact on the amount of toe scour to be expected.

INTRODUCTION

A thorough understanding of all the major mechanisms involved in the formation of beaches is necessary if effective remedies to coastal erosion problems are to be established. This paper suggests that the study of the movement of sediment on beaches has until recently tended to ignore or misjudge the effects of flow into and out of the beach. It has only recently been discovered that under-drainage can be used as an effective method of beach accretion and it would be highly surprising if we have nothing more to learn about how beaches behave.

Beach or seabed scour in front of and around coastal structures is possibly their most frequently occurring failure mechanism. However, the reliability of the advice that coastal engineering researchers can provide is dependent on how well these processes can be modelled.

The spectacular failure of several large breakwaters around the world and the discovery that scour is occurring near to many of them has led to increased interest in this area of research. Scour predictions are still usually derived from physical model studies with length scales of 1:20 or less. It is impossible to satisfy all the criteria for similarity in these models which are therefore subject to scale effect errors.

HOW SHINGLE BEACHES FORM

Coarse Material Transport

Broadly speaking the creation of a shingle beach is usually explained by reference to two mechanisms. First the movement of coarse material to the upper beach is explained on the assumption that coarse material moves as bed load and the peak bed velocity over each wave cycle is greater inshore than offshore. Also, since there is significant percolation into a shingle beach, the energy of the backwash is less than the energy of the swash. For example (Muir Wood, 1970) described this process admirably as:

“Whereas sand is moved by the sea predominantly in saltation and, near and inshore of the breaker line, in suspension, shingle is shifted by sliding and rolling along the bottom. The significance of this difference is that, whereas sand will tend to be moved in the direction of the vector representing residual wave velocity plus tidal velocity, shingle is only moved during that part of the wave cycle in which a certain threshold value is exceeded”.

Beach Slope

He also showed that the local slope of a beach is given by;

$$\tan \alpha = \frac{(1 - c)}{(1 + c)} \tan \phi$$

where α is the local beach angle, ϕ the angle of repose of the local beach material and c the ratio of the energy flux E_2 of the backwash to the energy flux E_1 of the upwash. This equation results in the limiting conditions of $c = 0$ at the top of the beach giving $\alpha = \phi$ and far offshore where $c = 1$ giving $\alpha = 0$ between these limits the equation results in the prediction of a parabolic beach form.

Fine Material Transport

The second mechanism which has been adduced to explain the formation of shingle beaches is the well known theory of Dean (Dean 1973). The theory has been shown to give extremely good correspondence with field results and it is highly probable therefore that it is essentially correct. However, the theory starts with an assumption for which no explanation has yet been given, viz. “It is assumed that the action of breaking waves is sufficient to place sand into suspension over at least a portion of the water column”.

Dean then goes on to explain how the relative fall times of the sediment lifted into suspension when compared to the wave period determines whether the sediment will move onshore or offshore.

Thus the analyses of both Dean and Muir Wood while both being clear and highly plausible do not provide a complete explanation. There is one piece missing from the jig-saw. How is the fine sediment carried into suspension not only from the surface, but also from within the beach? The jet caused by plunging waves creates a scour trench an associated bar and turbulence which could be deemed sufficient, but is there something else at work?

Winnowing

It is now suggested that there is a third mechanism at work which operates rather like the process of winnowing. As a wave approaches the breaking point the hydraulic gradient in the surface layers of the beach just in front of the wave reach a maximum. A number of experiments were carried out to investigate the nature and magnitude of these hydraulic gradients and to predict their possible consequences on sediment transport in the beach.

In one experiment dye was injected into a model shingle beach ($D_{50} = 5.6$ mm) near the breaker line. The movement of the dye indicated the direction of the instantaneous seepage velocity within the beach. The motion was seen to be rotary and in phase with the wave with the maximum velocity in the horizontal (onshore) direction just beneath the breaking wave. Just in front of the breaking wave the percolation velocity is vertically upwards and this was clearly visible as shown in Figures 1 & 2 as a jet of dye ejected into the flow. When the wave passes the dye cloud is swept forward up the beach.

Further experiments were carried out using a small probe inserted into the bed on which a cruciform of wire was fixed. Using electrolysis the wires were made to emit hydrogen bubbles as the waves passed and their movement was recorded on video. These experiments showed similar results and, because the probe could be moved about easily it was possible for a complete flow net to be constructed showing the hydraulic gradients in the beach beneath the breaking wave. Although these experiments proved that just in front of a breaking wave the upward direction of the seepage velocity in the bed is capable of squirting dye into the flow above the bed, it did not explain why this should preferentially eject the fine sediments.

In a third set of experiments some small pressure transducers were immersed in the bed. These showed that the hydraulic gradient in the bed frequently exceeded 1.0 in front of the breaking wave. This is the hydraulic gradient usually thought of as necessary to fluidise a soil sample.

Permeameter Tests

To investigate the hydraulic gradients needed to start soil migration a series of experiments was carried out using combinations of gravel and sand in a permeameter. These were reported briefly (Loveless & Grant, 1995) and showed conclusively that for gap-graded sediments the fine particles will start to migrate at very low hydraulic

Dye plume emerging from a shingle beach ($D_{10} = 4.0$ mm) under a breaking wave ($f = 0.5$ Hz).

Figure 2: Detail of dye plume emerging from shingle beach under a breaking wave ($f = 0.5$ Hz).

gradients, as low as 0.2 or 0.25. The results of these (and other) experiments are shown on Figure 3. The Stability Index is a measure of how gap-graded the soil is. It is defined as the percentage of a soil sample passing at a diameter $4D$ minus the percentage passing at a diameter D all divided by the percentage passing at a diameter D . A Stability Index less than 1.0 is a potentially unstable soil. Where the soil is gap-graded, as in a shingle beach, the hydraulic gradient required to initiate fine soil migration is only around 0.2 not 1.0 as for a normal soil as shown in Figure 3.

The Dynamics of the Swash Zone

Finally, it is readily observed in the field and laboratory that the swash zone is a very dynamic environment for the sediment. During storm events the face of the beach, to a considerable depth, is being reworked and this reworking it is suggested provides the final element in the process which leads to marked size segregation which is the hallmark of a shingle beach.

Thus to summarise it is suggested that fine sediments are ejected from the bed just in front of breaking waves by a winnowing like process as vertical hydraulic gradients in excess of 0.5 act on a bed which is effectively being fully fluidised at the same time by peak horizontal hydraulic gradients in excess of 1.0. The finer particles are more mobile and are moved both upwards and downwards. The process naturally strengthens as segregation causes the beach to become more and more permeable.

The fine material carried to the surface can be carried both inshore and offshore. This leaves the part of the beach subjected to the highest hydraulic gradients to protect itself with a shingle beach and what nature chooses to defend itself may not be able to be bettered by man.

SEDIMENT SELECTION AND SCALING FOR MODELS OF SHINGLE BEACHES

Since laboratory models of shingle beaches are still the ultimate source of design guidance for both physical and mathematical models it is very important that the best possible physical models should be constructed and the greatest care be taken to identify the various mechanisms at work.

It has recently been shown (Loveless 1994), that for normal wave approach, there are nine separate mechanisms which can produce scour near to the toe of a coastal structure. It has also been shown (Loveless & Grant 1995) that certain aspects of model sediment selection are commonly misunderstood or ignored.

Lightweight sediments

In the UK lightweight sediments have been used for over 30 years to construct models of shingle beaches. It has been shown however (Loveless 1994) that this means that one of the important forces is in error by a factor of six for an upward hydraulic gradient in the beach. Figure 4 is a diagram (not drawn to scale) of the main forces acting on a particle on a beach under the trough of a wave. The upward percolation force is significant when the upward hydraulic gradient is large as it is just

Figure 3: Critical hydraulic gradient against Stability Index.

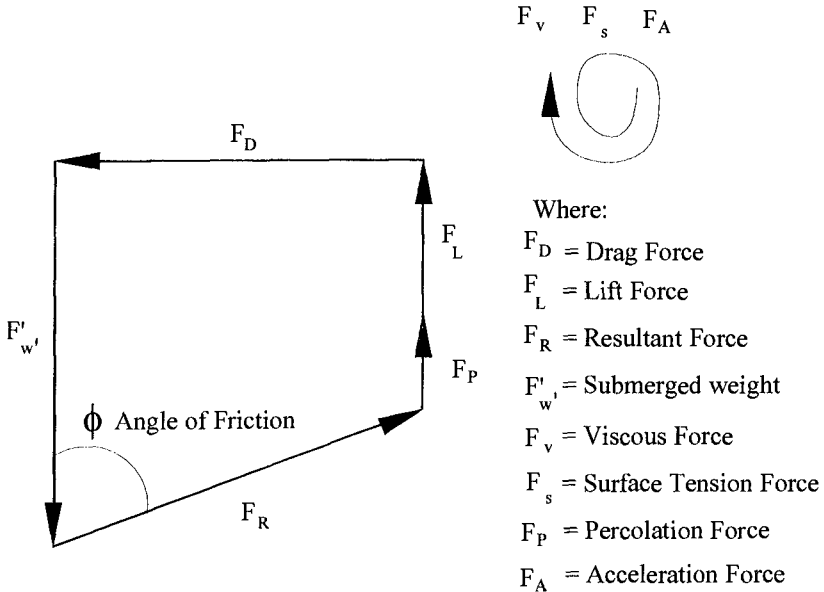

Figure 4: Forces on a sediment particle beneath a wave trough.

in front of a breaking wave. For similarity the ratio of the submerged weight and the upward percolation force should be the same in model and prototype. The ratio is given by,

$$\frac{F_{w^t}}{F_p} = \frac{i}{(1-n)(s-1)}$$

where i is the hydraulic gradient, n is the porosity of the soil and s is the specific gravity. If i and n remain the same, but s (model) equals say, 1.27 then a scale effect error of 6.1 would result if the prototype sediment had a specific gravity $s = 2.65$. Hence lightweight sediments will grossly overpredict scour at the toe of coastal structures.

If however a lightweight sediment is not used it is not possible to model the rate of percolation into the beach correctly for a sediment which satisfies similarity of the threshold of motion condition. In recent research we have found that a sediment having a specific gravity of about 2.0 would give scale effect errors not exceeding 3.0 for both percolation rate and percolation force. This may be the ideal compromise if such a material can be obtained at a reasonable price.

Angle of Repose

Another factor which appears to be ignored by researchers, but which is nevertheless important is the angle of repose of the sediment in model and prototype. To obtain similarity of the threshold of motion between model and prototype it can be shown that the following condition must be satisfied.

$$\frac{\lambda U_b}{\lambda_{W_s} \lambda_{\tan \phi}} = 1$$

where λ is the scale factor, U_b the near bed velocity, W_s the fall velocity of the sediment and ϕ the angle of repose. Hence ϕ directly affects one of the key similarity parameters and therefore must not be ignored.

A further important aspect of the variable ϕ is that it is reduced when a finer material is added to a gravel even when only 50% of the sample is sand. This effect was measured in the laboratory and a typical result is shown in Figure 5.

SCOUR EXPERIMENTS WITH GROUNDWATER FLOWS SUPERIMPOSED

A sea wall that is subjected to waves breaking near the toe of the structure, may at the same time experience a seaward groundwater flow under it. The experiments reported here show that the severity of scour is dramatically increased when these two scour mechanisms are combined. Similarly, if on the other hand the groundwater flow is reversed, accretion can be made to occur even under storm wave conditions and where, with no groundwater flow, a considerable scour hole would be formed. Although an experiment of this kind, with ground water flow being taken into account, is obviously a more realistic one than one which only considers waves we have not been able to trace a report of any such experiment having been performed

Figure 5: Value of ϕ for various combinations of sand and gravel.

Figure 6: Cross-section of the arrangement of the model beach and sea wall.

before. Figure 6 shows the arrangement that was used to test these conditions for both shingle and sand beaches. The experiments were conducted in a large 1.5m wide wave flume at the end of which there was a test section of 0.5m width. The dimensions of the shingle beach were as shown in Figure 6, giving an initial beach slope of 1:7. The sand beach however was arranged with a gap beneath the sea wall of 70 mm and a depth above this of 230 mm giving a total depth of sand of 300 mm at the sea wall. The beach extended for 800mm giving a beach slope of 1:26.7. The gravel used in the model had a $D_{10} = 4.0$ mm and a $\phi = 36^\circ$. It was selected to model, at a scale of 1:20, a shingle beach having a $D_{10} = 14$ mm. The reasons for this selection have been reported earlier (Loveless & Grant, 1995). The sand used in the model had a $D_{50} = 0.33$ mm and $\phi = 30^\circ$. It was used to model a beach sand having $D_{50} = 1.5$ mm and $\phi = 32^\circ$.

The beaches were subjected to regular waves except that, for the sand beach only, the beach was exposed to a JONSWAP Spectrum with the following characteristics for two hours: $f_p = 0.7$ Hz, $H_s = 7.4$ cm, σ_1 , left = 0.7, σ_1 , right = 0.09; water level, $h_o = 0$ or 170 mm above datum at the flume floor level.

The groundwater flows in the beach were created by means of a small submersible pump. To create an offshore flow the pump was placed in the main flume and water was pumped to the back of the sea wall. To create an onshore flow the pump was instead placed behind the sea wall. The maximum capacity of the pump was $2.0 \ell / s$ and with the gravel beach this flow created a difference in mean water levels of 80 mm in both directions. The sand beach was exposed to an increasing hydraulic gradient until at a difference of 280 mm it failed by boiling. During the tests it was subjected to water level differences of +20, +10 and -20 cms. These corresponded to pumping rates of +0.30, +0.15 and -0.30 ℓ / s .

The range of tests completed is shown in Tables 1 & 2. In these tables, h_o represents the mean sea level at the sea wall above the level of the beach. The scour depth, Y is measured at the structure and H_i is the offshore wave height incident on the beach and structure.

Figure 7 is a summary of the gravel beach results and shows clearly that the presence of a groundwater flow in the beach has a significant impact on scour at the structure. The most dramatic difference was obtained with Test 15 and the resulting profiles for this test are shown in Figure 8.

The toe scour occurring with offshore flow was much greater than the no flow case and the onshore flow actually caused accretion. Figure 9 again shows the significant difference in the resulting beach profile. The results for sand beaches, while not showing such dramatic changes in scour near to the toe of the structure nevertheless resulted in very different beach profiles as shown in Figure 10.

CONCLUSIONS

The paper has identified a new mechanism which it is believed is a fundamental mechanism in the formation of shingle beaches. It is proposed to call this mechanism "winnowing".

The paper has also suggested that aspects of the selection of model beach sediments which have tended to be ignored, such as the percolation force and the angle of repose of the sediment, should be taken into account when designing models.

The paper has reported on experiments which have shown how toe scour and beach profiles in the vicinity of coastal structures are affected by groundwater flows in the beach.

ACKNOWLEDGEMENT

Much of this research was conducted with the assistance of a grant from the UK Engineering and Physical Sciences Research Council for which the authors are grateful.

CHAPTER 168

Abrasion of Steel Pipe Piles by Sediment Motion in Coastal Zones

Gaku Matsuoka¹, Shinichi Ito², Toshihiko Yamashita³
Hiroshi Saeki⁴, Yoshihisa Kariyazono⁵, and Koichi Sato⁶

ABSTRACT

In the outer coastal zones, where wave conditions are severe, steel-pipe piles often undergo abrasion due to the collision of sand particles. The abrasion characteristics of steel-pipe piles were clarified from the results of full-scale experiments. The abrasion rate of steel-pipe piles was found to be approximately proportional to the second power of the amplitude of flow velocity. The larger the ratio of sand particle diameter to pile diameter was, the higher was the abrasion rate. As the collision energy of sand particles obtained by numerical analysis was nearly proportional to the measured abrasion rate, it was considered that the abrasion rate can be estimated from the collision energy.

INTRODUCTION

Large amounts of sand particles sometimes drift around pipe piles due to the action of waves, especially in outer coastal zones. Steel-pipe piles exposed to these drifting sand particles undergo abrasion due to the collision of sand particles with the piles. Durability is an important consideration in the construction of steel structures in coastal zones. Culbertson W. Ross (1949) reported severe abrasion and corrosion of

steel-pile groins at Palm Beach, Florida. There have also been reports of large decreases in the wall thickness of steel-pipe piles (more than 1mm/year) due to abrasion and corrosion in other outer coastal zones. The reported rates of decrease in the wall thickness are more than 10 times greater than the allowable corrosion rate of steel in sea water (0.1mm/year). However, except for our previous studies (Yamashita et al., 1989, 1990, 1991, 1992; Kariyazono, 1992), there have been very few experimental or theoretical studies on the abrasion of steel piles due to sediment motion. The behavior of sand particles during collision with the surface of piles and the resulting abrasion of the surface have not yet been clarified.

In the present study, full-scale experiments were carried out to investigate the abrasion characteristics of steel-pipe piles from the viewpoint of the effects of flow velocity, diameter of sand particles and diameter of piles. Also, from numerical analysis of the motion of suspended sand particles, the characteristics of the collision energy of sand particles against steel piles were investigated, and the relationship between collision energy and abrasion rate was clarified.

EXPERIMENTS

A series of abrasion tests on steel-pipe piles were carried out in the laboratory using a large-scale U-shaped tube that could generate a strong oscillatory flow with sand drift (Fig. 1). The tube is 10m in horizontal length, 5m in height and 1m in width. The horizontal part of the apparatus, which is 500mm in height, was filled with sand to a height of 400mm. Thus, the flow took place in the upper 100mm of the horizontal part. The experimental flow conditions were as follows: the period of oscillatory flow was 7.1 or 7.4 sec and the amplitude of velocity (u_0) was 2.0m/s ~ 4.0m/s. Three sizes of pipe piles (267, 140 and 76mm in diameter(ϕ)), and four grades of sand (0.75, 1.5, 4.0 and 7.0mm in diameter(d)) were used. The specific gravity was 2.65 in all sand particles. The steel piles, which were made of 392N/mm² carbon steel, were fixed securely to the bottom of the horizontal part of the apparatus

Fig. 1 Large-scale U-shaped tube that can generate a strong oscillatory flow with sand drift.

by steel caps and bolts. Rubber bands were wrapped around both ends of each steel-pipe specimen to prevent abrasion of the surface during the test. Most of the tests were carried out under conditions in which the period was 7.4 sec and the amplitudes of flow velocity were 2.0 or 3.0m/s. Flow velocity of 2.0 and 3.0m/s are equivalent to strong waves of 5.4 and 8.1m in height, respectively, which occur in coastal zones with a water depth of 10m.

Fig. 2 shows a schematic diagram of the apparatus used to measure the surface profile of each specimen. The surface profiles were measured in the longitudinal direction by a dial gage before and after each abrasion test. Surface profile measurements were carried out at intervals of 15 degrees to the main flow direction.

Fig. 2 Measurement of the surface profile of a pipe pile specimen.

RESULTS and DISCUSSION

Fig. 3 shows an example of the surface profiles of a steel pipe pile before and after the abrasion test. The Z-axis is the distance from the upper standard line of the pipe (see Fig. 4). The upper and lower parts of the pile were covered with rubber bands to prevent abrasion during the test. The amount of abrasion was obtained from the difference between surface profiles before and after the test.

Fig. 4 shows an example of the profile of the sand bed around a steel pipe pile after the test at a flow velocity of 3.0m/s. The diameter of the steel pipe pile was 267 mm. The depth of the sand far from the pile was about 440mm, while but sand around the pile was scoured to a depth of about 120mm. The degree of scouring was greater at a flow velocity of 3.0m/s than at 2.0m/s.

Fig. 5 shows an example of the distributions of the amount of abrasion. The dotted lines indicate the surface of the sand bed at the pile surface. The solid lines indicate the surface of the sand bed far from the pile. At the upper part of sand bed

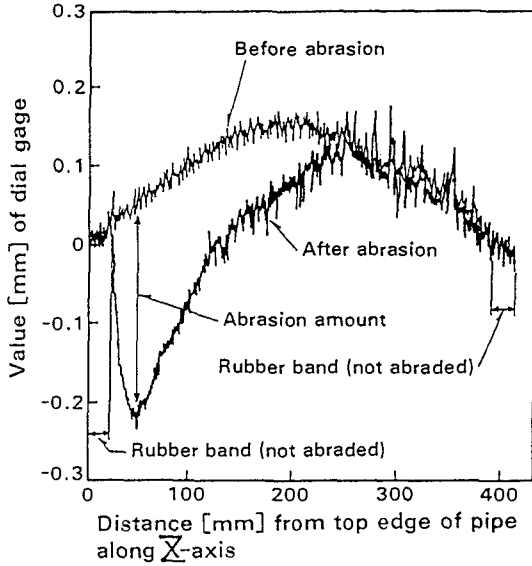

Fig. 3 Surface profiles of a specimen before and after abrasion.

Fig. 4 Profile of the sand bed around the pipe pile specimen.

surface from the dotted line, the amount of abrasion was largest at 15 or 30 degrees and smallest at 90 degrees. The maximum amount of abrasion was observed at about 50mm above the sand bed and at 15 or 30 degrees to the main flow direction. In the

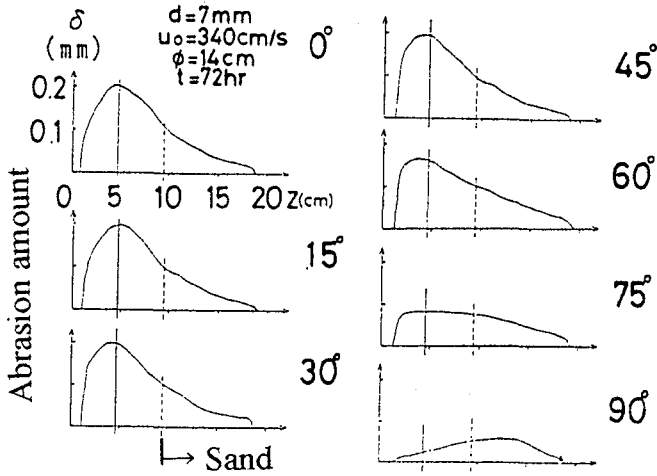

Fig. 5 Distributions of the amount of abrasion of the pile along the distance from the top standard line.

case where the sand particle diameter was 7mm and the flow velocity was 3.4m/sec, the maximum amount of abrasion was 0.2mm/3days. This value corresponds to 2mm/month. Thus, it was confirmed that a serious loss of 1mm/year in wall thickness was expected in coastal zones with severe sand motion. At the lower part of the sand bed surface, the amount of abrasion was rather small and was independent of the angle. At the upper part of the sand bed surface, abrasion occurred due mainly to the collision of suspended sand particles against the pile surface. At the lower part of the sand bed surface, however, the pile underwent sliding abrasion caused by sand particles in a state of liquefaction.

The results of the experiments indicate that the collision energy of suspended sand particles affects the maximum amount of abrasion on the surface of a steel pile. To determine the collision energy of sand particles against the surface of the pile, numerical analysis of the motion of suspended sand particles was performed.

Fig. 6 shows a sketch of sand particle motion. It was assumed that the fluid flow in the front of a pile was a two-dimensional, steady, potential motion. The sand particle motion was determined by Eq. 1.

$$M \frac{d\bar{U}}{dt} + C_M m \frac{d(\bar{U} - \bar{u})}{dt} = m \frac{d\bar{u}}{dt} + \frac{1}{2} C_D \rho_w A |\bar{u} - \bar{U}| (\bar{u} - \bar{U}), \quad (1)$$

where M and m are the mass of the sand particle and the mass of water displaced by the sand particle, respectively; \bar{U} and \bar{u} are the velocity vectors of the sand particle and fluid particle, respectively; A is the cross-sectional area of the sand particle; ρ_w

is the density of the fluid; and C_M and C_D are the virtual mass coefficient and the drag coefficient, respectively. From the study of Sawamoto (1979), we assumed C_M to be 0.5, and C_D was determined by Eq. 2.

$$C_D = 0.4 + \frac{24}{Re}, \tag{2}$$

where Re is Reynolds number. As we assume that abrasion of a pile occurs due to the collision energy of sand particles against the pile, dimensionless collision energy is defined as follows:

$$\text{Dimensionless collision energy} = \frac{CVn|\vec{U}|}{u_0^2}, \tag{3}$$

where \vec{U} is the collision velocity vector of sand a particle; Vn is the normal component of \vec{U} to the pile surface; u_0 is the amplitude of main flow velocity; and C is the dimensionless number of collision particles, defined as the ratio of the volume flux of sand particles at a point far from the pile to the volume flux when sand particles collided with the surface of the pile.

Fig. 6 Sketch of sand particle motion.

Fig. 7 shows the relationship between sand particle diameter, the calculated dimensionless collision energy, and the measured abrasion rate around a pile. Numerical analysis was carried out under the following conditions: flow velocity u_0 and diameter of pile ϕ were 3.0m/s and 30cm, respectively, and the diameters of sand d were 1, 4 and 10mm. Fig. 7 also shows the measured abrasion rates of steel piles of 267mm in diameter in a large U-shaped tube with sand of 7, 4, 1.5 and 0.75mm in diameter at a maximum flow velocity of 3.0m/s for 3 days. The horizontal axis θ is the angle of the pile surface. The collision energy increased as the sand particle diameter increased. The collision energy of large sand particles was distributed over

a wider range of angles θ compared with that of small sand particles. The rate of abrasion also increased as the diameter of the sand particles increased. The abrasion rate of large sand particles was distributed over a wider range of angles θ than that of small sand particles. The collision energy distributions obtained by numerical analysis almost coincide with the distributions of measured abrasion rates.

Fig. 7 Relationship between sand particle diameter, collision energy, and rate of abrasion around a pile.

Fig. 8 shows the relationship between sand particle diameter, maximum dimensionless collision energy, and maximum abrasion rate obtained from Fig. 7. The maximum collision energy of sand particles increased with increases in the sand particle diameter. The maximum collision energy was nearly proportional to the measured maximum abrasion rate.

Fig. 9 shows the relationship between pile diameter, dimensionless collision energy, and the rate of abrasion of the pile. The conditions for calculation were as follows: flow velocity is 3.0 m/s, sand particle diameter is 8 mm and pile diameters are 7.5, 10, 15, 30 and 100 cm. Fig. 9 also shows measured rates of abrasion of the steel piles of diameters of with 7.6, 14.0 and 26.7 cm under conditions in which the sand particle diameter is 7 mm and the amplitude of flow velocity is 3.0 m/s. The collision energy of the sand particles increased with decreases in the pile diameter. The collision energy of a small pile was distributed over a wider range of angles θ compared with that of a big pile.

Thus, the larger the sand particle diameter and the smaller the pile diameter are, the higher the abrasion rate and the wider the abrasion area become. The reason for this is as follows. Fig. 10 shows an illustration of the collision behavior of sand particles and the streamlines of fluid near a pile without sand particles. When the diameter of

Fig. 8 Relationship between sand particle diameter, maximum collision energy and maximum abrasion rate.

Fig. 9 Relationship between pile diameter, collision energy, and rate of abrasion around pile.

the sand particles is small, most of the sand particles tend to follow the fluid particles and do not contact with the surface of the pile because they have low inertia. Thus, the collision energy at the surface of the pile is very small. When the diameter of sand particles is large, however most of the particles collide with the surface of pile regardless of the flow of fluid around the pile, and thus the collision energy is very large. On the other hand, when the diameter of the pile is large, streamlines begin to curve at a point far away from the pile because of the pile's wall effect. When the diameter of pile is large, most of the sand particles closely follow the streamlines and do not contact with the surface of the pile due to the large wall effect.

	Streamline without sand.
	Most fine sand follows the streamline without collision because it has low inertia. The energy transferred to the pile is low.
	Most large sand particles collide with the pile due to inertia. The energy transferred to the pile is high.
	Most sand particles follow the streamline without collision because of the large wall effect. The energy transferred to the pile is low.

Fig. 10 Illustration of the collision behavior of sand.

Fig. 11 shows the relationship between the ratio d/ϕ of sand particle diameter to diameter of the pile and dimensionless maximum collision energy. The maximum collision energy is a function of only the ratio d/ϕ approximately. The larger d/ϕ is, the larger the maximum collision energy becomes.

Fig. 12 shows the relationship between d/ϕ , maximum dimensionless collision energy, and maximum abrasion rate. The maximum abrasion rate is also a function of only the ratio d/ϕ approximately. The collision energy obtained by numerical analysis is nearly proportional to the measured abrasion rate. This relationship is as follows. Dimensionless collision energy of 1.0 corresponds to an abrasion rate of 0.21mm/day at a flow velocity of 3.0m/s.

Fig. 11 Relationship between ratio of diameter (d) of sand to diameter (ϕ) of pipe and dimensionless maximum collision energy.

Fig. 12 Relationship between d/ϕ , maximum collision energy, and maximum abrasion rate.

Fig. 13 shows the relationship between flow velocity, dimensionless maximum collision energy, and maximum abrasion rate. If flow velocity is larger than 1.0m/s,

the dimensionless maximum collision energy is nearly constant. The maximum abrasion rate is roughly proportional to the maximum collision energy. The rate of abrasion of a steel pile is roughly proportional to the second power of flow velocity.

Fig. 13 Relationship between flow velocity and dimensionless maximum collision energy.

CONCLUSIONS

The distributions of abrasion rate around and along steel pipe piles were clarified. The maximum abrasion rate was observed about 50mm above the sand bed and 15~30 degrees in the main flow direction. It is confirmed that an abrasion rate of 1mm/year can be expected in coastal zones with severe sand motion.

The abrasion rate of a steel pipe pile is roughly proportional to the second power of the amplitude of flow velocity.

The larger the sand particle diameter is and the smaller the pile diameter, the higher the abrasion rate becomes and the wider the abrasion area. This reason for this is as follows. When the diameter of sand particles is small and the diameter of the pile is large, more of the sand particles tend to follow the fluid particles and do not contact with the surface of the pile due to their low inertia and the large wall effect, respectively. The collision energy of sand particles obtained by this numerical analysis is nearly proportional to the measured abrasion rate.

The maximum collision energy is approximately a function of only the ratio d/ϕ (sand particle diameter to pile diameter). The larger d/ϕ is, the larger the maximum of abrasion rate and the maximum collision energy become.

As the relationship between collision energy and measured abrasion rate has been clarified, the abrasion rate can be estimated from the collision energy.

CHAPTER 169

A Viscous Rotational Model for Wave Overtopping over Marine Structure

Fei Zhuang,¹ Jiin-Jen Lee²

Abstract

Wave overtopping problems continue to require more attention due to the complexity of the physical process and the lack of available predictive models. In a recent experimental study on the kinematics of wave overtopping on marine structure by Lee, Zhuang and Chang (1993), it was found that the overtopping wave constitutes a jet-like water mass impacting the shoreward region of the breakwater. This jet-like water mass induces strong vortices and large water particle velocities in both the horizontal and vertical direction in the shoreward region behind the marine structure. The large rotational velocity field is capable of removing the armor units of the breakwater and scouring the bed in the shoreward region of the breakwater. In the study of Zhuang, Chang and Lee (1994), a numerical model capable of generating the rotational velocity field in the vicinity of the shoreward face of the breakwater was proposed. This paper presents the computation results from a refined viscous rotational model and their comparisons with newly acquired experimental data.

1. Introduction

¹Postdoctoral Research Associate, Department of Civil Engineering, University of Southern California, Los Angeles, CA 90089-2531

²Professor of Civil Engineering, University of Southern California, Los Angeles, CA 90089-2531, Member of ASCE.

Overtopping of ocean waves over marine structures has been an important problem for ocean and coastal engineers due to the fact that it may severely damage the marine structure. The overtopping process may transmit significant wave energy toward the coastal zone which the marine structure (such as breakwater) is supposed to protect.

In a recent experimental study on the kinematics of wave overtopping on marine structure by Lee, Zhuang and Chang (1993), it was found that the overtopping wave constitutes a jet-like water mass impacting the shoreward region of the breakwater. This jet-like water mass induces strong vortices and large water particle velocities in both the horizontal and vertical direction. Moreover, the overtopping wave also generates waves in the shoreward region possessing significant wave energy with oscillatory wave trains. These two major conclusions have significant practical implications: The large rotational velocity field can remove the armor units of the breakwater and scour the bed. The generated waves could induce significant basin oscillations in the shoreward basin with resonant frequencies which are different from the incident wave frequencies. Such experimental results deviated significantly from the potential flow theory in certain regions. Thus, computational results based on the potential flow theory can not fully explain the experimental data without incorporating additional features. In the study of Zhuang, Chang and Lee (1994), a numerical model capable of generating the rotational velocity field in the vicinity of the shoreward face of the breakwater was proposed. This paper presents the computation results from a refined viscous rotational model and their comparisons with newly acquired experimental data.

2. Experiments

Experiments involving propagation of solitary waves over various submerged breakwater configurations are conducted in a wave tank 37.73 meter long, 39.4 centimeter wide, and 61 centimeter deep. A programmable piston type wave generator is installed at one end of the tank and a sloping beach is installed at the other end of the tank to aid the wave dissipation for the purpose of reducing the waiting time between experimental runs. Three different breakwater configurations are used in the experiment. Three resistance type wave gauges are installed at desired locations to make simultaneous wave profile measurements.

The water particle velocities are measured using a portable four-beam, two-component, fiber optic Laser Doppler Velocimeter (LDV) manufactured by TSI Inc.. Titanium Dioxide powder (TiO_2) is used in the experiments as

a seeding agent.

3. Numerical Models

The refined viscous rotational flow model consists of two basic elements: The velocity field generated by using the potential flow theory and the rotational velocity field generated by the separated flow (vortices) of the overtopping waves as they leave the breakwater site. For the potential flow theory, the Boundary Element Method has been used. The nonlinear boundary condition at the free surface is satisfied in the numerical model to allow simulation of large amplitude waves. The transient non-rotational flow field obtained by the potential flow theory is combined with the time dependent rotational flow field due to vortices generated in the separation zone.

The potential flow theory formulation using boundary element method has been presented in Lee, Chang and Zhuang (1992). The problem of wave overtopping on marine structure is formulated as a two-dimensional boundary value problem. The fluid in the solution domain is assumed to be incompressible and the flow is assumed to be irrotational. Viscous force is also neglected. Application of potential theory leads to the governing Laplace's equation for the velocity potential function ϕ :

$$\nabla^2 \phi(\mathbf{x}, t) = 0 \quad \mathbf{x} \in \Omega(t) \quad (1)$$

with the kinematic and the nonlinear dynamic free surface conditions as the boundary conditions on the free surface Γ_s :

$$\frac{D\mathbf{r}}{Dt} = \left(\frac{\partial}{\partial t} + \mathbf{u} \cdot \nabla \right) \mathbf{r} = \mathbf{u} = \nabla \phi \quad (2)$$

$$\frac{D\phi}{Dt} = -gy + \frac{1}{2} |\nabla \phi|^2 - \frac{p_a - p_o}{\rho} \quad (3)$$

where \mathbf{r} is the position vector of a free surface fluid particle, g the acceleration due to gravity, y the vertical coordinate, p_a the pressure at the surface, p_o a reference pressure and ρ the fluid density.

The solution to the boundary value problem is expressed as a boundary integral using the free space Green's function $G(\mathbf{x}_i, \mathbf{x}_j) = -\frac{1}{2\pi} \log |\mathbf{x}_i - \mathbf{x}_j|$ and Green's theorem:

$$\alpha(\mathbf{x}_i) \phi(\mathbf{x}_i) = \int_{\Gamma(\mathbf{x})} \left[\frac{\partial \phi}{\partial n} G(\mathbf{x}, \mathbf{x}_i) - \phi(\mathbf{x}) \frac{\partial G(\mathbf{x}, \mathbf{x}_i)}{\partial n} \right] d\Gamma(\mathbf{x}) \quad (4)$$

where \mathbf{x}_i and \mathbf{x} are position vectors for points on the boundary (\mathbf{x}_i can also be any where within the domain), $\Gamma(\mathbf{x})$ is the boundary of the fluid domain Ω , \mathbf{n} the unit outward normal vector and $\alpha(\mathbf{x}_i)$ a geometric coefficient. The boundary integral equation is then solved using the Boundary Element Method.

A time marching procedure which was first suggested by Dold and Peregrine (1986) has been used in the present analysis to update both the new position of the free surface and the potential value ϕ on the free surface at the next time step:

$$\mathbf{r}(t + \Delta t) = \mathbf{r}(t) + \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \mathbf{r}(t)}{Dt^k} + O[(\Delta t)^{n+1}] \quad (5)$$

$$\phi(\mathbf{r}(t + \Delta t), t + \Delta t) = \phi(\mathbf{r}(t), t) + \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \phi(\mathbf{r}(t), t)}{Dt^k} + O[(\Delta t)^{n+1}]. \quad (6)$$

The Boundary Element Method together with the time marching procedure form a unique solution technique for solving transient nonlinear wave problems.

The rotational flow field in the vicinity of the shoreward breakwater is simulated with the governing equations for the vorticity stream function formulation of incompressible laminar flow. Figure 1 shows the computational domain for this rotational flow field (ABCDE). The governing equations are:

$$\frac{\partial \omega}{\partial t} + u \frac{\partial \omega}{\partial x} + v \frac{\partial \omega}{\partial y} = \nu \left(\frac{\partial^2 \omega}{\partial x^2} + \frac{\partial^2 \omega}{\partial y^2} \right) \quad (7)$$

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = \omega \quad (8)$$

where ω is the vorticity vector; u, v are the horizontal and vertical components of the velocity vector, and ν is the kinematic viscosity of the fluid. The boundary conditions in conjunction with the governing equations (7) and (8) are listed as follows:

A-B and A-E:

$$u = 0, \quad v = 0, \quad \psi = 0$$

B-C:

$$\frac{\partial \psi}{\partial y} = u, \quad \omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x}$$

Figure 1: Sketch of the computational domain.

C-D:

$$\frac{\partial \psi}{\partial x} = -v, \quad \omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x}$$

D-E:

$$\frac{\partial \omega}{\partial x} = 0, \quad \frac{\partial^2 \psi}{\partial x^2} = 0$$

For each time step, the particle velocity solution is collected along B-C and C-D from the computational results based on the boundary element method (potential flow theory). These are used as the boundary conditions for the vorticity stream function formulation, hereafter we refer it as combined rotational model. Equation (8) is solved using Successive Over Relaxation method. Equation (7) is then solved using Alternating Direction Implicit method. The same computational procedure is repeated over the successive time steps. For detailed description of the numerical model, the reader is referred to Zhuang (1996).

For the two dimensional wave overtopping problem, potential theory with boundary element method has shown to have the following advantages: (1) the boundary element method can reduce the dimension of the original problem by one, thus reduce the computer storage requirements and speed up the computation. (2) the boundary element method is especially suitable for problems where the variables of primary interest are mainly located on the boundary, such as wave-related problems. (3) it has been proved by previous study (Lee, Chang and Zhuang (1992)) that potential theory results agree

well with the experimental data for the region near the free surface and the region far away from the separation zone near the breakwater. But, it is also shown through the present experimental data that in the separation zone (where vortex generation and large induced flow velocities are prevailing) potential theory can not be valid.

As for the vorticity stream function formulation with finite difference method, it includes elements of rotationality and viscous effect, and it can be used to describe flow separation and vortex generation. However, this formulation is difficult in dealing with free surface calculation and is not economical in terms of computational cost compared with the boundary element method.

In order to make the numerical model capable of simulating the whole wave overtopping process, and to take advantages of both the potential flow theory and the vorticity stream function formulation, the present study proposes a combined numerical model. In this model, potential flow theory with boundary element method is used to obtain the wave profile and flow field information in the region where the flow can be assumed inviscid and irrotational, i.e. the region near the free surface and the region far away from the separation zone. In the region near the shoreward breakwater, where flow separation and vortex generation are dominant, vorticity and stream function formulation is employed to capture the rotational flow motion in this region.

It is reasonable to expect that the computational results from the boundary element method based on the potential flow theory would fail at the separation zone due to its imposed assumption of inviscid fluid and irrotational condition. However, the computational results should be reasonably valid in the region far away from the separation zone. Therefore, our modeling strategy for the region near the separation zone is adopted as follows: As the incident wave propagates over the breakwater, the computed velocity field from the boundary element method in the regions BC and CD are used as input boundary condition for the rotational flow simulations based on equations (7) and (8). In this approach, the domain of computation is fixed thus the computational effort is greatly simplified.

4. Results and Discussion

During the experiment we have observed flow separation and vortex generation near shoreward face of the breakwater. These observed phenomena

and the inability of the potential flow theory to describe the flow phenomena motivated the development of the present combined rotational flow model. In this section, the focus will be in the separation zone. Flow patterns, detailed particle velocity time history obtained from both the experiments and the present combined rotational flow model will be presented.

Figure 2 and 3 present a series of four photographs taken during one experimental run of $H/d=0.3$ solitary wave overtopping on submerged Breakwater C (height=4.5in and width=15in) with water depth $d=9$ in. The blue dye is injected in the shoreward region of the breakwater before the wave is generated. The solitary wave propagates from left to right direction in the pictures. The breakwater can be seen at the lower left corner of the pictures. From Figure 2(A), we can see a vortex is starting to form at the shoreward edge of the breakwater while the wave crest is approximately on the top of the edge. The following three pictures show a complete process for the generation of a vortex. It is observed that a strong rotational flow field has been generated in the vicinity of the shoreward breakwater. Since this is a transient process, the vortex will grow bigger and bigger after the wave has passed and eventually move downstream and become disintegrated. A practical point to remember is that the rotational field so generated will induce more scouring capability in the shoreward region of the breakwater.

The velocity time history comparisons between the model results and the experimental data are presented in Figures 4 and 5. Figure 4 shows the velocity time history at a location P-825. The location P-825 is at the vertical position $-0.825d$ from the still water surface and $0.15d$ from the breakwater shoreward surface. Included in the figure are the results of the potential flow theory (solution from boundary element method) shown in solid line. The results from the combined rotational flow model are shown in dotted line. The velocity time history obtained by using the Laser Doppler Velocimeter measurement are plotted using the star symbols. The ordinates in both figures are the velocity components normalized with respect to \sqrt{gd} (the wave celerity in water depth d). The abscissa is the real time normalized as $t\sqrt{g/d}$. Examining both the horizontal and vertical velocities, it is seen that, at location P-825, both the combined rotational flow model and experimental data reveal that the horizontal velocity changes direction from positive to negative and the vertical velocity changes the direction from negative to positive. That means the flow direction at that point changes from forward and downward to backward (seaward) and upward. It clearly shows that a vortical motion has been generated during the wave overtopping process.

Figure 2: Pictures (A) and (B) of an experimental observation of vortex generation for solitary wave overtopping submerged breakwater. $H/d=0.3$, $d=9\text{in}$, Breakwater C.

Figure 3: Pictures (C) and (D) of an experimental observation of vortex generation for solitary wave overtopping submerged breakwater. $H/d=0.3$, $d=9\text{in}$, Breakwater C.

The present combined rotational flow model predicts this feature of particle movement and agree well with the experimental data. As expected, the potential theory predicts only positive horizontal velocity and negative vertical velocity. The results from the potential flow model deviate significantly from the experimental data beyond a very short time after the arrival of the waves. Thus, according to the potential flow theory, the particles are always going forward and downward directions during the overtopping process, representing no rotational motion. It is reasonable to expect that the computational results from the boundary element method based on the potential flow theory would fail in the separation zone due to its imposed assumption of inviscid fluid and irrotational condition.

Another noticeable feature to be observed from this time history graph is the magnitude of the positive vertical velocity and negative horizontal velocity, both are much greater than the particle velocities associated with an unmodified solitary wave. This feature of increased particle motion could contribute to the destabilization of the breakwater armor units in the shoreward face.

Figure 5 shows horizontal and vertical velocity time history comparisons between the present model and the experimental results at location P-75 for 0.3 solitary overtopping on Breakwater C. Location P-75 is $-0.75d$ from the still water surface and $0.15d$ from the breakwater shoreward surface. It is $0.075d$ above location P-825. As observed from Figure 4, velocity at location P-75 also shows the reversal of horizontal velocity from shoreward to seaward direction and the reversal of vertical velocity from downward to upward. Although location P-75 is very close to location P-825, we can see the velocity time histories from the two locations have significant differences. It indicates that there is a rapidly changing velocity field in this region. Notice that the vertical velocity reached the maximum when the horizontal velocity becomes small, indicating location P-75 is in the middle left portion of the clockwise rotating vortex, where the flow is basically going up. Again Figure 5 shows the results from the present rotational flow model agree quite well with experiments.

5. Conclusions

The major conclusions drawn from this study can be summarized as follows:

1. A numerical model has been developed to simulate wave induced vis-

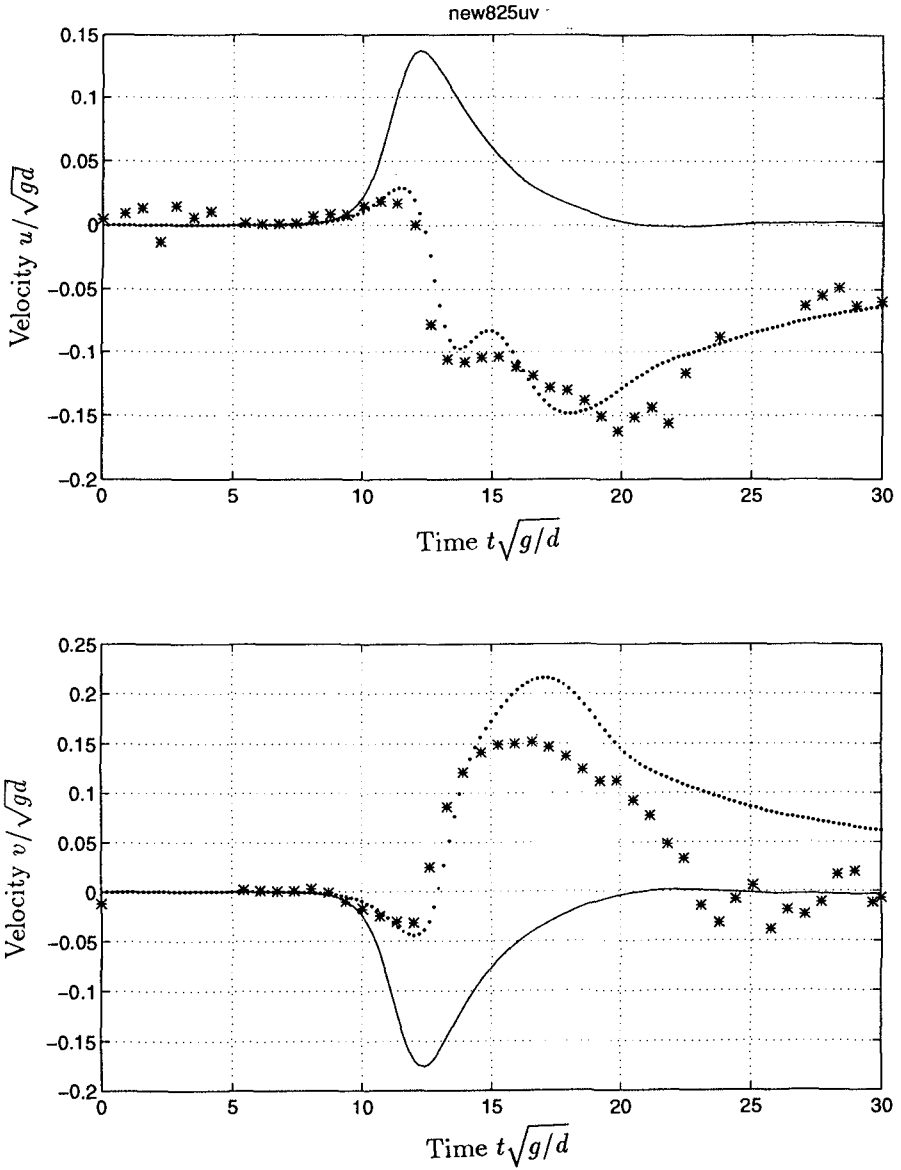

Figure 4: Comparison of particle velocity results from the present model, potential flow theory and experiment at $x^* = 0.15$ and $y^* = -0.825$ for solitary wave overtopping on breakwater C, $H/d = 0.3$, $d = 9in$; \cdots present model; $—$ potential flow model; $***$ experiment.

Figure 5: Comparison of particle velocity results from the present model and experiment at $x^* = 0.15$ and $y^* = -0.75$ for solitary wave overtopping on breakwater C. $H/d=0.3$, $d=9\text{in}$; \cdots present model; $***$ experiment.

cous rotational flow in the separation zone near shoreward breakwater surface. This model is referred as the combined rotational flow model because it combines two distinct theories and corresponding solution methods and it is capable of evaluating rotational separating flow field. It is seen that the combined rotational flow model describes the flow field quite well when compared with the experimental data. It offers a tool for modeling the flow field in the vicinity of the shoreward region of the breakwater. It is also seen that the potential flow results deviate from the experiments significantly. This demonstrates the importance of incorporating the rotational feature for modeling the flow field in the vicinity of the shoreward region of the breakwater.

2. Based on both the numerical and experimental results it is found that there is a vortex generated by the overtopping of solitary wave in the vicinity of the shoreward breakwater. The vortical motion remains there even when the wave has traveled to the region far away from the breakwater. This vortical motion produces a velocity field which could cause significant scouring in the region close to the breakwater.
3. Because of the vortex motion, there is a relatively large velocity component in the upward and seaward direction. This velocity component could produce a lifting force which could destabilize the armor units in the shoreward face of the breakwater.
4. The present combined rotational flow model can be easily implemented because of its time-saving feature. It only computes rotational flow field in a relatively small local domain, while the efficient potential theory using boundary element method offers the information away from the separation zone, where the irrotationality assumption is valid. Furthermore, this model can be extended to solve other wave-structure interaction problems.

CHAPTER 170

Overtopping of waves at a wall: a theoretical approach

M. Jervis ¹ and D.H. Peregrine ².

Abstract

The flow of water due to the overtopping of a vertical wall by waves is modelled. The waves are computed with an accurate irrotational flow solver. The case where a jet of water is projected up the face of the wall is considered. A simple estimation is made from the computation of the amount of water that can pass over the crest of a wall of finite height. The results for overtopping volume per wave show a roughly exponential decaying dependence on the height of the wall above the still water level. Results are given for waves of differing height and also for various sizes of berm in front of the wall. The effects of surface tension are included to investigate the possibility of errors in scaling experimental results to prototype scale. These are larger than expected.

Introduction

In many locations sea walls and breakwaters are built to prevent water from the open sea spreading inland, or disturbing harbours and their installations. There are many reasons for estimating how much water may overtop a wall of given height in given wave conditions. With sea walls, erosion of the back side may be the greatest danger, whereas damage to people and port installations may be of concern behind a breakwater.

Previous study of overtopping at vertical walls has been almost entirely based on small scale experiments (e.g. Franco 1994, Juhl & Sloth 1994). This is a theoretical study of wave overtopping. We focus on the case where waves slosh against a vertical wall sending a jet of water up to a height which may be as much as three times the height of the incident wave. Numerically accurate irrotational flow computations model the upward jet, then a simple model described in the next section is used to estimate how much of the water in the jet would overtop a wall of given height.

The results we present here are all for steep solitary waves meeting a wall. The solitary wave is the largest wave that can propagate on water of a given depth. As well as considering a vertical wall, bounding water of constant depth,

cases of walls with berms are also presented. There is interest in several aspects of the hydrodynamics of such flows, but we concentrate on the overtopping. The effect of a berm depends on both its horizontal extent and height. Small low berms have little effect. Larger berms change the wave behaviour.

There are two types of behaviour characteristic of extreme standing waves, or waves reflecting (Thais & Peregrine, in preparation). One is the thin sheet like jet that we see in figure 1, but a berm can also give the other almost "table-like" elevation as in figure 6, or wave breaking at or before the wall. The computations show strong variation of overtopping depending on the berm size, but are not capable of dealing with the cases of wave breaking.

A further variation is introduced to give an indication of scale effects. Often, experiments are performed on rather shallow water, e.g. 0.1m or less especially when a three-dimensional wave field is being modelled. In such cases surface tension is likely to have a significant influence on the tip of wave jets. By including surface tension in the program to calculate the incident wave and jet this scale effect is quantified and found to be more important than originally expected.

Overtopping model

The program used is that of Cooker, Peregrine, Vidal & Dold(1990) which is based on the accurate irrotational flow solver of Dold & Peregrine(1986). The computation assumes inviscid, irrotational and incompressible flow, solving Laplace's equation with a boundary-integral method, and using the fully non-linear boundary conditions to time step the computation. High-order numerical approximations are used.

The reflection of waves by a vertical structure such as a breakwater means that the waves in front of the structure are well modelled by standing or near-standing waves if no breaking occurs. Breakwaters are sometimes designed so as to guarantee the formation of standing waves in front of the structure. In this way the chances of the occasional very high impact pressures which might lead to structural failure are reduced. The appearance of the standing waves becomes more like a reflecting solitary wave as water depth is decreased. The largest waves that can approach any structure are shallow water waves whose crests are very similar to solitary waves. Thus we use solitary waves as incident waves for the examples here.

Impact on a vertical wall is modelled by considering the symmetrical collision of two steep solitary waves. That is, the initial condition in the computation corresponds to two accurate solitary waves heading towards each other, but sufficiently far apart that there is no initial interaction between them. An initial solitary wave of any height can be accurately modelled using Tanaka's (1986) method. The program can include simple deformations to a flat bed, such as beaches and half ellipses. A berm of quarter-elliptical shape in front of the wall is modelled by placing a semi-ellipse on the bottom directly below the line of symmetry of the surface, where the two solitary waves collide. Results for such cases are also reported. For sufficiently steep waves a vertical jet forms at the wall (see figure 1).

We are not able to explicitly model a wall of finite height using the present code. Substantial changes would be needed to do this. However, we make use of a feature of common to all jets arising from unsteady waves. That is once the jet forms the pressure field within the jet is very weak. This means that almost all the motion of water in the jet is close to purely inertial. Thus we assume that

Figure 1: Solitary wave collision with vertical wall. Wave height, $H = 0.75d$

once the jet has formed, the motion of any fluid particle in the jet is governed by its initial momentum and gravity. Portions of fluid are modelled by considering their motion once above the crest of the wall as if they are free particles moving under gravity, that is

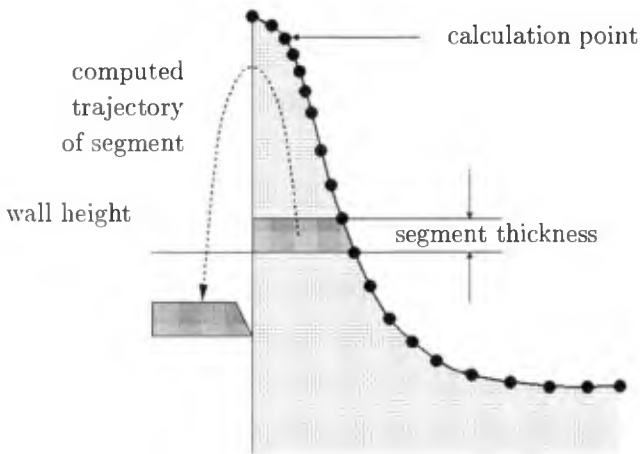

$$y(t) = y_0 + v_0(t - T_0) - gt^2/2 \quad (1)$$

$$x(t) = x_0 + u_0(t - T_0) \quad (2)$$

where the fluid particle has position (x_0, y_0) and velocity (u_0, v_0) at a time T_0 when it passes the crest of the wall.

As a jet ascends a wall there is some slight pressure against it. This is due to motion towards the wall as each portion of the jet stretches and thins. As the water passes the top of the wall this slight pressure drops to atmospheric, but the motion towards the line of wall continues. This means any portion of fluid passing the top of the wall has some momentum in a direction towards the wall which can carry it over the wall face and cause overtopping. Thus our model is as follows:

- Take horizontal slices of water as they pass the level chosen to represent the top of the wall.
- Work out their horizontal momentum.
- Treat each slice as a particle moving under gravity as in equations (1) and (2).
- Consider each slice as it returns to the level of the top of the wall. Use the position of its centre of mass to decide how much, if any, of the water has moved horizontally past the face of the wall and hence counts as overtopping.
- Add the contribution from all the slices that flow past the top of the wall to give an estimate of the total volume of water overtopping due to that wave.

This calculation could be further refined by allowing for the contraction of each slice under its initial velocity field. However, such contraction is influenced by the slight pressures exerted by adjacent slices, so that to try and include it would mean going beyond the simple modelling we wish to present here.

Slices were identified by stepping in time. The length of each time step and the vertical velocity together determining the thickness of each slice. Too short a time-step means good resolution but long computation times, too long a time step gives poor resolution. A time step size was chosen such that the thickness was always less than $10^{-4}d$, where d is the undisturbed water depth.

Limitations of simple model

In these calculations it is assumed that solitary waves are an accurate representation of the likely steepest incoming waves (see previous section). For the collision of solitary waves only the case of no surface tension and constant depth has been previously studied. When the waves are steepened by interaction with the berm a range of motions can develop, including flip-through motions as described by Cooker & Peregrine (1990). Flip-through motion is very sensitive to wave shape and can produce very violent jets. The present model is only applied to situations in which the free surface calculated by the potential flow solver has reached or passed the time of maximum run-up before breaking down. Thus we cannot model overtopping from breaking waves such as in figure 2, or the strong 'flip-through' impacts described by Cooker & Peregrine since in such cases we cannot compute up to the time of maximum elevation. On the other hand these give very thin jets. If the wave has already broken any resulting jet is small and mostly fails to overtop the structure. Thus the cases to which our model is restricted are those which happen to be responsible for a significant amount of overtopping.

Our model is inaccurate for wall heights below the height of jet formation, or for waves where no significant jet is formed, i.e. where the force due to internal pressure on a fluid particle is not negligible compared to gravity. Thus for example it does not apply to surging over low walls. In practice this means that

Figure 2: Solitary wave steepening over wide berm.

only solitary waves of steepness greater than $0.5d$ were used, and the results are restricted to the higher end of the dimensionless freeboard range (approximately to above $R/H=1.8$ in the calculations presented here).

Results with gravity waves.

Since these calculations assume two-dimensional waves the overtopping volumes calculated are volume per unit length of the wall, Q . The undisturbed water depth, d , is used as the unit of length in computations, so for example the wave height, H , is a dimensionless ratio of wave height to that water depth. Following the presentation of results in previous papers on overtopping rates, the quantities presented in the following section are in terms of the overtopping volume Q/H^2 , and dimensionless wall crest free board R/H , where R is the height of the top of the wall above the undisturbed water level. Note, for these solitary wave computations the undisturbed level corresponds to trough level in a periodic or irregular wave train.

Figure 3 shows the results of dimensionless overtopping against dimensionless crest free board for the case of a horizontal bed. The dimensionless overtopping volume is plotted on a logarithmic scale. For solitary waves of amplitude 0.5 or less, no significant jet is formed at the wall. Thus our model is less accurate for the wave of lower amplitude for which it is only likely to give a rough indication of overtopping volumes. The variation with wave height reflects the greater height of run-up at wall for the highest waves. This is described in Cooker *et al.* (1997). Dimensionless overtopping volume increases with wave height.

For the case of a berm in front of the wall figures 4 and 5 show the results of dimensionless overtopping volume against dimensionless crest free board for a solitary wave with amplitude $0.7d$ for berm widths d and $2d$. These include a range of results for berms of different heights. Rather surprisingly, for berms of

Figure 3: Solitary wave overtopping on water of constant depth; different wave heights, H

width d , $2d$, the overtopping decreases with increasing berm height. For these short berm widths, the higher berm interferes with the water motion near the wall. The influence on the shape of the resultant jet shape is small in the case of length d , but strong for the berm of length $2d$ (see figure 6 for example), making it increasingly wide and short.

It can be seen in figure 6 that the berm forces the water level at the wall up earlier than in the case with no berm. The result is that the strong accelerations normally seen at this time are reduced and the water just sloshes smoothly against the wall. In this case the reduction in the violence of the collision also corresponds to a reduced impact pressure at the wall. However, since the motion of the water is directed up by the berm at the wall this may give larger overtopping volumes at low crest free-boards. This is beyond the scope of our current model. For berms of width $3d$, the effect seen with the $2d$ berm and that of wave steepening appear to cancel each other. The overtopping predicted is very close to that with no berm. For wider berms still, wave steepening is the dominant effect, which increases the violence of the motion and the corresponding overtopping volume.

Figure 7 shows the dimensionless overtopping volume against dimensionless crest free board for berms of fixed height but different width. For dimensionless free-boards up to 2.5 there is little difference; it is only in the free-boards near the maximum run-up height that the influence of the berms can be clearly seen. Results show that a berm of width less than $3d$ decreases Q , compared to the no berm case. Over wider berms, the wave steepens giving a stronger jet on impact. A roughly exponential relation between individual dimensionless overtopping volume and dimensionless free-board (i.e. a straight line on the graph) can be seen over much of the valid range.

Figure 4: Solitary wave overtopping; berm width = d , different berm heights.
 $H = 0.7d$

Figure 7: Solitary wave overtopping; berm height = $0.2d$, $H = 0.7d$.

Comparison to existing experimental data

To the authors' knowledge there are no experimental results for individual overtopping volumes for a vertical breakwater in which the required geometric and hydraulic characteristics are all given. Indeed, the purpose of this study is partly to fill that gap. We can however draw some parallels between the calculations presented here and experimental results. From the knowledge of wave steepnesses (defined in related experimental work as wave height/distance between crests) and the nondimensional wave speed in our model, we can work out a rough overtopping rate. Values for wave heights are given in terms of a significant wave height, defined as the mean height of the 1/3 highest waves. In conversion to approximate rates we use this as equivalent to the height of our test wave. Where a range of significant wave heights is given our test wave is chosen equal to the mean of the range.

The overtopping rate is defined as the overtopping volume divided by the time between overtopping events. The time between overtopping events usually differs from the wave period as only a limited percentage of the incident waves produce overtopping.

A series of model test are carried out by Juhl (1995). Results for dimensionless overtopping rates are presented for differing angles of wave attack and wind velocities. Our model is only applicable to the results with zero wind velocity and normal wave attack. Again, we have to be careful when comparing our model to results with overtopping rates. Suppose we assume that only 10% of waves produce overtopping, a likely figure from various experimental results. Our model thus only gives a rough approximation to the experimental data.

Figure 8 compares the rate of overtopping found with zero wind velocity and 0° angle of wave attack to that predicted by our simple model over its range of validity. The period between overtopping events used to find the rate is derived by assuming the a periodic train of solitary waves which give a steepness equal to the average used in the tests, multiplied by the probability. We see that our model produces results that are of the same order of magnitude over most of the range. However there is a tendency for under-prediction at higher dimensionless free boards. This is explained earlier. The non-dimensional overtopping rate compares well to that of Juhl for dimensionless free boards in the range 2 to 3.

Overtopping with gravity-capillary waves

Surface tension plays an important local role where-ever the surface curvature is sufficiently high. In the calculations above, extremely thin jets are often produced which have a region of very high curvature at the tip. Surface tension can have a significant effect on the shape of the jet at this tip. This in turn might effect the predicted overtopping volumes. There are two ways in which surface tension is likely to effect overtopping - by affecting the profile of the incident wave, and by affecting the resulting jet shape. We ask, at what scale would surface tension become significant in overtopping experiments? The lack of data on scale correction factors to date has been reported as substantially hindering the application of research results to practical engineering analysis or design. Our model permits the inclusion of surface tension in the evolution of the surface. There are, of course, other scale effects not included in our model. These include the break up of jets into water drops and the effects of any wind. There may also be problems including any air entrainment effects.

Figure 8: Comparison of estimated overtopping rates with Juhl (1995) (wind speed=0, angle of attack= 0°)

The results are described in terms of the properties of clean water. Hence the description of water depth is used to specify scale of motion and thus the relative strength of surface tension. In our symmetric approximation we implicitly assume a contact angle $\theta = 90^\circ$. In practice the contact angle may differ from this, and the water is not usually clean.

Run-up of solitary type waves with surface tension

Figure 9 shows the jet at the time of maximum run-up for a solitary waves of $a = 0.7d$ with $d = 5\text{cm}$. In Jervis (1996), it was found that for the particular case of a solitary wave with $a = 0.7d$, propagating on depths 5cm and larger no noticeable capillary waves formed. Experimenters might then expect surface tension to play no measurable role in experiments. The main effect of the inclusion of surface tension is to modify the shape of the jet produced in the solitary wave collision. The jet is generally broader and shorter due to surface tension. A decreasing non-dimensional run-up height with increasing surface tension (i.e. decreasing scale) is found. For the $d = 5\text{cm}$ case for example, the decrease in non-dimensional run-up height is approximately 10%.

Overtopping volumes with surface tension

Figure 11 shows the dimensionless overtopping predicted by our model for a solitary wave of amplitude $a = 0.7d$. Results for depths of 5cm, 10cm, 20cm and 50cm are shown alongside the result for no surface tension. Results for depth 2cm are not shown: at this scale surface tension restricted the formation of a jet too much for our overtopping model to be valid. For small dimensionless free-boards we see that the results coincide. At higher dimensionless free-boards the

Figure 9: y/d against x/d at time up to maximum run-up for a solitary wave $a=0.7d$, $d=5\text{cm}$, berm width= $4d$, berm height= $0.1d$.

difference in jet shape shown in figure 10 is affecting overtopping volumes. At smaller scale (higher nondimensional surface tension values) the run-up height is less, and the average velocity towards the wall is reduced. Even for the calculation for $d=50\text{cm}$ there is a noticeable underprediction.

We can then see that even experiments carried out on depths of the order 20 to 50cm there is an underprediction at the upper limits of dimensionless free-board. For experiments where the incident wave is only 5-10cm relatively large underpredictions of overtopping volume and wave run-up can occur when scaling results back to full scale for use in breakwater design for $R/H > 2.6$. Of course here we are modelling only the non-breaking waves. More violent impacts produce jets beyond the scope of this simple model.

Figure 12 shows dimensionless overtopping for a wave on 5cm depth where the wave is steepened by a berm of width $4d$. As with no surface tension, wave steepening increases the strength of the jet produced. This can be seen in the trend towards a straight line for much of the range on figure 12 for higher berms. Without surface tension, overtopping is recorded for dimensionless crest free-boards of over 3.6, compared to only 2.85 with the corresponding 5cm calculation. It is clear then that extrapolating experimental results from such a small scale can give misleading values at high relative crest free-boards.

Figure 10: y/d against x/d at time of maximum run-up for a solitary wave $a = 0.7d$, for $d=2\text{cm}$, 5cm , 10cm , 20cm , 50cm and with no surface tension. (Surfaces have been shifted vertically for clarity).

Figure 11: Dimensionless overtopping volume against dimensionless free-board for a solitary wave $a = 0.7d$, $d= 5\text{cm}$, 10cm , 20cm , 50cm and ∞ i.e. no surface tension.

Figure 12: Dimensionless overtopping volume against dimensionless free-board on a berm of width $4d$ for a solitary wave $a = 0.7d$, for $d=5\text{cm}$ with surface tension.

Further work and conclusion

It appears that this simple theoretical approach gives plausible results for overtopping volumes per wave for non-breaking solitary waves. When strong jets are formed, particularly in calculations where the wave is steepened by interaction with a long berm, it is found that the overtopping volumes have a roughly exponential dependence on run-up for waves of a given height. Such an exponential relationship is similar to experimental results on overtopping rates (Franco, 1994, Juhl and Sloth, 1994, for example). The method predicts the same trends as previously reported in measurement of overtopping rates. A comparison of the results to measured overtopping volumes per wave is needed to validate the method however. Quantitatively, overtopping rates compare well with experimental results of Juhl (1995), allowing for the expected underprediction at high relative crest free boards.

From the results it appears that for the parameter range studied the short high berms decrease overtopping perhaps by interfering with the water motion near the wall, whereas wider berms steepen the incoming wave and make its encounter with the wall more violent and increase overtopping. Wide berms act to steepen the incident wave. In case where the flow was calculated up to the maximum run-up, wide berms tended to increase overtopping volume. Cases where the flow could not be computed up to the time of maximum run-up involved wave steepening often to the point of breaking before impact with the wall. In this case the likely impact pressures can be considerably higher (see Cooker 1990 for example). For the higher berms the shape of the jet can vary significantly, as can be seen in figure 6.

Wind can also play a role in overtopping. A wind force can break jets into spray above wall height. It can thus act to significantly increase or decrease overtopping, according to direction. Such a wind force could easily be incorporated into the simple mathematics of this overtopping model.

Most experiments are carried out at scales where surface tension plays a role in the jet dynamics. The effect of surface tension is generally not taken into account when extrapolating experimental results to full scale. Results here show that for overtopping rates that the effect of surface tension cannot be ignored for high crest free-boards. The action of surface tension on the tip of the jet leads to a considerable reduction in overtopping volume at relative crest free-boards greater than 2.6 for wave on depths up to the order of 20cm, and a corresponding reduction in non-dimensional run-up height. Since our model fits the most common mode of overtopping, we expect experimental results to be affected also, even though they generally include other modes of overtopping not covered here.

CHAPTER 171

Wind Effects on Runup and Overtopping of Coastal Structures

by Donald L. Ward¹, Assoc. Member, ASCE; Jun Zhang², Assoc. Member, ASCE;
Christopher G. Wibner³; and Charles M. Cinotto⁴

ABSTRACT

Effects of strong onshore winds on runup and overtopping of coastal revetments were studied in a wave flume with wind-generating capabilities. Runup and overtopping were measured during tests with onshore wind blowing over mechanically-generated waves. The addition of a constant wind over monochromatic waves added substantial energy to the wave field but the energy spectrum remained single peaked if the generated wave period was short (one second). These single-peaked incident spectra of the combined wind/wave tests were then reproduced mechanically using just the mechanical wave generator, with runup or overtopping again being measured. Runup and overtopping were both found to be considerably higher with similar incident spectra under the influence of onshore winds. Results are presented for a range of structure slopes, wind speeds, wave periods, and wave heights. Both smooth and rough revetments were tested.

I. INTRODUCTION

Design storm conditions for coastal structures typically include strong onshore winds that play an obvious role in transport of splash and spray, and may have a significant effect on wave runup elevations and overtopping rates. Design for runup and overtopping on coastal structures, however, typically ignores wind effects. Traditionally, runup distances and overtopping rates have been calculated from empirical equations determined from series of small-scale physical model tests (e.g., Weggel 1976, Ahrens and Martin 1985, Ahrens and Heimbaugh 1988, de Waal and van der Meer 1992, Ward 1992, Yamamoto and Horikawa 1992, van der Meer and Janssen 1994) that were conducted in the absence of wind. Numerical models currently available for runup and overtopping also neglect effects of onshore winds (e.g., Kobayashi and Wurjanto 1989, Wurjanto and Kobayashi 1991, van der Meer et al. 1992, Kobayashi and Poff 1994).

Because of the importance of accurate estimates of runup heights and overtopping rates, the Coastal Engineering Research Center (CERC) of the US Army Engineer Waterways Experiment Station has initiated a joint research project with Texas A&M University (TAMU) to investigate effects of onshore winds on runup and overtopping of coastal structures. Using a wave flume with wind-generating capabilities at TAMU, a series of tests were conducted on model revetments using a range of structure slopes, incident wave conditions, and wind speeds. Runup elevations or overtopping rates were measured, along with changes in the incident wave spectra due to influence of the wind.

II. TEST FACILITY

The two-dimensional wind/wave flume at TAMU is a glass-walled flume 36.0-m-long by 0.6-m-wide and 0.9-m-deep (Figure 1). Wave generation was by a pair of Seasim Ltd. (presently Commercial Hydraulics) dry-back hinged-flap wavemakers. Wave generation was controlled by an IBM personal computer interfaced to the wavemaker through an analog output card using software developed at TAMU.

Figure 1. Wind/wave test facility at Texas A&M University

Wind generation was provided by an exhaust blower connected to the end of the flume away from the wavemakers. Air was pulled into the flume through a vertically-adjustable intake manifold equipped with horizontal vanes to help introduce a uniform flow field into the flume.

Runup tests were conducted on plywood test structures with slopes of 1:1.5 (V:H), 1:3, and 1:5. Each slope was tested both as a smooth slope and as a rough slope. Rough slopes replicated riprap revetments and were covered with a filter layer and two-layer-thick riprap armor layer designed in accordance with Engineering Manual EM 1110-2-1614, Design of Coastal Revetments, Seawalls, and Bulkheads (1995).

Data inputs included twin-rod resistance-type wave gauges, resistance-type and capacitance-type runup gauges on the test structures, and a three-cup anemometer for measuring wind speeds. In addition, visual observations of runup elevations were recorded, wind speeds were measured by a pitot-static tube connected to an oil-filled manometer with wind speeds being visually observed, and overtopping rates were determined by measuring water surface elevations in an overtopping basin located behind the test structures at the beginning and end of each test run.

III. TEST PROCEDURE AND RESULTS

A. Determination of Incident Wave Conditions

All tests were conducted with monochromatic waves produced in short bursts such that wave generation would cease before waves reflecting off the test structures could reach the wave board and contaminate the incident wave train. Selection of wave heights was limited by the capabilities of the wavemaker. Wind speeds selected were 50%, 75%, and 100% of blower capacity (providing wind speeds of 6.5 m/s, 12 m/s, and 16 m/s, respectively), as well as the no-wind condition. Tests were conducted at a constant depth of 0.5 m; all wave tests conducted were classified as intermediate waves.

To determine incident wave spectra under the influence of wind, a 1:5 plywood slope was placed in the flume and covered with a wave absorber comprised of several layers of rubber matting ("horse hair") to a thickness of approximately 30 cm near the toe and 23 cm near the crest. A wave gauge placed near the toe of the structure (26 m from the wavemaker) recorded the incident wave train. The method of Goda and Suzuki (1976) was used to examine the recorded signals from a set of wave gauges centered 23 m in front of the wavemaker to separate incident and reflected wave trains and confirm that reflection was minimal. Each of the test conditions was run with the wave-absorbing slope to establish incident wave

conditions. Energy spectra showing the effects of wind are given in Figure 2 for generated waves with a 1-sec period and wave heights of 5, 7, and 10 cm.

Figure 2. Wave energy growth for 1-sec mechanically-generated monochromatic waves of wave heights (left to right) 5 cm, 7 cm, and 10 cm.

During tests of wind-wave energy growth and tests to establish incident wave conditions for the combined wavemaker/wind generator tests, the amount of wind-induced setup at the revetment was measured. It was found that the wind-induced setup remained constant for each wind velocity, virtually independent of incident wave conditions or structure slope. Observed wind-induced setup elevations were 1 cm, 3 cm, and 5 cm for wind speeds of 6.5 m/s, 12 m/s, and 16 m/s, respectively.

The addition of wind energy to the generated wave train clearly adds energy to the wave spectrum. Earlier tests with mechanically-generated wave periods of 1.75 and 2.5 sec had demonstrated that the majority of the energy increase due to wind produced a second peak in the spectrum at a frequency of about 2 Hz. This second peak is missing in Figure 2 for wave spectra with mechanically-generated wave periods of 1.0 sec, where the additional energy is shown as an increase in the single peak of the mechanically-generated wave. There are two reasons the spectra of the one-second waves remain as a single peak. First, as the wind-wave field developed during the first several meters of fetch, the wind-wave field was characterized by a high-frequency, short wave length wave field. As the steep one-second mechanically-generated waves propagated down the wind-wave flume, high frequency wind waves were blocked at the forward face of the steep mechanical waves and the wind waves were not allowed to form. This phenomenon of capillary/gravity wave blockage was described by Phillips (1984), Shyu and Phillips (1990) and Zhang (1995). Phillips (1984) noted that while this phenomenon is not

of great significance in the field, it can significantly affect the wave spectrum in laboratory wind-wave flumes with short fetches.

The second factor restricting development of the second peak in the wave spectra was the significant growth of the mechanically-generated waves due to modulation of the air pressure field. Because the crests of the large mechanically-generated waves were closer to the top of the flume than were the troughs, airflow was constricted by the reduction in cross-sectional area above the crests, resulting in higher local wind velocities at the crests. The opposite, of course, was true at the troughs. This modulation of wind velocities resulted in modulation of the air pressure field according to the Bernoulli equation. The modulated air pressures were in phase with the mechanically-generated waves and led to the growth of the mechanically-generated waves. The modulation of air pressure was not as significant for the longer wave lengths due to the smaller heights used due to limitations of the wave generator.

B. Runup Tests

For the runup tests, the wave-absorbing slope was removed and test slopes of 1:1.5, 1:3, and 1:5 were installed. Each slope was tested both as a smooth slope and built as a typical riprap revetment.

As was seen in Figure 2, the addition of wind to a mechanically-generated wave period of 1 sec remained as a single-peaked spectrum. For these single-peaked cases, it is possible to determine wind effects on runup by mechanically reproducing the combined wind/wave spectra. That is, the stroke of the wave generator can be increased to produce a similar spectrum to that obtained by a lesser stroke under the influence of wind.

Figure 3 plots runup on smooth slopes of 1:1.5, 1:3, and 1:5; Figures 4 plots runup on rough slopes. In both Figures 3 and 4, the abscissa is significant wave height (average of one-third highest waves) recorded near the structure toe, regardless of the height of the mechanically-generated wave. The ordinate is "equivalent" runup, that is, maximum runup adjusted for the increase in still water level due to wind setup. Symbols used in the figures indicate wind velocity used during each test. Figures 3 and 4 clearly illustrate the wind effects: for waves of similar wave height, the runup is considerably greater when the wave height is obtained by a small mechanically-generated wave plus influence of a strong wind, than when the wave height is purely mechanically driven (in the absence of wind).

Overtopping occurred in all tests conducted on the smooth 1:1.5 slope with wind speeds of 12 m/s and 16 m/s, and on the smooth 1:3 slope with wind speeds of 16 m/s and all but one test at 12 m/s. If overtopping occurred, maximum runup is not defined and no data are presented in the figures. On tests with smooth slopes

Figure 3. Runup elevations for (top to bottom) 1:1.5, 1:3, and 1:5 smooth slopes.

Figure 4. Runup elevations for (top to bottom) 1:1.5, 1:3, and 1:5 rough slopes.

(Figure 3) and rough slopes (Figure 4), the 6.5 m/s wind is seen to have negligible effect on runup elevations. Wind speeds of 12 m/s and 16 m/s cause significant increases in runup elevations on the smooth slopes, and on the rough 1:1.5 slope. For flatter rough slopes, the 12 m/s wind has little effect and only the 16 m/s wind significantly increases runup elevations.

Runup under the influence of the 12 m/sec wind and 16 m/sec wind is seen to increase linearly with incident wave height, then the runup tapers off or even decreases with increasing incident wave height. This is due to wave breaking under the influence of the wind prior to the wave reaching the test structure.

C. Overtopping Tests

In cases where the crest elevation was lower than the wave runup, overtopping was collected and measured in a basin behind the revetment. Different crest elevations on the revetment were tested, therefore a given incident wave condition may appear both in the runup figures (high crest elevation) and in the overtopping data (lower crest elevation).

Figure 5 plots overtopping on smooth slopes of 1:1.5, 1:3, and 1:5. The abscissa is "equivalent" crest elevation (crest elevation adjusted for wind-induced setup) divided by significant wave height measured near the structure toe. Ordinate of the

Figure 5. Overtopping tests for (top to bottom) 1:1.5, 1:3, and 1:5 smooth slopes.

figure is overtopping rate per cm of revetment width.

Overtopping results were similar to the runup results: higher wind speeds produced higher overtopping for similar wave heights, and wind effects were more pronounced on steeper slopes.

For no-wind conditions, measurable overtopping was only obtained on the smooth 1:1.5 slope and 1:3 slope. On the smooth 1:1.5 slope, winds of 6.5 m/s are seen to have negligible effect over the no-wind tests, but winds of 12 m/s and 16 m/s produced significant increases in overtopping rates. On the smooth 1:3 slope, winds of 6.5 m/s and 12 m/s appear to have little effect on overtopping rates, and only the 16 m/s winds show an appreciable effect.

IV. DISCUSSION

Physical model studies of prototype locations will typically reproduce certain parameters of a design storm wave environment, but do not reproduce storm winds associated with the design storm. Selected design storm wave heights are reproduced in a wave flume by a mechanical wave generator in the absence of wind. The study reported herein examines the effects on wave runup elevation and overtopping rates of reproducing a given wave height by purely mechanical means and failing to include the associated onshore winds.

Strong onshore winds have been shown to produce appreciably higher wave runup elevations and overtopping rates for waves of similar heights at the structure toes. Wind speeds of 6.5 m/s (23 km/hr) showed little effect on runup or overtopping, but wind speeds of 12 m/s (43 km/hr) and higher greatly increased both runup and overtopping. The significance of the wind effects, however, requires a consideration of the scaling effects involved.

Wind effects on runup and overtopping include wind energy input into the wave energy spectrum and wind induced setup. Both of these factors have been fully accounted for in the study reported herein. However, mechanically reproducing a wind/wave spectrum does not necessarily reproduce the *shape* of the individual waves. Different wave shapes due to wind forces acting on the waves, and changes in wave breaking due to wind effects, may change the wave kinematics at the structure causing the observed increases in runup and overtopping. Additionally, wind effects on the wave upwash on the structure slope may affect runup not only by helping “push” the upwash up the slope but possibly by reducing the effects of downwash on the subsequent wave. Wind advection of splash and spray has an obvious affect on overtopping rates. Each of these factors is currently being further studied.

V. ACKNOWLEDGEMENT

The testing program reported herein is funded by the U.S. Army Corps of Engineers, and the authors gratefully acknowledge this support. Permission to publish this paper was granted by the Office, Chief of Engineers.

CHAPTER 172

Wave Overtopping of Vertical Structures including Wind Effect

Johannes P. de Waal¹, Patrick Tönjes², Jentsje W. van der Meer³

ABSTRACT

The influence of both wave breaking and wind on the wave overtopping discharge of vertical sea-walls were assessed. In a qualitative way the influences of wave breaking agreed with the trends as pointed out by Goda (1985). The influence of wind on overtopping appears to be only relevant in specific conditions related to wave breaking. Even in these conditions the influence appeared to be smaller than expected.

1 INTRODUCTION

Intuitively, the influence of wind on wave overtopping is regarded to be relevant, but it is not clear to what extent. There are several types of possible wind influences. In this study the possible influence of wind on wave overtopping was subdivided as follows:

- Wind may cause overtopping of the part of the breaker spray which would have fallen back into the sea in a situation without wind;
- Wind may cause the breaker type to change by deforming the incident waves;
- Wind may cause overtopping by so-called "basic" spray, that is, spray which is generated by the wind at open sea.

Wind influence on the water level at the structure is assumed to be accounted for in the assessment of the design water level. A problem which is closely linked to the different (though coupled) wind influences is the measurability, especially the appropriate interpretation of measurements in a small scale model.

³Manager and senior engineer, Delft Hydraulics, PO Box 177, 2600 MH Delft, The Netherlands

2 SET-UP OF THE INVESTIGATION

Due to the large number of relevant parameters and the very complex water motion at the structure, a theoretical approach to the wave overtopping problem is hardly feasible. Therefore, it was decided to perform physical model tests in a wave flume in order to develop a set of empirical formulae for overtopping. However, in a physical scale model one should be aware of the following scale effects:

- Water drops in the air are not to scale: they are far too big in the model.
- The drop transport capacity of wind is not known.
- The influence of wind on the wave-form depends on the shear stress on the water surface, therefore the shear velocity of the wind should be to scale.
- The "flip-through" breaker type (see Section 4.4) probably occurs more often than in prototype, because the air entrainment is not to scale. At this point also the salinity of water is of significance, which makes the problem very complicated.

Due to these scale effects the three possible wind influences could not be modelled at one time in a physical scale model. For this reason, it was decided to focus the physical model investigation on an accurate modelling of the influence of wind on the breaker-spray transport only. The other two wind effects were studied theoretically.

The following basic dimensionless parameters are identified:

$$\text{Mean overtopping discharge} \quad Q = q/\sqrt{gH_{os}^3} \quad (2.1)$$

$$\text{Relative crest height} \quad R = R_c/H_{os} \quad (2.2)$$

$$\text{Wave steepness} \quad S = H_{os}/L_{op} \quad (2.3)$$

$$\text{Relative local water depth} \quad D = d_t/H_{os} \quad (2.4)$$

With:

g	= acceleration due to gravity (= 9.81)	(m/s ²)
d_t	= water depth at the structure	(m)
H_{os}	= significant wave height at deep water	(m)
L_{op}	= wave length in deep water, based on T_p	(m)
q	= average overtopping discharge per metre structure width	(m ² /s)
R_c	= crest level with respect to SWL	(m)
T_p	= wave period at the peak of the spectrum	(s)

These dimensionless parameters will provide a basis both for the set-up of test programmes and for the development of (empirical) overtopping formulae. A generally applicable form of the wave overtopping formula is the basic relationship between the dimensionless overtopping discharge Q and the relative

crest height R:

$$Q = c_1 \exp(c_2 R) \quad (2.5)$$

The coefficients c_1 and c_2 are also dimensionless and may be dependent upon all parameters except Q and R. A common way to present a measured or computed relationship between Q and R is a plot of $\log(Q)$ (or Q on a logarithmic scale) against R. Formula (2.5) implies that this type of presentation yields a straight line. In some other approaches the lines are curved very slightly downward, as indicated by Battjes (1974, for slopes) and Goda (1985, for vertical walls). However, the proposed straight line has proven to be a very good approximation and is fairly comfortable in computations.

The wave height H_{os} is very important in the basic overtopping formula and should be accurately assessed. If overtopping data are available in which the value of the wave height is uncertain within a band between plus and minus 10%, then the overtopping data lie within a band of which the maximum values are 3 to 6 times the minimum values, even when all other measured parameters are exact!

3 ANALYSIS OF GODA'S GRAPHS

Goda (1985) presents six separate graphs for wave overtopping of a vertical wall at specific combinations of the foreshore slope and the wave steepness. Compared with other information on wave overtopping in literature these graphs have proven to be very well applicable. The dimensionless overtopping discharge is plotted on a logarithmic scale against the relative local water depth, identifying lines for constant values of the relative crest height. Note the small difference between the definition of the dimensionless overtopping discharge used by Goda and the one used in this paper:

$$\text{Goda: } Q^* = q/\sqrt{2gH_{os}^3}; \quad \text{this paper: } Q = q/\sqrt{gH_{os}^3}$$

The information in the graphs was tabulated for $D \geq 1.0$. This table provided the opportunity to analyze the influences of the relative crest height R, the local water depth D, the wave steepness S and the foreshore slope $\cot\alpha_f$ on the dimensionless overtopping discharge Q. These aspects are discussed below in a qualitative way.

For constant values of $\cot\alpha_f$, S and D the relation between Q and R is well approximated by an exponential relation. A linear regression analysis has yielded the coefficients c_1 and c_2 . The value of c_1 appeared to be almost independent of $\cot\alpha_f$, S and D: $c_1 \approx 0.045$. This result proves to be very convenient, because the analysis of Goda's graphs may now be restricted to c_2 as a function of $\cot\alpha_f$, S and D. The optimum values of c_2 have been calculated again, but now with the assumption that $c_1 = 0.045$. The resulting c_2 -values have been plotted against D, identifying the different combinations of S and $\cot\alpha_f$, see

Figure 1.

In this Figure the following trends may be identified:

- The influence of S and D are approximately independent of $\cot\alpha_f$ if $D > 3.0$. In other words: the influence of the foreshore slope on wave overtopping is negligible for relatively deep water. This seems quite reasonable.
- If $1.0 \leq D < 3.0$, the c_2 -values (read: overtopping discharges) for $\cot\alpha_f = 10$ are greater than those for $\cot\alpha_f = 30$. This also seems reasonable because at a steeper foreshore the waves have less time and space for breaking. For milder foreshore slopes more wave energy is lost on the foreshore before the waves reach the wall.
- With increasing D the c_2 -values decrease. This is probably caused by the decreasing peakedness of the wave crests, but this effect is intuitively expected to be smaller than Goda's graphs suggest.
- The influence of S decreases with an increasing D . However, even at very deep water this influence seems fairly significant in Goda's graphs, whereas the influence of the wave steepness is expected to vanish at already intermediate relative water depths.

Figure 1. Influence of wave steepness, relative water depth and foreshore slope

4 TESTS ON THE INFLUENCE OF BREAKER SPRAY TRANSPORT

4.1 Model set-up

The objective of this model investigation was to assess the maximum possible influence wind can have on the mean wave overtopping discharge. The experiments were carried out in the Scheldt Flume of DELFT HYDRAULICS, De Voorst location in October 1993.

The foreshore was 8 m long and had a slope of 1:20. The vertical structure was 0.40 or 0.60 m high and had a sharp crest. Five vertical plates were installed perpendicularly to the structure in order to prevent or reduce transverse

oscillations in the flume. In order to prevent the loss of spray out of the flume the side walls of the flume were heightened after which a sort of a tunnel was created by covering this part of the flume with a horizontal board.

Scale effects in the total volume of water rising above the crest are intuitively considered to be small and the essential assumption in this investigation is that these scale effects may be neglected. In the second half of the test programme all spray rising above the crest was mechanically transported over the crest by means of a rotating paddle wheel, whose dimensions are presented in Figure 2. The optimum rotation speed is the maximum speed at which there is still enough time for all the water collected by a paddle to drain from the paddle and be collected behind the crest. This rotation speed appeared to be 21.4 revolutions per minute, which implied that the average number of strokes (paddles passing the crest) was 4.3 per second.

Figure 2. Paddle wheel for mechanical breaker spray transport

Irregular waves were generated according to a JONSWAP spectrum. Two wave gauges at deep water were used for the wave analysis. The signals of the wave gauges were sampled at 25 Hz. The test duration was 30 minutes.

The wave overtopping was characterized by the average overtopping discharge only. The storage capacity of the reservoir was about 300 litres. In addition, pumps with a constant discharge were used at intervals when this was necessary in order to prevent the reservoir from overflowing. The total pumping time was measured with a stopwatch. A water level gauge was installed at the reservoir for the measurement of water levels before and after each test.

The test programme consisted of two series. In the first series the overtopping was measured without the paddle wheel. Table 1 presents the target values of the dimensionless parameters. However, not all the possible combinations were tested. The first test series consisted of 18 tests. After installation of the paddle wheel this series was repeated, yielding the second test series. During the four tests with $D = 1.5$, video recordings of the water motion at the structure and of the performance of the paddle wheel were made.

Parameter	Notation	Values in test programme
Relative local water depth	D	1.0 1.5 2.0 3.0
Relative crest height	R	1.4 1.7 2.0 2.3
Wave steepness	S	0.02 0.04

Table 1. Target values of dimensionless parameters in overtopping tests

4.2 Analysis method

In order to describe the influence of a specific dimensionless parameter, such a parameter should have been varied while keeping all other relevant dimensionless parameters unchanged. Although the test programme was set up to account for such series, the actually measured wave conditions were not exactly equal to the desired values. Interpolation techniques were applied in order to obtain representative test results at the target values of the dimensionless test conditions.

For the quantitative analysis of the influence of spray transport we introduced a so-called "spray transport factor" W_s , defined as:

$$W_s = \frac{Q_{\text{with spray transport}}}{Q_{\text{without spray transport}}} \quad (4.1)$$

W_s is calculated on the basis of the test results at the target values of the dimensionless parameters.

In the analysis the definition of the significant incident wave height was based on spectral analysis. The incident and reflected wave energy (m_{oi} and m_{or}) were calculated from a cross-spectrum analysis of the recordings of the two wave gauges. The significant incident wave height was defined as:

$$H_{os} = 4\sqrt{m_{oi}} \quad (4.2)$$

4.3 Observations during tests

The water motion at the structure and the process of wave overtopping vary strongly, even during a single test:

- Ordinary overtopping occurs when the crest of a standing wave reaches higher than the crest of the structure: so-called "green water" flows over the crest.
- Collision of a steep wave crest with the wall results in an upward accelerating compact body of water, which spurts up moderately high and almost completely overtops the crest.
- When air entrainment at the wall is about to occur, the collision of the wave crest with the wall will result in a so-called "flip-through". The sound of the collision is still more like "zip" instead of a bang. A thin water sheet spurts up extremely high, almost vertically. The water sheet rapidly disperses into drops. About half of the upspurting water volume falls back into the flume.

- Wave slamming together with a loud bang will occur when a wave crest hits the wall about horizontally and some air is entrained. The water spurts up high, in big drops, in a great variety of directions.
- When the wave crest tip is already moving downward as it collides with the wall and much air is entrained, there is no clear "bang" heard any more. There is a lot of turbulence and the water spurts up chaotically and moderately high.
- When the wave is already broken as it reaches the wall almost no "bang" will be heard any more, partially due to the fact that the breaking wave itself already produces noise. The water does not spurt up very high and most of the big drops fall back into the flume.

The sequence of the phenomena described above corresponds with the transition from relatively deep local water to relatively shallow local water at the structure. In a single test with irregular waves this development corresponds with the transition from relatively small waves to relatively large waves. In tests with an intermediate relative local water depth ($D = 1.5$ to 2.0) this whole variation of phenomena could be observed.

The effectiveness of the mechanical spray transport was assessed by means of extensive visual inspections during the tests. These inspections led to the estimation that at least 90% of the volume of water which should have been transported by the paddles actually was transported. (Of course one can see some water falling back into the flume but it is very hard to conclude whether or not this water actually had risen higher than the crest). This estimated effectiveness is considered to be amply sufficient for this investigation.

4.4 Tests results

Figure 3. Comparison of test results with values based on Goda's graphs

Figure 3 shows the comparison between the measured overtopping and the calculated overtopping on the basis of Goda's graphs. The calculated values were

based on the measured hydraulic conditions. Most of the measured overtopping discharges appear to be considerably greater than the values according to Goda's lines.

The results for tests without spray transport are presented in Figure 4 and 5.

Figure 4. Influence of relative local water depth and relative crest height without mechanical breaker spray transport for $S = 0.02$

Figure 5. Influence of relative local water depth and relative crest height without mechanical breaker spray transport for $S = 0.04$

From these Figures the following conclusions may be drawn:

- The overtopping discharge clearly decreases with an increasing relative crest height. The four measurement points from the test series with $D = 2.0$ are at equidistant positions. This confirms the assumed linear relationship between $\log(Q)$ and R for tests without spray transport. (From a closer analysis it is concluded that the c_1 and c_2 values are not constant for the different values of

- D. The c_1 values may be approximated by a single constant of about 0.050 for $D = 2$, which agrees with the value based on Goda's graphs, but for $D = 1$ the measurements show a different tendency.)
- The overtopping decreases with increasing wave steepness, which agrees with Goda's graphs. This influence is the most obvious for tests with $D = 2.0$.
 - The overtopping discharge seems to reach a maximum at $D = 1.5$ to 2.0 , which agrees with Goda's graphs. For $S = 0.02$ this maximum is clearer than for $S = 0.04$.

Figure 6 and 7 show the results for the spray transport factor.

Figure 6. Measured spray transport factor for $S = 0.02$

Figure 7. Measured spray transport factor for $S = 0.04$

All tests with spray transport resulted in more overtopping than the corresponding tests without spray transport ($W_s > 1$). This seems a trivial conclusion, but a greater scatter in the measurement results could have caused less

consistency. The maximum value of the spray transport factor was about 3.2. The overtopping discharge in tests with spray transport still decreased with an increasing relative crest height, but the linear relationship between $\log(Q)$ and R appeared to be no longer valid.

From Figure 6 and 7 it may be concluded that the influence of spray transport increases with increasing relative crest height. This may be explained by the fact that the horizontal velocity of the water rising above the crest is smaller for a higher crest. This implies that for a higher crest a larger portion of the water falls back into the flume and the effect of spray transport may therefore be larger.

The spray transport factor sharply decreases with increasing relative local water depth. The explanation of this trend is similar to the explanation of the relative crest height influence. In shallower water, more waves have already broken when they reach the structure. The spray, resulting from collision of broken (or breaking) waves and the wall, has a great variety of directions. A relatively large portion of the water volume (spray) rising above the crest of the structure falls back into the flume. The influence of spray transport is considerable.

A comparison between Figure 6 and 7 leads to the conclusion that the influence of spray transport hardly depends on the wave steepness. In only a few tests the spray transport factor appears to be greater for the steeper waves.

5 INFLUENCE OF WIND ON WAVE OVERTOPPING

5.1 Additional breaker-spray transport due to wind

The physical model investigation has yielded fairly accurate quantitative information about the maximum additional breaker-spray transport due to wind. The upper limit of this wind occurs for breaking or broken waves and appears to be about 3 times the overtopping discharge for a vertical wall without wind. This factor may be regarded to be relatively small; it is of the same order as the scatter in overtopping data from other investigations. Therefore, the assessment of the relation between the actual wind speed and the additional portion of transported breaker spray is not considered to be very useful. The relatively small factor also implies that the error in past investigations due to the absence of additional spray transport was small.

5.2 Influence of wind on the wave breaker type

The effect of wind on the wave height at the structure should be accounted for in the substitution of the significant wave height term in the overtopping formula. However, wind may also change both the wave shape and the wave breaker type at the structure. As yet, there are no computation methods to assess this effect. Qualitatively, the influence of onshore wind on wave breaking can be summarized as follows (Douglass, 1989):

- Waves tend to break earlier (in deeper water).
- The type of wave breaking tends towards a spilling breaker type.

Douglass (1989) discusses only waves breaking on a mild slope, such as a beach. By a first approximation, the above tendencies may also be assumed to be valid for a mild slope ending in a vertical wall. However, the wave reflection with a vertical wall differs completely from that without a wall. The influence of wave reflection on the wave deformation by wind may be significant but is as yet unknown.

The wind effects on wave breaking are similar to the influences of a decrease in local water depth together with a decrease in foreshore slope. A decrease in local water depth causes the wave-breaking location to change: a decrease in foreshore slope the wave breaker type to change. This implies that an approximation of the influence of wind on wave breaking may consist of a reduction in both the local water depth and the foreshore slope in the overtopping formulae. This approximation is first roughly quantified and substituted afterwards into the overtopping formula.

On the basis of information from literature, Douglass suggests that the water particle velocity in the wave crest be increased by 3% of the wind speed to account for the onshore wind. The wave is assumed to break as soon as this water particle velocity exceeds the wave phase velocity. The reduction of the water depth at which wave breaking occurs may be approximated by:

$$\frac{d_b \text{ (with wind)}}{d_b \text{ (without wind)}} = \left(1 + 0.03 \frac{u_{a,10}}{\sqrt{g d_b}}\right)^2 \quad (5.1)$$

with:

$$\begin{aligned} d_b &= \text{water depth at which wave breaking occurs} \quad (\text{m}) \\ u_{a,10} &= \text{wind speed at 10 m height} \quad (\text{m/s}) \end{aligned}$$

For a numerical example of this wind effect a situation is considered in which waves break at a water depth of 5.0 to 10.0 m if there is no wind. Now a heavy onshore storm is considered in which the wind speed reaches 30 m/s. From Equation (5.1) it is concluded that the wind effect causes the same waves to break in 1.27 to 1.19 times deeper water than without wind. This change in location of wave breaking would also be caused by a reduction in water depth by about 20%.

The wave breaker type is characterized by the breaker parameter ξ_{op} , which is in this case determined by the slope of the foreshore instead of the slope of the structure:

$$\xi_{op} = \tan \alpha_f / \sqrt{S} \quad (5.2)$$

However, the type of wave breaking is very difficult to quantify and the

influence of wind on the breaker type is only qualitatively described. For a first indication, the influence of wind on the breaker type is approximated arbitrarily by a reduction in foreshore slope by 20%. This effectively decreases the value of the breaker parameter, thereby representing a transition towards a more spilling breaker type. In view of this arbitrary decision, the small influence of the reduction of the foreshore slope on the wave-breaking location has been neglected.

In order to estimate the order of magnitude of this wind effect on overtopping the influence of the representative changes in the foreshore on overtopping is assessed using Goda's lines. Figure 8 presents the wave-deformation factor due to wind, defined as:

$$W_d = \frac{Q_{\text{with wave deformation due to wind}}}{Q_{\text{without wind}}} \quad (5.3)$$

From this Figure it can be concluded that due to this wind effect, the overtopping discharge increases by a factor of about 3.0 for a relatively high crest and an intermediate relative local water depth ($D \approx 3$). On the other hand, the overtopping discharge decreases for a smaller relative local water depth ($1 \leq D \leq 2$).

Figure 8. Wave deformation factor due to wind for $\cot \alpha_f = 20$ and $S = 0.03$

The wind effect in question seems to have the same order of magnitude as the influence of wind on the breaker-spray transport, although it reaches a maximum under different circumstances. However, the verification tests showed that the influence of the relative water depth on overtopping is less pronounced than Goda's graphs suggest. This implies that the maximum factor of increase in overtopping due to wave deformation is probably less than 3. Still, one should be aware of the rough approximations which form the basis of this conclusion. This wind effect requires further investigation before it can be quantified accurately.

5.3 Contribution of basic spray to overtopping

In storm conditions the air above the sea surface is filled with spray. This spray is called "basic spray" in this paper. There is a dynamic equilibrium of the spray distribution over the height above the sea surface. This equilibrium is maintained by spray generation and turbulence in the air on the one hand and gravity on the other hand. The equilibrium is disturbed at the transition from sea to land, where the spray starts to be deposited. The amount of this type of overtopping was compared with the overtopping by waves (including breaker spray) and rainfall.

The following simple exponential equation for the spray concentration is applied:

$$c = c_0 \exp\left\{-\frac{w}{D_t}(z - z_0)\right\} \quad (5.4)$$

With:

- c = volumic spray concentration (-)
- c_0 = average spray concentration at $z = z_0$ (-)
- t = time (s)
- z = vertical coordinate, positive upward and $z=0$ at mean sea level (m)
- z_0 = reference level for spray concentration distribution (m)
- w = average fall velocity of spray (drops) in air (m/s)
- D_t = turbulent diffusion coefficient (m^2/s)

We introduce a horizontal coordinate x , being zero at the structure crest and negative at the open sea. We assumed a stationary situation. We assumed that the vertical distribution of spray concentration is transported with the horizontal wind velocity u_a , which was assumed to be uniform (independent of z). The total spray discharge (per m crest width) over the crest level R_c is given by:

$$q_b = \int_{R_c}^{\infty} c u_a dz \quad (5.5)$$

As soon as this spray distribution passes the structure crest (at $x = 0$), the production of basic spray at $z = 0$ stops. For $x > 0$ we neglect the influence of diffusion and simply assume that all spray falls down, having a velocity w . The total discharge of basic spray falling on the first L metre behind the crest (per metre crest width) is now given by:

$$q_b = \frac{D_t}{w} u_a c_0 \exp\left\{-\frac{w}{D_t}(R_c - z_0)\right\} \left(1 - \exp\left\{-\frac{w}{D_t} L\right\}\right) \quad (5.6)$$

The governing parameters in this formula were chosen as follows. The amount of spray strongly depends on the wind velocity. In the calculations a wind velocity u_a of 30 m/s is applied, representing wind force 11 on the Beaufort scale. The spray fall velocity w strongly depends on the drop size. Since the variety of drop sizes in the spray is very great, the representative fall velocity is difficult to assess. Therefore, two values have been applied, namely 0.5 and 2.5 m/s, representing a low and a high estimate respectively. The turbulent diffusion

coefficient D_t is unknown but is at first approximation regarded to be related to the average wind velocity. Two values have been applied, namely 5.0 and 50 m/s. The average spray concentration c_0 at the reference level $z = z_0$ is based on a rough estimation. The concentration of water in air during intensive rainfall is estimated at 10 ml/m^3 . This yields $c_0 = 10^{-5}$. The level of z_0 is assumed to be equal to the level of R_c . For the length L behind the structure crest in which basic spray is deposited two values were applied: 50 m and 100 m.

An estimation of the contribution of rainfall to the average overtopping was based on an intensity of 10 mm/hr. A representative value for the wave overtopping discharge was based on $H_{os} = 5 \text{ m}$, $S = 0.04$, $D = 2.0$ and $R = 1.7$. This yields $Q \approx 0.001$, which results in $q = 0.035 \text{ m}^2/\text{s}$. The results of the computations are presented in Table 2.

	w (m/s)	D_t (m^2/s)	q (l/m/s)	
			L = 50 m	L = 100 m
Basic	0.5	5	0.2	0.5
	0.5	50	0.2	0.5
Spray	2.5	5	0.5	0.6
	2.5	50	1.1	2.0
Rainfall			0.1	0.3
Wave overtopping			35	

Table 2. The contribution of basic spray to overtopping

From these results we concluded that the contribution of basic spray to the overtopping discharge is only slightly greater than the contribution of rainfall and is still negligibly small in comparison with representative wave overtopping discharges.

ACKNOWLEDGEMENTS

The Dutch Rijkswaterstaat and the Technical Advisory Committee for Water Defences are gratefully acknowledged for their substantial financial contribution and scientific support to this project.

CHAPTER 173

Bridge Pier Scour Assessment for the Northumberland Strait Crossing

C.D. Anglin¹, Associate Member, R.B. Nairn¹,

Abstract

In 1997, the Northumberland Strait Crossing will form a 13 km fixed link (bridge) between New Brunswick and Prince Edward Island in the Canadian Maritimes. This \$800 million project has presented many engineering challenges, one of which has been the assessment of scour protection requirements for the 65 bridge piers. A multi-faceted coastal engineering investigation was undertaken by Baird & Associates to assess the potential for scour, and, where required, to design scour protection. Key activities included geotechnical investigations to define the seabed characteristics, numerical modelling to define the wave, current and water level conditions at the crossing site, physical modelling of wave-current interaction with the bridge piers, and the development of a new methodology to estimate the erosion potential of the seabed under extreme wave and current conditions.

The direct application of standard scour prediction techniques was not possible for this project due to the combination of complex flow conditions (waves and currents), complex pier geometry (conical base, with some piers located in dredged pits), and complex seabed conditions (highly weathered and fractured bedrock). A new methodology to estimate the potential for scour, considering these complex conditions, was developed using the empirical erodibility approach of Annandale (1995). Measurements of actual scour around one of the first four bridge piers installed early in the project were used to calibrate/verify the methodology. Using this new methodology, scour protection was recommended at approximately one-quarter of the bridge piers. The protection system consists of a 10 m wide band of either armour stone or tremie concrete placed around the base of the piers.

Overview of Project

The Northumberland Strait separates Prince Edward Island (PEI) from the mainland provinces of New Brunswick (NB) and Nova Scotia (NS), as shown in Figure 1.

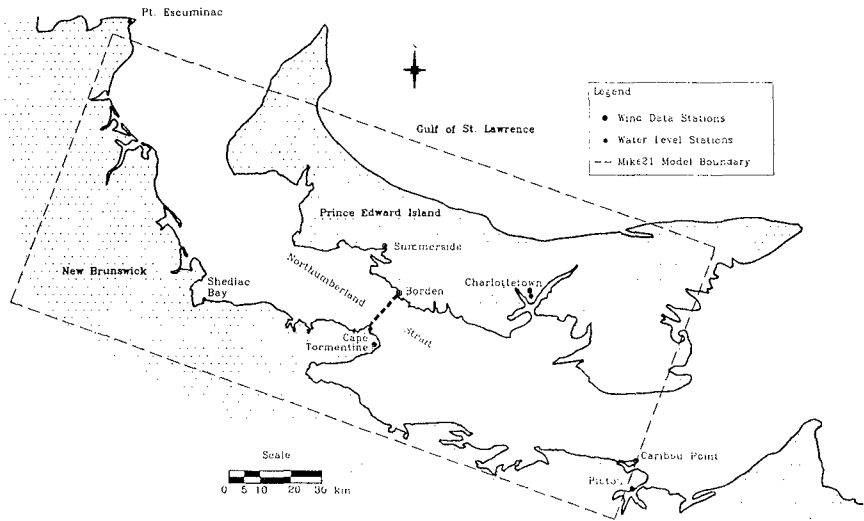

Figure 1 - The Northumberland Strait

At the crossing location, the Strait is approximately 13 km wide, with water depths ranging from 0 to 30 m (typically in the order of 15 m). Under extreme design conditions, this site (and the bridge) may be exposed to 120 kph winds, 4.5 m/9 s waves (H_s/T_p) and 2.5 m/s currents (the latter generated by the combined effects of tides, surges and wave-driven longshore currents). In addition, the Strait has a very dynamic ice environment, with ice present two to three months per year, level ice thicknesses of up to 1.2 m, and first year pressure ridges with keel depths of up to 15 m.

Ice forces on the bridge, and the effect of the bridge on ice breakup in the Strait, were the dominant design considerations for the bridge. The bridge structure consists of the east (PEI) and west (NB) approach bridges (93 m spans) and the main bridge (250 m spans). There are 7 approach piers on the PEI side and 14 on the NB side, and 44 main piers in between. Figure 2 provides a schematic illustration of one of the main piers, and shows the conical pier base, the conical ice shield and the pier shaft. For the approach piers, which are located in shallow water (depth < 8 m), the conical pier base is also the ice shield.

Figure 2 - Typical Main Bridge Pier

In order to meet the very tight project schedule, the primary bridge components (pier bases, ice shield/pier shaft, approach spans, main spans and drop-in spans) were all pre-cast in two production yards. Simultaneously, the pier foundations were prepared, including dredging/excavation to the founding elevation, and the placement of "hardpoints" to provide a level surface on which to place the pier bases. The main bridge components were then transported and placed using the heavy lift vessel (HLV) "Svanen" (see Figure 3), followed by connection of individual components. Construction began in the middle of 1994, and the final main bridge component was placed by the "Svanen" in November 1996. The bridge is scheduled to open in May 1997.

Figure 3 - Bridge Under Construction and HLV "Svanen" (view from PEI)

Overview of Development of Scour Assessment Methodology

Initially, an extensive literature survey was undertaken in an attempt to identify scour assessment techniques that could be applied to the Northumberland Strait Crossing Project (NSCP) (Baird, 1996). After reviewing all of the available information, including the HEC-18 manual of the U.S. Department of Transportation (1993), it was concluded that there was no acceptable technique to define scour potential for the NSCP bridge piers due to the following unique features/conditions associated with the project:

- combined waves and currents;
- conical shape of the pier bases;
- location of some pier bases in dredged pits (up to 7 m deep); and
- highly weathered/fractured and variable bedrock seabed.

An initial laboratory study was undertaken (Cornett et al, 1994) in an attempt to characterize and quantify the erosion potential of the various seabed materials at the crossing location. This investigation was completed in a tilting flume, and consisted of exposing intact samples (both slabs and cores) of various materials (glacial till, mudstone, siltstone and sandstone) to both open channel flows and submerged jet flows. The erosion process was found to be quite complex, and it was not possible to reliably quantify erosion of these materials as a function of either near bed velocity or shear stress.

Following these tests, the literature review was updated (Baird, 1996), leading to the identification of a promising new approach (Annandale, 1995) to estimate the erosion potential of “complex materials” (such as weathered and fractured bedrock). In general terms, Annandale’s (1995) approach relates the driving force for scour, as defined by the “stream power” parameter, P (which provides a measure of the rate of energy dissipation in the near bed flow), to the resistance to scour, as defined by the “erodibility index” parameter, EI (which provides a measure of the in-situ strength of the material based on data derived from borehole logs). Annandale’s (1995) database, and his relationship between stream power and erodibility index (which defines the threshold for scour) is based on observations of scour (or no scour) in spillways downstream of dams. In order to develop and apply this methodology to the NSCP, it was necessary to not only define the stream power (driving force for scour) and erodibility index (resistance to scour) for the unique conditions associated with the NSCP, but also to calibrate and verify the methodology for the assessment of scour potential around conical bridge piers exposed to combined waves and currents.

Driving Force for Scour

Two general issues must be addressed with respect to quantifying the driving force for scour for the NSCP bridge piers. First, the ambient flow conditions (waves and currents) at the crossing location must be defined, and second, the local influence of the bridge piers on these flow conditions must be defined.

Ambient Flow Conditions

Numerical modelling techniques were utilized to define the ambient flow conditions at the crossing location. A parametric wind-wave hindcast model was used to estimate the wave height, period and direction at four points along the crossing alignment on an hourly basis between 1960 and 1995. This 36 year period corresponded to the duration of available wind data in the vicinity of the Northumberland Strait. The hindcast model was calibrated (through modification of the overland wind data to represent overwater winds) against recorded wave data (five months) available in the immediate vicinity of the crossing, and excellent agreement was obtained for both wave height and period. Weekly composite ice charts were also reviewed, and wave conditions were set to zero during periods of significant ice cover on the Strait (typically two to three months per year).

The MIKE21 hydrodynamic model, developed by the Danish Hydraulic Institute, was used to estimate water levels and currents throughout the Strait on an hourly basis for the 23 year period between 1973 and 1995. The model utilized a 2.5 km grid spacing, and covered a total area of 95 by 208 km. The model boundary conditions were defined by recorded water level data at the model boundaries (Pictou, NS, and Pt. Escuminac, NB), thereby incorporating the effects of both tides and surges. The model was calibrated using recorded current data in the vicinity of the crossing location, and was verified against recorded water level data at locations on either side of the crossing (Charlottetown, PEI and Shediac Bay, NB). The model provided excellent agreement with the recorded current data, and also provided a good simulation of the very different tidal conditions at the two intermediate water level stations. The model results (hourly estimate of water level and current speed and direction) were extracted for the same four points as used in the wind-wave hindcast analyses. A sample output (vector plot of currents) for the hydrodynamic model is provided in Figure 4.

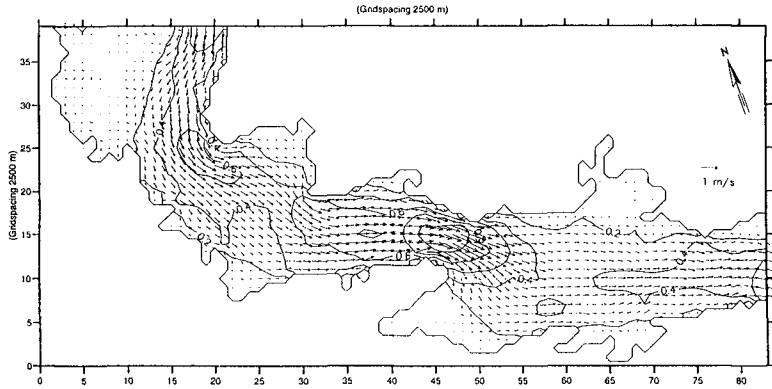

Figure 4 - Sample of Hydrodynamic Model Results (vector plot of currents)

A combined database (23 year hourly time series) was then developed for the four points along the crossing alignment, including wave height, period and direction, current speed and direction and water level. Shallow water processes, including refraction, shoaling, breaking and wave-driven longshore currents, were then estimated using the COSMOS model of coastal processes (Southgate and Nairn, 1993) in order to estimate the wave conditions at the shallow water approach piers (depth < 8 m). The stream power parameter, P , which defines the rate of energy dissipation in the flow, was then calculated as the product of the near bed shear stress and the near bed velocity, considering the combined effect of both waves and currents. The combined near bed shear stress was calculated using the method of Myrhaug and Slaatelid (1990), as presented in Soulsby et al (1993). The combined near bed velocity was calculated as the vector sum of the maximum wave orbital velocity and the depth-averaged tidal/surge current. Stokes second order wave theory was used in “deep” water (Ursell number < 26.3), while Cnoidal wave theory was used in “shallow” water (Ursell number > 26.3). Given the importance of water depth on wave orbital motions, these calculations were completed for a range in water depths representative of the 65 bridge pier locations.

Based on these calculations, a 23 year hourly time series of stream power was developed for a range in representative water depths. Severe stream power events were identified and extracted for each water depth, and extreme value analyses were completed to define the stream power parameter as a function of return period. The 100 year stream power event (considering the combined effect of waves and tidal/surge currents) was selected as the ambient design event for this project.

Local Influence of Bridge Piers

The presence of the piers in the Strait will result in accelerated flows and vortices in the immediate vicinity of the piers, leading to an increase in the driving force for

scour around the base of the piers. The influence of the various pier shapes and dredged pit depths (0 to 7 m) on the local flow conditions around the base of the piers was investigated for a representative range of water depths using a 1:70 scale model in a test flume at the Canadian Hydraulics Centre (Cornett, 1996). Figure 5 shows a photograph of typical model approach and main piers.

Figure 5 - 1:70 Scale Models of Bridge Piers
(L - West Approach Pier, C - Main Pier, R - East Approach Pier)

The test flume was connected to a 0.2 m³/s pump and flow circulation system to generate unidirectional currents, and a wave generator at both ends of the flume capable of generating both regular and irregular wave conditions. As such, it was possible to test waves with both following and opposing currents. The test section was located on a raised floor in the center of the flume. The flow patterns around the base of the pier were defined with the aid of a laser doppler velocimeter, acoustic velocity meters, flow visualization and tracer materials. Figure 6 presents a schematic diagram of the test flume.

Figure 6 - Schematic Diagram of Test Flume

Stream power magnification factors were developed for the various water depths and pier geometries encountered at the 65 bridge piers through a comparison of the stream power required to initiate the scour of a tracer material (coarse sand or fine gravel) with and without the pier in place. The stream power magnification factors varied from 1.5, for a deepwater main pier founded in a 7 m dredged trench (Figure 7), to approximately 6, for a shallow water approach pier founded directly on the seabed (Figure 8). The product of the local 100 year ambient stream power and the local pier influence factor (stream power magnification factor) defined the design driving force for scour at each of the 65 bridge piers.

Figure 7 - Scour in Tracer Material for Main Pier Founded in a Dredged Pit

Figure 8 - Scour in Tracer Material for Approach Pier Founded on Seabed

Seabed Resistance to Scour

Estimating the erodibility of the various highly weathered bedrock materials was one of the most challenging aspects of this project. As noted earlier, the laboratory tests in the initial phase of the investigation revealed that the erosion process was very complex, and was not a direct function of either near bed shear stress or near bed velocity. Ultimately, the empirical erodibility approach developed by Annandale (1995) was adopted. In this approach, the erosion resistance of the material is quantified by the “erodibility index”, EI, which characterizes in-situ strength of the material, considering the mass strength of the material, the typical “particle” size, and the interparticle “friction”. This parameter is calculated as the product of four dimensionless variables, all defined from information derived from standard geotechnical borehole logs, as summarized below:

$$EI = K_m * K_b * K_d * J_s$$

where EI = Erodibility Index
K_m = Mass Strength Number
K_b = Block Size Number
K_d = Joint Roughness Number
J_s = Joint Structure Number

As part of the geotechnical investigation undertaken to support the design of the NSCP bridge piers and foundations, between two and ten boreholes were drilled at each of the 65 bridge piers locations. For the scour assessment study, erodibility indices were calculated by the geotechnical engineer (Golder Associates) for each core run (approximately 0.3 m lengths) for each of these boreholes (approximately 300 in total). In general, the erodibility indices showed considerable variation (orders of magnitude) in both the horizontal and vertical dimensions. This variation reflected the highly variable nature of the materials on which the bridge piers are founded. In addition, it is noted that all of the boreholes were located under the pier bases, and not in the zone surrounding the pier bases where scour would initiate. This variability and uncertainty in the strength (erosion resistance) of the seabed materials was a primary consideration in the incorporation of a factor of safety in the assessment of scour potential for the bridge piers.

Calibration of Methodology

The NSCP represents the first application of Annandale’s (1995) approach to bridge piers, waves and currents, or design of any kind. As such, calibration and verification of the methodology was a key component of the investigation.

Fortuitously, observations of actual scour experienced around one of the first four approach piers installed early in the project provided valuable information for calibration of the new methodology. More specifically, scour around one of these approach piers (Pier E7) was noted following a storm event (in November 1994) during construction of the piers. Figure 9 provides a schematic illustration of the observed scour, which extended up to 5 m out from the base of the pier, with undermining up to 1 m in and 1.5 m below the base. Scour was not observed around the other piers in place at the time of this event.

Figure 9 - Scour in Bedrock Observed Around and Under Pier E7

The wave and current conditions which caused the scour during this event were hindcast using the numerical models described earlier, and indicated that the event had a return period (based on the stream power parameter) of approximately five years. The flow patterns around the pier were modeled for this event in the 1:70 physical model investigation. Based on this information, along with the geotechnical data describing the seabed conditions in the vicinity of the four approach piers, an attempt was made to calibrate Annandale's (1995) methodology for this project. The key calibration parameters were the wave height (ie. H_{avg} , H_s , $H_{1/10}$, H_{max}), the wave period (ie. T_{avg} , T_p , T_{max}), the shear stress (ie. T_{mean} , T_{max}) and the bottom roughness (k_s). Ultimately, the best comparison between estimated and observed scour at Pier E7 was obtained using H_{max} , T_{max} , T_{max} and a bottom roughness of 0.3 m. The use of the maximum wave height, period and shear stress values can be qualitatively justified by the hypothesis that the erosion of the highly weathered and fractured bedrock materials present at this site is a threshold process, and that once a rock fragment has been dislodged and removed from the matrix, the remaining material can be readily eroded. The lack of scour at the other three piers in place at the time of the November 1994 storm event can be explained by the presence of stronger materials (ie. higher EI values) on the seabed at these pier locations.

A qualitative confirmation of the scour assessment methodology was also made through consideration of the morphological development of the sea bed across the Strait. Through the application of the erodibility index approach, it was possible to explain the existence of a glacial till (soft clay/silt/sand) over the underlying bedrock for areas with depths greater than about 13 m. More specifically, in these areas, the 100 year stream power was less than the stream power required to erode the till material according to Annandale's (1995) approach. Together, the quantitative and qualitative observations of scour substantiated the methodology for the assessment of scour potential for the Northumberland Strait conditions.

A detailed review of Annandale's (1995) database, in particular the critical data points which describe the threshold condition for scour for erodibility indices similar to those encountered at the pier bases for the NSCP, was also undertaken in order to assess the compatibility of Annandale's database to the hydrodynamic and geotechnical conditions associated with the NSCP. In general, it was found that the critical data points which define the threshold condition for rock and complex earth materials represent similar rock conditions to those encountered in this project. Further, the hydrodynamic conditions for these data points, although not generated by wind-waves and tidal/surge currents, were associated with high velocities and turbulent flow conditions. As such, it was concluded that Annandale's (1995) scour threshold relationship could be applied to the NSCP.

Requirement for Scour Protection

A pier by pier assessment was undertaken in order to assess the requirement for scour protection at each of the 65 bridge piers. In general, this assessment consisted of the following steps:

- define the "critical depth zone" beneath the foundation of each pier (considering the allowable scour, which varies from 0 to 0.5 m the various approach and main pier foundation designs);
- define erodibility indices (based on available borehole data) within the critical depth zone, and estimate the corresponding threshold stream power for scour;
- compare local design stream power (100 year ambient value times pier magnification factor) to local threshold stream power;
- recommend protection if factor of safety is less than two to four.

The factor of safety was incorporated to address uncertainties associated with the driving forces, resisting forces and scour threshold relationship. The key uncertainty was the highly variable seabed conditions. A higher factor of safety was applied at piers with greater variation in seabed conditions, and/or where the tolerance for scour was lower. Ultimately, scour protection was recommended for approximately one quarter of the 65 bridge piers.

Design of Scour Protection

The design of the scour protection system around the base of the piers was developed and optimized using a physical model investigation. The test facilities and setup were very similar to that described earlier for the tracer tests undertaken to quantify the pier magnification factors. In general, these tests indicated that the influence of the piers on flow conditions extended approximately 7 to 9 m out from the toe of the conical pier bases. As such, a 10 m wide band of scour protection was adopted. Scour protection designs were initially developed using either one or two layers of armour stone. For the shallow water approach piers, these armour stones were in the order of 2 to 7 tonnes. Smaller armour materials were adequate for deep water piers. Figure 10 shows a picture of a scour protection test in progress.

Figure 10 - Scour Protection Test at Shallow Water Approach Pier

Subsequently, construction considerations led to the development of a scour protection system using tremie concrete. Again, this system extended out 10 m from the base of the pier. The key design details associated with the tremie concrete solution were careful cleaning of the seabed prior to concrete placement, and construction and monitoring operations adequate to provide a minimum 0.5 m thick mat of concrete over the seabed.

Monitoring Program

An extensive monitoring program has been recommended in order to quantify potential scour events over the design life of the Northumberland Strait Crossing Project, and to document scour which may occur around the base of the bridge piers. This monitoring program has been recommended for several reasons, as noted below:

- the scour assessment methodology utilized for this project is new, and has never been applied to bridge piers, waves and currents, or design of any kind;
- there are uncertainties associated with the estimation of both the driving forces for scour and the seabed resistance to scour;
- there is a desire to minimize seabed survey requirements around the base of the bridge piers associated with the monitoring program.

The monitoring program will consist of a near real-time wave and tide prediction system installed at the site. The prediction system will utilize numerical models similar to those used to develop the design database for this project. This system will run continuously, and will quantify the magnitude of potential scour (ie. stream power) events to which the bridge is exposed. Over time, a data base will be developed for each pier documenting the conditions to which the pier has been previously exposed (based on the prediction system) and the response of the seabed to these conditions (ie. scour or no scour, based on detailed surveys of the seabed). The database will be updated on a regular basis, and the system will identify any requirement for action by the bridge operation and maintenance staff. For example, additional surveys of the seabed around any particular pier will be required if the pier has been exposed to an event greater than any prior event, or if a certain period of time has elapsed since the last survey.

Conclusions

A multi-faceted coastal engineering investigation has been completed to support the assessment of scour around bridge piers for the Northumberland Strait Crossing Project. The application of conventional scour design techniques to this project was precluded by the unique conditions associated with this project, including complex flow conditions (combined waves and currents), complex pier base geometry (conical pier bases, with some located in dredged pits), and complex foundation materials (highly weathered and fractured bedrock).

The investigation has led to the development of a new methodology to assess scour potential around bridge piers which can address the unique conditions noted above, but can also be applied to more conventional/less complicated scour design problems. The new methodology is based on the empirical erodibility approach of Annandale (1995), and has been developed, calibrated and verified, to the extent possible, for this project. A detailed, long-term monitoring program will be implemented upon completion of the project in 1997, and will be used to verify this new scour design methodology.

CHAPTER 174

WAVE SETUP AT RIVER ENTRANCES

David J Hanslow¹, Peter Nielsen² and Kevin Hibbert¹

Abstract

Detailed mean water level measurements from the Brunswick River on the NSW North Coast have, to date, suggested that the contribution of wave setup to the super-elevation of river entrance water levels is quite small. Data indicate that the over heights inside the area of wave breaking in rivers are typically smaller than at the same depth in a beach surf zone with the same waves. It is thought that difference between beach surf zones and river mouths is due to the momentum flux of the river current and the current's influence on the wave breaking process. Nevertheless, tidal anomalies of the order 0.5m are measured once or twice a year by tide gauges just inside river entrances along the east coast of New South Wales. These anomalies are thought to be mainly due to freshwater outflow and/or oceanic phenomena.

Introduction

The largest part of disaster relief in Australia is related to flooding by river systems. In New South Wales alone the cost of flooding from coastal rivers is of the order M\$50 per annum. Hence, realistic modelling of flood flows and water levels in the rivers is a national concern. The State of the art of flood modelling is however unsatisfactory because the interaction between the ocean and the river systems is poorly understood.

A flood model of a river system will have two main inputs namely rainfall over the catchment and tail water level, i.e., the water level where the river meets the sea. The present paper addresses the estimation of these tail water levels.

The tail water level at a river mouth is influenced by several processes not all of which are well understood. The most predictable component is the astronomical tide. Its origin relating to the gravitational influence of the sun and the moon. In most places this component is quite predictable based on long tidal records.

Differences between the astronomical tide and the actual tide level are often referred to as tidal anomalies. In the deep ocean anomalies occur due to barometric pressure variations

¹ Coastal Management Program, NSW Department of Land and Water Conservation, Sydney, NSW, Australia

² Department of Civil Engineering, University of Queensland, St Lucia, Queensland, Australia

and to temperature variations in the water. In coastal areas additional anomalies can be caused by winds and waves, and in estuaries the water levels may be increased due to fresh water outflow.

The following contains a review of available theory and recent observations of tidal anomalies in the lower parts of a few rivers on the east coast of Australia, and the contribution of wave setup to these anomalies.

The main emphasis is on the Brunswick River in Northern New South Wales which is trained by almost parallel breakwaters that are approximately 40m apart at the seaward end. It has a catchment of 200 km² and a (spring) tidal prism of 4.8×10^6 m³ (Figure 1). The Brunswick River has a fairly shallow bar where even the smallest waves tend to break, and was therefore considered ideal for studying the contribution of wave setup to river tail water levels. The "ocean tide gauge" on the Brunswick River is situated at the confluence of Simpson's Creek with the River approximately 640m upstream from the ends of the breakwaters (Manly Hydraulics Laboratory, 1993).

Figure 1. The Manometer tube system at the Brunswick River.

Anomaly Statistics for the Brunswick River

In the period 1986 to 1995 there were eight events during which the Brunswick Ocean tide gauge recorded water levels greater than 0.5m above the predicted astronomical tide level. The largest of these tidal anomalies was 0.87m occurring on April 11 1988. Of these major anomalies, all except for 17/3/1993 (Cyclone Roger), were associated with very large daily rainfalls on the catchment (more than 65 mm at Mullumbimby).

An example of two different anomaly events is shown in figures 2 and 3. In these figures anomalies recorded at the Brunswick tide gauge and at an offshore pressure gauge located in 26m of water offshore of Tweed Heads (30 km north of Brunswick Heads) are presented for the periods 24-29 April 1989 and 7-11 March 1990. Also presented are the offshore root mean square wave height (H_{orms}) recorded at the Byron Bay wave rider (located approximately 10km south of Brunswick Heads in 80m water depth) and the hourly rainfall recorded at Huonbrook in the Brunswick hinterland. As seen in these figures both events saw similar wave conditions with maximum RMS wave heights of around 4m in each event (5.8m significant wave height). Rainfall patterns were however very different for each event with a total of 369mm of rain being recorded over the period 24-29 April 1989, but only 35 mm recorded over the period 7-11 March 1990.

During the March 1990 event maximum anomalies recorded at both the offshore gauge and the Brunswick River entrance were of similar order (0.38m and 0.42m at the offshore gauge and the Brunswick river entrance respectively). The similarity of anomalies recorded between the two locations during this event suggests the absence of any effects of wave setup within the Brunswick River Entrance. During the April 1989 event however, maximum tidal anomalies measured at the two sites are significantly different with the Brunswick River site being elevated approximately 0.44m above the offshore water level. (0.33 and 0.77m were measured at the offshore site and the Brunswick River gauge respectively). Given the similar wave conditions during each of these events the difference between the offshore anomalies and that recorded in the river entrance between these two events appears to be related to the effects of rainfall and the resulting flood gradient.

The correlation of tidal anomalies with daily rainfall is indicated in figure 4A. For a few major events 24 hourly anomaly values have been plotted against the same daily rainfall total. This leads to the "vertical clusters" where the lower anomalies would have occurred before the bulk of the rainfall is felt at the tide gauge.

The incorporation of more detailed (spatially and temporally) rainfall information combined with the cumulative effect of rain on previous days would enable closer correlation to be obtained.

In contrast to this obvious correlation between tidal anomalies and rainfall, there is virtually no correlation between tidal anomalies and offshore wave height. This is shown by figure 4B where the tidal anomalies at the Brunswick "ocean tide gauge" are plotted against the root mean square wave height H_{orms} off Cape Byron. Both gauges are operated by the Manly Hydraulics Laboratory. The plot shows no significant correlation between tidal anomaly and wave height. An explanation for this lack of correlation may be found in the following discussion of wave set up in surf zones.

The tidal anomalies observed at the “ocean tide gauge” in the Brunswick River plotted versus (A) Daily Rainfalls at Mullumbimby; and (B) offshore wave height H_{oms} off Cape Byron for wave heights $H_{oms} > 2.5\text{m}$. Vertical clusters in the rainfall data occur where several anomalies are plotted against the same daily rainfall value. Data courtesy of Manly Hydraulics Laboratory.

Wave Setup

Surf Zone Wave Setup

The phenomenon of wave setup in surf zones has been known from observations (eg. Savage 1957) since the nineteen fifties and quantitatively understood since the development of the concept of wave radiation stress by Longuet-Higgins and Stewart (1964).

It occurs because the radiation stress or thrust S_{xx} of the waves is gradually translated into a mean water surface overheight, the setup B , as the waves decay towards the shore. Based on the force balance on a surf zone control volume, the governing equation is found to be

$$\rho gh \frac{dB}{dx} = -\frac{dS_{xx}}{dx} + \tau_w + \tau_b \quad (1)$$

where the wind τ_w and the bed shear stress τ_b are often neglected.

The earliest setup models by Longuet-Higgins and Stewart (1964) and Bowen et al (1968) which assume a constant ratio between wave height and depth ($H - \gamma h$) through the surf zone and use linear wave theory to express the radiation stress.

$$S_{xx} = \frac{3}{16} \rho g H^2 \quad (2)$$

lead to a linearly increasing setup towards the shore. However, experiments, eg. van Dorn (1976), have shown that such a distribution is only realistic for short waves on flat slopes or more precisely for small values of the surf similarity parameter $\xi = \tan\beta L_o/H \leq 0.2$, where L_o is the deep water wave length and $\tan\beta$ is the beach slope.

For larger values of the surf similarity parameter, the H/h ratio is not constant through the surf zone and Equation (2) is not a good approximation. The result is an upward concave mean water surface (MWS), see eg. Nielsen (1989) and Gourlay (1992).

The variability of the height of natural (irregular) waves also tends to make the MWS upward concave even at small values of ξ see eg. the field data of Nielsen (1988). The reason is that the onset of breaking occurs at different depths for waves of different heights.

While setup profiles due to regular laboratory waves show great shape variability depending on the surf similarity parameter, it turns out that the shape of setup profiles on natural beaches varies very little. An empirical description of these profiles will be given in the following.

An Empirical Model for Setup on Natural Beaches

The shoreline setup level (that is the setup at zero water depth) varies very little between natural beaches and between naturally occurring wave conditions as documented by Hanslow & Nielsen (1994). They found that data from the full spectrum of New South Wales beaches showed no systematic deviations from either of the shoreline setup (B_s) formulae

$$B_s = 0.38 H_{orms} \quad (\text{correlation coefficient } 0.65) \quad (3)$$

or

$$B_s = 0.048 H_{orms} L_o \quad (\text{correlation coefficient } 0.77) \quad (4)$$

where H_{orms} is the deep water root mean square wave height and L_o is the deep water wave length. Correspondingly, the whole setup distributions measured on different beaches under not too unusual wave conditions are very similar. (Note that laboratory conditions with very flat waves on steep slopes corresponding to $\xi = \tan\beta_F L_o/H_o > 3.0$ may lead to very large relative shoreline setup, eg., $B_s/H > 2.0$ and that very long swell waves might generate similar results in the field. Such conditions would however be very rare).

A typical set of setup profile data from a single storm event (Brunswick Heads 22/8 1989) is shown in Figure 5.

The curve fitted to this setup profile is given by

$$B(h) = \frac{B_s}{1 + \alpha h / H_{orms}} \quad \text{with } \alpha = 10 \quad (5)$$

For other beach topographies the shape is similar, but the value of α may vary by a factor 2 either way, i.e. $5 < \alpha < 20$.

Figure 5. Measured setup profile data from Brunswick Beach August 22 1989.

S_{xx} according to measured setup profiles

The simplified setup equation $\rho gh \frac{dB}{dx} = -\frac{dS_{xx}}{dx}$ which for a monotonically sloping bottom can be rewritten $\frac{dS_{xx}}{dh} = -\rho gh \frac{dB}{dh}$ gives through integration by parts

$$S_{xx} = -\rho g \left[Bh - \int B dh \right] \tag{5}$$

which with (5) inserted gives

$$S_{xx}(h) = \rho g H_{orms}^2 \frac{B_y}{H_{orms}} \left[\frac{1}{\alpha} \ln \left(1 + \alpha \frac{h}{H_{orms}} \right) - \frac{h / H_{orms}}{1 + \alpha h / H_{orms}} \right] + \text{constant} \tag{6}$$

The constant of integration is found by matching with S_{xx} for non breaking waves at a suitable depth outside the surf zone. The alternative: $S_{xx}(0) = 0$ does not apply for natural beaches where runup occurs beyond $h = 0$.

Estimation of River Mouth Setup from Surf Zone Profiles

If one boldly assumes that a similar relation exists between depth and setup in a river entrance as in a surf zone (Equations 2 and 9) one might use the following estimate for the wave setup contribution to the river tailwater level

$$B_{\max} = \frac{B_y}{1 + \frac{\alpha h_{\min}}{H_{orms}}} \tag{7}$$

where h_{min} is the minimum depth in the river mouth. The shoreline setup B_s , determined from either (3) or (4).

As an example with reference to the Brunswick River one might choose $H_{min} = 2.0, \alpha = 10$ and $H_{orms} = 2.5m$, which gives $B_{max} \approx 0.2m$. We shall see in the following that this estimate is quite excessive which indicates that the assumptions required (see Section 8 for details) for this approach are not satisfied.

Detailed Mean Water Surface Measurements from the Brunswick River

In order to obtain detailed experimental data on river mouth water levels a manometer tube system, similar to the surf zone system described by Nielsen (1988), was installed in the Brunswick river in 1988 and extended in 1990, see Figure 1

From this system a large data base has been accumulated including river water levels during the flood event of April 26-27 1989 shown in Figure 6.

These measurements show that during this event the water level at the tide gauge was considerably above the ocean level due to the hydraulic gradient in the entrance.

In contrast, events with moderately large waves but little rainfall show very little water level difference between the inner and outer tubes, see Figure 7.

The fact that a water level difference of about 1m exists between the swash zone on the beach and the river on the other side of the breakwater some times results in large scour holes.

Figure 6. River water levels during a flood event (26/4/89), even at high tide the hydraulic gradient in the river generates water level differences of over 30 cm between the tide gauge (chainage -460m) and the ocean (chainage +150m).

Figure 7. Time series of water levels offshore, inside of the wave breaking in the river and at the shoreline of the southern adjacent beach 22/6/89. A shoreline setup of the order of 1.0m is observed while the river levels only reflect the small tidal gradient ie. no setup was observed during Cyclone Nancy (2-4 March 1990).

The occurrence of the scour holes is of course conditional upon the water finding a path through the breakwater, which is not supposed to occur as most breakwaters are designed to be impermeable. Nevertheless, they are not uncommon. Professor M. Losada of the University of Cantabria has observed them at river entrances on the North Coast of Spain (personal communication 1992) and Mr J Bodycott (personal communication 1990) has reported on “mystery sand banks” occurring inside some of the New South Wales rivers with no other plausible explanation that the sand being washed through the breakwater by the mechanism shown above.

Anomalies due to Long Period Waves in the Ocean

Storm events which seem quite similar in intensity and shape may cause very different amounts of tidal anomaly. For example, Cyclone Roger (March 1993) produced an anomaly of about 0.5 m while Cyclone Violet (March 1995) produced an anomaly of only half this amount. This is despite the fact that several of the contributing mechanisms would have been stronger at Brunswick Heads during Cyclone Violet. See the time series of rainfall, wave height and measured anomaly in Figures 8a,b.

These figures show that the tidal anomaly caused by Cyclone Roger was two times greater than that caused by Cyclone Violet even though the wave height at the nearby Cape Byron wave rider was greater during Violet and the rainfall was greater as well. Furthermore, the atmospheric pressure in the Brunswick area would have been considerably lower during Cyclone Violet, which came very close to Brunswick Heads, than during Roger which came no further south than Maryborough.

A

B

Figure 8. Time series of rainfall, wave height and measured tidal anomaly in the Brunswick River during (A) Cyclone Roger and (B) Cyclone Violet.

These observations point towards long periodic ocean waves as the main contributors to tidal anomalies in the absence of rainfall effects. These long waves would also contribute to tidal anomalies measured at Coffs Harbour and in Sydney Harbour where the effect of waves and fresh water flow would be negligible. For a discussion of tidal anomalies in Sydney Harbour, see Wyllie et al (1993).

The fact that anomalies of the ‘‘Cyclone Roger type’’ do not occur in connection with all cyclones underlines the complication nature of the long periodic ocean waves that might cause them (eg Tang & Grimshaw, 1995).

Modelling River Entrance Water Levels

The approximate role of waves, winds and currents in generating river entrance water levels can be understood using a fairly simple numerical model as indicated in the following.

Governing equations

The model is based on the momentum principle applied to the control volume in Figure 9.

The x- momentum equation for this volume can be written:

$$\rho h \delta x W \frac{\partial U}{\partial t} = -\delta(\rho[D + \eta]WU^2) - \delta(\rho g \eta[D + \eta]W) - \delta(S_{xx}W) + \tau_w \delta_x W - \tau_b \delta_x W \tag{8}$$

Figure 9. Control volume at a river mouth. The width of the channel is $W=W(x)$, h is the total depth $h=D+\eta$, and x is positive landwards.

Where U is the velocity averaged over a wave period so that the left hand side represents acceleration of the mean flow for example due to tidal changes. On the right hand side, the first term represents the change in current momentum flux over the length δ_x . The second term is the change in the hydrostatic pressure force, the third is the wave radiation stress force, the fourth is the wind stress force and the fifth is the bed shear stress force. Friction

along the sides of the channel is also included in the last term. As usual, ρ is the density of water and g is the acceleration of gravity.

If the length of the model area is short compared to $T_{tidal} \sqrt{gD}$ quasi steadiness can be assumed and the left hand side becomes zero. Then division by $\rho g W [D + \eta]$ leads to

$$\delta\eta = -\delta\left(\frac{U^2}{2g}\right) - \frac{1}{\rho g [D + \eta]} \delta S_{xx} + \frac{\tau_w \delta x}{\rho g [D + \eta]} - \frac{\tau_b \delta x}{\rho g [D + \eta]} \tag{9}$$

This equation can, with a given discharge $Q = UW (D + \eta)$ be used alternatively to find the setup $\eta (x)$ starting from the seaward boundary (x_s, D_s, η_s) with $D + \eta \approx D$ in the first iteration.

Preliminary Results

To gain a general impression of the behaviour of the system an example is shown in Figure 10 a, b.

These results show that the spreading current generates a set down effect of the order U^2_{max}/gh at the end of the breakwaters ($x=0$) which works opposite to the setup caused by wave breaking in the same area. This is probably why the detailed water level measurements from the Brunswick River show no measurable setup even in conditions with a metre or more of shoreline setup at the neighbouring beach. For the case above, the shoreline setup would be of the order $0.4 H_o = 0.8m$.

A

B

Figure 10(A) Assumed distributions of wave height, depth and current velocity. (B) Resulting surface elevations with current alone, waves alone and with both waves and current. The bed (+side) friction was calculated as: $\tau_b = 0.5\rho f_c |U| U$ with $f_c = 0.001$, and the wind stress as: $\tau_w = C_{10} \rho_{air} U_{10}^2 \cos\alpha_w$ with $U_{10} = 10m/s$, $C_{10} = 0.003$ and $\alpha_w = 20^\circ$.

Conclusions

Detailed mean water level measurements from the Brunswick River suggest that waves generate very little setup at river entrances of this type. Measurements indicate that over heights inside the area of wave breaking in the Brunswick River are typically smaller than at the same depth in the neighbouring surf zone with the same waves. This difference between surf zones and river mouths is thought to be due to the momentum flux of the river current and the current's influence on the wave breaking process. Nevertheless, tidal anomalies of the order 0.5m are measured once or twice a year by tide gauges just inside river entrances along the east coast of New South Wales. These anomalies are thought to be mainly due to freshwater outflow and/or oceanic phenomena which have yet to be fully explained.

Acknowledgments

This study was funded through the Floodplain, Estuary and Coastal Management Programs of the NSW Department of Land and Water Conservation.

Tidal anomaly, wave and rainfall data used in the paper were supplied Manly Hydraulics Laboratory. The assistance of Steve Wyllie and Peter Davidson is gratefully acknowledged.

CHAPTER 175

Scour at Coastal Inlet Structures

Steven A. Hughes¹ and J. William Kamphuis²

Abstract: Scour at inlet navigation structures was investigated using a series of movable-bed physical models. Experiments included ebb and flood flows, sometimes combined with wave action. A new and potentially important scour mechanism was identified for situations where the ebb-flow discharge is redirected by a navigation structure. As ebb flow is deflected, flow velocities increase and a scour trench forms adjacent to the jetty.

In this paper formulations from inviscid jet theory are used to develop an easily-applied, but crude, prediction capability for maximum flow velocity in terms of entrance channel velocity and inlet geometry. A simplified scour prediction method is also provided, but much needs to be done to make it more realistic. Preliminary conclusions are given about scour produced by flood flow combined with waves.

1 Introduction

Scour hole formation adjacent to the channel-side toe and near the head of protective inlet jetty structures is a troublesome problem at many navigation inlets. Without remedial action, continued scour hole growth may result in jetty instability and partial collapse of the structure. In addition, deep scouring adjacent to the channel side of a protective jetty may be accompanied by shoaling of the maintained navigation channel, shifting the navigation channel dangerously close to the jetty.

These inlet scour problems were investigated through a comprehensive set of movable-bed model experiments conducted jointly by Queens University in Canada and the Coastal Engineering Research Center (CERC) in the United States. The experiments examined flood-flow and ebb-flow scour that develops at inlets under various combinations of tidal flow discharge, flow direction, and incoming wave action. The goal of the experiments was to develop simple empirical relationships for

¹Research Hydraulic Engineer, US Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, Mississippi 39180-6199 USA.

²Professor, Department of Civil Engineering, Ellis Hall, Queens University, Kingston, Ontario, K7L 3N6 CANADA.

estimating maximum scour depth in terms of easily determined parameters related to tidal discharge, channel geometry, and incident wave parameters.

From a survey of scour problems experienced at inlets (Lillycrop and Hughes 1993), it appears that one of the more important physical mechanisms causing scour at inlets during ebb flow is strong ebb currents that exit the inner bay and impinge on the structure at an angle as shown schematically by Figure 1. Laboratory observations indicated that as the ebb flow is deflected, the width of the flow parallel to the navigation structure is reduced, much like the deflection of a water jet. This results in increased flow velocity adjacent to the structure in order to maintain the same flow discharge over the reduced cross-section. Over many ebb-tidal cycles the increased velocities scour the bottom and enlarge the flow cross-sectional area until eventually flow velocities are reduced to non-scouring levels. The scour process is further complicated by the influence of short-period waves in the channel, entrainment at the flow shear interface, changes in flow velocity over the ebb cycle, and the influence of a porous jetty structure.

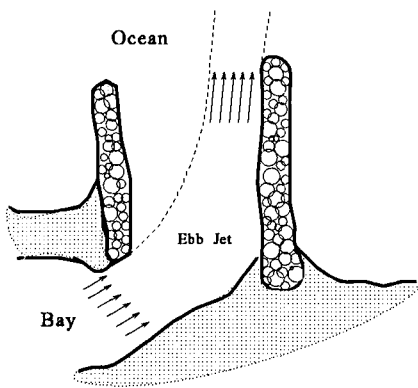

Figure 1: Ebb Flow Deflection.

Figure 2: Depth-Averaged Ebb-Flow Velocities at Ponce de Leon Inlet.

Field evidence of velocity increases due to ebb-flow deflection is shown in Figure 2, which plots depth-averaged ebb-flow velocity measurements obtained at Ponce de Leon Inlet, Florida. At the time of these measurements a scour trench had already formed adjacent to the jetty. Otherwise, the velocities would likely be even greater next to the jetty.

2 Laboratory Experiments

A series of deflected ebb-flow laboratory movable-bed model tests were conducted in a 15-m-wide wave flume at CERC with an undistorted nominal length scale of 1:20 and a water depth of 30 cm. These tests expanded on earlier studies conducted at Queens University at 1:30 scale. The experiment layout is sketched in Figure 3.

A conventional model jetty was constructed on a 45-cm-deep flat bed of fine quartz sand having mean diameter of 0.13 mm. The jetty toe was protected with a small stone scour blanket. The current manifold position and angle were adjustable to allow

Figure 3: Ebb Flow Experiment Layout.

Figure 4: Scour After 10 Hours with 60° Deflection (View from Seaward of Jetty).

different deflection angles (30° , 45° , 60°) relative to the jetty centerline. Adjustable vertical flow guides were used to direct the ebb flow, and flow straighteners helped to make the flow more uniform before passing over the movable bed. Total flow discharge was monitored and controlled at an upstream valve.

Laboratory measurements of flow velocity throughout the study region were accomplished using an array of three SonTek acoustic Doppler current meters (ADV's) mounted on an instrument catwalk spanning the flume. At each location the ADV's recorded a 3-minute velocity time series (25-Hz sample rate) at a depth 15 cm below the water surface. (All measurement values throughout this paper are in model units.)

Mean velocity at the input entrance channel was adjusted to be slightly above the 28–30 cm/s estimated to be required for incipient motion of the sediment. Dye injection indicated the deflected flow width adjacent to the jetty narrowed considerably similar to Figure 1. This gave rise to increased velocities adjacent to the jetty and significant scour along the jetty structure. Depending on the flow deflection angle, mid-depth mean velocities adjacent to the structure varied between 40–50 cm/s at the start of the experiments while the sand bed was still horizontal and scour was in initial stages.

Experiments continued for a total of 10 hours by which time it appeared that scour had reached an equilibrium for that flow condition. A portion of the scoured sediment was transported seaward by the ebb flow and deposited in a “fan” in a deeper part of the flume, whereas some sediment was deposited in a “berm” running parallel to the scour trench. Typical scour results are illustrated by the photograph in Figure 4, which was taken from a seaward position after an experiment with a 60° deflection angle. The photograph shows that the scour apron may have helped protect the armor slope.

Post-experiment surveys of the bed were completed using a Delft bed profiler mounted on the traversing catwalk. Bed elevation data were obtained at 4-cm spacings on survey lines running perpendicular to the jetty centerline. There was 20-cm spacing between survey lines.

3 Deflected Ebb Jet Theory

3.1 Analogy to Jet Flow

The deflected ebb-flow observed in the laboratory experiments is quite similar to a two-dimensional jet impinging on a solid boundary, and an analytical approach to deflected ebb-flow hydrodynamics was developed based on this analogy. Using the notation and coordinate system detailed in Figure 5, an inviscid, potential flow solution can be specified that links the flow field to the geometry of the solid boundaries.

The assumptions associated with this flow solution are given as:

- Incompressible, nonviscous, ideal fluid (no boundary layers, boundary layer separation, or flow entrainment at the jet “free boundary”)¹
- Steady flow in two dimensions (horizontal bottom)

¹The term “free boundary” refers to the interface between the jet and the adjacent still water as represented by the dashed line in Figure 1.

Figure 5: Ebb Jet Coordinate System.

- Nonrotational flow (velocity potential exists)
- Gravity has no effect on flow (implies relatively high velocities, and no cross-channel water surface setup due to centrifugal forces)

On solid boundaries and on flow streamlines there is the “no-flow” condition, i.e.,

$$\frac{\partial \phi}{\partial n} = 0 \tag{1}$$

and on the “free boundaries” pressure is assumed constant. This means that on the free boundary streamline, Bernoulli’s Equation is given as

$$\frac{V_o^2}{2} + gz = constant \tag{2}$$

Neglecting gravitational effects reduces the free-boundary condition of Eqn. (2) to

$$V_o = Constant \tag{3}$$

3.2 Potential Flow Solution

The solution to this particular jet-flow problem was given in Gurevich (1965). Without presenting details, the solution was found by conformally mapping the jet and its boundaries into a unit circle in the complex plane. Conformal mapping is a typical approach for this family of jet-flow problems. Other techniques are unsuccessful because the location of the jet free boundaries is not known *a priori*.

The resulting solution² is expressed as the following three equations (Eqns. 4-6)

²Note that in Gurevich (1965), page 63, the denominator of the second term under the integral of Eqn. (6) was incorrectly given as “ $t + (1/h)$ ” rather than the correct value of “ $t - (1/h)$ ”.

$$\frac{\ell}{L} = \frac{h^\kappa}{\pi} \int_0^1 \frac{d\xi}{\xi^\kappa} \left[\frac{1}{\xi+h} + \frac{1}{\xi+(1/h)} - \frac{2[\xi+\cos(\beta)]}{\xi^2+2\xi\cos(\beta)+1} \right] \quad (4)$$

$$\frac{a}{L} = 1 - \frac{\ell}{L} \sin(\pi\kappa) \quad (5)$$

$$\frac{b}{L} = \frac{\ell}{L} \cos(\pi\kappa) - \frac{h^\kappa}{\pi} \text{V.P.} \int_0^1 \frac{dt}{t^\kappa} \left[\frac{1}{t-h} + \frac{1}{t-(1/h)} - \frac{2[t-\cos(\beta)]}{t^2-2t\cos(\beta)+1} \right] \quad (6)$$

where "V.P." in Eqn. (6) means take the Cauchy principal value of the integral. In these equations, the parameter h is defined by the expression

$$h^\kappa = \frac{V_m}{V_o} \quad (7)$$

and the angle β is related to the jet exit angle, ϕ , by the geometric relationship

$$\beta = \frac{\phi}{\kappa} + \pi \quad (8)$$

with both angles given in radians.

The main difficulty with this solution is that the equations explicitly solve for the deflected jet geometry (ℓ/L , a/L , b/L) given the entrance and exit velocities (V_m , V_o), jet deflection angle ($\theta = \kappa\pi$), and jet exit angle (ϕ). In application to inlets, the geometry is usually known, and the flow solution is sought. Because the equations cannot be inverted, the only recourse is an iterative or nomogram solution.

Figure 6 presents an example of a nomogram that was generated for an ebb-flow deflection angle of 45° ($\kappa\pi = \pi/4$). This nomogram was constructed by solving Eqns. (4) and (6) at over 850 evenly distributed grid points bounded by the axes shown in Figure 6, and then contouring the results. The solid lines are contours of equal values for ℓ/L and the dashed lines represent constant values of b/L . For a given inlet geometry the unique solution is found at the intersection of the appropriate values of ℓ/L and b/L . The jet exit angle, ϕ , in degrees is read from the abscissa, and the velocity function, h , is read from the ordinate. The unknown velocity, V_o , corresponding to a value of V_m can now be determined from Eqn. (7). Figure 7 illustrates the variation in velocity ratio, V_o/V_m as a function of ebb-jet deflection angle, θ , and geometry parameter, B/L (see Figure 5 for definition of B).

Once values of h and ϕ are known, it is also possible to specify the location of the inviscid "free boundary" using the following equations that were derived based on Gurevich's (1965) formulation of the complex velocity potential.

$$dx = \frac{Lh^\kappa}{\pi} \left[\frac{\sin\sigma\kappa + h\sin\sigma(1-\kappa)}{(\cos\sigma-h)^2 + \sin^2\sigma} + \frac{\sin\sigma\kappa + \frac{1}{h}\sin\sigma(1-\kappa)}{(\cos\sigma-\frac{1}{h})^2 + \sin^2\sigma} - \frac{\sin\sigma\kappa + \sin[\sigma(1-\kappa)-\beta]}{2-2\cos(\sigma-\beta)} - \frac{\sin\sigma\kappa + \sin[\sigma(1-\kappa)+\beta]}{2-2\cos(\sigma+\beta)} \right] d\sigma \quad (9)$$

Figure 6: Nomogram for Ebb-Flow Deflection Angle of 45°.

Figure 7: Effect of Geometry on Ebb Jet Velocity Ratio.

$$\begin{aligned}
 dy = \frac{Lh^\kappa}{\pi} & \left[\frac{\cos \sigma \kappa - h \cos \sigma (1 - \kappa)}{(\cos \sigma - h)^2 + \sin^2 \sigma} + \frac{\cos \sigma \kappa - \frac{1}{h} \cos \sigma (1 - \kappa)}{(\cos \sigma - \frac{1}{h})^2 + \sin^2 \sigma} - \right. \\
 & \left. - \frac{\cos \sigma \kappa - \cos [\sigma (1 - \kappa) - \beta]}{2 - 2 \cos(\sigma - \beta)} - \frac{\cos \sigma \kappa - \cos [\sigma (1 - \kappa) + \beta]}{2 - 2 \cos(\sigma + \beta)} \right] d\sigma
 \end{aligned} \quad (10)$$

Values of x , y on the free boundary relative to the origin shown in Figure 5 are found by numerically integrating Eqns. (9-10) between zero and different values of σ lying between $0 \rightarrow \beta$, where β (in radians) is given by Eqn. (8).

3.3 Caveats!

It is important to note that the inviscid jet theory does **NOT** include any allowance for the following important “*real world*” effects related to deflected ebb flow at inlets:

- Turbulent flow entrainment between the ebb jet and adjacent still water
- Boundary layer losses due to the jetty structure and the bottom
- Effects of gravity on the ebb flow (possible secondary flows)
- Sloping, porous rubble-mound structures rather than vertical side walls

- Nonuniform entrance flow distribution
- Nonuniform depth in approach channel
- Wave effects on the ebb jet

Nevertheless, this initial flow approximation technique provides a conservative estimate of maximum flow velocity that would occur in the absence of the "real world" effects, and it can be used as a foundation on which to incorporate empirical approximations for these effects.

4 Comparison to Measurements

Figure 8 plots time-averaged velocity vectors measured at mid-depth for an experiment where the entrance channel was oriented 60° to the jetty. The average entrance velocity was $V_m = 32$ cm/s, and the dashed line in the figure is the inviscid "free boundary" calculated using Eqns. (9) and (10) with appropriate values of h and ϕ from the nomograms. Velocity increase along the jetty is clearly evident, as is flow entrainment along the ebb jet free boundary.

Ebb-jet theory estimates of maximum velocity, V_o , are compared to measured values near the seaward end of the jetty in Figure 9. Flow deflection angles of 60° (upper) and 45° (lower) are shown, and the plots are oriented with the structure to the left side (view from offshore). The theory predicts a constant velocity from the jetty out to the jet free boundary, at which point the velocity becomes zero at the interface.

Close to the jetty, the inviscid jet theory provides good estimates based only on geometry and entrance velocity, V_m (32 cm/s). Further away from the structure, flow entrainment between the ebb jet and adjacent still water had a significant impact.

Neglected altogether is the possibility that some of the flow acceleration might be due to secondary flows generated by a slope in the water elevation caused by centrifugal forces as the flow is deflected. This mechanism is thought to be important in river bends. Field measurements at an inlet where ebb flows are deflected by a structure would provide insight into whether secondary flows may also be an important factor in flow acceleration and subsequent scour.

5 Conservative Scour Prediction

Inviscid jet theory, coupled with flow continuity, can provide very crude (and overly conservative) scour estimates for deflected ebb-jet flows. Flow continuity requires the discharge at the entrance section (Q_m) be equal to the discharge at the narrowest part of the jet (Q_o), i.e.,

$$V_m d_m L = V_o d_o W_o \quad \text{or} \quad \frac{V_m}{V_o} = \frac{d_o}{d_m} \frac{W_o}{L} \quad (11)$$

where d_m and d_o are the total depths at the entrance and narrow section, respectively, and W_o is the width of the jet at its narrowest. Assuming an initially flat bottom where $d_m = d_o$, the width ratio W_o/L in Eqn. (11) can be expressed as

Figure 8: Measured Mid-Depth Velocities for 60° Deflection Angle.

Figure 9: Ebb-Jet Theory Compared to Mid-Depth Velocity Measurements.

$$\frac{W_o}{L} = h^\kappa \quad (12)$$

where the velocity ratio was replaced by Eqn. (7). If we assume the velocity, V_m , in the entrance channel is just at the sediment incipient motion criteria, we expect the bottom to erode at the narrowest part of the ebb jet until the velocity at that location reduces from V_o to V_m . Provided the width of the jet does not change, the depth increase necessary to maintain flow discharge is found from Eqn. (11) with $V_o = V_m$ and W_o/L given by Eqn. (12), i.e.,

$$\frac{d_o}{d_m} = h^{-\kappa} \quad (13)$$

Figure 10 shows two applications of this simplified scour prediction method compared to movable-bed model scour results. The dashed line indicates scour prediction using inviscid jet theory. Obviously, neglecting the effects of shear flow entrainment and bottom boundary layer flow reduction (and possibly secondary flows) has resulted in substantial over-prediction of scour. The assumption of constant W_o is also suspect.

6 Flood Scour Observations

Kidney-shaped scour holes situated at the tips of coastal inlet structures are a commonly observed type of scour. In some instances these scour holes are permanent features, but don't appear to threaten the structure toe. In other cases, structure toe instability has resulted with subsequent unraveling of the head armor layer and structure damage.

Preliminary tests conducted at Queens University examined development of scour holes at jetty heads under various combinations of flood-flow magnitude and direction, wave severity, and incident wave directions of -20° , 0° , and $+30^\circ$ relative to the jetty axis. In these tests the most severe jetty-tip scouring under flood flow currents occurred when both waves and currents approached from a -20° direction as illustrated in Figure 11.

Apparently, flood flow is accelerated as it is bent around the jetty tip similar to the classical case of potential flow around a sharp corner. The addition of waves from the same direction as the current resulted in wave diffraction around the jetty tip, which when combined with the current, increased the depth and areal extent of the scour.

7 Conclusions

Based on movable-bed laboratory experiments, a new and potentially important scour mechanism has been identified for situations where the ebb-flow discharge is redirected by an inlet navigation structure. As the ebb flow is deflected, flow velocities increase resulting in the formation of a scour trench adjacent to the jetty structure toe. This flow situation was recognized to be somewhat analogous to a free jet impinging on a wall, and inviscid jet theory was used to develop an easily-applied, but crude, prediction capability for maximum velocity in terms of entrance channel velocity and

Figure 10: Conservative Scour Estimates for Two Experiments.

Figure 11: Example of Flood-Flow Scour Model Results.

boundary geometry. Comparison of inviscid theory to laboratory measurements indicated reasonable agreement near the jetty structure, but over-prediction away from the structure due to flow entrainment at the shear interface between the ebb-jet and adjacent still water.

A simple, overly conservative, scour prediction method was offered based on inviscid jet theory, but the method suffers from not including empirical adjustments for the "real world" effects of shear flow entrainment and bottom boundary layers. However, this inviscid theory could be used as a starting point for incorporating these necessary features. Future efforts will extend and refine these preliminary design tools.

An initial examination of movable-bed model experiments simulating scour holes produced near the tips of jetties by flood currents indicated that the most severe erosion occurs on the lee side of the jetty tip when currents and waves approach at an angle to the jetty centerline. Although currents alone are sufficient to create scour holes, the addition of waves promotes more rapid scour to greater depths over a wider area.

CHAPTER 176

Probability distribution of the maximum wave height along a sea wall with finite width

Akira Kimura ¹ and Takao Ohta ²

Abstract

A probability distribution of the simultaneous maximum wave amplitude within a finite width along a virtual vertical plane placed in a 3-dim. irregular sea state is studied theoretically. The probability distribution differs considerably from the Rayleigh distribution even when the width of the structure is an order of 1/10 significant wave length. The difference increases with the interval width. Especially, apparent probability of large amplitude is considerably larger than that expected from the Rayleigh distribution. Coastal structures which were designed with sufficient safety margin have sometimes failed. There are possibilities that the structures were not attacked by "unexpectedly large waves" but large waves which could have been possibly expected if we had taken the width effect into account.

1. Introduction

Probability distribution of zero-crossing irregular wave heights measured by a "fixed wave gauge" agrees well with the Rayleigh probability distribution regardless of a wave spectrum. A zero-crossing wave height is defined as a difference between the maximum and minimum water levels within a zero-crossing wave period in the ordinary definition. When a short crested irregular wave acts on the structure such as a breakwater, wave height along it changes spatially. Although visual observation can roughly recognize a maximum wave height and its location, but single wave gauge can not always catch 3-dim. wave peaks and troughs of the short crested waves but only record a water surface displacement at its fixed position (Fig.1). However, if a big wave hits any part of the structure, it is recognized that the structure is attacked by a big wave. Suppose many wave gauges

¹Prof. of Tottori Univ., Faculty of Eng., Koyama Minami 4-101, Tottori, Japan

²Research Associate of Tottori Univ., Faculty of Eng., Koyama Minami 4-101, Tottori, Japan

are set up with negligibly small intervals on the structure, even though it seems unpractical. And if the largest one is adopted selectively among measured wave heights with these wave gauges as a simultaneous wave height during an action of a single (short crested) wave, a probability distribution of the wave height defined in this way may change according to the width of the structure. Statistical properties of the selectively defined wave height seems necessary to consider in a design of structure, if the structure is such a type that a local damage may induce a failure of the whole structure. This study deals with a theoretical probability distribution of the spatially maximum wave amplitudes along a structure with a finite width placed in a 3-dim. irregular sea state. A quite different probability distribution of wave amplitudes from the Rayleigh distribution is obtained if the width is not small.

Fig.1 3-dim. wave profile and a wave gauge

2. Wave number spectrum

x and y axes are taken on a still water level so that x axis takes a dominant wave direction and z axis is taken positive upward. Water surface elevation ξ of a 3-dim. short crested irregular wave is expressed as,

$$\xi = \sum_{i=1}^{\infty} c_i \cos(\mathbf{k}_i \mathbf{x} + 2\pi f_i t + \varphi_i) \tag{1}$$

in which c_i , \mathbf{k}_i , f_i and φ_i are amplitude, wave number, frequency and phase angle of the i -th component wave respectively, $\mathbf{x}=(x, y)$ and t is time. c_i is determined from

$$\sum_{f_i, \theta_i}^{f_i+df, \theta_i+d\theta} c_i^2/2 = E(f_i, \theta_i) df d\theta = S(f_i)G(\theta_i; f_i) df d\theta \tag{2}$$

where θ and $E(f, \theta)$ are the direction of wave and the directional wave spectrum, $S(f)$ is a power spectrum, $G(\theta; f)$ is a directional function. A wave number

spectrum $E(k_x, k_y)$ is derived from $E(f, \theta)$ as,

$$E(k_x, k_y) = C_g/2\pi \mathbf{k} \cdot E(f, \theta) \quad (3)$$

where k_x , k_y and C_g are x, y components of a wave number \mathbf{k} and group velocity corresponding to the frequency f respectively. New x , y axes which are anti-clockwise rotation of x and y axes around z axis are taken. The angle between x and x axes is θ . The wave number components on the new axes are expressed as,

$$\begin{aligned} k_x &= k_x \cos \theta + k_y \sin \theta \\ k_y &= -k_x \sin \theta + k_y \cos \theta \end{aligned} \quad (4)$$

For simplicity, k_x , k_x , k_y and k_y are replaced by u , u , v and v respectively. Wave profile in the new coordinate is expressed as,

$$\xi = \sum_{n=1}^{\infty} C_n \cos(u_n x + v_n y + 2\pi f_n t + \varepsilon_n) \quad (5)$$

and if a vertical virtual plane H is placed on the new x axis, cross section of ξ on H at $t = 0$ is given as,

$$\zeta = \sum_{n=1}^{\infty} C_n \cos(u_n x + \varepsilon_n) \quad (6)$$

where C_n and ε_n are amplitude and phase angle of the n -th component wave. C_n is determined from,

$$\sum_{u_n, v_n}^{u_n+du, v_n+dv} C_n^2/2 = E(u_n, v_n) du dv \quad (7)$$

The wave number spectrum $E(u, v)$ in eq.(3) is transformed into $E(u, v)$ using the relations,

$$\begin{aligned} u &= u \cos \theta - v \sin \theta \\ v &= u \sin \theta + v \cos \theta \end{aligned} \quad (8)$$

and

$$E(u, v) = \frac{\partial(u, v)}{\partial(u, v)} E(u, v) \quad (9)$$

where $\partial(u, v)/\partial(u, v) = 1$. One dimensional wave number spectrum $E_\theta(u)$ for ζ is given by an integration of $E(u, v)$ in terms of v ,

$$E_\theta(u) du = \sum_{du, v} C^2/2 = du \int_{-\infty}^{\infty} E(u, v) dv \quad (10)$$

When $\theta = \pi/2$, $E_\theta(u)$ is symmetry about $u = 0$. Small angle shift from $\theta = \pi/2$ brings, however, less unsymmetry on $E_\theta(u)$.

3. Maximum amplitude within a finite interval

Amplitude of zero-crossing wave is approximated with a wave envelope. Solid line in Fig.2 shows schematically a wave envelope $R(x)$ on H for $\zeta|_{t=0}$. $R(x)$ is determined by the Rice(1945) method (eq.20). Taylor series expansion of $R(x)|_{t=0}$ around $x = 0$ is given as,

$$R(x) = R(0) + R'(0) x + R''(0) x^2/2 + \dots \dots \dots \tag{11}$$

$R(0)$, $R'(0)$ and $R''(0)$ are amplitude of $R(x)$, its first and second derivative in terms of x at $x = 0$ respectively. First three terms in eq.(11) are used to approximate $R(x)$ in this study assuming the width of concern in Fig.2 ($-\Delta L \leq x \leq \Delta L$: width of the structure) is not large. A difference between the maximum amplitude R_m within the interval and $R(0)$ is given as

$$\begin{aligned} |R'(0)/R''(0)| &\leq \Delta L ; \\ R_m - R(0) &= -\{R'(0)\}^2/2R''(0) \end{aligned} \tag{12}$$

$$\begin{aligned} |R'(0)/R''(0)| &> \Delta L ; \\ R'(0) &\geq 0 \\ R_m - R(0) &= R'(0) \Delta L + R''(0) (\Delta L)^2/2 \\ R'(0) &< 0 \\ R_m - R(0) &= -R'(0) \Delta L + R''(0) (\Delta L)^2/2 \end{aligned} \tag{13}$$

Fig.2 $R(x)$, $R(0)$ and R_m ; wave envelope its amplitude at $x = 0$ and its maximum amplitude within the interval $-\Delta L \leq x \leq \Delta L$

Putting $\delta R = R_m - R(0)$, probability distribution of δR is defined as

$$P(\delta R)_R = \int_S P [R'(0), R''(0); R(0)] dS \tag{14}$$

in which $P[R'(0), R''(0); R(0)]$ is a conditional joint probability distribution for $R'(0)$ and $R''(0)$ and S is a region in which $\Delta R < \delta R < \Delta R + dR$ on condition $R(0)$. Figure 3 schematically shows the region S . Since S is symmetry about R'' axis, a half region ($R' > 0$) is shown. A probability distribution for the maximum amplitude R_m within the interval $-\Delta L \leq x \leq \Delta L$ is defined by

$$P_m(R) = \int_S P(\delta R)_R P [R(0)] dR(0) \tag{15}$$

where $P [R(0)]$ is a probability distribution of $R(0)$ (Rayleigh distribution). Connecting eqs.(14) and (15), $P_m(R)$ is calculated from

$$P_m(R) = \int_R^\infty \int_S P [R(0), R'(0), R''(0)] dS dR(0) \tag{16}$$

in which $P[R(0), R'(0), R''(0)]$ is a joint probability distribution of $R(0), R'(0)$ and $R''(0)$. For simplicity, $R(0), R'(0)$ and $R''(0)$ are expressed as R, R' and R'' respectively.

Fig.3 Region of integration S

4. Joint probability distribution for R, R' and R''

Following Rice (1945), joint probability distribution for R, R' and R'' is given as,

$$p(R, R', R'') = \frac{R^3}{8\pi^3 B} \int_0^{2\pi} d\phi \int_{-\infty}^{\infty} d\phi' \int_{-\infty}^{\infty} d\phi''$$

$$\begin{aligned} & \times \exp \left\{ -\frac{1}{2B^2} \left[B_0 R^2 + 2B_1 R^2 \phi' - 2B_2 (RR'' - R^2 \phi'^2) \right. \right. \\ & + B_{22} (R'^2 + R^2 \phi'^2) \\ & - 2B_3 (RR'' \phi' - 2R'^2 \phi' - R' R \phi'' - R^2 \phi'^3) \\ & \left. \left. + B_4 (R''^2 - 2RR'' \phi'^2 + 4R'^2 \phi'^2 + 4RR' \phi' \phi'' + R^2 \phi'^4 + R^2 \phi''^2) \right] \right\} \end{aligned} \tag{17}$$

in which

$$\begin{aligned} B_0 &= (b_2 b_4 - b_3^2) B, & B_{22} &= (b_0 b_4 - b_2^2) B, \\ B_1 &= -(b_1 b_4 - b_2 b_3) B, & B_2 &= (b_1 b_3 - b_2^2) B, \\ B_3 &= -(b_0 b_3 - b_1 b_2) B, & B_4 &= (b_0 b_2 - b_1^2) B, \\ B &= b_0 b_2 b_4 + 2b_1 b_2 b_3 - b_2^3 - b_0 b_3^3 - b_4 b_1^2 \end{aligned} \tag{18}$$

b_n , ($n = 0, 1, 2, 3, 4$) is determined as,

$$\begin{aligned} b_0 &= \langle I_{c1}^2 \rangle = \langle I_{s1}^2 \rangle \\ b_2 &= \langle I_{c2}^2 \rangle = \langle I_{s2}^2 \rangle \\ b_4 &= \langle I_{c3}^2 \rangle = \langle I_{s3}^2 \rangle \\ b_1 &= \langle I_{c1} I_{s2} \rangle = \langle I_{c2} I_{s1} \rangle \\ b_3 &= \langle I_{s2} I_{c3} \rangle = \langle I_{c2} I_{s3} \rangle \end{aligned} \tag{19}$$

in which $\langle \rangle$ means an ensemble mean, I_{ci} , I_{si} , ($i = 1, 2, 3$), R and ϕ are given as,

$$\begin{aligned} I_{c1} &= \sum_{n=1}^{\infty} C_n \cos(u_n x - u_m x + \varepsilon_n) \\ I_{s1} &= \sum_{n=1}^{\infty} C_n \sin(u_n x - u_m x + \varepsilon_n) \\ R &= \sqrt{I_{c1}^2 + I_{s1}^2} \\ \phi &= \tan^{-1}(I_{s1}/I_{c1}) \end{aligned} \tag{20}$$

and

$$I_{c2} = (I_{c1})', \quad I_{s2} = (I_{s1})', \quad I_{c3} = (I_{c1})'', \quad I_{s2} = (I_{s1})'' \tag{21}$$

u_m is a mean wave number of $E_\theta(u)$ (eq.10). In these equations ' and '' mean the first and second derivative in terms of x respectively. For simplicity $E_\theta(u)$ is assumed to be symmetry about $u = 0$. This assumption approximately holds if $|\theta - \pi/2|$ is not large. Integrating eq.(17) in terms of ϕ and ϕ'' ,

$$p(R, R', R'') = 2\alpha \int_0^\infty \exp\{-\beta\phi'^4 - \gamma\phi'^2\} d\phi' \quad (22)$$

$$\alpha = \frac{R^2}{(2\pi)^{3/2} \sqrt{B_4}} \exp\left\{-\frac{1}{2B^2} (B_0 R^2 - 2B_2 R R'' + B_{22} R'^2 + B_4 R''^2)\right\} \quad (23)$$

$$\beta = B_4 R^2 / 2B^2 \quad (24)$$

$$\gamma = (B_{22} R^2 - 2B_4 R R'' + 2B_2 R'^2) / (2B^2) \quad (25)$$

Although Rice(1945) gave an analytical solution for eq.(22), calculation is made numerically in this study.

5. Probability distribution of the maximum amplitude

Bretschneider-Mitsuyasu type wave spectrum is applied for $S(f)$ in eq.(2).

$$S(f) = 0.257 H_{1/3}^2 T_{1/3} (T_{1/3} f)^{-5} \exp[-1.03(T_{1/3} f)^{-4}] \quad (26)$$

where $H_{1/3}$ and $T_{1/3}$ are significant wave height and period. Mitsuyasu type directional spreading function $G(\theta; f)$ modified by Goda et al. (1975) is used.

$$G(\theta; f) = G_0 \cos^{2S}(\theta/2) \quad (27)$$

in which

$$G_0 = 2^{2S-1} \Gamma^2(S+1) / [\pi \Gamma(2S+1)] \quad (28)$$

and

$$S = \begin{cases} S_{\max} \cdot (f/f_p)^5 & : f \leq f_p \\ S_{\max} \cdot (f/f_p)^{-2.5} & : f > f_p \end{cases} \quad (29)$$

f_p is a peak frequency of $S(f)$. Goda et al.(1975) showed that $S_{\max} = 10, 25$ and 75 are suitable for fully saturated sea state, swell sea states with short and long decay distances respectively. Significant wave height and period of $H_{1/3} = 5.5m, T_{1/3} = 10s$ are used to realize a fully saturated sea state in the present calculation. $L_{1/3}, R(0)_{rms}$ and $H_{1/3}/L_{1/3}$ are $156m, 1.35m$ and 0.035 respectively in deep sea condition.

Fig.4 Distributions of δR on conditions $R = 1.0m$ and $R = 2.0m$
 ($S_{max} = 10, \Delta L = 0.05L_{1/3}$)

Figure 4 shows $P(\delta R)_R$ when $R = 1.0m$ and $2.0m$ for $\Delta L = 0.05L_{1/3}$, $h/L_{1/3} = 1.0$, and $S_{max} = 10$. Dotted line shows a part of the distribution when local maxima (eq.12) appear within $-\Delta L \leq x \leq \Delta L$ and chain line shows a part of the distribution when local maxima appear outside of the interval. Maximum amplitude within the interval is $R(-\Delta L)$ or $R(\Delta L)$ in the latter distribution (eq.13). Total of the dotted and chain lines gives $P(\delta R)_R$. When $R = 2.0m$, total distribution is narrower than that of $R = 1.0m$. This may correspond that when $R(0)$ is large, R_m presumably exist within a vicinity of $x = 0$. When $R(0)$ is small, on the contrary, the probability that the local maximum exist outside of the interval becomes large.

(a) $S_{max} = 10, h/L_{1/3} = 1.0$

(b) $S_{max} = 10, h/L_{1/3} = 0.25$

(c) $S_{max} = 20, h/L_{1/3} = 1.0$

(d) $S_{max} = 20, h/L_{1/3} = 0.25$

Fig.5 $P_m(R)$ (●), Rayleigh (solid line) and Weibull (broken line) distributions.

Figure 5 shows a calculated example of $P_m(R)$ (•) when (a) $h/L_{1/3} = 1.0$, $S_{max} = 10$, (b) $h/L_{1/3} = 0.25$, $S_{max} = 10$, (c) $h/L_{1/3} = 1.0$, $S_{max} = 20$, and (d) $h/L_{1/3} = 0.25$, $S_{max} = 20$. Two values for ΔL ($0.05L_{1/3}$, $0.1L_{1/3}$) are used in the calculations. Solid line shows the Rayleigh distribution ($\Delta L = 0$). Increasing interval brings a larger departure from the Rayleigh distribution. Broken lines are the Weibull distribution shown for comparisons. Shape parameters for the Weibull distribution are calculated using a Weibull probability paper (Yamauchi, 1972). Agreements of the calculated results and the Weibull distributions are fairly well in all cases.

Fig.6 Change of the shape factor with $\Delta L/L_{1/3}$
($h/L_{1/3} = 1.0$, $S_{max} = 10$)

Figure 6 shows a change of the shape factor with $\Delta L/L_{1/3}$ when $h/L_{1/3} = 1.0$, $S_{max} = 10$ (Fig.5(a)). It increases with ΔL while it is small but takes almost constant value $2.5 \sim 2.6$ where $\Delta L/L_{1/3} > 0.06$. Figure 7 shows a change of rms value for R_m calculated from $P_m(R)$ in Fig.5(a). Similar results as shown in Figs.6 and 7 are obtained in other cases. $P_m(R)$ (•), Rayleigh (solid line) and Weibull (broken line) distributions are compared for large value of R ($> 3.8m$) in Fig.8 ($h/L_{1/3} = 0.1$, $S_{max} = 25$ and $\Delta L/L_{1/3} = 0.1$). $P_m(R)$ is considerably larger than the Rayleigh and Weibull distribution in this area.

6. Modification of the spectrum

High frequency component of a wave spectrum brings small fluctuations on R (Tayfun et al., 1989). Sometimes a few local maxima appear on R within a given width. Eqs.(12), (13) may give δR between the nearest local maximum and $R(0)$, instead of between the maximum R_m within the interval and $R(0)$ in this case. To eliminate insignificant fluctuations on R , high frequency (large wave number; $k > 0.2$, $L \leq 0.2L_{1/3}$) part of the spectrum is neglected so that no wave component has shorter wave length than the mentioned widest width ($-\Delta = 0.1L_{1/3}$) in this study.

Fig.7 Change of the rms value for R_m with $\Delta L/L_{1/3}$ ($h/L_{1/3} = 1.0, S_{max} = 10$)

Fig.8 $P_m(R)$ (●), Rayleigh (solid line) and Weibull (broken line) distributions in a large R region. ($h/L_{1/3} = 1.0, S_{max} = 10$)

7. Concluding remarks

This study deals with a probability distribution of the maximum wave amplitude within a finite width along a virtual vertical plane placed in a 3-dim. irregular sea state. The probability distribution departs considerably from the Rayleigh distribution. This difference increases with the interval width. Especially, probability of the large amplitude is considerably larger than that of the Rayleigh distribution. It could be considered that unexpectedly large wave, appearance probability of which is very small, attacked when failure of coastal structures took place. However, the width effect for the apparent probability of large waves we has not been taken into account. Some of the failure may take place since this width effect on the probability distribution of wave heights is neglected. When structures are planed, three-dimensional properties of waves seems necessary to consider.

CHAPTER 177

Beach Response in Front of Wave-Reflecting Structures

Roy C. Seaman¹ and Tom O' Donoghue²

Abstract

The results of an experimental study of beach response in front of wave-reflecting structures are presented. The particular beach response problem is the so-called "N-type" response where sand is eroded in the area between the node and antinode and is transported towards the node. The characteristics of the equilibrium beach profile are presented and an equation describing the profile is proposed. The beach response is fundamentally dependent on the interaction between the flow and the ripples superimposed on the larger bedforms. Particle image velocimetry (PIV) has been used to look closely at the ripples and the flow. It is found that the sand transport towards the node results from larger vortex growth on the antinodal side of ripples than on the nodal side caused by the asymmetry in the main flow velocity time history which itself is a result of the superposition of the non-linear incident and reflected waves.

Introduction

Under a standing wave two main types of sediment transport can occur: transport of sand in suspension from under nodes towards antinodes or transport of sand as bed-load from between node and antinode towards the node. The former is often referred to as "L-type" movement and the latter as "N-type" movement. Previous notable research in this area (de Best *et al* (1971), Irie and Nadaoka (1984) and Xie (1985)) has shown that a "movability parameter", defined as the ratio of shear velocity to sediment fall velocity, can be used to determine which of the two types of transport is likely to occur for a given set of conditions. For relatively low values of the movability parameter, beach material transport is N-

²) Lecturer, University of Aberdeen, Department of Engineering, King's College, Aberdeen AB24 3UE, Scotland, U.K.

type and for relatively high values of the movability parameter, the transport is L-type.

N-type movement is demonstrated very easily in the laboratory by sprinkling some sand onto a fixed flat bed: under a standing wave the sand, provided the movability parameter is sufficiently low, oscillates on the bed and gradually advances towards the node. The reason why this occurs is because the direction of mass transport at the bottom of the wave boundary layer under a standing wave is towards the node as described originally by Longuet-Higgins (1953) and, in the context of the development of offshore sand bedforms, by Carter, Liu and Mei (1973). However, for a fully-mobile bed under a standing wave, ripples form very quickly and subsequently play a crucial role in the sand transport process.

The present paper presents the results of an experimental investigation of N-type beach response. Two main aspects of the problem are addressed: first, the characteristics of the "equilibrium" beach profile and, second, the fundamental dependence of the sand transport on the interaction between the flow and the ripples superimposed on the larger bedforms.

Experimental Set-up

All experiments were conducted in a 20m long, 0.45m wide random wave flume with a water depth at the paddle of 0.7m (Figure 1(a)). A horizontal tray, approximately 3m long and supported in the wave tank by a frame fixed to the tank, held a 200mm deep sand bed, the top 100mm or so consisting of a well-sorted sand with $D_{50}=0.32\text{mm}$. A vertical, impermeable wall was located at the shoreward end of the sand bed. The water depth in front of the wall was 150mm. Waves approached the sand bed from the deeper 0.7m depth at the paddle via a sloping false floor with a 1:20 slope over most of its length and constructed from perspex panels supported on an aluminium frame.

Figure 1(a): Experimental Set-up

Seventeen experiments corresponding to a wave frequency range of 0.7-1.1Hz and incident wave height range of 30-60mm were conducted in which the bed development from flat bed to equilibrium profile was observed. Once the equilibrium condition was reached for a given wave condition, the water level in the tank was lowered and the beach measured using a laser displacement sensor. The sensor has a spot diameter of 1mm and a resolution of 50 μ m and was mounted on a computer-controlled x-y table. For each experiment a total of 31 profiles were measured at 10mm intervals across the wave tank over a 300mm wide central section and at a resolution of 2mm in the longitudinal direction stretching from the wall to the first offshore antinode.

In order to study the underlying processes of the beach response, the detailed flow behaviour for a single wave condition ($f = 0.9$ Hz and $H = 50$ mm) was examined using particle image velocimetry (PIV). At selected stages in the development of the beach profile the bed was made rigid by sprinkling a thin layer of cement over the bed and allowing it to harden. PIV was then used to measure the instantaneous 2-d velocity field over and around individual ripples at selected phases of the wave cycle.

The PIV system used is based on a cross-correlation camera with two 756x458 CCD arrays. The camera is part of a completely integrated imaging system which includes the camera, PCI frame-grabber and camera-control card and Windows-based image acquisition and processing software. The camera views a part of the seeded, illuminated flow-field. Illumination was achieved using an 18W argon-ion laser beam carried by fibre-optic cable to a rotating mirror positioned above the wave tank which directed the beam via a lens to a thin sheet of glass held semi-immersed in the water (Figure 1(b)). The plane of the glass sheet was perpendicular to the mean water level and parallel to the sides of the wave tank. The purpose of the glass sheet was to avoid problems associated with bringing the laser beam through a fluctuating air-water interface. The light sheet was approximately 300mm long but only a fraction of this was viewed by the camera when measuring flow over the ripples.

Figure 1(b): Illumination for PIV

Overview of Beach Response

Figure 2 illustrates the typical development of the beach with time from the initial flat bed condition to the final, equilibrium profile. At the beginning of an experiment sand on the flat, horizontal bed began to oscillate back and forth. Oscillations were most vigorous underneath the node where velocity amplitudes were highest resulting in the rapid development of ripples here. Ripple formation then propagated towards the antinodes on either side until a point was reached beyond which the near-bed velocities were too low to initiate movement of the sand. These points are referred to as the limits of movement in the present paper. The ripple wavelength and height decreased with distance from the node, a result which is consistent with the reduction in the radius of water particle orbits with distance from the node. The characteristics of the ripples remained largely unchanged throughout the experiment as the underlying larger bedform developed. Beach development progressed as sand continued to move towards the node from the areas close to the limits of movement resulting in areas of scour adjacent to the limits of movement and a zone of accretion around the node. The scour holes deepened with time and velocities within the scoured areas decreased until no further sand transport could occur. At this stage sand movement towards the node ceased. Sand close to the node continued to oscillate back and forth under the high velocity amplitudes present there, but no further net transport was produced and the bed was said to have reached "equilibrium".

Figure 2 Sample beach profiles through time for $f=0.9\text{Hz}$ and $H=0.05\text{m}$

The Equilibrium Profile

The underlying larger bedform of the equilibrium profile is of significant engineering interest. The following equation is proposed to describe its major features:

$$\text{for } x_l \leq x \leq \left(\frac{\lambda}{2} - x_l\right) \quad \eta_b = \frac{a}{3} \sin\left\{\frac{2\pi}{3\lambda_b}(x - x_l)\right\} - a \sin\left\{\frac{2\pi}{\lambda_b}(x - x_l)\right\} \quad \dots[1]$$

where x is distance from the wall, x_l is the distance from the wall to the first limit of movement (equal to the distance from the second limit of movement to the offshore antinode), λ is the wave wavelength, η_b is the bed elevation above the initial flat bed level, a is a measure of the amplitude of the profile and λ_b is the bed profile wavelength where

$$\lambda_b = \frac{4}{3} \left(\frac{\lambda}{4} - x_l \right) \quad \dots[2]$$

For a given incident wave wavelength the function is fully defined if the positions of the limit of movement x_l and the amplitude factor a are known. The integral of the function over a half wavelength (antinode to antinode) is zero. The highest point on the profile is

$$\eta_{b_{\max}} = \frac{4}{3}a \quad \dots[3]$$

$$\text{The maximum scour depth is } \eta_{b_{\min}} = -\frac{5}{6}a \quad \dots[4]$$

For a given measured profile the limits of sand movement can be determined by calculating the local bed gradient as one advances from the antinode (where the bed gradient is zero) to a point where the gradient suddenly changes. The a value is then determined from a least squares regression of equation [1] onto the measured data. Two examples of measured profiles and their corresponding fitted functions are presented in Figure 3. Generally the function provides a good fit to the overall bed profile shape: it picks out the positions of maximum accretion and maximum scour satisfactorily and the method used to establish the limits of movement is seen to be successful. However, the function does tend to slightly under-predict the maximum scour and the gradient of the slopes leading up to the peak.

Figure 3: Measured profiles and corresponding best-fit of equation [1]. Top: $f=0.9\text{Hz}$, $H=30\text{mm}$; Bottom: $f=1.1\text{Hz}$, $H=40\text{mm}$

The values of x_l were determined for each of the 31 longitudinal profiles of each experiment. Of course two limits are obtained for each profile: the first limit is the shoreward limit denoted x_{l1} (i.e. the limit closest to the wall); the second is the seaward limit and is denoted x_{l2} . Figure 4 shows the results obtained for the limits of movement for three different wave period conditions. The results show the expected shift seaward of the limits of movement as the wave period increases, reflecting the seaward shift of the node of the standing wave. The results also show that the limits of movement are generally reasonably consistent across the width of the wave tank, significant scatter being observed only in the seaward limit of the longest period waves.

Figure 4. Measured limits of movement for 3 experiments.

A comparison of the measured limits of movement with the limits predicted using an incipient motion criterion is presented in Figure 5. The incipient motion criterion used is that proposed by Losada and Desire (1985) given by

$$\frac{A}{D_{50}} = \alpha' \left(\frac{Re^{\frac{2}{3}}}{D_*} \right)^{\frac{9}{5}} \quad \text{with} \quad D_* = D_{50} \left(\frac{\gamma g}{\nu^2} \right)^{\frac{1}{3}} \quad \text{and} \quad Re = \frac{u_{max} A}{\nu} \quad \dots[5]$$

where A is the amplitude of water particle excursion at the bed, D_{50} is the sediment size, γ is sediment specific gravity, ν is kinematic viscosity and u_{max} is the amplitude of horizontal water particle velocity at the bed. A limited study on the point of incipient motion of the sand used in this study was undertaken prior to the main body of experiments. For a number of wave periods, the wave height was increased in increments of 10mm until a value was reached at which movement of the sand could be clearly seen. The positions of the two points, one either side of the node, marking the separation of the area of bed where sand moves and the area where no sand movement occurs were measured and from this a threshold velocity calculated. The results obtained agreed very well with Losada and Desire's presentation of Goddet's data with α' equal to 1.34.

Figure 5 Comparison of predicted and measured limits of movement.

In Figure 5 the measured limits of movement are the average values of the 31 profiles. Figure 5 shows that the seaward limits of movement of the equilibrium profiles are well predicted using the incipient motion criterion. However, there is poor agreement between the measured and predicted shoreward limits. It is not known at this stage why this should be the case: the measured results suggest that the threshold velocity for sand movement near the wall is less than the threshold velocity away from the wall; of course the predicted threshold velocity is the same at the seaward and shoreward predicted limits of movement.

Although care was taken during the experiments to ensure that the wall was perfectly perpendicular to the incident waves, the response of the beach was never perfectly 2-dimensional, i.e. the beach profile varied across the width of the tank. Some evidence of this was seen in Figure 4 in respect of the limits of movement. Figure 6 shows the variation in a across the width of the tank for three different wave periods; a has been non-dimensionalised with respect to the mean value of the 31 a values of each test. The results show that a can deviate from the mean a value by as much as 20% of the mean value. This is an important result in that it illustrates the extent to which the developed beach is not perfectly 2-dimensional and reveals the dangers of obtaining results from a single longitudinal profile.

Figure 6 Variation in a across the wave tank for three example conditions.

Figure 7: Relationship between the amplitude and wavelength of the equilibrium bed profile.

The average a and its standard deviation was calculated from the 31 profiles of each experiment. The average bed profile wavelength λ_b was calculated from the measured limits of movement of the 31 profiles. Figure 7 shows the plot of average a against average λ_b , the error bars on a corresponding to \pm the standard deviation of a . Although there is some scatter, there is a reasonably good correlation between a and λ_b , particularly at lower values of λ_b . The results show that, for the conditions of the present study, the value of a is between 1/20th and 1/30th of the bed profile wavelength λ_b .

Mechanism of Sand Transport Towards the Node

During the very early stages of the beach development the primary mechanism causing sand transport towards the node is mass transport at the bottom of the wave boundary layer as described by Carter, Liu and Mei (1973). However, as the ripples grow, first at the node and later further out, they become large enough to shed vortices. Observations indicated that these vortices then become the dominant mechanism in further sand transport. In order to study the behaviour of the vortices, a single experimental condition was selected ($f = 0.9\text{Hz}$, incident $H = 50\text{mm}$) and flow around the ripples was studied using PIV.

Before looking at some of the PIV results it is first necessary to look at the characteristics of the main flow, i.e. the flow at a position away from the bed. LDA measurements of velocity were made at a height of 25mm above the initial flat bed at 8 positions in front of the reflecting wall. Figure 8 presents the results for the horizontal component of velocity along with a prediction of the horizontal velocity based on the superposition of two Stokes second order waves. There is good agreement between the measured and predicted velocity time series. The maximum velocity towards the wall (positive velocity) and away from the wall (negative velocity) are approximately equal to each other at each of the 8 positions. However, the velocity function is generally asymmetrical, meaning that accelerations are not of the same magnitude in the two directions. For example, at position 1 maximum acceleration away from the wall is much greater than the maximum acceleration towards the wall, or, in other words, acceleration is greater towards the node; at the corresponding position on the other side of the node, position 7, maximum acceleration towards the wall is much greater than that away from the wall, or, again, maximum acceleration is greater towards the node. So, maximum acceleration is always greater towards the node than away from the node and, because the degree of asymmetry decreases as the node is approached, the difference between maximum acceleration towards and away from the node decreases as the node is approached.

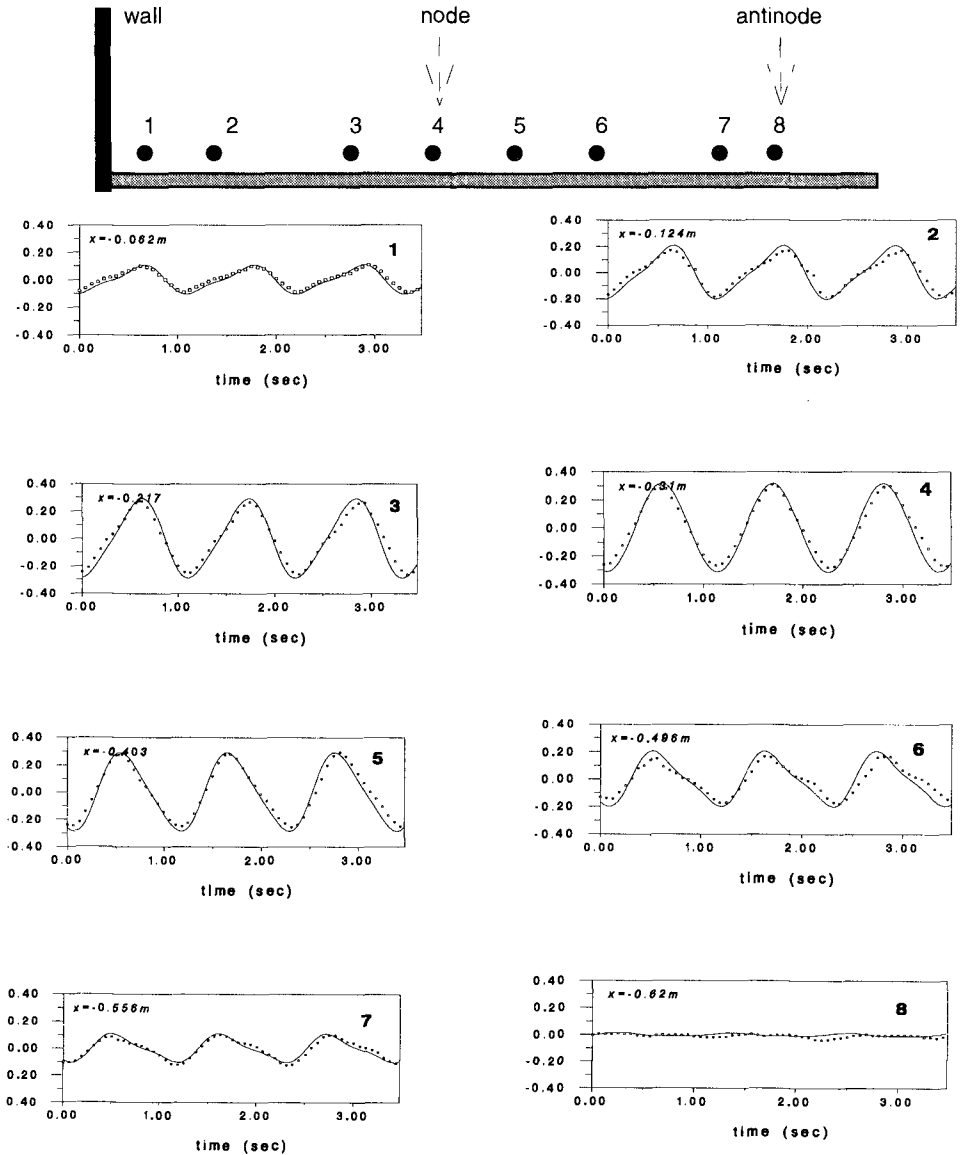

Figure 8: Time-history of horizontal velocity at 8 positions in front of the wall, 25mm above flat bed, $f=0.9\text{Hz}$, $H=50\text{mm}$. The node is at $x=-0.31\text{m}$ (posn.4) approximately; $x=-0.062\text{m}$ (posn.1) and $x=-0.558\text{m}$ (posn.7) correspond approximately to the shoreward and seaward limits of movement; $x=-0.62\text{m}$ (posn.8) corresponds to the offshore antinode. The solid line is the velocity predicted using Stokes 2nd order theory; the discrete symbols are the LDA measurements of the velocity.

A vortex grows in the lee of a ripple as the main flow velocity decreases from maximum velocity to zero velocity at flow reversal. Vortex growth on the antinodal side of a ripple occurs as the main flow acceleration is increasing from zero to maximum acceleration towards the node and vortex growth on the nodal side of a ripple occurs as the main flow acceleration is increasing from zero to maximum acceleration towards the antinode. Because the maximum acceleration towards the node is greater than the maximum acceleration towards the antinode, a larger vortex forms on the antinodal side of the ripple than on the nodal side. The larger vortex entrains more sand as it grows making it available for transport towards the node as the flow reverses.

Figure 9 presents PIV-measured vector plots of the flow over and around a ripple located at a position between 2 and 3 in Figure 8. Flow to the left is towards the wall/antinode; flow to the right is towards the node. Six vector plots are shown corresponding to 6 different phases of the wave. In Figure 9(a) the main flow has just started to decrease from maximum velocity towards the wall. The beginning of the vortex growth on the antinodal side of the ripple can be seen. Figure 9(b) shows the vortex well established as the flow reversal stage is approached while Figure 9(c) shows flow reversal with the vortex lifting off the bed. Figure 9(d) shows the situation before maximum velocity towards the node is reached while 9(e) and 9(f) show the vortex growth on the nodal side of the ripple with 9(f) corresponding to flow reversal.

Figure 9 clearly illustrates the asymmetry in vortex generation: a much larger vortex is formed on the antinodal side of the ripple than on the nodal side. As a result, when the bed is mobile, a larger volume of sand is entrained by the larger vortex on the antinodal side of the ripple than is entrained by the smaller vortex on the nodal side half a wave cycle later. The larger volume of sand is available for transport towards the node at flow reversal, while the smaller volume is available for transport towards the antinode. Therefore, the effect over a complete wave cycle is net transport of material towards the node.

The present description of the role played by the vortices in determining the net sand transport under standing waves echoes what has been observed by others for the case of nonlinear progressive waves (e.g. Sato and Horikawa (1986). Like the standing wave case, vortex growth is not the same on the two sides of a ripple in the case of non-linear progressive waves. However the reason for the asymmetry in vortex growth is not the same for progressive and standing waves: in the case of non-linear progressive waves the velocity function is skewed with the maximum shoreward velocity greater than the maximum seaward velocity. The result is larger vortex growth on the shoreward side of the ripple as the flow velocity decreases from maximum velocity shoreward to zero velocity at flow reversal. The net effect is greater sand transport seaward than shoreward.

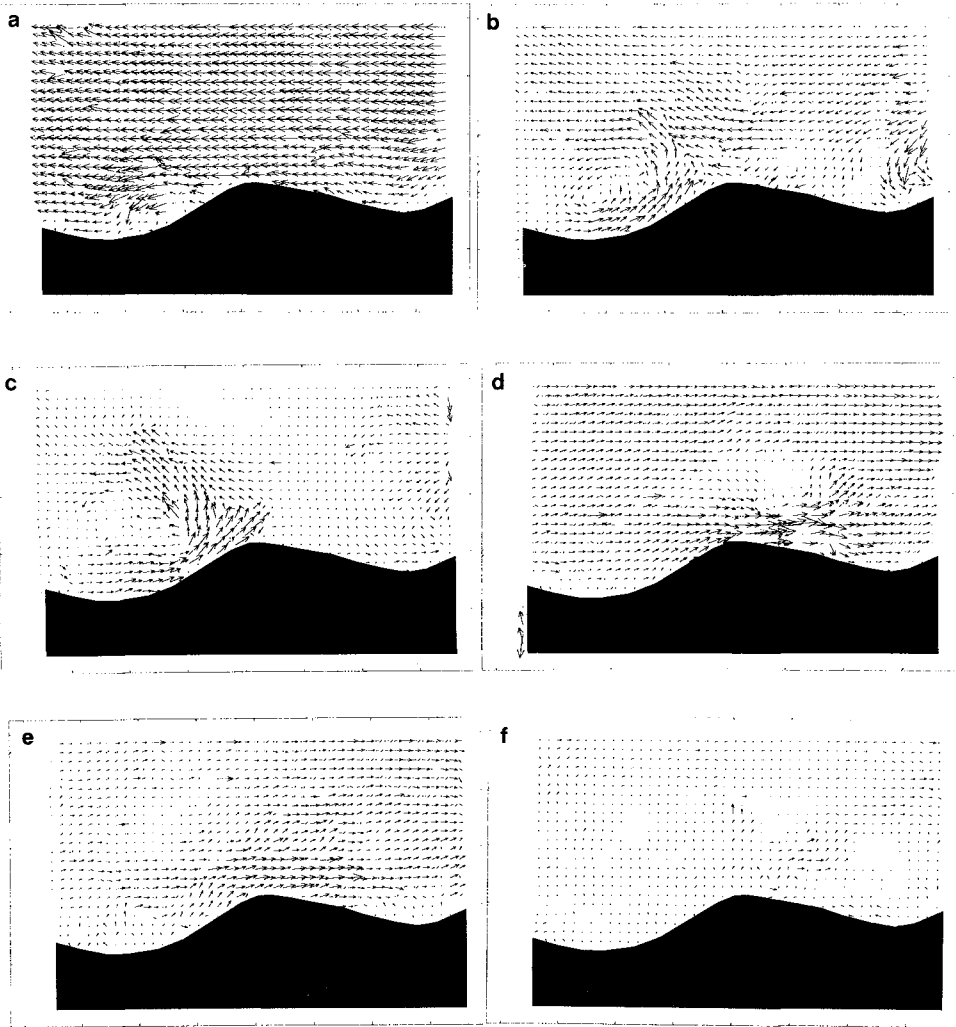

Figure 9: PIV-measured velocity fields corresponding to 6 phases of the wave, $f=0.9\text{Hz}$, $H=50\text{mm}$; the ripple shown is located between positions 2 and 3 in Figure 8.

Conclusions

Two main aspects of N-type beach response in front of wave-reflecting structures have been studied: (i) the characteristics of the equilibrium beach profile and (ii) the underlying mechanism causing sand transport towards the node.

The major features of the underlying larger bedforms of the equilibrium beach profile are well characterised by an equation which is fully defined for a given wave condition if the positions of the limits of movement and the amplitude factor a are known. The limits of movement can be estimated using an incipient motion condition although good agreement was not achieved in the present study between the predicted and measured shoreward limits. For the sand used in the study the amplitude factor a is approximately 1/25th of the equilibrium bed profile wavelength λ_b ; maximum scour depth is therefore approximately 1/30th of λ_b . Further work is needed at larger scale with different sand sizes to see if these results have general application.

The ripples superimposed on the larger bedforms play a crucial role in the sand transport process. Asymmetry in the main flow velocity time-history, resulting from the superposition of non-linear incident and reflected waves, causes larger vortex growth on the antinodal side of the ripple than on the nodal side. Because vortex growth occurs as the flow is slowing down and the vortex is at its largest and lifting off the bed at flow reversal, more sand is transported towards the node than towards the antinode with each wave cycle. PIV is a very effective way of studying the flow over and around the ripples.

CHAPTER 178

Fundamental Characteristics of Wave Transformation Around Artificial Reefs

Toshio Aono¹

Eric C. Cruz²

Abstract

The fundamental characteristics of the wave field around an existing artificial reef in Japan are studied based on field measurements and wave simulations using a nonlinear wave model that takes reef porosity into account. Results of two-dimensional simulations and comparison with field data of significant wave heights and reef velocities indicate characteristic wave evolution of nonbreaking and breaking waves and confirm the damping effect of the reef.

1. INTRODUCTION

Artificial reefs are a type of submerged breakwater. Unlike ordinary submerged breakwaters, however, they are usually designed with a permeable interior, a broad crown and steep face slopes. A permeable interior allows better water exchange with the sea when incident waves are small and yet induces wave energy dissipation through porous damping when the incident waves are high. A broad crown improves the damping effect of the reef over a wider frequency range while the steep face slopes are structural merits exploited when certain types of armor units are used to protect the reef when used as a breakwater. Hence, there are at least three important properties which must be considered when analyzing an actual artificial reef: (1) porosity (2) a wide depth regime, that is, shallow on the reef crown and deep on either side; and (3) steep face slopes.

A considerable number of artificial reefs have been constructed near the coasts in Japan, but there are no published reports on detailed field measurements around such structures. Part of this paper reports on a series of field measurements around Yugawara artificial reef which is one of such existing reefs in a Japanese coast. These measurements include the water surface profiles as well as reef velocities on

¹ Senior Research Engineer, Numerical Analysis Laboratory, Technical Research Institute, Toa Corporation, 1-3 Anzen-cho Tsurumi-ku Yokohama 230, Japan.

² Research Engineer, ditto

the reef crown.

Results obtained from a synthesis from these field measurements were used to verify the applicability of a mathematical model originally developed for wave transformation on porous beds. Mathematical models have been proposed in recent years to model the wave field around submerged structures. Inclusion of wave non-linearity in these models is important due to the small depth on the crowns of submerged structures. A second requisite is good dispersivity in order to reproduce frequency-dependent phenomena such as propagation in deep water, transformation and wave grouping of irregular waves and wave decomposition at the lee. For an artificial reef used as a submerged breakwater, the porous interior dissipates wave energy and hence porosity is an important property that affects the evolution of the wave.

This paper is part of a study which aims to analyze the effects of the existing Yugawara reef with a broadened crown on the surrounding coastal environment, particularly on the revetment which protects the adjacent coast. As an initial step, a simplified treatment of the wave field is chosen to serve as basis for launching a more detailed set of computations. The objective of the present paper is therefore to identify basic characteristics of the wave field based on field measurements and wave simulations with practical assumptions on reef composition and wave dimensionality.

2. FIELD MEASUREMENTS

General Description of Yugawara Artificial Reef

The layout of the existing reef is shown in **Fig. 1(a)** and the section through the center is shown in **Fig. 1(b)**. The reef was constructed to reduce the damage during high wave conditions to the vertical wave-absorbing revetment onshore which, in turn, protects the structures on the coast used for commercial fishing. The reef crown is 170m long and 70m wide. The crown width was increased from the previous 32m (shown dashed in **Fig. 1**) to make it more effective in dissipating the wave energy over a wider range of relative

Fig.1 Layout of Yugawara artificial reef and measuring devices. (a)plan view (b)cross section

water depths. The seaward slope is 1:3 while the shoreward slope is 1:2. The seaward slope and the seaward 32m of the crown are protected with 10-ton X-block armor units while the shoreward slope and the remaining portion of the crown are covered with 2-ton armor stones. The reef interior consists of 30 to 200kg medium-sized stones. The crown is submerged about 1.5m from mean water level and the depth to the seabed is around 8.5m at the crown center.

Field Measurements

Field measurements were conducted continuously for 2 months from February 1 to March 31, 1994. The measuring devices and their location are shown in Fig. 1. The water depths and surface elevations were measured by pressure-type gauges and velocity components at a fixed distance from the reef bed were measured directly using electro-magnetic current meters. Incident wave conditions were based on measurements at station 0 located 600 m from the revetment at a depth of 22 m. Six stations were disposed along the reef centerline with Stations 3, 4 and 5 on the shallow crown while Stations 7 and 8 were installed as shown to evaluate the effect of reef edge. The bed configuration and reef shape were determined from design drawings. However, field measurements of depths indicate that the bed slope has changed from its design value of 1:30 to 1:39 and the seaward slope from its design value of 1:3 to 1:3.16 due probably to slump of the reef and scouring at the toe. These measured slopes were applied to the bathymetry used in the computations .

Fig. 2 Time series of $H_{1/3}$, $T_{1/3}$, H_{max} , T_{max} and incident wave direction

Fig. 2 shows the observed time series of the significant wave height and period, maximum wave height and period and incident wave direction. The critical wave occurred on February 21 with a significant wave height of 2.90m and maximum

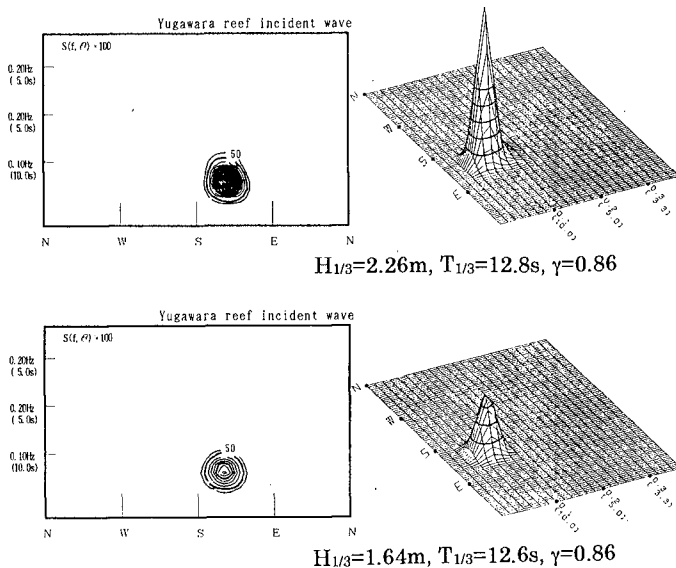

Fig.3 Directional spectrum (incident wave)

wave height of 5m. This wave was due to a low-pressure atmosphere. The significant wave period fluctuates but the highest value coincided with the significant wave height. This critical wave condition was used in the simulation. Incident wave direction was almost constant during the entire observation period. The wave direction was oriented almost normally to the reef. **Fig.3** shows the directional spectrum of incident wave. The method of calculation is EMEP by Hashimoto(1992). The shape of this directional spectrum is a single peak type and the long crestedness parameter is 0.86 so the directional spreading is relatively small. Observed directional spectrum data show an almost similar tendency.

Fig.4 shows the significant wave heights $H_{1/3}$ at stations along the center of the reef. We observed that it first increases on approaching the reef's seaward slope. Then it decreases abruptly due to breaking. Along the reef crown, the significant height continues to decrease due to the damping action of the porous interior. However, the rate of decrease is smaller than that due to

Fig.4 Distribution of $H_{1/3}$ along the center of reef

breaking. At the back of the reef, the wave height can still increase depending on the incident wave conditions.

3. MODEL EQUATIONS FORMULATION AND ANALYSIS

Model Equations

The basic depth-averaged nonlinear equations for horizontal one-dimensional wave transformation over porous beds have been derived using the perturbation method (Isobe et al., 1991; Cruz, et al., 1992). The leading order of nonlinearity has been included but nondispersive waves were vicariously assumed. The model can reproduce the generation of higher harmonics on the shallow crown but cannot predict the decomposition of waves beyond the structure. By reformulating the basic governing equations in the water and porous layers as a potential flow problem in terms of nondimensionalized variables, Cruz et al. (1996) obtained a set of Boussinesq equations for porous beds. These equations possess a second-order accurate linear dispersion relation and are applicable to weakly dispersive waves. By extending the linear dispersion relation to fourth-order accuracy through the addition of higher-order momentum terms, the Extended Boussinesq Equations for Porous Beds were obtained. For two-dimensional wave transformation, they are written as:

$$\eta_x + [(h + \eta)u]_x + (\varepsilon h_s u_s)_x = 0 \quad (1)$$

$$u_t + \frac{1}{2}(u_s^2)_x + g\eta_x - \varphi + F_\varepsilon + F_B = O(\delta\mu^2, \mu^4) \quad (2)$$

$$C_r \left[u_{st} + \frac{1}{2}(u_s^2)_x \right] + g\eta_x + \alpha u_s - \varphi_s = O(\delta\mu^2, \mu^4) \quad (3)$$

where η is the water surface displacement, u and u_s the depth-averaged velocities in the water and porous layers, ε the porosity, g the gravity acceleration, h and h_s the thickness of the water and porous layers, respectively, F_ε the boundary absorption term, F_B the wave breaking dissipation term, C_r the inertial coefficient, t the time and x the horizontal coordinate. Subscripts denote partial differentiation. α denotes the resistance coefficient of the porous medium:

$$\alpha \equiv \alpha_1 + \alpha_2 |u_s| = \frac{\nu\varepsilon}{K} + \frac{C_f \varepsilon^2}{\sqrt{K}} |u_s| \quad (4)$$

where ν is the kinematic viscosity, K the intrinsic permeability and C_f is the turbulent friction coefficient. φ and φ_s are the extended dispersion terms defined as

$$\varphi \equiv \left(\frac{1}{3} + \gamma \right) h^2 u_{xxt} + \left(\frac{1}{2} + \gamma \right) h h_x u_{xt} + \left(\frac{1}{2} + \gamma \right) h (h_x u_t)_x + \gamma g h (h \eta_x)_{xx} + \frac{1}{2} h (h_p u_{st})_{xx} \quad (5)$$

$$\begin{aligned} \varphi_s \equiv & \frac{1}{2} C_r \left[\frac{2}{3} h_s^2 u_{sxx} + h_s (h_{bx} u_{st})_x - h_s (h_x - h_{sx}) u_{sxt} - 2 h_x h_{bx} u_{st} \right] \\ & + \frac{1}{2} \alpha \left[\frac{2}{3} h_s^2 u_{sxx} + h_s (h_{bx} u_s)_x - h_s (h_x - h_{sx}) u_{sx} - 2 h_x h_{bx} u_s \right] + \frac{1}{2} (h^2 u_t)_{xx} \\ & + (1 + \beta) \left[h (h_p u_{st})_x \right]_x + \frac{\beta g}{C_r} \left[h (h_p \eta_x) \right]_x + \frac{\beta g}{C_r} \left[h (h_p u_s)_x \right]_x \end{aligned} \quad (6)$$

where $h_p \equiv \epsilon h_s$ is the effective porous thickness, $h_b \equiv h + h_s$ the bottom depth, and γ and β the celerity and damping extension factors. The right sides of **Eqs. (1) to (3)** indicate the truncation error in the dispersivity parameter $\mu \equiv h_o/l$ and nonlinearity parameter $\delta \equiv a/l$ where h_o , l and a are the characteristic depth, wavelength and amplitude, respectively.

Linear Analysis of Model Equations

A linear analysis of the model equations has been carried out by neglecting the dynamic volume flux term in Eq. (1), the convective terms in Eqs. (2) and (3) and the nonlinear resistance term α_2 in α . This leads to the following dispersion relation for porous beds:

$$\frac{\omega^2}{k^2 gh} \left[1 + \left(\frac{1}{3} + \gamma \right) k^2 h^2 \right] \left\{ \left(C_r + i \frac{\alpha}{\omega} \right) \left(1 + \frac{1}{3} k^2 h_s^2 \right) + k^2 h h_p \left(1 + \beta + i \frac{\beta \alpha}{\omega C_r} \right) \right\} = \left(1 + \gamma k^2 h^2 \right) + \frac{h_p}{M h} \left[1 + \left(\frac{1}{3} + \gamma \right) k^2 h^2 \right] \left[1 + \frac{\beta}{C_r} k^2 h h_p \right] \tag{7}$$

$$- \frac{k^2 h h_p}{2 M} \left[\left(1 + \frac{\beta}{C_r} k^2 h h_p \right) - \frac{\omega^2 h}{g} + \left(1 + \gamma k^2 h^2 \right) \right]$$

$$M = \left(C_r + i \frac{\alpha}{\omega} \right) \left(1 + \frac{1}{3} k^2 h_s^2 \right) + \lambda k^2 h h_s \left(1 + \beta + i \frac{\beta \alpha}{\omega C_r} \right) \tag{8}$$

For progressive waves of angular frequency ω , the complex wave number k consists of a real part k_r that governs the phase celerity and an imaginary part k_i which gives the spatial porous damping rate. The values of γ and β have been determined by comparing these wave properties with those of the theoretical dispersion relation for porous beds up to deep water. Eq. (7) reduces to the dispersion relation of Madsen et al. (1991) when $h_p=0$. **Fig. 5(a)** plots the normalized celerity r_1 as a function of frequency in terms of h/L_0 , where $L_0=2\pi g/\omega^2$, for various relative porous thickness h_s/h . **Fig.5(b)** shows the dependence of the normalized damping rate r_2 on frequency. Plots similar to **Fig. 1** were obtained for values up to $\epsilon=0.7$

Fig.5 Summarized curve of r_1 (a) and r_2 (b) of the extended model equations

which leads to the optimum values $\gamma=1/21$ and $\beta=1/15$ up to $h/L_0=0.50$, $h_s/h=10$, $\varepsilon=0.7$ and $R=1.0$. These upper limits of the wave and porous layer parameters already encompass their practical limits.

Wave Breaking Dissipation

Due to the steep seaward slope, wave breaking occur mostly as plunging breakers. At present however, there is no adequate model for plunging random breakers even for solid beds. In this simplified treatment, a surface roller approach (Deigaard, 1989; Schaffer et. al., 1992) ignoring the effects of the porous bottom is employed.

$$F_B = \frac{\partial \psi}{\partial x} = \frac{\partial}{\partial x} \left[\frac{\delta(h + \eta - \delta)}{(h + \eta)^2} (C - u)^2 \right] \tag{9}$$

Where, ψ is momentum flux correction, δ the roller thickness, C the wave celerity. In this model, breaking is determined based on the crest toe angle. The roller approach is adopted due to its ability to deal with temporally and spatially migrating breakers as obtained in an irregular wave field on a non-monotonic bathymetry.

Velocity Field

The fluid particle horizontal velocities can be obtained from the depth-averaged velocities by invoking their definitions in terms of the velocity potentials. The horizontal velocity U in the water layer is given by

$$U(z) = u - \frac{1}{2} \left[(z + h)^2 - \frac{h^2}{3} \right] u_{xx} - \frac{1}{2} (h + 2z) [(h_x u)_x + h_x u_x] - \frac{\varepsilon}{2} (h + 2z) (h_s u_s)_{xx} \tag{10}$$

and the velocity U_s in the porous layer by

$$U_s(z) = u_s + \frac{1}{2} \left\{ \left(\frac{h_s^2}{3} + h h_b - z^2 \right) u_{sxx} + [h_s - 2(z + h_b)] (h_b u_s)_{xx} \right\} \tag{11}$$

where z is taken positive upward from the still-water level. Eqs. (10) and (11) satisfy the following boundary condition at the interface $z = -h(x)$,

$$U_n = \varepsilon U_{s,n} \tag{12}$$

where n denotes the direction normal to the interface. The velocity potential, when truncated at the order consistent with Eqs. (2) and (3), therefore, prescribes a parabolic vertical distribution of horizontal velocities in both layers.

Fig.6 Finite difference module for solution of model equations.

4. NUMERICAL COMPUTATIONS

Eqs. (1) to (3) were discretized using the finite difference method on a staggered grid (Fig. 6). η is defined on the main grid, u and u_s on the secondary grid and the depths h, h_s on both grids. Eqs. (2) and (3) are first solved for u and u_s , and then Eq. (1) is used to solve for η in alternating time steps spaced at $\Delta t/2$.

Waves are introduced at the left end of the computation domain and the transmitted waves exit the open boundary at the right end. Because waves are reflected from the steep seaward slope of the reef, numerical wave absorbers were placed on both ends to absorb the outgoing wave components. The properties of the absorber, namely, its damping distribution, maximum damping coefficient and absorber width were determined from simulation aid graphs theoretically developed for regular and irregular wave fields (Cruz and Isobe, 1994). Computations were continued until the wave profile has become stable from one period to the next. Considering the presence of absorbers at both ends, this condition is achieved after the first crest has traveled a distance of about $5X_D$, where X_D is the total width of the computation domain.

Reef Material Distribution

The vertical section at the centerline of the reef, Fig. 1(b), was taken as the representative section for the preliminary one-dimensional calculation reported here. Due to the variability of materials in the reef armor and interior, reef porosity is not uniform. Fig. 7 shows the cross-section make-up of the present Yugawara Reef along its centerline. The previous 32-meter reef was formed with medium-sized rocks and covered with 10ton X-blocks. The added portion has an interior similar to the older one but was protected with different armors. To carry out wave simulations, however, it was necessary to use a uniform porosity in the model equations. Noting that the flow field near the seaward corner of the crown is critical, we used values of the material properties based on the X blocks and assumed that the entire reef is a homogeneous structure. For purposes of analysis, it was assumed to be uniform. In the simulation, The following parameters were used:

$$\begin{aligned} \epsilon &= 0.20, \quad \nu = 1.3 \times 10^{-6} \text{ m}^2/\text{s} (10^\circ \text{C}), \\ K &= 8 \times 10^{-7} \text{ m}^2, \quad C_f = 0.20 \end{aligned}$$

Zone	Material	Weight
A	X-Blocks	10tons
B	armor rocks	250kg
C	armor rocks	2tons
D	armor rocks	500~800kg
E	medium-size rocks	30~200kg

Fig.7 Reef material distribution of Yugawara artificial reef.

K and C_f were obtained by linearly extrapolating the data of Sollit and Cross (1972) for a mean block size of 1.0m.

Simulation of the Regular Wave Field (Non-breaking)

To examine the characteristic of the model, simulation is performed using regular waves. In order to utilize the field data, the incident wave has the properties of the significant wave, namely, $T_{in} = (T_{1/3})_{Sta.0}$ and $H_{in} = (H_{1/3})_{Sta.0}$. The spatial profiles of η at $T_{in}/8$ intervals beginning at $t=t_{rec}$ are shown in Fig. 8(a). The incident wave is linear at station 0 (Ursell No. $Ur=0.17$) and becomes

Fig. 8 Wave field (a) Simulated evolution of η (b) Comparison of calculated and measured

Fig. 9 Vertical field of U and U_s at $T_{in}/4$ intervals

nonlinear at the reef crown because of its shallowness. Higher harmonics are generated on the crown and the resultant wave propagates largely undeformed on the crown (ignoring the damping effect of the reef) because the higher harmonics and the primary wave travel at essentially at the shallow-water celerity. These bound harmonics are released behind the reef as free-waves that travel at their frequency-dependent celerities. Further leeward, the free waves interact with each other and the primary wave resulting in the nonpermanent profiles as seen in the figures.

Fig. 8(b) show the comparison of the simulated wave heights H and the significant wave heights $H_{1/3}$ of the field data. Prior to the crown, these wave heights agree very well. The underestimation of H at station 6 is partly due to the neglect of reflection from the revetment which has been confirmed in the field measurements (Ohnaka and Yoshizawa, 1994).

The spatial distribution of the velocities can be used to obtain the vertical field of fluid particle velocities U and U_s through Eqs. (10) and (11). **Fig. 9** show the velocity profile at the reef toe is that of linear wave. As the wave moves into the crown, the upper portion of the reef is engaged in redistributing the wave energy through the interface boundary conditions, for example, Eq. (11). The wave crest does not have to travel far into the crown because a relatively thick porous medium is available to dissipate a relatively small interface velocity.

Fig. 10 Simulated evolution of η

Simulation of Irregular Wave Field Non-Breaking Wave

Fig. 10 shows the results of the simulation of an irregular non-breaking

wave. The input frequency spectrum is Bretschneider-Mitsuyasu type with a period of 12.0 s and height of 0.35m. The time profile at Station 0 is generated using linear random wave theory consisting of 256 waves with random phases. Simulations are done for 138 significant periods and the last 128 periods

Fig. 11 Comparison of calculated and measured wave heights are used for synthesis.

In Fig. 10, the time profiles at Stations 0 to 6 for the last 60 periods is shown. In particular, the frequency components are reduced drastically by passage on the reef. At the back, the high-frequency portion is somewhat recovered. Fig. 11 shows the measured and simulated significant wave heights. Dominant shoaling effect at Station 1 is simulated well and the high wave on Station 3 is satisfactorily predicted. However, deviations are noticeable for the shoreward Stations.

Fig. 12 Simulated evolution of η (breaking wave)

Breaking Wave

Fig. 12 shows the time profiles for the simulation of the highest recorded significant wave at Station 0 with incident wave height of 2.90 m and period of 12.6 s. Compared to the nonbreaking case, high-frequency reduction of the incident profile

occurs earlier. This is attributed to the active damping by the porous layer when the velocity penetrates the reef interior. However, breaking between Stations 2 and 3 still causes the major reduction in wave energy. **Fig. 13** shows the significant wave heights. The high wave on the slope is still predicted well but there is considerable underestimation of wave energy beginning at Station 3. The trend of wave height is still predicted correctly.

Fig. 13 Comparison of calculated and measured wave height (breaking wave)

Simulation of the Velocity Field

The velocity field is obtained simultaneously in the solution of Eqs. (1) to (3). **Fig. 14** shows the time series of depth-averaged horizontal velocity in water layer at Stations 3 and 4 on the reef crown for the breaking wave case. Since the crown is shallow at these stations, the measured point velocity essentially represents the depth-averaged value. Segments of the velocity measured at the current meters located 70 cm above the crown are shown for comparison. Although a direct comparison of the ob-

Fig. 14 Time series of the calculated and measured velocity *u*.

served and simulated velocities is strictly not meaningful due to the different phase relationships in the incident wave, the profiles indicate the velocity magnitudes after breaking. The simulation based on a depth-averaged treatment of the momentum exchange in a breaker tends to overestimate the amount of energy dissipated on the crown primarily because the breaking point predicted by the model occurs seaward of the reef crown, resulting in a wider region within which energy is apparently decimated. A surface roller approach tends to be sensitive to reflection which leads to a preemptive prediction of breaking.

Fig.15 shows the root-mean-square depth-averaged velocities u_{rms} obtained by a second run in which the roller parameters were determined such that the breaking point occurs just before the reef crown. In this case, u_{rms} are closer to the measured values especially before the breaking point and the general trend is predicted well. However, the values are significantly underestimated beyond Station 3 due to various factors, the most important of which is the variable material makeup of the actual reef.

Fig. 15 Comparison of calculated and measured rms value of velocities.

5. CONCLUSIONS

The following summarizes the leading conclusions of this study:

- a. Measurements of the wave and current fields around the existing Yugawara Reef in Japan are reported. A synthesis of the significant wave parameters is discussed.
- b. A set of nonlinear wave equations with an extended range of dispersivity and porous damping rate is used to simulate the nonbreaking wave field along the reef centerline. Breaking waves are modelled using surface rollers.
- e. The wave field is generally characterized by a strong seaward reflection, decaying

wave heights on the crown and decomposing waves beyond the reef.

- d. There is a general agreement of wave energy distribution around the reef. However, deviations from measured values are observed. These are attributed to the simplifications in modelling the material composition of the reef, directional nature of the incident wave spectrum, the assumed two-dimensionality of the wave field and boundary influences such as external reflections.

CHAPTER 179

Performance of a Submerged Breakwater for Shore Protection

Albert E. Browder¹, A. Member, ASCE; Robert G. Dean², Member, ASCE;
and Renjie Chen³

Abstract

A summary is presented of the results from a 3-year monitoring study of a submerged breakwater placed alongshore for shore protection. The experimental breakwater project, located in Palm Beach, Florida, USA, was concluded in August, 1995. The monitoring program was instituted to determine changes in wave climate and bathymetry, and to assess the shoreline response relative to pre-project conditions. The Palm Beach breakwater consisted of 330 interlocking concrete units, each 1.8 meters in height, 3.7 m long, and 4.6 m wide, which formed a 1,260 m-long shore parallel barrier. The breakwater, termed the Prefabricated Erosion Prevention (P.E.P.) Reef was placed in approximately 3 m of water roughly 73 m from the shoreline. The project was intended to increase shore protection against storm waves and to create a wider beach in the lee of the Reef. Wave transmission measurements indicated a 5 to 15% reduction in incident wave heights due to the Reef. The results of the monitoring program at the end of two years indicated erosion throughout the project area, primarily in the lee of the Reef, where the annual volumetric erosion rate was measured to be 2.3 times higher than the pre-project rate. The submerged breakwater is interpreted to have increased the longshore currents via ponding of water trapped behind the breakwater, which was then diverted alongshore. Laboratory experiments were conducted to investigate this ponding phenomenon and to test the performance of various segmented and repositioned breakwater arrangements. Shoreline erosion in the lee of the Reef was sufficiently severe to warrant removal of the structure in August, 1995.

Introduction

The Town of Palm Beach lies on the southeast coast of Florida, U.S.A. The project site is 7.2 km south of the Port of Palm Beach Entrance (see Figure 1). This tidal entrance was created artificially in 1918, followed by the construction of jetties on either side of the inlet in 1925. The excavation of the inlet resulted in the rapid recession of the shoreline to the south along Palm Beach Island. The erosion problems experienced alongshore prompted the Town of Palm Beach to take action in three ways:

- ◆ The construction of seawalls alongshore,
- ◆ The use of beach nourishment, beginning in 1944,
- ◆ The construction and operation of a sand bypassing plant at the Port entrance, which was built in 1958. The plant operated until 1990, when it was damaged by storms. The plant re-opened in 1996.

The latter two actions resulted in the placement of over 5.86 million m³ of sand along the shoreline south of the Port entrance between 1944 and 1990. As a result, the average shoreline position in 1990, from the Port entrance southward 11 km, lies some 18 m seaward of its 1944 location, despite a persistent background erosion rate attributed mainly to the Port Entrance. This background erosion rate was estimated to be about 9.3 m³/m/yr by the U.S. Army Corps of Engineers (1987).

Figure 1 Location of P.E.P. Reef Site in the Town of Palm Beach, FL. The site lies approximately 7.2 km south of the Port of Palm Beach Entrance.

In an effort to provide a long-term "hard" solution to the erosion problem, the Town of Palm Beach investigated the use of a narrow-crested submerged nearshore breakwater, which was intended to increase shore protection against storm waves and to create a wider beach in the lee of the Reef.

The project involved the installation of 330 pre-cast concrete P.E.P. Reef units, each of which weighed 23 metric tons. The units were 1.8 m in height, 4.6 m in cross-shore width, and 3.7 m in length alongshore. When assembled the units extended 1,260 m alongshore. The units were placed in approximately 3 m water depth, about 73 m from the existing seawall along the heavily armored shoreline (see Figure 2).

Construction of the project began in July, 1992, with the placement of 57 units. Hurricane Andrew passed through southeast Florida in August, 1992, after which significant settling of the placed units was observed. The settlement of the units suspended construction of the project until the following summer. The remaining 273 units were placed between May and August, 1993. All 330 units were placed directly on the sandy bottom with no underlayment or foundation bedding.

To gauge the performance of the installation against its pre-project expectations, a monitoring program was conducted by the University of Florida Coastal and Oceanographic Engineering Department beginning in August, 1993. The program included quarterly topographic and hydrographic surveys of the site, wave transmission and unit settlement measurements, and an analysis of the background erosion processes and rates.

Figure 2 Schematic profile illustrating the relative location of the P.E.P. Reef structure to the shoreline.

Wave Transmission

To measure the effects of the Reef on the incident wave climate, two bottom mounted pressure-velocity gages were installed approximately 25 m on either side of the Reef just south of the centerline of the structure. The offshore and inshore gages were deployed in 4 and 2 m water depths, respectively. These gages collected data on an hourly basis, taking average pressure and bi-directional current measurements. Wave measurements were collected beginning in October, 1993, and continuing to the end of the monitoring period in June, 1995. Transmission coefficients were computed from each hourly measurement by calculating the ratio of the measured nearshore wave height to the wave height measured offshore, after shoaling the offshore wave height to the depth of the nearshore gage via linear wave theory. Figure 3 illustrates a schematic of the wave measurement arrangement and the summarized results.

Results from the initial wave measurements indicated a wave height reduction of as much as 15 to 25% (Dean and Chen, 1995). The range in wave height attenuation reflects the variable water levels and wave heights in the project area. The structure would have a greater effect (i.e., more wave height reduction) on larger waves and/or at lower water levels. The wave measurements indicated wave height reductions somewhat greater than anticipated by published literature (e.g., 0 to 10%, Ahrens, 1987). Additional wave measurements were taken at similar cross-shore locations south of the Reef structure. Analysis of the resulting data indicated a partial reduction in wave height due to natural effects such as wave breaking and bottom friction of approximately 10% (Browder, 1994). Thus, for an overall wave height reduction of 15 to 25%, the reduction due to the Reef was estimated to be 5 to 15%.

Figure 3 Schematic illustrating the cross-shore location of the wave gages and the P.E.P. Reef. The Reef was found to reduce incident wave heights by 5 to 15%, with another 10% reduction attributed to natural causes.

Littoral Performance

The littoral performance of the P.E.P. Reef project was measured via extensive hydrographic surveys, conducted on a quarterly basis during the project. The performance of the project was gaged against the historical shoreline behavior in the area. Ten surveys were conducted during the monitoring program, beginning in July, 1992, with the pre-construction survey. Each survey included 75 profile lines based from the Florida Department of Environmental Protection (FDEP) "R" monuments, which are spaced approximately 300 m apart alongshore. Additional profiles were surveyed between R-monuments at spacings of between 23 and 122 m.

The beach profiles were surveyed using standard land surveying techniques (swimming surveys with a rod and level) and boat/fathometer surveys. The swimming portion of the surveys extended at least 15 m seaward of the Reef to provide adequate overlap with the boat surveys. Each profile extended at least 365 m offshore. On annual surveys, the profiles were surveyed out to 1,070 m offshore. Profiles surveyed from R-monuments extended offshore 1,980 m. The hydrographic surveys were conducted on the following dates: July, 1992; April, August, and December, 1993; March, July, November, and December, 1994; and March and June, 1995. The November and December, 1994, surveys represent pre- and post-storm surveys of the area due to the passage of Tropical Storm Gordon.

Figure 4 shows the change in location of the Mean High Water Line (MHWL, approximately +0.6 m above the National Geodetic Vertical Datum, NGVD, which is approximately Mean Sea Level of 1929) measured alongshore over the course of the monitoring period. In the figure, the MHW shorelines are plotted relative to the July, 1992, *pre-project* shoreline location. It is important to note that in many places alongshore, the pre-project MHWL as well as the various surveyed project MHW shorelines fall on the seawall, thus limiting the landward recession of the shoreline in these areas.

Figure 4 indicates that during the first 13-month monitoring period, the shoreline south of R-98, in the vicinity of the original 57 units, advanced seaward an average of over 11 m. Along the remaining project shoreline north of R-98, recession of 2.8 m on average was measured, with some areas experiencing over 10 m of recession at the MHWL. Once again the presence of the seawall limited recession at many locations.

Following complete installation of all 330 units in August, 1993, the shoreline in the lee of the reef began to recede landward toward the seawall, as indicated by the July, 1994, surveyed MHWL. This recession continued through the end of the monitoring program, at which time (June, 1995) the shoreline along the majority of the 1,260-m project length had retreated to the seawall (with the exception of the shoreline at R-96 (Clarke Avenue), where there is no seawall; whereat the shoreline receded almost 23 m over 35 months).

Figure 4 Location of the Mean High Water Line (MHWL) relative to the July, 1992, *pre-project* shoreline. The figure indicates the recession of the shoreline along the southern portion of the project, while the central and northern portions remain mostly unchanged. This is due to the presence of the seawall alongshore. Most of the central and northern MHWL was located at the seawall prior to the project, and no seaward advancement of the MHWL occurred at these locations.

Figure 5 illustrates the changes in one beach profile measured over the 35-month period between July, 1992, and June, 1995, at monument R-98J, approximately 23 m north of monument R-99, at the southern end of the Reef. Inspection of the three profiles plotted in the figure indicates that between July, 1992, and August, 1993, the shoreline had advanced seaward roughly 15 m (measured at Mean High Water). This time period spans the time in which the first 57 Reef units were already in place and the remaining 273 units were installed.

Between August, 1993, and June, 1995, however, the profile at R-98J retreated landward of the pre-project, July, 1992, position, to the seawall. The profile lowered over 2 m in front of the seawall in the 22-month period following completion of the entire Reef structure. Over the entire area in the lee of the 1,260-m long structure, i.e., between the Reef and the seawall, the seabed lowered an average of 0.7 m between August, 1993, and June, 1995.

Figure 5 Profile changes measured at monument R-98J, near the southern terminus of the Reef. The plot indicates an initial seaward advance of the upper beach, followed by extreme erosion over the last 22 months of the monitoring program.

On a volumetric basis, analysis of the survey data indicates a net erosional signal in the area surrounding the installation. Figure 6 presents the measured volumetric changes in six zones surrounding the P.E.P. Reef installation. During the first year following complete installation (August, 1993, to August, 1994), the area in the lee of the Reef lost $28,600 \text{ m}^3$ of material while the area immediately to the south gained $13,500 \text{ m}^3$ (Dean & Chen, 1995). It is noted that of the $28,600 \text{ m}^3$ of erosion measured in the lee of the Reef, the majority (over 80%) of the erosion occurred in the first four months following complete installation of the Reef. Figure 6 indicates that in the remaining 4 zones, very little volumetric change occurred during this 12-month period.

Over the last year of monitoring, from July, 1994 to June, 1995, the area in the lee of the Reef continued to erode at roughly the same rate, losing $36,500 \text{ m}^3$ while the area immediately to the south lost $40,500 \text{ m}^3$ of material. Volumetric changes to the north of the project and offshore of the Reef again were relatively small (Figure 7).

Overall, during the full 35-month monitoring period, the area between the Reef and the seawall lost some $81,700 \text{ m}^3$ of sand (Figure 8). This loss translates to an average lowering of the seabed of 0.9 meters. Cumulative measurements of scour in the vicinity of the Reef's northern end indicate that the seabed immediately adjacent to the Reef had lowered between 0.5 and 1.05 m during the monitoring study.

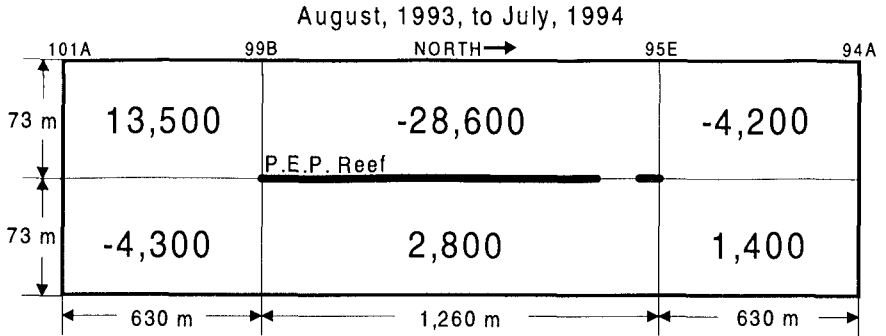

Figure 6 Volumetric changes (m^3) measured in six zones surrounding the P.E.P. Reef Installation between August, 1993, and August, 1994.

Figure 7 Volumetric changes (m^3) measured in six zones surrounding the P.E.P. Reef Installation between July, 1994, and June, 1995.

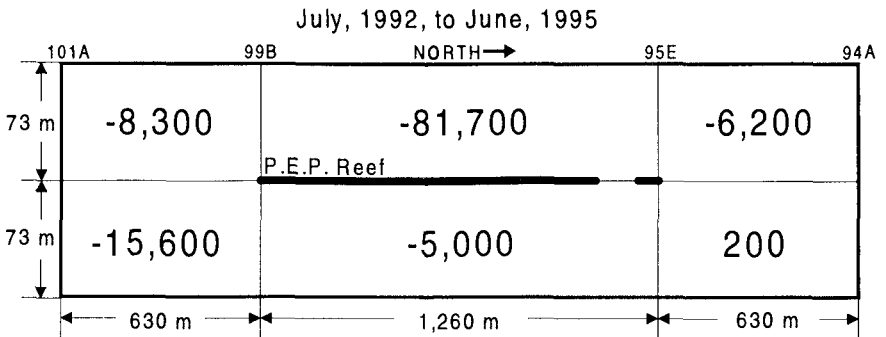

Figure 8 Volumetric changes (m^3) measured in six zones surrounding the P.E.P. Reef Installation between July, 1992, and June, 1995.

While the area to the south of the Reef had indicated accretion during the first two years of the study, erosion in the last year (40,500 m³, Figure 7) resulted in a net erosional signal south of the Reef over the 35-month monitoring period. Referring back to Figure 4, by June, 1995, only the southernmost 500 meters of the shoreline (some 300 meters south of the southern terminus of the Reef) were significantly seaward of the July, 1992, pre-project shoreline at the end of the study. Over the entire monitored area, 116,600 m³ of sand eroded during the 35-month period.

Pre-project data indicate that the project area is sediment-starved, due at least in part to the presence of the Port of Palm Beach Entrance. To compare the erosion rates measured during the monitoring program to the background erosion rates, two separate comparisons are investigated. Inspection of Figure 8 reveals that over 35 months, the erosion rate immediately in the lee of the Reef was 5.6 times higher than the rate along a combined equivalent shoreline distance north and south of the Reef. During the 23 months that the entire 330 Reef units were in place, the erosion rate was 2.5 times higher in the lee of the Reef than the adjacent shorelines (Figures 6 & 7). By reference to approximately 50 years of historical shoreline data, the overall erosion rate during the project was found to be 2.3 times higher than the pre-project rate estimated by the U.S. Army Corps of Engineers (1987)⁴.

The degree of erosion immediately landward of the Reef as compared to the areas to the north and south suggests the following mechanism for the overall erosion patterns. The monitoring data suggest that waves 'pump' water over the Reef, creating a ponding situation in which the ponded water is prevented from returning offshore in the normal return flow fashion and is instead redirected alongshore. This augments the natural longshore current and increases sediment transport in the lee of the Reef (Figure 9). With very little sediment supplying the area in pre-project conditions, the addition of the Reef (which did not introduce additional sand) caused a 'pumping out' of sediment from behind the Reef. This sediment was transported predominantly south to the adjacent shoreline, where it was temporarily deposited until the natural littoral transport carried it farther southward, resulting in an overall erosive condition.

Unit Settlement

In addition to the beach profiles, measurements of the top elevations of each unit were conducted during each quarterly survey to document the vertical settlement of the 330 units. The units were placed directly on the sandy bottom, with no foundation bedding or underlayment. The analysis of the settlement is divided into the average settlement of the original 57 units, which were in place a total of 35 months, and the remaining 273 units, which were in place 23 months.

4

USACE (1987) estimates the erosion rate to be 9.3 m³/yr/m alongshore. Along the 1,260 m shoreline in the lee of the Reef, this translates to 11,720 m³/yr of erosion.

Figure 9 Schematic of Currents Generated Leeward of a Submerged Breakwater

Figure 10 illustrates the settlement of the units over time, relative to their estimated design depth. The original 57 units settled an average of 0.84 m, over 46% of the height of the Reef units (1.8 m). The remaining units settled an average of 0.60 m, 33% of the structure’s height. While it is unclear exactly how much the passage of Hurricane Andrew in August, 1992, affected the first 57 units, Figure 10 suggests that the hurricane may have contributed significantly to the settlement of these units.

The settlement of the units reduced the degree to which the units block the water column, which directly relates to the level of protection from wave attack afforded by the structure. At the same time, however, the lower structures may have prevented additional erosion caused by diverting more return flow water alongshore. Inspection of the bathymetric surveys and scour rod measurements conducted adjacent to the Reef suggests that the settlement was due primarily to the overall lowering of the sea floor in the vicinity of the Reef, rather than locally, structure-induced scour.

Figure 10 Average settlement of the first 57 units and the later 273 units.

Laboratory Findings

Laboratory experiments were conducted in conjunction with the monitoring program to investigate the ponding and associated phenomenon and to test the performance of various segmented and repositioned breakwater arrangements. Previous laboratory tests with two-dimensional tanks could not reveal the longshore current generation. Using the 3-d wave basin at the University of Florida Coastal and Oceanographic Engineering Laboratory, 1:16 scale models of the P.E.P. Reef units were tested on a fixed bed.

Laboratory measurements in this study included wave transmission and current velocities. Wave height measurements yielded transmission coefficients of approximately 95% for conditions simulating the Palm Beach P.E.P. Reef (i.e., continuous Reef structure with less than 50% of the vertical water column blocked by the Reef).

The lab tests, for all arrangements of the units, were able to reproduce the “pumping current” hypothesized from the littoral performance of the structure in the field (see Figure 9). Figure 11 illustrates the trajectories of bottom drogues documented in the laboratory report (Dean et al., 1994). Figure 11 indicates that for normally incident waves, in which there is no predominant wave or tidal generated longshore current, the presence of the submerged breakwater generates a longshore current that originates from the centerline of the structure in the lee of the Reef and flows toward the open ends, where the current is reduced through expansion.

While this longshore current was never directly measured in the field, the patterns of erosion measured in the lee of the Reef, relative to the volumetric changes along the adjacent shorelines, suggests that this “ponding and pumping” mechanism does in fact exist. It is believed that the pumping current existed as a secondary current to the longshore current, and was sufficient to increase the sediment transport rates along the seabed in the lee of the Reef, resulting in the substantial erosion measured between the Reef and the shoreline.

Figure 11 Typical circulation patterns witnessed in laboratory study using neutrally buoyant drogues. The patterns indicate that the Reef generates longshore currents in its lee that flow toward the ends of the Reef.

Summary

The results from a 3-year monitoring study of the Palm Beach, FL, Prefabricated Erosion Prevention Reef (P.E.P Reef), indicate that the reef modified both the incident wave climate and the nearshore current patterns. As defined by the State of Florida Department of Environmental Protection (FDEP), the project was intended to increase shore protection against storm waves and to create a wider beach in the lee of the Reef. Wave transmission measurements indicated a 5 to 15% reduction in incident wave heights due to the Reef. The results of the monitoring program at the end of two years indicated erosion throughout the project area, primarily in the lee of the Reef, where the annual volumetric erosion rate was measured to be 2.3 times higher than the pre-project rate. The submerged breakwater was found to have increased the longshore currents via ponding of water trapped behind the breakwater, which was then diverted alongshore. Laboratory experiments were conducted to investigate this ponding phenomenon and to test the performance of various segmented and repositioned breakwater arrangements.

Shoreline erosion in the lee of the Reef was sufficiently severe to warrant removal of the structure in August, 1995. Immediately following the dismantling of the submerged breakwater, a large-scale beach nourishment project was constructed on the site. This project utilized some of the P.E.P. Reef units as the core material for shore-perpendicular groins within the beach-fill. The remaining units were moved into deeper water offshore to create artificial reef habitat

Acknowledgements

The authors would like to express their appreciation to FDEP and the Town of Palm Beach for supporting the project. Sea Systems, Inc., of Pompano Beach, FL, conducted the surveys in a professional and timely manner.

CHAPTER 180

Nonlinear Wave Transformation over a Submerged Triangular Breakwater

Lifen Dong¹ Akira Watanabe and Masahiko Isobe²

Abstract

This study deals with wave transformation over a submerged triangular breakwater that is composed of a series of elements with a triangular horizontal cross-section. The idea of such a triangular breakwater is founded on the use of the wave refraction due to peculiar spatial change in water depth around it.

A numerical model is developed to predict nonlinear wave transformation over and around the breakwater on the basis of fully nonlinear wave equations proposed by Isobe (1994). Laboratory experiment has also been conducted in a wave basin. The validity of the numerical model is examined by comparing the computations with the measurements.

1. Introduction

When waves propagate over a submerged triangular breakwater, wave refraction will happen. The superiority of a submerged triangular breakwater lies in its capability of controlling the wave direction as well as the height as compared to conventional submerged breakwaters with rectangular cross-section. For example, a breakwater as shown in Fig. 1 (a) can control even the longshore current through the change in the wave direction, whereas the one as illustrated in Fig. 1 (b) may be employed to increase the wave height in the locations where the waves converge for purposes such as effective wave energy use and surfing.

This paper presents the results of numerical computation based on fully nonlinear mild-slope equations proposed by Isobe and compares them with those of a laboratory experiment for breakwaters of the type (b).

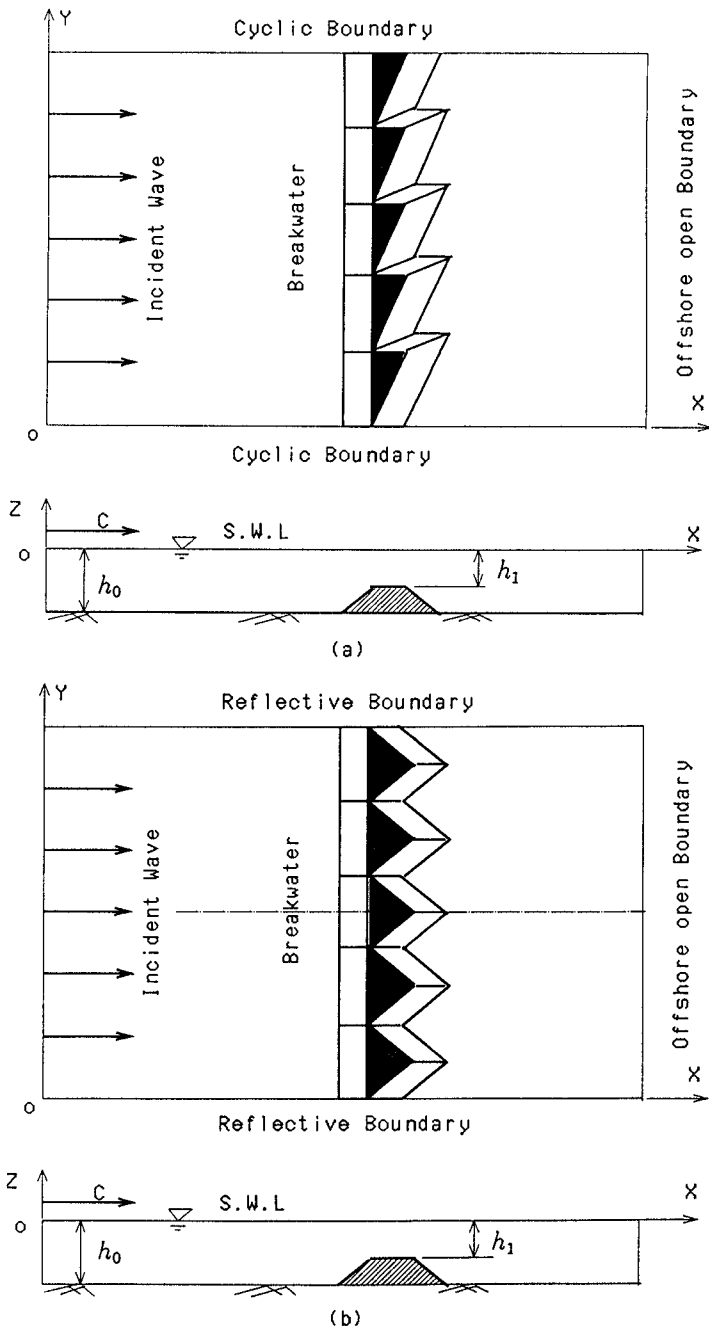

Fig. 1 Two types of submerged triangular breakwaters.

2. Numerical Model

2.1 Governing equations

The mild-slope nonlinear equations proposed by Isobe (1994) are as follows:

$$Z_\alpha^\eta \frac{\partial \eta}{\partial t} + \nabla(A_{\alpha\beta} \nabla f_\beta) - B_{\alpha\beta} f_\beta + (C_{\beta\alpha} - C_{\alpha\beta}) \nabla f_\beta \nabla h + \frac{\partial Z_\beta^\eta}{\partial h} Z_\alpha^\eta f_\beta \nabla \eta \nabla h = 0 \quad (1)$$

$$g\eta + Z_\beta^\eta \frac{\partial f_\beta}{\partial t} + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \nabla f_\gamma \nabla f_\beta + \frac{1}{2} \frac{\partial Z_\gamma^\eta}{\partial z} \frac{\partial Z_\beta^\eta}{\partial z} f_\gamma f_\beta + \frac{\partial Z_\gamma^\eta}{\partial h} Z_\beta^\eta f_\gamma \nabla f_\beta \nabla h = 0 \quad (2)$$

where $Z_\alpha^\eta = Z_\alpha|_{z=\eta}$, h is the water depth, and the water surface elevation η and the function f_α are unknown variables. The vertical distribution function Z_α is related to the velocity potential ϕ and defined as

$$\phi(x, y, z, t) = \sum_{\alpha=0}^N Z_\alpha(z, h(x, y)) f_\alpha(x, y, t) \quad (3)$$

$$Z_\alpha(z, h(x, y)) = \left(1 + \frac{z}{h}\right)^{2\alpha} \quad (4)$$

The coefficients $A_{\alpha\beta}$, $B_{\alpha\beta}$ and $C_{\alpha\beta}$ can be obtained from Z_α by

$$A_{\alpha\beta} = \int_{-h}^{\eta} Z_\alpha Z_\beta dz \quad (5)$$

$$B_{\alpha\beta} = \int_{-h}^{\eta} \frac{\partial Z_\alpha}{\partial z} \frac{\partial Z_\beta}{\partial z} dz \quad (6)$$

$$C_{\alpha\beta} = \int_{-h}^{\eta} \frac{\partial Z_\alpha}{\partial h} Z_\beta dz \quad (7)$$

2.2 Boundary conditions

For the present case, the following perfectly reflective boundary condition is imposed on the side boundaries by virtue of the symmetry of the structure and the resulting wave field.

$$\frac{\partial \phi}{\partial y} = 0 \quad (8)$$

By substituting the expression of ϕ into Eq. (8), the following two expressions are obtained as side boundary conditions.

$$\frac{\partial \eta}{\partial y} = 0, \quad \frac{\partial f_\alpha}{\partial y} = 0 \quad (9)$$

The Sommerfeld radiation condition is used on the onshore open boundary.

$$\frac{\partial \phi}{\partial t} + C \frac{\partial \phi}{\partial \bar{n}} = 0 \quad (10)$$

The substitution of ϕ yields the onshore boundary conditions as follows:

$$\frac{\partial \eta}{\partial t} + C \frac{\partial \eta}{\partial \bar{n}} = 0, \quad \frac{\partial f_\alpha}{\partial t} + C \frac{\partial f_\alpha}{\partial \bar{n}} = 0, \tag{11}$$

in which \bar{n} is the length of the mean direction vector of transmitted waves and C denotes the wave celerity.

The offshore boundary condition is given by

$$\cos \bar{\alpha}_r \frac{\partial \phi}{\partial t} - C \frac{\partial \phi}{\partial x} = (1 + \cos \bar{\alpha}_r) \frac{\partial \phi_0}{\partial t} \tag{12}$$

where ϕ_0 , the potential of the incident waves, is expressed as

$$\phi_0 = \sum_{\alpha=0}^N Z_\alpha f_{\alpha 0} = Z_\alpha f_{\alpha 0} \tag{13}$$

Substituting of the expressions of ϕ and ϕ_0 into Eq. (12), we obtain

$$\cos \bar{\alpha}_r \frac{\partial \eta}{\partial t} - C \frac{\partial \eta}{\partial x} = (1 + \cos \bar{\alpha}_r) \frac{\partial \eta_0}{\partial t} \tag{14}$$

$$\cos \bar{\alpha}_r \frac{\partial f_\alpha}{\partial t} - C \frac{\partial f_\alpha}{\partial x} = (1 + \cos \bar{\alpha}_r) \frac{\partial f_{\alpha 0}}{\partial t} \tag{15}$$

where η_0 is the water surface elevation of the incident waves and $\bar{\alpha}_r$ is the mean direction of reflected waves.

2.3 Expression of incident waves

Even in the computation of nonlinear wave transformation, the incident waves will be reasonably expressed by a small amplitude wave theory if the Ursell number is not so large at the offshore boundary. Assuming that the incident waves are monochromatic sinusoidal waves propagating along the x -direction, their potential ϕ_0 can be expressed as

$$\phi_0 = \frac{a_0 g}{\sigma} \frac{\cosh k_0(z + h_0)}{\cosh k_0 h_0} \sin(k_0 x - \sigma t) \tag{16}$$

$$= \sum_{\alpha=0}^N Z_\alpha f_{\alpha 0} \tag{17}$$

which corresponds to the water surface displacement η_0 given by

$$\eta_0 = a_0 \cos(k_0 x - \sigma t) \tag{18}$$

where a_0 and k_0 are the amplitude and the wave number of the incident waves, h_0 is the offshore water depth, and σ is the angular frequency.

By expanding $\cosh k_0(z + h_0)$, ϕ_0 can be expressed as

$$\phi_0 = \sum_{\alpha=0}^N \frac{a_0 g}{\sigma} \frac{(k_0 h_0)^{2\alpha}}{(2\alpha)! \cosh k_0 h_0} \sin(k_0 x - \sigma t) \left(1 + \frac{z}{h_0}\right)^{2\alpha} \quad (19)$$

From this equation we obtain

$$f_{\alpha 0} = \frac{a_0 g}{\sigma} \frac{(k_0 h_0)^{2\alpha}}{(2\alpha)! \cosh k_0 h_0} \sin(k_0 x - \sigma t) \quad (20)$$

2.4 Finite difference equations

Numerical solutions of the governing equations are obtained using a finite difference technique. Central difference and forward difference are adopted in space and in time, respectively. To the nonlinear equations into a finite difference form for the present two-dimensional problem, ADI (Alternating Direction Implicit) scheme (Fletcher, 1987) is employed, namely, Eqs. (4.1) and (4.2) are splitted into x -sweep and y -sweep finite difference equations.

x -sweep

During the first half-step the following discretization is made.

$$\begin{aligned} & Z_\alpha^\eta \frac{\eta_{i,j}^{m+\frac{1}{2}} - \eta_{i,j}^m}{\Delta t/2} + A_{\alpha\beta i,j} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} + f_{\beta(i-1),j}^{m+\frac{1}{2}} - 2f_{\beta i,j}^{m+\frac{1}{2}}}{\Delta x^2} \\ & + A_{\alpha\beta i,j} \frac{f_{\beta i,j+1}^m + f_{\beta i,j-1}^m - 2f_{\beta i,j}^m}{\Delta y^2} - B_{\alpha\beta} f_{\beta i,j}^{m+\frac{1}{2}} \\ & + \frac{A_{\alpha\beta(i+1),j} - A_{\alpha\beta(i-1),j}}{2\Delta x} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \\ & + \frac{A_{\alpha\beta i,j+1} - A_{\alpha\beta i,j-1}}{2\Delta y} \frac{f_{\beta i,j+1}^m - f_{\beta i,j-1}^m}{2\Delta y} \\ & + (C_{\beta\alpha} - C_{\alpha\beta}) \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} \\ & + (C_{\beta\alpha} - C_{\alpha\beta}) \frac{f_{\beta i,j+1}^m - f_{\beta i,j-1}^m}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \\ & + \frac{\partial Z_\beta^\eta}{\partial h} Z_\alpha^\eta f_{\beta i,j}^{m+\frac{1}{2}} \left(\frac{\eta_{i+1,j}^m - \eta_{i-1,j}^m}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} + \frac{\eta_{i,j+1}^m - \eta_{i,j-1}^m}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \right) \\ & = 0 \end{aligned} \quad (21)$$

$$\begin{aligned} & g\eta_{i,j}^{m+\frac{1}{2}} + Z_\beta^\eta \frac{f_{\beta i,j}^{m+\frac{1}{2}} - f_{\beta i,j}^m}{\Delta t/2} + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \left(\frac{f_{\gamma(i+1),j}^m - f_{\gamma(i-1),j}^m}{2\Delta x} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \right) \\ & + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \left(\frac{f_{\gamma i,j+1}^m - f_{\gamma i,j-1}^m}{2\Delta y} \frac{f_{\beta i,j+1}^{m+\frac{1}{2}} - f_{\beta i,j-1}^{m+\frac{1}{2}}}{2\Delta y} \right) + \frac{1}{2} \frac{\partial Z_\gamma^\eta}{\partial z} \frac{\partial Z_\beta^\eta}{\partial z} f_{\gamma i,j}^m f_{\beta i,j}^{m+\frac{1}{2}} \end{aligned}$$

$$\begin{aligned}
 & + \left(\frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} + \frac{f_{\beta i,j+1}^m - f_{\beta i,j-1}^m}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \right) \\
 & \frac{\partial Z_\gamma^\eta}{\partial h} f_{\gamma i,j}^m Z_\beta^\eta \\
 & = 0
 \end{aligned} \tag{22}$$

in which, Δx and Δy are the space intervals and Δt is the time interval. The quantities $\eta_{i,j}^{m+\frac{1}{2}}$ and $f_{\beta i,j}^{m+\frac{1}{2}}$ are the unknowns, whereas $\eta_{i,j}^m$, $f_{\beta i,j}^m$ and other parameters are given in the previous time step m .

y-sweep

During the second half-step the following discretization is made.

$$\begin{aligned}
 & Z_\alpha^\eta \frac{\eta_{i,j}^{m+1} - \eta_{i,j}^{m+\frac{1}{2}}}{\Delta t/2} + A_{\alpha\beta i,j} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} + f_{\beta(i-1),j}^{m+\frac{1}{2}} - 2f_{\beta i,j}^{m+\frac{1}{2}}}{\Delta x^2} \\
 & + A_{\alpha\beta i,j} \frac{f_{\beta i,j+1}^{m+1} + f_{\beta i,j-1}^{m+1} - 2f_{\beta i,j}^{m+1}}{\Delta y^2} - B_{\alpha\beta} f_{\beta i,j}^{m+1} \\
 & + \frac{A_{\alpha\beta(i+1),j} - A_{\alpha\beta(i-1),j}}{2\Delta x} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \\
 & + \frac{A_{\alpha\beta i,j+1} - A_{\alpha\beta i,j-1}}{2\Delta y} \frac{f_{\beta i,j+1}^{m+1} - f_{\beta i,j-1}^{m+1}}{2\Delta y} \\
 & + (C_{\beta\alpha} - C_{\alpha\beta}) \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} \\
 & + (C_{\beta\alpha} - C_{\alpha\beta}) \frac{f_{\beta i,j+1}^{m+1} - f_{\beta i,j-1}^{m+1}}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \\
 & + \frac{\partial Z_\beta^\eta}{\partial h} Z_\alpha^\eta f_{\beta i,j}^{m+1} \left(\frac{\eta_{i+1,j}^{m+\frac{1}{2}} - \eta_{i-1,j}^{m+\frac{1}{2}}}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} + \frac{\eta_{i,j+1}^{m+\frac{1}{2}} - \eta_{i,j-1}^{m+\frac{1}{2}}}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \right) \\
 & = 0
 \end{aligned} \tag{23}$$

$$\begin{aligned}
 & g\eta_{i,j}^{m+1} + Z_\beta^\eta \frac{f_{\beta i,j}^{m+1} - f_{\beta i,j}^{m+\frac{1}{2}}}{\Delta t} + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \left(\frac{f_{\gamma(i+1),j}^{m+\frac{1}{2}} - f_{\gamma(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \right) \\
 & + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \left(\frac{f_{\gamma i,j+1}^{m+\frac{1}{2}} - f_{\gamma i,j-1}^{m+\frac{1}{2}}}{2\Delta y} \frac{f_{\beta i,j+1}^{m+1} - f_{\beta i,j-1}^{m+1}}{2\Delta y} \right) + \frac{1}{2} \frac{\partial Z_\gamma^\eta}{\partial z} \frac{\partial Z_\beta^\eta}{\partial z} f_{\gamma i,j}^m f_{\beta i,j}^{m+1} \\
 & + \left(\frac{f_{\beta(i+1),j}^{m+\frac{1}{2}} - f_{\beta(i-1),j}^{m+\frac{1}{2}}}{2\Delta x} \frac{h_{i+1,j} - h_{i-1,j}}{2\Delta x} + \frac{f_{\beta i,j+1}^{m+1} - f_{\beta i,j-1}^{m+1}}{2\Delta y} \frac{h_{i,j+1} - h_{i,j-1}}{2\Delta y} \right)
 \end{aligned}$$

$$\frac{\partial Z_\gamma^n}{\partial h} f_{\gamma_{i,j}}^m; Z_\beta^n = 0 \quad (24)$$

in which $\eta_{i,j}^{m+1}$, $f_{\beta_{i,j}}^{m+1}$ are the unknowns, and $\eta_{i,j}^{m+\frac{1}{2}}$, $f_{\beta_{i,j}}^{m+\frac{1}{2}}$ and other parameters are given at the previous time step ($m + \frac{1}{2}$).

2.5 Numerical solutions

Solutions of the finite difference equations are obtained by using the boundary conditions given above. In the numerical computation, the intervals of space and time are taken as follows: $\Delta x < L_0/20$, $\Delta y < L_0/20$, $\Delta t = T/250$, where, T is the wave period and L_0 is the wavelength.

At any time step m , the water surface elevation $\eta_m(x_i, y_j)$ can be obtained by solving the above equations. Then the root mean square value of the water surface displacement $\eta_{\text{rms}}(x_i, y_j)$ can be given by

$$\eta_{\text{rms}}(x_i, y_j) = \sqrt{\sum_{m=1}^n \eta_m^2(x_i, y_j)/n} \quad (25)$$

where n is the total sampling number of water surface elevation within several wave periods.

3. Laboratory Experiment

3.1 Experimental setup

In order to observe the wave deformation process and to examine the numerical computation model, a two-dimensional laboratory experiment on wave transformation over submerged triangular breakwaters has been made in a wave basin, of which the flow domain is 3.55×0.75 m. A flap-type wave maker is equipped to generate regular waves, and a wave absorber is placed on the onshore boundary in order to avoid the wave reflectoin.

Only a half element of the breakwater has been taken in the experiment (as well as in the computation) because of the symmetry of the breakwater as shown in Fig. 1 (b). Two types of model breakwaters have been modeled. The first one has a purely triangular horizontal cross-section with seaward and shoreward side slope of $1/3$, whereas the second one has a cross-section composed of triangular and rectangular parts as shown in Fig. 2. In all the cases, the direction of incident waves is in parallel to the x -axis and no wave breaking over the breakwater has occurred.

3.2 Data acquisition and processing

The water surface displacement was measured at many points with small spacing in the x -direction along the nine sections shown in Fig. 2 with the capacitance-

Fig. 2 Experimental setup.

type wave gages. After preliminary processing, the root mean square value of the water surface elevation η_{rms} was obtained for every point.

$$\eta_{rms} = \sqrt{\sum_{i=1}^n \eta^2(t_i) / n} \tag{26}$$

By utilizing the separation technique for incident and reflected wave components (Goda and Suzuki, 1976) from two adjacent wave records measured along the x -direction at the same time, the amplitude of incident waves a_{0j} was evaluated. Then the root mean square of water surface displacement of the incident waves was obtained by using the following expression.

$$\eta_{0rms} = \sqrt{\sum_{j=1}^m \frac{a_{0j}^2}{2}} \tag{27}$$

where m is the number of incident wave components.

Finally relative values of the water surface elevation η_{rms} / η_{0rms} were calculated.

4. Results and Conclusions

4.1 Results

For the two types of breakwaters, the experiment and computation were carried out under various incident wave conditions. In the numerical computation, the mean direction angle of reflected waves $\bar{\alpha}_r$ was taken as 0.0 degree for all the cases, and the mean direction of transmitted waves was assumed to be parallel to the x -direction at any grid point on the onshore boundary. The range of α in the vertical distribution function $Z_\alpha(z)$ is taken from 0 to 3, i.e., four terms are taken in the expression of velocity potential ϕ .

Fig. 3 shows examples of the comparisons between the measurements and the computations of the relative root mean square of the water surface displacement along the sections (1), (3), (5), (7) and (9) for the first type of the breakwater. The total water depth is 15 cm, the breakwater height is 10 cm, and the incident wave height and period are 0.85 cm and 1.0 s. Fig. 4 shows the comparisons between the measurements and the computations of time histories of the water surface displacements at several points along the x -direction for the same condition. Both the figures demonstrate a rather good agreement between the measurements and the computations.

Fig. 3.1 Distributions of RMS of surface displacements.

Fig. 3.2 Distributions of RMS of surface displacements.

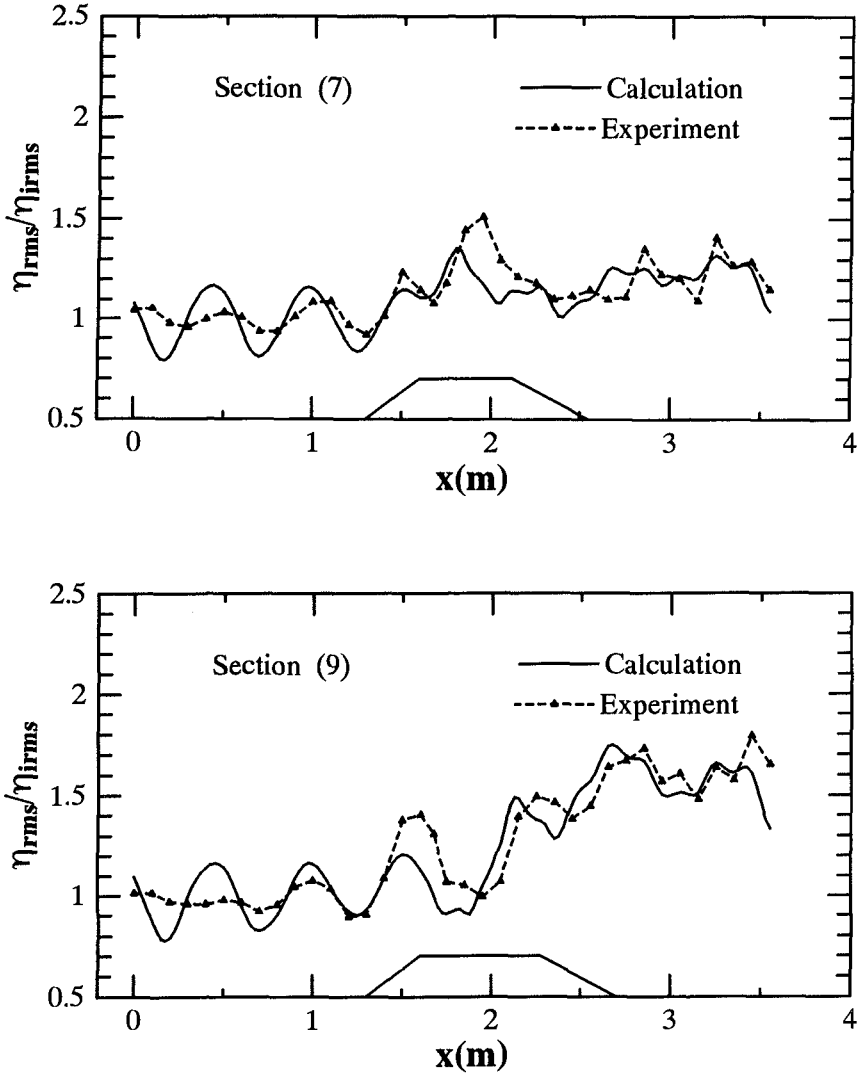

Fig. 3.3 Distributions of RMS of surface displacements.

In Fig. 3, we can see significant variations in the cross-shore distributions of water surface displacements for different sections. Usually the water surface displacement in the region behind the breakwater increases from section (1) to section (9); the mean relative water surface elevations are less than unity from sections (1) to (7), while they are larger than unity for the section (9). The mean value of the transmission coefficients reaches a value of 0.85.

In Fig. 4, a remarkable change in the time histories of the water surface displacements along the x -direction can be seen. In the region before the breakwater, the water surface elevation at position 1 ($x = 0.5$ m) behaves without peculiarities, whereas the time history at position 4 ($x = 2.0$ m) on the top of the breakwater shows strongly nonlinearity with steep peaks. In the region behind the breakwater, two peaks appear in the wave profiles at position 5 ($x = 2.5$ m), i.e., higher harmonics exist.

Fig. 4.1 Time history of the surface displacements.

Fig. 4.2 Time history of the surface displacements.

4.2 Conclusions

It has been shown that the agreement between the measurements and the computations is good enough for practical use. For all the other cases, the agreement has been as good as for this case. It will be concluded that the present model reproduces well not only the root mean square wave height distribution but also the temporal variations of surface displacement at every point even when higher harmonic components strongly appear above and behind the breakwater owing to the high nonlinearity of waves.

These results indicate the validity of the present model as well as the interesting effects of the wave direction change due to the presence of a submerged triangular breakwater on the wave deformation.

CHAPTER 181

BREAKING LIMIT, BREAKING AND POST-BREAKING WAVE DEFORMATION DUE TO SUBMERGED STRUCTURES

Koichiro IWATA¹, Koji KAWASAKI², and Do-Sam KIM³

ABSTRACT

The aim of this paper is to investigate experimentally and numerically the breaking limit, breaking and post-breaking wave deformation due to three different types of submerged structures such as bottom-seated, non-bottom-seated fixed and tautly-moored structures. Based on laboratory experiments, the breaking limits have been formulated for three different types of the submerged structures. Moreover, a modified SOLA-VOF method with the non-reflective wave generation method has been proposed and found to be very effective in evaluating the wave breaking process and post-breaking wave characteristics.

INTRODUCTION

An accurate prediction of the wave deformation due to a submerged structure is very important for the nearshore sea environment. Most of the foregoing researches have discussed wave breaking and breaking wave deformation only due to bottom-seated submerged structures. On the other hand, the breaking limit and breaking wave deformation for other types of submerged structures have been little investigated. Recently, a research and development of numerical computation techniques has been highlighted to evaluate the wave breaking process with a strong energy dissipation (for example; Miyata et al., 1988, Takigawa et al., 1991, Park and Miyata, 1994, and van Gent et al., 1994). A reliable numerical analysis model, however, has not been established yet to compute the wave deformation after breaking.

This paper is aimed to discuss experimentally and numerically the breaking limit, length of breaker zone, and post-breaking wave deformation due to three different submerged structures such as bottom-seated, non-bottom-seated, and tautly-moored structures. First of all, breaking limits, breaker

types and length of breaker zone are experimentally investigated for three different submerged structures in a two-dimensional regular wave field. Next, a numerical analysis model which combines the SOLA-VOF method (Hirt and Nichols, 1981) with the non-reflective numerical wave source (Brorsen and Larsen, 1987) has been developed to evaluate the wave breaking and its post deformation in the regular wave field. The validity of the present numerical calculation method is proved by comparing the computed results with the experimental ones.

LABORATORY EXPERIMENTS

Two-dimensional laboratory experiments were carried out using a wave tank at Nagoya university. The still water depth h was 40, 50 and 60cm. The structural types employed in this experiment are bottom-seated (Type I), non-bottom seated (Type II) and tautly-moored structures (Type III), as shown in Fig. 1. The non-dimensional structural width B/L (B : width of the structure, L : incident wavelength) for Type I ranged from 0.025 to 1.2, and the non-dimensional structural height D/h (D : height of the structure) was 0.4, 0.6 and 0.8. The length and height of the structures (Type II and III) were 68cm and 23 or 34cm, respectively. The initial angle θ_0 of the mooring line to the bottom was 45 degrees in case of Type III. The submerged water depth h_d was 6, 9 and 12cm. The regular waves with periods $T=0.6 \sim 1.68$ s and steepness $H/L=0.02 \sim 0.13$ (H : incident wave height) were generated. The total number of experimental runs was about 540. For each experimental run, the water surface profile η and the water particle velocities u and w were measured with capacitance-type wave gages and electromagnetic type velocimeters, respectively. Also, the wave breaking process was recorded using a video camera.

Fig. 1 Structural Types

NUMERICAL ANALYSIS

The numerical analysis model which combines the SOLA-VOF method with the non-reflective numerical generator has been proposed. The governing equation consists of the continuity equation Eq.(1), Navier-Stokes equations Eqs.(3) and (4) for incompressible fluid, and the advection equation Eq.(5)

which represents the behavior of the free-surface. These equations involve the source term because the wave generation source is placed within the computational domain.

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = q(x, z, t) = \begin{cases} q^*(z, t) & : x = x_s \\ 0 & : x \neq x_s \end{cases} \quad (1)$$

$$q^*(z, t) = \begin{cases} \{1 - \exp(-0.5t/T)\} \cdot 2U & : t/T \leq 3 \\ 2U & : t/T > 3 \end{cases} \quad (2)$$

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial(wu)}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial z^2} \right) + uq \quad (3)$$

$$\frac{\partial w}{\partial t} + \frac{\partial(uw)}{\partial x} + \frac{\partial w^2}{\partial z} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} + \nu \left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial z^2} \right) + wq + \frac{1}{3} \nu \frac{\partial q}{\partial z} \quad (4)$$

$$\frac{\partial F}{\partial t} + \frac{\partial(Fu)}{\partial x} + \frac{\partial(Fw)}{\partial z} = Fq \quad (5)$$

where the Cartesian coordinate system (x, z) is employed, and u and w are the velocity components in the respective directions of x and z , t the time, p the pressure, ρ the fluid density, ν the kinematic viscosity, g the gravitational acceleration, and q the wave generation source with q^* as the source strength which is only located at $x = x_s$. The wave generation source q^* with the horizontal velocity U corresponding to the third-order Stokes wave is gradually intensified, as given in Eq.(2), in order to produce a regular Stokes wave train and T is the incident wave period. The VOF function F represents the volume fraction of the cell occupied by the fluid; the cell with $F=0$ is the air cell (the empty cell), the cell with $0 < F < 1$ is the air and water mixture cell (the surface cell) and $F=1$ is the water cell (the full cell).

Employing the modified SOLA-VOF method with the wave generation source, the velocity components (u and w) and the pressure p at the next time step are determined by using the continuity and momentum equations (Eqs.(1), (3) and (4)). The staggered mesh was adopted for discretization of the calculational domain. The flow chart of this numerical scheme is shown in Fig. 2, where $D = \partial u / \partial x + \partial w / \partial z - q$. Regarding the boundary conditions, Sommerfeld radiation condition Eq.(6), where Q is a quantity representing the velocities u , w and C is the wave celerity, is applied for the open boundaries. The non-slip condition is used on both the structure surface and the sea bed.

$$\frac{\partial Q}{\partial t} \pm C \frac{\partial Q}{\partial x} = 0 \quad (6)$$

The computational domain is taken as 500cm times 70cm in the respective directions of x and z . As shown in Fig. 3, the wave generation source is located at an appropriate location determined according to the wavelength, and the origin of x coincides with the wave generation source. While, the positive direction x -axis is taken toward the structure and the vertical axis z is taken positive upward with its origin being on the still water level. The cell

length Δx and Δz are $1/50L$ and $1/40h$ in respective directions of x and z , and the successive time interval Δt , initially $\Delta t_i=0.01s$, is determined at every time step so that the Courant condition Eq.(7) is satisfied. Here, $\gamma=0.5$ in this study, and $|u|_{\max}$ and $|w|_{\max}$ are, respectively, maximum velocity of u and w .

$$\Delta t < \gamma \cdot \min \left\{ \frac{\Delta x}{|u|_{\max}}, \frac{\Delta z}{|w|_{\max}} \right\} \tag{7}$$

Figure 4 shows one example of the time history of the calculated water surface profile $\eta(t)$ (solid line) in which the theoretical value of third-order Stokes wave (open circle) is simultaneously shown for comparison. It is obvious that the calculated water surface profile becomes stable and regular after the fifth generated wave. Moreover, both the calculated and theoretical results

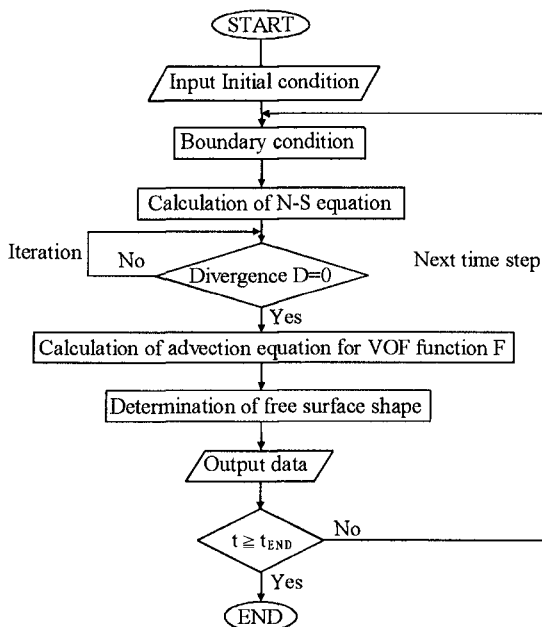

Fig. 2 Flow chart of Numerical Calculation

Fig. 3 Definition Sketch

Fig. 4 Time History of Water Surface Profile ($h/L=0.5$ and $H_i/L=0.057$)

agree well and, hence, the validity of the wave generation by the wave source method is proved.

RESULTS AND DISCUSSIONS

I. Laboratory Experiment

a) Breaking Limit : Analyzing the laboratory experiments, the breaking limit for three different structures is, first of all, discussed. Figures 5(a) and (b) show the relationship between the wave steepness H/L and the non-dimensional submergence depth h_d/L in cases of Type II and III structures, respectively. The critical wave steepness $(H/L)_b$ in case of Type II structure can be represented only by one curve, regardless of the values of h_d/h , while the critical value $(H/L)_b$ in case of Type III structure takes a peak value at certain value of h_d/L according to h_d/h , as shown in Fig. 5(b). This took place under the resonance condition that the natural period of the motion of the tautly-moored structure is close to the wave period. Employing the concept of breaking limit of partial standing wave (Iwata and Kiyono, 1985), the breaking limit for Type II and III structures can be formulated as

$$\left(\frac{H}{L}\right)_b = \xi \left[0.0845 \left\{ 1 - \exp\left(-1.675\pi \frac{h_d}{L_0}\right) \right\} \left(\frac{1 - K_R}{1 + K_R}\right) + 0.218 \tanh\left(\frac{2\pi h_d}{L_b}\right) \left(\frac{2K_R}{1 + K_R}\right) \right] ; \xi = \beta / [\{\alpha(T_n - T)\}^2 + 1] + 1 \quad (8)$$

where, $(H/L)_b$ is the critical wave steepness, K_R the reflection coefficient, L_0 the wavelength at deep water, T_n the natural period of the tautly-moored structure, and α and β are numerical constants (see Fig. 5(b)) which are zero for fixed structures.

Equation (8) agrees well with the experimental values, as shown in Fig. 5. The comparison between Figs. 5(a) and (b) shows that the breaking limit $(H/L)_b$ in case of Type III structure is slightly larger than that in case of Type II structure. In other words, the non-bottom-seated structure is more effective to break waves than the tautly-moored structure.

Equation (8) can be also applied to define the breaking limit for Type I structure. In addition, the breaking limits $(H/h_d)_b$ for Type I structure can be

formulated, as shown in Fig. 6, in terms of B/L for $h/L=0.13$ and 0.4 without using the reflection coefficient K_R . The breaking limits for Type I structure are formulated as follows:

$$\left. \begin{aligned} (H/h_d)_b &= 0.3656 + 0.3668 \exp(-10B/L) \\ &\quad ; 0.1 \leq B/L \leq 0.6 \text{ for } h/L = 0.13 \\ (H/h_d)_b &= 0.3641 + 0.2313 \exp(-10B/L) \\ &\quad ; 0.1 \leq B/L \leq 0.6 \text{ for } h/L = 0.2 \\ (H/h_d)_b &= 0.4417 + 0.2252 \exp(-10B/L) \\ &\quad ; 0.1 \leq B/L \leq 1.0 \text{ for } h/L = 0.4 \end{aligned} \right\} \quad (9)$$

(a) Non-Bottom-Seated Structure (Type II)

(b) Tautly-Moored Structure (Type III)

Fig. 5 Breaking limit

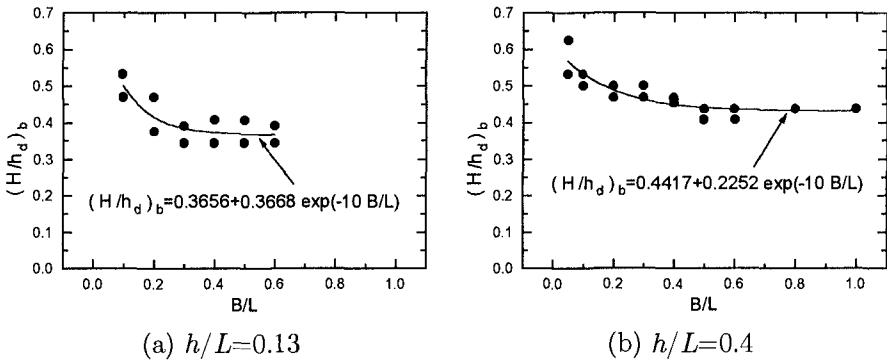

Fig. 6 Breaking Limit for Bottom-Seated Structure (Type I)

b) Breaker Type : As shown in Figs. 6 and 7, the change in the breaking limit and the breaker type become very small for $B/L > 0.5$ in case of $h/L=0.2$ and 0.4 , and for $B/L > 0.3$ in case of $h/L=0.13$. The breaker type changes from Spilling breaker to S-P breaker (an intermediate type between Spilling and Plunging breaker) and finally to Double breaker (Katano et. al., 1992) as H/h_d increases. It is also revealed from Fig. 7 that the critical values of H/h_d for the wave breaking and the breaker type classifications in case of $h/L=0.4$ is larger than other cases. Also, the non-bottom-seated structure, among three different types of the submerged structures, is found to be the most effective one to break waves because a strong circulating flow is usually formed around the structure.

c) Breaking Position : As shown in Fig. 8, the non-dimensional breaking position x_b/L (x_b : distance from the front of the structure to the breaking position) shifts to the offshore side of the structure by an increment of H/h_d and is almost constant at $x_b/L \approx -0.05$ near the antinode position of the partial standing wave in front of the submerged structure for $H/h_d \geq$ about 1.0. Inspection of Figs. 7 and 8 reveals that x_b/L shifts to the offshore side of the structure according to the change of the breaker types from Spilling to S-P, and to Double breakers.

d) Breaker Zone Length : Non-dimensional breaker zone length L_b/L is plotted versus H/h_d in Fig. 9 with parameters of h_d/h and B/L , where L_b is the distance from the breaking point to the location where the breaking wave-caused turbulence with air entrainment disappears. As H/h_d increases, L_b/L becomes larger regardless of h_d/h . Further, L_b/L for $h_d/h=0.2$ is larger than that for $h_d/h=0.4$ because of the stronger non-linear interaction between the wave and the structure.

e) High Harmonic Components : Figure 10 shows the spatial distribution of the non-dimensional wave height spectrum $2A(f)/H$ around the submerged structure, where $A(f)$ is the amplitude spectrum for frequency f and B.P. is the breaking point. It is found from Figs. 10(a) and (b) that the fundamental harmonic component increases in front of the structure and decays toward the

onshore side of the structure because of the wave energy dissipation due to the wave breaking. On the other hand, higher frequency components grow up above the structure, especially the second harmonic component becomes larger around the submerged structure. This is accounted by the wave energy transfer from the fundamental harmonic component to the second harmonic component due to the non-linear interaction between the wave and the structure. Figures

Fig. 10 Spatial Distribution of Non-dimensional Wave Height Spectrum (Type I)

10(b) and (c) reveal that the spatial distribution of $2A(f)/H$ depends on h_d/h and that larger wave energy dissipation takes place with decreasing h_d/h . It is obvious from Fig. 10(d) (case of a weak Spilling breaker) that the second harmonic component is seen to change periodically after breaking. According to Massel(1983) who calculated the wave transformation due to submerged structures for non-breaking waves, the beat length λ_2 has been formulated in Eq.(10), where k_1 and k_2 are the wave numbers for the fundamental and second harmonic components, and σ is the angular frequency of the fundamental component. Applying Eq.(10) to the case presented in Fig. 10(d), $\lambda_2/L \cong 0.6$ is obtained and found to coincide with the corresponding experimental one. Therefore, it can be thought that the free second harmonic component wave is generated even under the breaking wave condition.

$$\lambda_2 = 2\pi / (k_2 - 2k_1) \quad ; \quad \sigma^2 = gk_1 \tanh k_1 h_d, \quad 4\sigma^2 = gk_2 \tanh k_2 h_d \quad (10)$$

II Numerical Calculation

The post-breaking wave deformation due to a submerged structure is computed using the modified SOLA-VOF method. The non-dimensional water surface profiles η/H_i measured at $x=174\text{cm}$ offshore side and $x=290, 314$ and 338cm onshore side of the Type II structure are plotted versus t/T in Figs. 11(a)~(d) in case of a spilling breaker. In Fig. 11, laboratory experimental values are also shown for comparison. It is found that higher frequency component waves are generated as mentioned above and, hence, the time history

(c) 36cm onshoreward from structure
($x/L=2.08$)

(d) 60cm onshoreward from structure
($x/L=2.24$)

Fig. 11 Comparison of Calculated and Experimental Water Surface Profile (Type II ; $H/L=0.04, h/L=0.33$)

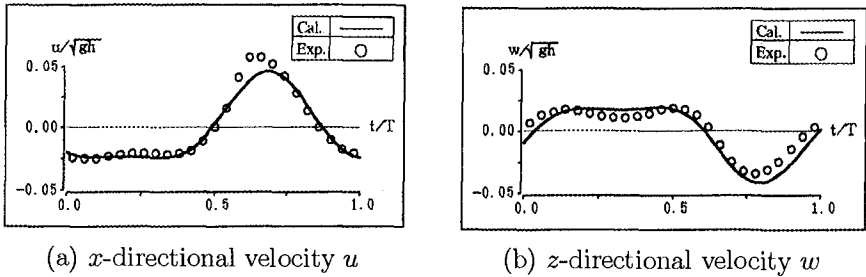

Fig. 12 Comparison of Calculated and Experimental Velocity Profile
(Type II ; $H/L=0.04$, $h/L=0.33$, $x/L=1.92$, $z/h=-0.2$)

of the water surface profile has a complex form in the onshore region of the structure after breaking. From Fig. 11, the calculated values are found to be in good agreement with experimental ones. Good agreement between the calculated values and laboratory experiments is also confirmed for the water particle velocity, as shown in Fig. 12. Therefore, it is demonstrated that the present numerical calculation method can reproduce well the water surface profile and the water particle velocity before and after breaking due to a impermeable submerged structure.

Figures 13(a)~(d) show the spatial variations of the water surface profiles and the particle velocities around the structure at $t=7.55$, 7.60, 7.72 and 7.83s, respectively, under the same condition stated in Fig. 11. Figures 13(a) and (b) show that the wave passing over the submerged structure breaks with an overturning wave front, and Figs. 13(c) and (d) show that the broken wave is deformed into several wave components with two or three peaks in one wavelength. According to Fig. 14, in case of Type I structure, large vortex is found to be formed on the onshore side of the submerged structure after the wave passes over it. In addition, analysis of video tape recorder confirms that the breaker type and wave deformations evaluated with the numerical calculations are very similar to those measured at the laboratory. However, the air-bubbles entrainment due to wave breaking, which was observed by the video tape recorder and the visual observations, cannot be simulated in the numerical calculations.

As shown in Fig. 15, both the numerical and experimental results show that the high mean onshore velocity is generated near the free-surface onshore side of the structure and the high mean downward velocity is observed to occur near $x=340\text{cm}$. The mean offshore velocity, i.e. the return flow, is also generated to compensate the onshore mass transport caused by wave breaking around the still water level. The return flow is, in particular, strong below the structure because the flow cross sectional area below the structure abruptly diminishes from the onshore side of the structure, which could accelerate the flow velocity. According to Fig. 15(a), the upward velocity takes place in front of the structure where the antinode of the partial standing wave seems to appear, and the offshore steady flow takes place just above the crown of the structure. However, it is expected that there is a strong onshore steady flow above the wave trough (i.e. around the still water level) over the structure. Judging from

(a) $t=7.55s$

(b) $t=7.60s$

(c) $t=7.72s$

(d) $t=7.83s$

Fig. 13 Results of Numerical Calculation (Type II)
 $(H/L=0.04, h/L=0.33)$

the above-stated, it can be said that a circulating flow is formed around the submerged structure. Judging from Figs. 15(a) and (b), the proposed numerical calculation scheme is shown to agree well with the measured mean wave velocity field in laboratory experiments.

CONCLUSIONS

The breaking limit, breaking and post-breaking wave deformation due to three different types of submerged structures have been discussed experimentally and numerically. Main conclusions in this study are summarized as follows:

- 1) Breaking limits have been formulated experimentally for three different types of submerged structures.
- 2) Breaker types have been also formulated experimentally for two types of submerged fixed structures.
- 3) Among the three types of structures, the non-bottom-seated structure has been found to be the most effective one to break the waves.
- 4) A numerical model using the modified SOLA-VOF method has been found to evaluate well the wave deformation before and after breaking in case of a spilling breaker.

CHAPTER 182

ITALIAN EXPERIENCE ON SUBMERGED BARRIERS AS BEACH DEFENCE STRUCTURES

by Alberto Lamberti* & Alessandro Mancinelli**

Abstract

The use of submerged barriers in Italy is rather new starting in the first 80's. Since that time more than 50 submerged barrier defence system were constructed and this type of structure is progressively complementing and substituting the traditional use of parallel emerging breakwaters.

The paper presents documentation about the experience gained on the topic and describes and compares to prototype experience the design criterion suggested by the authors, based essentially on the selection of a proper wave attenuation necessary to obtain to desire profile modifications.

1 Introduction

Since the XV century, beach erosion has been taking place in many parts of the Italian coastline. The numerous historical maps document, for instance, erosion due to the construction of channel-harbour in the Adriatic Sea such as Cesenatico, Rimini, Pesaro, Fano, Senigallia, Pescara, etc. The extension of jetties in these ports carried out at different times in order to avoid silting up of the entrance, gave rise to down drift erosion (in the Adriatic sea north of these structures).

The first coastal defence structures built in Italy date back to the beginning of this century. An exception though, is to be found in the Venetian Republic which had already started to construct seawalls in the XVII century, to protect the sandy strip which separated the lagoon from the sea, the so-called "murazzi".

The erosion phenomenon remarkably increased between the 50's-60's largely due to the extension of existing ports or to the construction of new harbour and to the first structures of river engineering works.

* Professor, DISTART, University of Bologna, viale del Risorgimento 2, 40136 Bologna, Italy

** Professor, Hydraulics Institute, University of Ancona, via Breccie Bianche, 60131 Ancona, Italy

In addition to the causes mentioned above, the indiscriminate extraction of sand and gravel from the low-water bed of rivers was also responsible for the rapid beach erosion.

The first defence interventions carried out on the Adriatic coast consisted of natural rubble-mound seawalls or breakwaters of the emerging type. Instead, in Liguria, beach nourishment using a narrow strip of sand has been adopted since the 1950's (Savona, Lavagna).

The construction of longitudinal detached emerging breakwaters which determine down drift erosion, forced the Administrations of Emilia Romagna and Marche to build breakwaters of the emerging type for almost 80 km. Beaches are essential in supporting the tourist economy which has been rapidly growing since the 1960's.

At the end of the 1970's, the erosive phenomenon aggravated and this was particularly severe in Emilia Romagna because of subsidence. Therefore, the Administrations of the two Regions predisposed for legislative interventions which prohibited extraction of sand and gravel from the low-water bed and limited the gas and water extraction from the subsoil. Regional Plans were also set up to protect the coast. Their aim was to study and gain knowledge on this phenomenon in addition to finding alternative interventions to breakwaters of the emerging type.

Thus, at the beginning of the 80's, submerged barriers were tested. When the first author was performing his first analysis and tests on this type of structure, Lamberti & Tomasicchio (1981), only very few real life applications were observable in Italy and all of them were using a very special technology (Longard tubes). Since then, more than 50 submerged barrier defence systems have been constructed and this type of structure is progressively complementing and substituting the traditional use of parallel emerging breakwaters.

Two main types of structures have been constructed:

- sand-bag barriers, mainly used in combination with beach nourishment, and characterised by a high submergence and small section; they do not provide a significant reduction of wave height nor an effective retaining capacity on sand, but they are supposed to provide stabilization of natural sand bars and are appreciated because of their very low impact;
- rubble-mound submerged breakwaters, used alone or in combination with nourishment, with or without gaps, with or without a bed protection at the gaps, used to reduce wave transmission through the gaps of emerging parallel breakwater systems or to protect the bed from erosion in correspondence of the gaps.

In the meantime, many model tests have been carried out, Aminti & al. (1983), Lamberti & al., (1985), DH (1983, 1989, 1990) and others. Detailed monitoring of their behaviour in nature was also performed in some cases, Ferrante & al. (1992).

The evolution of defence systems with the introduction of submerged barriers will be examined for typical cases in three Italian regions: Veneto, Emilia Romagna and Marche situated on the Adriatic sea.

The Adriatic Italian coast is low and very flat in the Northern reach pertaining to Veneto and Emilia Romagna, and is an alternation of alluvial plains and moderately high erosion coasts in Marche region. Tidal excursion at spring ranges from 1.0 m in

Venice to 0.6 m in southern Emilia Romagna. Tide is substantially lower and mainly diurnal in the Marche region. Extreme storm surge ranges from 1.1m in Venice to 0.8 m in Ancona.

Typical 1 year return period waves are about 3.5 m and extreme about 6.0 m

2 Case histories

2.1 Emilia Romagna

The protective systems built after 1983 are nourishments protected by submerged barriers formed with sand-bags. Transversal groins made with sand-bags or rock in the emerging part and connected to the submerged barriers, are almost always present.

The new intervention extend for about 13.8 km in length with the use of 2.130.000 m³ of sand nourishment coming from borrowed land quarries.

In these first interventions, sand-bag barriers had a small section, a volume of 1 m³ and were generally arranged in two rows of 3 and 2 bags at a depth of -2.50, -3 metres.

The high submergence of these barriers does not produce any appreciable reduction of wave action. The barriers, however, stabilize the natural sand bars giving rise to a localized inshore erosion and to raising of the bed offshore (see Fig. 1).

Frequently sand-bag barriers can undergo static failures. To avoid erosion produced by breakers falling on the sand, the dimensions of the sand-bags and the width of the barriers were enlarged during subsequent interventions (see Fig. 2).

The only work carried out in Emilia Romagna with submerged barriers of natural rock is that of Lido di Dante (Ravenna) (see Fig. 3) where a series of emerged groins had been incapable of preventing erosion. The submerged barriers have a crown width of 12 m and are 0.5 m deep in water, as shown in Fig. 3. The last groin is connected to the barrier in order to prevent leakage of the sediments northwards. The volume of nourishment is such that the equilibrium profile has a closure depth between the coastline and the submerged barrier, producing a maximum shoreline advancement of about 30 metres from the.

Figure 4 shows the beach of Lido di Dante after the above intervention was carried out. Before the intervention the shoreline was just at the toe of the house.

2.2 Marche

Since 1982-83, in alternative to breakwaters of the emerging type or rubble-mound seawalls, a series of defence interventions were performed in the Marche region. Submerged barriers with nourishment were used for low coasts while those without nourishment were used for rocky coasts [Fiorenzuola (PS), Sirolo and Numana (AN)]. In some cases (Pesaro, Fano, Montemarçiano) the typology was the same as in Emilia Romagna with sand-bag barriers or Longard tube barriers. In other cases, south of Ancona, the first submerged barriers in natural rock were used, both as breakwaters and as a defence at the foot of the nourishment. Figure 5 shows an intervention at Grottammare; the characteristics of a submerged barrier can be seen

with a crown width of 3.00 m and a submergence of 0.90 m. The barriers have gaps of 30 m and link two stretches of emerged breakwater barriers.

The drawbacks of these first submerged barriers are the following:

- heavy erosion in the gaps and in the terminal head arising from strong return currents;
- scouring effects at shore-side foot of the barriers;

Fig. 1 – Sand bags submerged barriers and their effects - First intervention.

Fig. 2 – Protective system whit sandbags - New intervention.

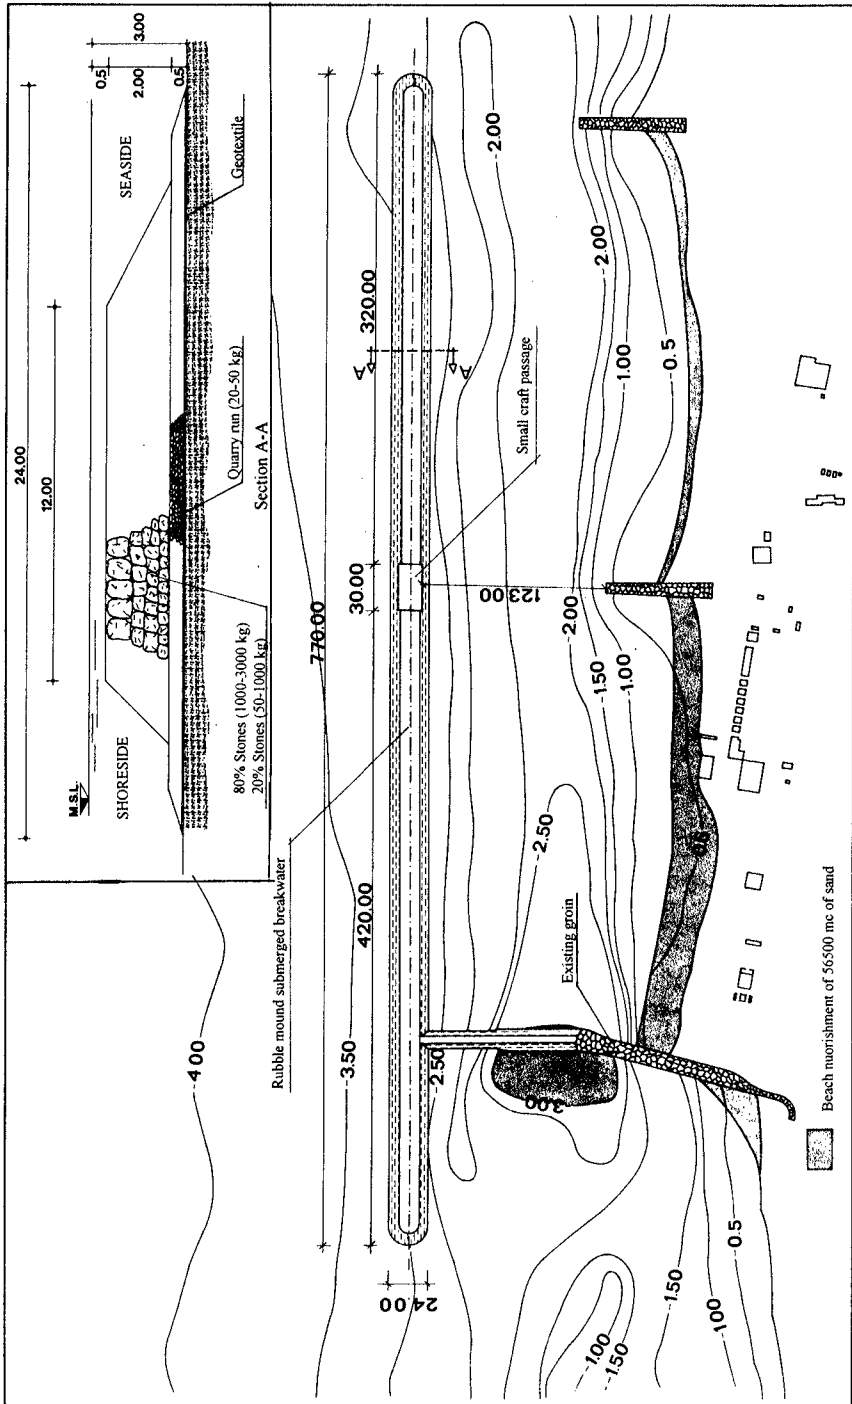

Fig. 3 - Protected nourishment at Lido di Dante (RA, Emilia Romagna): plan of the area and section of the submerged breakwater.

Fig. 4 – Lido di Dante after intervention.

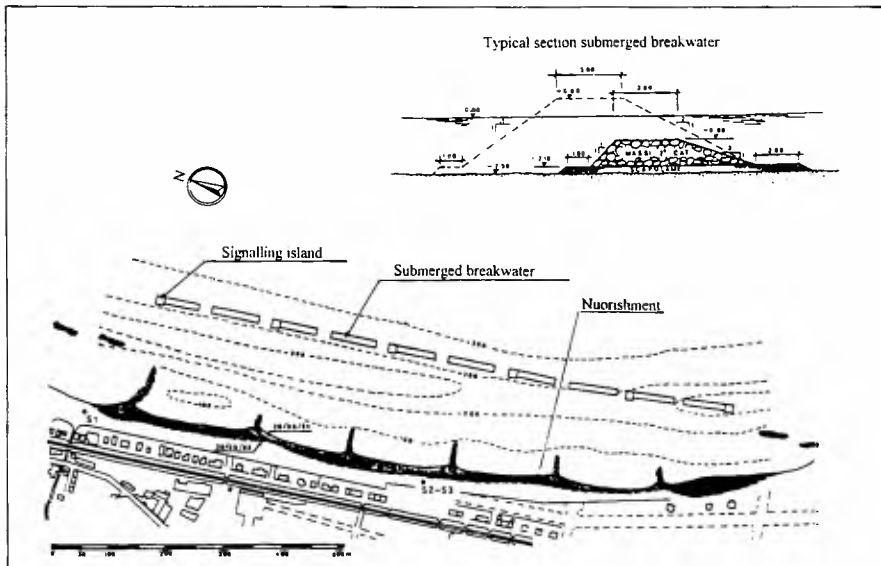

Fig. 5 – Protective system at Grottammare (AP, Marche)

- rock displacement due also to an imperfect execution when building the barriers, since it is difficult to place rocks in cloudy water;
- high submergence particularly stressed during Southeast sea-storms characterized by a remarkable rising of the average sea level. This produces an insufficient dissipation of wave energy.

The second generation of submerged barriers carried out in the Marche region have a considerably wider transversal section. This was done by increasing the crown width to 10-12 m, by lowering the submergence to -0.5 m and by increasing the slope of both barriers sides (see Fig. 6).

The gaps between the barriers are covered with a quarry run mattress in order to extend the base of the foundation between one gap and the next.

Second generation submerged barriers were used in place of emerging breakwaters or along stretches of the coast subjected to new erosion, without nourishment (see Fig. 7 on the intervention in Montemarignano (AN)). These replacements were carried out with the aim of improving the quality of the water and the sediments.

When emerging barriers are placed close to the shoreline, an insufficient water circulation is created which leads to the formation of slimy and annoying deposits of material for bathers.

In Montemarignano, the submerged barriers defend the facing coast. These barriers have been subjected to displacement of the stones along the slopes facing the shore and sea. The erosive process moves down drift (see Fig. 8), similarly to what happens with the emerging barriers.

Bathymetric measurements carried out at different intervals, show the formation of scouring effects both offshore and inshore of the structures and in proximity of the head of the extreme segments.

In Senigallia, the substitution of emerging barriers with submerged ones has led to the disappearance of sand "tombolo" and subsequent withdrawal of the shoreline by 20-30 metres (see Fig. 9).

Longard tubes and sand-bag barriers have not been used anymore in the Marche. The negative results of these typologies were seen in those beaches with a steep bed slope.

2.3 Veneto

In interventions regarding the defence of venetian beaches which began in the 60's, the structures used were mainly groins with rigid seawall. Breakwaters of the emerging type were used only in a small stretch off the coast of Jesolo.

On the coast of Caorle (1985), submerged barriers in Longard tubes or sand-bags were experimented to create a protective nourishment.

At present, a project predisposed by the Consorzio Venezia Nuova is underway for interventions regarding the defence of the Cavallino and Pellestrina shores situated in the stretch of coast which separates the lagoon of Venice from the sea. The work which has been underway since 1995, foresees the construction of an artificial beach contained inside areas delimited by lateral groins, in part submerged and in part emerging, and by a submerged structure which connects these groins.

Fig. 6 – Submerged breakwater at Marina di Montemarcano (AN, Marche).

Fig. 7 – Protective system at Marina di Montemarcano (AN, Marche).

Fig. 8 – Down drift erosion of the submerged breakwater Marina di Montemarciano.

Fig. 9 – Protective system at Senigallia (AN, Marche).

Once finished, the artificial beach will stretch for 9 km with an average width of 100 metres at the time of sand-filling which should stabilize around 70 metres.

The main source supplying nourishment sand (12.000.000 m³) has been individuated off Malamocco, 20 km from the coast at an average depth of -20 metres.

The characteristics of the intervention are visible in figures 10, 11 and 12.

3 The suggested design criterion

3.1 Relevant components of the dynamics of submerged barriers

The most important effect of submerged barriers is the depth induced wave breaking; even in the absence of breaking relevant effects on wave agitation take place. The limited submergence cause the generation of higher harmonics, see Fig. 7, and the relevant friction exerted by armour stones in the shallow stream flowing over the crests cause significant energy dissipation and modification of wave spectrum.

The breaking of wave over the crest is the cause of a potentially high wave set-up inshore the barrier. Set-up is significantly reduced by gaps in the barrier or at the ends of the barrier, but contemporary strong currents are induced through the gaps, where the bed must be adequately protected.

The mutual effects of energy dissipation by breaking and by friction must be adequately balanced because while they cooperate in reducing wave energy, they act in an opposite direction on wave set-up and currents, which are recognized as negative effects of the barriers.

3.2 Criterion For Global Retaining Efficiency

As a consequence of turbulence induced by breakers, the resuspension capacity of waves just inshore of the barriers is greater than for normal waves of the same height. Therefore, if sand is transported from the shore to the barrier, it will probably be resuspended and transported out of the barrier.

In order to be retained, sand should not reach the barrier, i.e. the reduction of wave height on the barrier should be strong enough to ensure the formation inshore of the barrier itself of a beach profile down to its closure depth.

Wave transmission is evaluated by formulae or experiments. Approximately $H_{st} \cong s_c$ (H_{st} = transmitted wave; s_c = barrier submergence).

Transmission coefficient depends on scaled values of:

- barrier submergence
- crest-berm width
- stone size
- wave steepness

Closure depth (h_c) for sandy beaches is evaluated by formulae or, approximately, as $h_c = 2H_{st}$. On gravel beaches a no movement condition at the foot of the inshore barrier can be imposed. The equilibrium beach profile is evaluated according to Dean 2/3 power relation. The turbulence decay area of the breaker can be approximately evaluated as $10h$.

Fig. 10 – Protected nourishment at Pellestrina (VE, Veneto): plan of the area and section of the submerged barrier.

Fig. 11 – Pellestrina litoral before the works.

Fig. 12 – Pellestrina litoral after the interventions.

High water conditions are obviously the most severe for the beach stability; since $h_c \approx 2s_c$, a sea level rise cause an almost double increase of closure depth and an almost equal lowering of the closure point.

3.3 Most frequently used formulae

The Goda-Seelig (SPM), (Goda, 1985) and Van der Meer & Daemen (1994) formulae are most frequently used to calculate the wave transmission from the barrier.

For the closure depth of the equilibrium beach profile, Hallermeir's (1980, 1981) formula is used for sandy sediments.

For gravel beaches a modified Shield criterion is used in combination with a friction formula returning shear velocity from the orbital wave velocity at the bed.

For the armour stones stability Van der Meer (1993), Vidal (1995) and other formulae are normally used.

4 Open problems

The development of currents induced by the barrier is a 3-D complicated phenomenon, since the limited size of the barrier make the use of a mild slope approximation questionable. As a consequence the capacity of providing quantitative and reliable predictions of sediment transport by rip and longshore currents is limited and consequently of erosion in the vicinity of the structure and of effects on the beach.

Even if barriers made of rocks are stable according to the calculation formulae used, their transversal section show changes probably due to sinking of the rocks in the sediments of the bottom. This could be due to a probable underestimation of the structure-foundation interactions caused by the dynamic actions induced by the waves.

The structural resistance of sand bags showed to be insufficient. Most works constructed with this technique were destroyed after few years and in some case the remnants could not be found after 8-10 years.

Some damages to bags are probably caused during construction. During lifetime bag are covered with vegetation and mussels, the effects of which is poorly known, or abided by sand.

Finally quite often the sandy bed on which they are posed is ploughed by mussels fishers damaging the barrier.

5 Conclusions

In order to be efficient sand retaining structures, submerged barriers should be:

- sufficiently high and wide, so that they cause a significant reduction of the transmitted wave height and avoid erosion of the bed at their inshore foot:
 - $s_c < h/2$ ($s_c = h/3$ at high water level)
 - $b_c < 3h$ ($b_c = 3h$ at high water level)
- sufficiently distant from the shoreline, so that turbulence produced by induced

breakers decays before reaching the inner beach.

Wave transmission and hydraulic stability of their stones are rather well known, particularly in the absence of cross-currents.

The knowledge of barrier behaviour is nevertheless still insufficient regarding several aspects:

- induced set-up and currents influencing sediment transport and water quality;
- related sediment transport causing littoral sand trapping efficiency or sand losses;
- local bed erosion at inshore and offshore toe of the barrier and in the gaps;
- barrier sinking mechanism, which must be controlled in order to preserve barrier submergence and efficiency.

CHAPTER 183

Resonant Reflection and Refraction-Diffraction of Surface Waves due to Porous Submerged Breakwaters

Hajime Mase¹⁾, Akira Kimura²⁾ and Hiroshi Sakakibara³⁾

ABSTRACT: A wave equation, taking account of the effects of porous medium, is transformed into coupled parabolic equations. It is assumed in the theory that the mean water depth and the thickness of porous layer are slowly varying and the bottom undulation is rapidly varying compared to the wavelength of surface waves. Though we can utilize the Bragg reflection to reduce transmitted waves behind breakwaters in one-dimensional case, wave heights behind breakwaters do not always decrease due to wave refraction-diffraction in horizontal two-dimensional case. By adding a dissipation term to the coupled parabolic equations, we can calculate the wave breaking deformation.

INTRODUCTION

Porous submerged coastal structures are superior from the view points of seascape, water quality conservation, and fishery resources. If artificial reefs for fish habitat, consisted of blocks, are arranged to form a suitable bar field, we can expect a function of wave control as well as the function of creating fishery resources. Such porous bar fields make wave reflection and transmission smaller than those by impermeable bar fields.

Davies and Heathershaw (1984) studied the reflection from sinusoidal undulation over a horizontal bottom and derived a solution of reflection coefficient. Mei (1985) and Naciri and Mei (1988) developed theories of wave evolution at and close to the resonant condition by shore-parallel sinusoidal bars and two-dimensional doubly sinusoidal undulations over a slowly varying topography. Kirby (1986) derived a general wave equation which extends the mild slope equation of Berkhoff (1972). These existing theories don't take account of the effects of seabed permeability. Izumiya (1990) obtained an extended mild slope equation for waves propagating over a permeable submerged breakwater. However, since the assumption that the slope of the structure is very gentle is employed, the theory cannot be applied to the case of seabed with rapidly varying undulations.

In this study, a wave equation over porous rippled beds (Mase and Takeba, 1994), taking into account the effects of porous medium, is transformed into coupled para-

bolic equations of forward- and backward-scattering waves. Numerical calculations are carried out to examine wave transformations or the Bragg scattering by a group of porous submerged breakwaters over constant and sloping beaches in horizontal two-dimension.

WAVE EQUATION OF ELLIPTIC TYPE

Mase and Takeba (1994) and Mase et al. (1995) derived a wave equation over porous rippled beds:

$$\nabla_h \cdot (\alpha \nabla_h \hat{\phi}) + \alpha k^2 \hat{\phi} - \frac{\cosh^2 kh_s}{D^2} (1 - \gamma) \nabla_h \cdot (\delta \nabla_h \hat{\phi}) = 0 \tag{1}$$

where

$$\alpha = \frac{1}{4kD^2} \left\{ \cosh^2 kh_s \sinh 2kh \left(1 + \frac{2kh}{\sinh 2kh} \right) + \gamma \sinh 2kh_s (\cosh 2kh - 1) + \gamma^2 \sinh^2 kh_s \sinh 2kh \left(1 - \frac{2kh}{\sinh 2kh} \right) + \gamma \sinh 2kh_s \sinh 2kh \left(1 + \frac{2kh_s}{\sinh 2kh_s} \right) \right\} \tag{2}$$

$$D = \cosh kh_s \cosh kh (1 + \gamma \tanh kh_s \tanh kh) \tag{3}$$

$$\gamma = n / (\tau + i f) \tag{4}$$

$$\omega^2 = gk \frac{\tanh kh + \gamma \tanh kh_s}{1 + \gamma \tanh kh \tanh kh_s} \tag{5}$$

where $\hat{\phi}$ is the complex amplitude of velocity potential, δ is the rapidly varying undulation, h and h_s are slowly varying water depth and thickness of porous layer, ∇_h is the horizontal gradient operator, f is the linearized friction factor, n is the porosity, τ is the inertia coefficient, and ω is the angular frequency. The effects of the porous medium are taken into account through the complex wavenumber k given by Eq.(5) and the complex coefficients α and γ .

Eq.(1) contains the existing models such as the mild slope equation by Berkhoff (1972) and the general wave equation by Kirby (1986), see Mase and Takeba (1994).

COUPLED PARABOLIC EQUATIONS

We need the boundary condition along a closed curve surrounded an analytical domain to solve Eq.(1) of elliptic type. In problems of predicting wave transformations over sloping topography, we cannot set the shoreward boundary condition a priori. A parabolic approximation method developed by Radder (1979) is useful for such problems. Here, following Kirby (1986), we transform Eq.(1) into coupled parabolic equations.

Multiplying Eq.(1) by the gravity acceleration g makes the dimension of αg same as that of CC_g (phase velocity \times group velocity). Hereafter, αg and $g \cosh^2 kh_s / D^2$ are described as α and β , respectively. Manipulating Eq.(1) yields

$$\{\alpha - \beta(1-\gamma)\delta\}\phi_{xx} + \{\alpha_x - \beta(1-\gamma)\delta_x\}\phi_x + \alpha k^2\phi + (\alpha\phi_y)_y - \beta(1-\gamma)(\delta\phi_y)_y = 0 \quad (6)$$

and Eq.(6) is rewritten as

$$\phi_{xx} + v^{-1}v_x\phi_x + v^{-1}\alpha k^2\phi + v^{-1}(\alpha\phi_y)_y - v^{-1}\beta(1-\gamma)(\delta\phi_y)_y = 0 \quad (7)$$

where

$$v = \alpha - \beta(1-\gamma)\delta \quad (8)$$

$$v_x = \alpha_x - \beta(1-\gamma)\delta_x + O(k\delta)^2 \quad (9)$$

$$v^{-1} = \alpha^{-1} \left\{ 1 + \frac{\beta}{\alpha}(1-\gamma)\delta + O(k\delta)^2 \right\} \quad (10)$$

Let's introduce the following pseudo-operator:

$$\mu^2\phi = k^2 \left[\left\{ 1 + \frac{\beta}{\alpha}(1-\gamma)\delta \right\} \phi + \frac{1}{k^2\alpha}(\alpha\phi_y)_y - \frac{\beta(1-\gamma)}{k^2\alpha}(\delta\phi_y)_y \right] + O(k\delta)^2 \quad (11)$$

Treating μ^2 to be a numerical value and taking the square root of it gives

$$\mu\phi = k \left[\left\{ 1 + \frac{\beta}{2\alpha}(1-\gamma)\delta \right\} \phi + \frac{1}{2k^2\alpha}(\alpha\phi_y)_y - \frac{\beta(1-\gamma)}{2k^2\alpha}(\delta\phi_y)_y \right] + O(k\delta)^2 \quad (12)$$

Now we express the potential ϕ as a sum of the forward-scattered potential, ϕ^+ , and the backward-scattered potential, ϕ^- , as

$$\phi = \phi^+ + \phi^- \quad (13)$$

and express their derivatives as

$$\phi_x^+ = i\mu\phi^+ + F(\phi^+, \phi^-) \quad (14)$$

$$\phi_x^- = -i\mu\phi^- - F(\phi^+, \phi^-) \quad (15)$$

where $F(\phi^+, \phi^-)$ is a coupling term, and μ is a kind of wavenumber. Using Eq.(11), Eq.(7) is expressed as follows:

$$\phi_{xx} + \frac{v_x}{v}\phi_x + \mu^2\phi = 0 \quad (16)$$

$F(\phi^+, \phi^-)$ is found to be

$$F(\phi^+, \phi^-) = -\frac{(\mu\nu)_x}{2\mu\nu}(\phi^+ - \phi^-) \tag{17}$$

by substituting Eqs.(13)~(14) into Eq.(16). The pseudo-operator $\mu\nu$ can be given by

$$\mu\nu = k\left\{\alpha - \frac{\beta}{2}(1-\gamma)\delta\right\} + O(k\delta)^2 \tag{18}$$

Differentiating Eq.(18) with respect to x yields

$$(\mu\nu)_x = (k\alpha)_x - \frac{1}{2}\{k\beta(1-\gamma)\delta\}_x \tag{19}$$

Using Eq.(12) and Eqs.(17) ~ (19), Eqs.(14) and (15) can be expressed as follows:

$$\begin{aligned} \phi_x^+ = ik \left[\left\{ 1 + \frac{\beta}{2\alpha}(1-\gamma)\delta \right\} \phi^+ + \frac{1}{2k^2\alpha}(\alpha\phi_y^+)_y \right. \\ \left. - \frac{\beta}{2k^2\alpha}(1-\gamma)(\delta\phi_y^+)_y \right] - \left\{ \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta}{4\alpha}(1-\gamma)\delta_x \right\} (\phi^+ - \phi^-) \end{aligned} \tag{20}$$

$$\begin{aligned} \phi_x^- = -ik \left[\left\{ 1 + \frac{\beta}{2\alpha}(1-\gamma)\delta \right\} \phi^- + \frac{1}{2k^2\alpha}(\alpha\phi_y^-)_y \right. \\ \left. - \frac{\beta}{2k^2\alpha}(1-\gamma)(\delta\phi_y^-)_y \right] + \left\{ \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta}{4\alpha}(1-\gamma)\delta_x \right\} (\phi^+ - \phi^-) \end{aligned} \tag{21}$$

The relation between the potential amplitude and the wave amplitude is

$$\phi^+ = -\frac{ig}{\omega} A e^{ik_0x} \tag{22}$$

$$\phi^- = -\frac{ig}{\omega} B e^{-ik_0x} \tag{23}$$

where k_0 is a reference wavenumber. Substituting Eqs.(22) and (23) into Eqs.(20) and (21) yields

$$\begin{aligned} A_x + \left[ik_0 - ik \left\{ 1 + \frac{\beta(1-\gamma)\delta}{2\alpha} \right\} + \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta(1-\gamma)\delta_x}{4\alpha} \right] A \\ - \frac{i}{2k\alpha}(\alpha A_y)_y + \frac{i\beta(1-\gamma)}{2k\alpha}(\delta A_y)_y = \left\{ \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta(1-\gamma)\delta_x}{4\alpha} \right\} B e^{-2ik_0x} \end{aligned} \tag{24}$$

$$\begin{aligned}
 B_x + \left[-ik_0 + ik \left\{ 1 + \frac{\beta(1-\gamma)\delta}{2\alpha} \right\} + \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta(1-\gamma)\delta_x}{4\alpha} \right] B \\
 + \frac{i}{2k\alpha} (\alpha B_y)_y - \frac{i\beta(1-\gamma)}{2k\alpha} (\delta B_y)_y = \left\{ \frac{(k\alpha)_x}{2k\alpha} - \frac{\beta(1-\gamma)\delta_x}{4\alpha} \right\} A e^{2ik_0x} \quad (25)
 \end{aligned}$$

Eqs.(24) and (25) are the coupled parabolic equations for forward- and backward-scattered waves. Detail deviation is seen in Mase et al. (1995).

BRAGG SCATTERING DUE TO POROUS SUBMERGED BREAKWATERS

Procedure of numerical calculations

Eqs.(24) and (25) were finite-differentiated by the Crank-Nicolson method. The procedure of numerical calculations is as follows:

- 1) Setting $B = 0$ in the right hand side of Eq.(24), we calculate Eq.(24) for A in the forward direction;
- 2) Using the calculated A for the right hand side of Eq.(25), we calculate Eq.(25) for B in the backward direction;
- 3) Using the calculated B in the previous step, we solve Eq.(24) for A ;
- 4) Using the calculated A in the previous step, we solve Eq.(25) for B .

The procedure of 3) and 4) is repeated until getting convergence of the calculated results of A and B . A preliminary calculation revealed that four repetition was enough to reach the convergence.

Numerical conditions

The following conditions were adopted in the numerical calculations:

- 1) The analytical domain is 500 m \times 500 m;
- 2) The model beaches are constant water depth of 8 m, and 1/25 uniform slope;
- 3) Impermeable and permeable submerged breakwaters of elliptic shape (see, Mase et al., 1995), are installed at the interval of 40 m over constant and sloping beaches;
- 4) The height of the breakwaters is changed by 1.5 m and 2.5 m;
- 5) Characteristics of porous medium are selected as $n = 0.4$, $\tau = 1.0$, and $f = 1.0$;
- 6) Waves propagate in the direction of x axis. The incident wave amplitude is 1 m, and the wave period is changed by 8 s, 10 s, and 12 s.

Calculated results and discussions

When the wave period is 10 s, the resonant Bragg reflection condition is satisfied in the constant water depth. The calculated results to be shown hereafter are those in the case of wave period of 10 s. Figure 1(a) shows the contour of the forward-scattered wave amplitude, Fig.1(b) the backward-scattered wave amplitude, and Fig.1(c) the total wave amplitude for the case of impermeable submerged breakwaters of which height is 2.5 m. It is seen from Fig.1(a) that the amplitude becomes large behind the elliptic breakwaters similar to the case of a large shoal. Fig.1(b) indicates that the breakwaters generate the reflected waves. In Fig.1(c), the two-dimensional standing wave pattern can be seen.

(c) Total Wave Amplitude

Fig.1 Wave Transformation due to Impermeable Submerged Breakwaters over Constant Water Depth

Fig.2 Spatial Change of Total Wave Amplitude along Two Lines

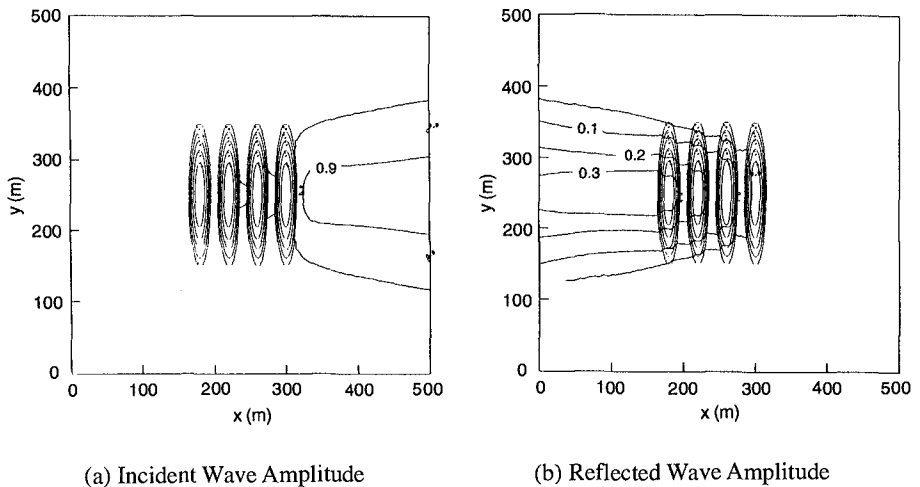

Fig.3 Wave Transformation due to Permeable Submerged Breakwaters over Constant Water Depth
(Continued)

The spatial distribution of the wave amplitude along $y = 250$ m and $y = 350$ m is shown in Fig.2. In an one-dimensional case, we can see that the transmitted waves downstream the ripples are reduced by utilizing the Bragg resonant scattering (Mase and Takeba, 1994); however, in a two-dimensional case, the wave height behind submerged breakwaters does not become small.

(c) Total Wave Amplitude

Fig.3 Wave Transformation due to Permeable Submerged Breakwaters over Constant Water Depth

Fig.4 Spatial Change of Total Amplitude along Two Lines

Figure 3 shows the result of the case of permeable breakwaters of 2.5 m in height, where the figure (a) is the contour of the forward-scattered wave amplitude, the figure (b) the back-scattered wave amplitude, and the figure (c) the total wave amplitude. Figure 4 is the spatial change of total wave amplitude along $y = 250$ m (solid line) and $y = 350$ m (dotted line). Comparing these figures with those of Figs.1 and 2, we can see that the standing wave pattern and the increase in wave height behind the breakwaters are weakened due to energy dissipation in the porous medium.

Within the surf zone, wave energy is dissipated. To include the energy dissipation due to wave breaking in the coupled parabolic equations, an energy dissipation term is required. Dally et al. (1985) proposed an energy dissipation model which assumed that there is a stable wave height after breaking equal to some fraction of the water depth and that the rate of energy dissipation in the surf zone is proportional to the difference between the actual wave energy flux and the stable wave energy flux, $(EC_g)_s$. The model is as follows:

$$\frac{d(EC_g)}{dx} = -W = -\frac{K}{h} \{ EC_g - (EC_g)_s \} \quad (26)$$

where E is the wave energy. The stable wave height is given by $H_s = \gamma h$. In this study,

Fig.5 Wave Transformation due to Permeable Submerged Breakwaters over Sloping Beach

Fig.6 Spatial Change of Total Amplitude along Line of $y = 250$ m

$K = 0.15$ and $\gamma = 0.4$ were adopted. And the wave breaking condition of $H_b = 0.78h$ was employed, where wave height H is defined as $2|A|$.

A coefficient of energy dissipation is defined as

$$W_r = W / E \tag{27}$$

In order to include energy dissipation in the coupled parabolic equations, the term of $W_r A / (2C_g)$ was added in the left hand side of Eq.(24).

Figure 5 shows the wave transformation over a uniform sloping beach existing a group of permeable submerged breakwaters. Figure 6 shows the spatial distribution of wave amplitude along the line of $y = 250$ m. Wave breaking occurs around $x = 300$ m, and wave begins to decrease and again increases toward the shore. Second wave breaking occurs around $x = 380$ m, and wave amplitude continues to decrease.

CONCLUSIONS

In order to deal with wave transformations due to permeable submerged breakwaters, we developed a wave equation of elliptic type taking account of the effects of porous medium, and the wave equation was transformed into coupled parabolic equations. It was assumed, in the theory, that the mean water depth and the thickness of porous layer were slowly varying and the bottom undulation was rapidly varying compared to the wavelength of surface waves.

Numerical examples of the Bragg scattering were shown in horizontal two-dimensional case. Wave amplitudes became large behind a group of submerged breakwaters due to the wave refraction-diffraction, even when the resonant Bragg reflection condition was satisfied. When the breakwaters were permeable, the standing wave pattern and the increase in wave height behind the breakwaters were weakened due to energy dissipation in the porous medium.

CHAPTER 184

BEM-FEM COMBINED ANALYSIS OF NONLINEAR INTERACTION BETWEEN WAVE AND SUBMERGED BREAKWATER

N.Mizutani¹, W.G. McDougal², A.M. Mostafa³

ABSTRACT:

A combined BEM-FEM model has been developed to study the nonlinear dynamic interaction between a submerged breakwater and waves. The resistance coefficients in the equations of motion inside the porous media have been experimentally determined based on measured values of the wave forces on spherical armor units in a submerged breakwater. Comparisons of the numerical model results with the experimental measurements indicate that this modification has improved the model accuracy in simulating the wave deformation and the energy dissipation due to a submerged breakwater. Results also show that the model gives good estimates for the wave kinematics inside and around the breakwater which are necessary to compute the stable armor stone weight.

INTRODUCTION:

Submerged breakwaters have several advantages over the conventional surface piercing structures including aesthetics, less impact on the near shore water quality and ability to trigger early wave breaking. Their use is also recommended on recreational beaches to ensure safe conditions. They are usually constructed from rubble and may be protected by an armor layer of large stones or concrete blocks.

Earlier researchers focused on wave deformation and energy dissipation due to submerged breakwaters, but less interest was given to their internal properties and shape. Driscoll et al. (1992) studied the harmonic generation and transmission past

³ Graduate student, M.Eng., Dept. of Civil Eng., Nagoya University, Nagoya 464-01, Japan

a submerged impermeable rectangular obstacle. They conducted laboratory experiments and compared the results with a linear scattering model and a fully nonlinear model. Cruz et al (1992) derived a set of nonlinear vertically integrated equations similar to that of Boussinesq to estimate the wave transformations past a submerged permeable breakwater. They found that their equations work well in the region of cnoidal waves, but the transmitted and the broken wave characteristics could not be well predicted. Gu and Wang (1992) linearized the porous flow equations inside the submerged breakwater using the equivalent energy principle and developed a model based on the Boundary Equation Method (BEM). They found that maximum wave energy dissipation can be achieved at practical permeability levels.

Based on modified Navier-Stokes equations, McCorquodale and Hannoura (1978) developed the flow equations inside the porous media and applied them to the case of rubble mound breakwaters. A mixed numerical model was also developed to simulate the wave motion inside rubble mound breakwaters and, hence, check the stability of the seaward slope (Hannoura and McCorquodale, 1985). Ohyama and Nadaoka (1991) developed an idealized numerical wave tank consisting of sponge layer(s) and the non-reflective wave source developed by Brorsen and Larsen (1987). They used the BEM and proved that their proposed wave tank is applicable for use with irregular and nonlinear wave fields.

Sakakiyama et al. (1991) developed a porous body model analysis of nonlinear wave transformations to study the velocity, pressure fields and free surface displacement in and near rubble mound and composite breakwaters. They considered the flow to be rotational inside and outside the porous media, but their numerical model required a very long CPU run-time. Moreover, in a comparison between permeable and impermeable submerged breakwaters, it has been found that the wave reduction is slightly affected by the porosity of the breakwater (Sakakiyama, 1992).

For wide crown submerged breakwaters, the flow velocities and the wave field behind the breakwater are small and assuming irrotationality of the flow in the wave field may be reasonable. This will reduce the computation time and cost. Therefore, a hybrid-type numerical model has been developed and used to simulate the non-linear dynamic interaction between waves and rectangular permeable submerged breakwater considering irrotational flow in the wave field, but rotational flow inside the porous media (Mizutani et al., 1995).

This study has been conducted to develop an accurate numerical model for the simulation of the nonlinear dynamic interaction between waves and submerged breakwater with irregular cross section. An idealized wave tank, similar to that of Ohyama and Nadaoka (1991), has been used to simulate the nonlinear wave field. Modified Navier-Stokes equations have been employed to simulate the flow inside the porous media (McCorquodale and Hannoura, 1978). The Boundary Element Method (BEM) has been used to develop a numerical model for the wave field.

The Finite Element Method (FEM), based on the weighted residual technique, has been used to solve the flow problem inside the submerged breakwater. The link between the two models has been maintained through boundary conditions on the interface between the wave and porous media fields. The BEM-FEM model computes the wave deformations and the flow inside the submerged breakwater simultaneously at each time step in a time marching scheme.

The resistance coefficients in Navier-Stokes equations have been modified through comparison with a Morison type equation for evaluating the wave forces on a spherical armor unit. The measured values of the wave forces and velocities in the experiments (Mizutani et al., 1994) have been used to estimate the drag and inertia coefficients.

GOVERNING EQUATIONS AND MODEL DEVELOPMENT

Wave Field

The flow in the wave field has been assumed to be irrotational and the water is considered inviscid and incompressible. The idealised wave tank used in this study is shown in Fig.1 and it is governed by the following Poisson equation (Brorsen and Larsen, 1987).

$$\frac{\partial^2 \phi}{\partial X^2} + \frac{\partial^2 \phi}{\partial Z^2} = q^* \tag{1}$$

$$q^* = U^*(Z, t)\delta(X - X_s) \tag{2}$$

where ϕ is the velocity potential; X and Z are the horizontal and vertical coordinates, respectively; q^* corresponds to the flux density at the wave-making source and is zero elsewhere; U^* is the flux density at the wave-making source; δ is Dirac's delta function and X_s is the X -position of the wave-making source. Eq.1 is subjected to the following boundary conditions (see Fig.1):

Fig.1 Wave tank for wave-submerged breakwater dynamic interaction

$$\frac{\partial \phi}{\partial n} = n_z \frac{\partial \eta}{\partial t} \quad (\text{on } S_f) \quad (3)$$

$$\frac{\partial \phi}{\partial n} = 0 \quad (\text{on } S_b) \quad (4)$$

$$\frac{\partial \phi}{\partial n} = V_n \quad (\text{on } S_s) \quad (5)$$

$$\frac{\partial \phi}{\partial t} + \frac{1}{2}(\nabla \phi)^2 + g\eta + \mu\phi - \int_{X_1}^X \frac{\partial \mu}{\partial X} \phi dX = 0 \quad (\text{on } S_e) \quad (6)$$

$$\frac{\partial \phi}{\partial X} = \frac{1}{\sqrt{gh}} \left(\frac{\partial \phi}{\partial t} + \mu\phi + \int_{X_2}^X \frac{\partial \mu}{\partial X} \phi dX \right) \quad (\text{on } S_L) \quad (7)$$

$$\frac{\partial \phi}{\partial X} = -\frac{1}{\sqrt{gh}} \left(\frac{\partial \phi}{\partial t} + \mu\phi - \int_{X_3}^X \frac{\partial \mu}{\partial X} \phi dX \right) \quad (\text{on } S_R) \quad (8)$$

$$\mu_{\max} = (0.25 \sim 0.50) \sqrt{\frac{g}{h}} \quad (9)$$

where n_z is the directional cosine of the normal outward from the boundary with the Z axis; t is time; V_n/m is the porewater velocity normal to the boundary; m is the porosity; h is the water depth; and η is the water surface elevation above SWL. μ is a damping factor which varies linearly inside the sponge layer from zero at the beginning of the layer to μ_{\max} at the open boundary (see Fig. 1).

Ohyama and Nadaoka (1991) have found that if the value of the coefficient in Eq. 9 ranges from 0.25 to 0.50 and the sponge layer width is more than one wave length, the coefficient of reflection from the sponge layer will be less than 2%. Eq. 6 can represent the free surface inside and outside the sponge layer since $\mu = \partial \mu / \partial X = 0$ outside the layer and, hence, the equation is reduced to the original dynamic boundary condition.

Applying Green's theorem, the integral form of Eq. 1 can be written as follows (Brebbia and Walker, 1980):

$$\alpha(q)\phi(q) + \int_s \left(\phi \frac{\partial G}{\partial n} - \frac{\partial \phi}{\partial n} G \right) ds + \iint_{\Omega} q * G d\Omega = 0 \quad (10)$$

where $\alpha(q)$ and $\phi(q)$ are the internal boundary angle and velocity potential at point (q) , respectively; s represents the outer boundary; and G is the Green's function defined as:

$$G = \ln(1/r) + \ln(1/R) \quad (11)$$

where r is the distance between the point of interest (q) and other domain points and R is the distance between the point (q) and the image of other domain points considering the seabed as a mirror line.

The weighted residual method has been applied to integrate the dynamic boundary condition on the free surface using linear elements and weighting factor ϖ resulting in the following integral equation.

$$\int \varpi \left\{ \frac{\partial \phi}{\partial t} + 0.5 \left(n_z^2 \left[\frac{\partial \eta}{\partial t} \right]^2 + \left[\frac{\partial \phi}{\partial s} \right]^2 \right) + g\eta + \mu\phi - \int \frac{\partial \mu}{\partial X} \phi dX \right\} ds = 0 \quad (12)$$

Further details about this method are given in Ohyama and Nadaoka (1991).

Initial condition:

The water surface elevation above the SWL, the velocity potential and their time derivatives are set to zero at the initial time step of the program (cold start). The model ramps up from this condition. Iterations for the location of the nonlinear water surface are made at each time step in a time marching scheme.

Porous Media

The flow in the porous media is considered to be rotational and the porewater is assumed to be incompressible but viscous. The continuity equation and the equations of motion (McCorquodale and Hannoura, 1978) for the flow inside the porous media are as follows:

$$\frac{\partial U}{\partial X} + \frac{\partial W}{\partial Z} = 0 \quad (13)$$

$$A \frac{\partial U}{\partial t} + BU \frac{\partial U}{\partial X} + CW \frac{\partial U}{\partial Z} + D \frac{\partial P}{\partial X} + EU + FU \sqrt{U^2 + W^2} = 0 \quad (14)$$

$$A \frac{\partial W}{\partial t} + BU \frac{\partial W}{\partial X} + CW \frac{\partial W}{\partial Z} + D \frac{\partial P}{\partial Z} + EW + FW \sqrt{U^2 + W^2} = 0 \quad (15)$$

where

$$A = \frac{\left(1 + \frac{1-m}{m} C_{AX}\right)}{mg}, \quad B = C = \frac{1}{m^2 g}, \quad D = \frac{1}{\gamma}, \quad E = \frac{4.6\nu}{gmD^2}$$

$$F = \frac{0.79}{gm^{1/2}D}, \quad P = p + \gamma Z$$

and U, W, P are the horizontal and vertical water particle velocities and the porewater pressure, respectively; p is the dynamic porewater pressure; C_{AX} is the added mass coefficient; g is the acceleration of gravity; ν is the kinematic viscosity of water; γ is the unit weight of water; and D is the mean particle diameter.

The porous media equations are subjected to the following boundary conditions:

$$P = -\frac{\partial \phi}{\partial t} - \frac{1}{2} \left\{ \left(\frac{V_n}{m} \right)^2 + V_s^2 \right\} - \gamma Z \quad (\text{on } S_s) \quad (16)$$

$$V_n = (W \cos \theta \pm U \sin \theta) \quad (\text{on } S_s) \quad (17)$$

$$V_s = \frac{\partial \phi}{\partial S} \quad (\text{on } S_s) \quad (18)$$

$$V_n = 0 \quad (\text{on } S_b) \quad (19)$$

where V_s is the water particle velocity in the tangential direction to the boundary and θ is the inclination of the permeable boundary on the X axis.

The continuity of the normal velocity component (V_n) and the porewater pressure have been considered along the surface boundary of the submerged breakwater. The tangential component of the water velocity along the breakwater surface has been solved using the Finite Difference Method (FDM).

The FEM in the porous media is based on the weighted residual method. A special isoparametric trapezoidal element has been considered for discretization of the FEM domain. A four node element for the velocity (u and w) and eight node element for the pressure (p) have been employed to solve the problem. Linear interpolation and weight functions have been used for the continuity equation but a special technique has been applied to the equations of motion (Mizutani et al., 1995).

Initial conditions:

The velocity, pressure and their derivatives have been set to zero at the initial time step of the program (cold start) and a time marching scheme has been used to compute the flow inside the porous media at subsequent steps.

BEM-FEM Model Development

The BEM model for the simulation of the wave motion and the FEM model for porous flow have been linked together into one model that computes simultaneously the wave deformations outside the breakwater and the porous media flow inside the breakwater. The time derivative of any variable ψ at any time step (n) in the porous media or the wave field equations is solved using Taylor series expansion as follows:

$$\left(\frac{\partial \psi}{\partial t}\right)^n = 2 \frac{\Delta \psi}{\Delta t} - \left(\frac{\partial \psi}{\partial t}\right)^{n-1} \quad (20)$$

The nodes along the surface boundary of the breakwater and the water surface are located at spacing less than $L/20$ (where L is the wave length). The location of the FEM nodes are selected to be the same as that of the BEM along the interface between the breakwater and the wave domain. The time step of the model is initially selected to be $T/24$ and then the results are compared to the experimental results. If the difference between the numerical and experimental results is more than an accepted tolerance, smaller time steps are selected. It has been found that time increments less than $T/24$ may be needed for steep waves.

PHYSICAL MODEL

Submerged breakwater experiments were conducted in the coastal engineering laboratory at Nagoya University. These experiments measured the wave forces on spherical armor units (F_x and F_z), wave deformations and the water velocity around the surface of the breakwater. The submerged breakwater was constructed of spherical glass balls 3.0 cm in diameter and placed in a wave tank of 25.0 m long and 0.70 m wide. The breakwater had a crown width of 220 cm, height of 21 cm, and the seaward face had a slope of 3.2 (horizontal) : 1 (vertical). The balls were arranged to produce the maximum densely packed arrangement and their computed corresponding porosity was 26%. Two possible positions were considered for the spheres, namely, embedded and non-embedded positions (Mizutani et al., 1992). The experiments were conducted in a water depth of 28.0 cm so that the still water depth over the crown was 7.0 cm. Wave heights (H) of 3.0, 5.0, 7.0 and 10.0 cm and wave periods (T) of 1.0, 1.40 and 1.80 sec were examined. Records were sampled for one minute at a rate of 50 Hz.

It was observed that the waves pass over the breakwater without breaking for wave heights 3.0 and 5.0 cm, but break for larger heights. Studies were formerly conducted to estimate the wave forces on armor units over a submerged breakwater and proved that the dimensionless non-breaking wave force, normalised by the wave height, on the armor is higher than the breaking one (Mizutani et al., 1992). Therefore, the non-breaking wave conditions will only be used for comparison and discussions in this study.

ESTIMATION OF WAVE FORCES

Standard Morison type equations have been found to be generally applicable to estimate the horizontal wave forces on the spherical armor units of submerged breakwaters (Rufin et al., 1996). However, in this study, the wave force has been considered to be composed of three components as follows:

$$F_x = \frac{1}{6}C_{MX}\rho\pi D^3 \frac{\partial u_r}{\partial t} + \frac{1}{8}C_{DX1}\rho\pi D^2 u_r \sqrt{u_r^2 + w_r^2} + 3C_{DX2}\rho v\pi D u_r \quad (21)$$

By applying Eq.21, the horizontal wave force acting on a small element of a homogeneous porous submerged breakwater can be written as follows:

$$F_x = \rho V C_{MX} \frac{\partial u_r}{\partial t} + \frac{1}{2} C_{DX1} \rho A_x u_r \sqrt{u_r^2 + w_r^2} + C_{DX2} \frac{3\rho v S}{D} u_r \quad (22)$$

where u_r and w_r are the porewater velocity components in the horizontal and vertical directions, respectively; S is the surface area of the armor unit affected by friction with the flow; ρ is the porewater density; C_{MX} is the coefficient of mass; and C_{DX1} and C_{DX2} are the drag coefficients in the X direction. A_x is the projected area of the armor unit in the X direction and V is its volume. This form of the Morison equation includes the common inertia and quadratic drag terms but also has a linear drag term. This linear term is analogous to Darcy flow in groundwater.

To solve the modified Morison equation, the porewater velocities (u_r , w_r), V , S and A_x have been expressed as follows and inserted into Eq.22.

$$A_x = (1 - m)\Delta Z \quad (23)$$

$$V = (1 - m)\Delta X\Delta Z \quad (24)$$

$$S = 2(1 - m)\Delta X \quad (25)$$

$$u_r = \frac{U}{m}, \quad w_r = \frac{W}{m} \quad (26)$$

where ΔX , ΔZ are the horizontal and vertical dimensions of the computational unit, respectively. Therefore, Eq.22 can be now expressed in terms of the flow parameters inside the porous media and the computational unit size as follows:

$$F_x = \rho \frac{(1-m)}{m} C_{MX} \frac{\partial U}{\partial t} \Delta X \Delta Z + \frac{1}{2} C_{DX1} \rho \frac{(1-m)}{m^2} U \sqrt{U^2 + W^2} Z + C_{DX2} \frac{3\rho v S}{D} U \quad (27)$$

Furthermore, the force per unit weight of the porewater (f_x) can be expressed as follows:

$$f_x = \frac{(1 - m)}{gm^2} C_{MX} \frac{\partial U}{\partial t} + \frac{C_{DX1}(1 - m)}{2m^3 g \Delta X} U \sqrt{U^2 + W^2} \Delta Z + \frac{3C_{DX2} v}{gmd} U \quad (28a)$$

$$d = \frac{m\Delta X\Delta Z}{S} \quad (28b)$$

By comparing Eq.28 with the horizontal equation of motion in the porous media (Eq.14), the coefficients E and F are now modified and can be expressed as follows:

$$E = \frac{3C_{DX2} v}{gmd} \quad (29a)$$

$$F = \frac{C_{DX1}(1 - m)}{2m^3 g \Delta X} \quad (29b)$$

The size of the computation unit should be selected such that the side length is not less than D and, therefore, the value of $\Delta X = \Delta Z = D$ has been used in Eq.29 to compute the resistance coefficients as shown in Eq.30. Consequently, the coefficients C_{MX} , C_{DX1} and C_{DX2} should be first estimated in order to be able to use the modified equations of motion.

$$E = \frac{6(1 - m)C_{DX2} v}{gm^2 D^2} \quad (30a)$$

$$F = \frac{C_{DX1}(1 - m)}{2m^3 g D} \quad (30b)$$

ESTIMATION OF THE RESISTANCE COEFFICIENTS

Using the experimentally measured values of the wave forces and water velocities, the values of the coefficients (C_{MX} , C_{DX1} and C_{DX2}) have been estimated for the previously described wave conditions by means of the least square technique applied to Eq.21. The corresponding values of these coefficients for the case of non-embedded spheres have been plotted against, the Keulegan-Carpenter number, KC_x in Figs. 2-4. The KC_x number is $U_m T/D$ where U_m is the maximum horizontal porewater velocity. Also shown are the data for the case of isolated spheres by Iwata and Mizutani (1989).

Fig.2 Coefficient of mass (C_{MX}) versus KC_x

Fig.3 Coefficient of drag (C_{DX1}) versus KC_x

Fig.4 Coefficient of drag (C_{DX2}) versus KC_x

It is clear in Fig.2 that the value of C_{MX} is almost constant and independent of KC_x . Also, the values for isolated spheres and armor spheres are very similar. The value of C_{MX} has been estimated to be 0.96 ($C_{AX} = -0.04$) by taking the average over all computed values. This value has been used in the numerical model for comparison with the experiment.

The value of C_{DX1} ranges from 0.20 to 0.60 and is only weakly dependent upon KC_x as shown in Fig.3. The values of C_{DX1} for isolated spheres are generally higher than that for the armor units of a submerged breakwater. It is worth mentioning that the coefficient of drag C_{DX1} , formerly estimated by a standard Morison type equation and neglecting the linear friction term, experienced large scatter at small values of KC_x (Rufin et al., 1996). It has been estimated that $C_{DX1} = 0.45$ for use in the numerical model computations by taking the average over all the computed values.

The experimental results for C_{DX2} show large scatter, especially at large KC_x . The range is from a minimum of near zero for low KC_x to a maximum near to 200 for high KC_x . However, it has been found that the relative importance of the linear friction term including the drag coefficient C_{DX2} is very small at values of $KC_x > 10$, where flow separation occurs. Its effect is only considerable at low values of KC_x . Therefore, a value of $C_{DX2} = 25.0$ has been estimated for use in the numerical model by considering the average of its computed values for the range of $KC_x < 10.0$.

RESULTS AND DISCUSSIONS

The BEM-FEM model, employing modified resistance coefficients and their experimentally estimated values, has been used to model waves over a submerged breakwater. The comparisons with experimental results confirm the importance of the modified coefficients.

A velocity vector diagram and the wave profile along the wave tank at $t/T=5.0$ are shown in Fig.5. It is obvious that the water flows into the breakwater at the locations of the wave crests and flows out of it at locations of the wave trough. The areas over the leading edge of the crown and on the offshore slope have higher velocities than the other locations inside the breakwater. There is a rapid change in the free surface as the waves encounter the structure.

Fig.5 Wave deformation around and water velocity inside the breakwater at $t/T=5.0$ ($h/gT^2 = 0.029$, $H/h = 0.11$)

The computed and measured water surface levels over the crown of the breakwater at $X/L=0.30$ and $X/L=0.50$ for a wave height (H) 3.0 cm and period (T) 1.40 sec are plotted in Fig.6. The BEM-FEM model agrees well with the measured water levels along the crown of the submerged breakwater. The waves are very nonlinear and asymmetric. Computations have also been conducted to evaluate the average wave setup ($\bar{\eta}$) at $X/L=0.30$ and 0.50 over the crown. It is obvious that the differences between the BEM-FEM model results and the experiment are small (Fig.6).

Fig.6a Free surface elevation at $X/L=0.30$ over the crown
($h/gT^2 = 0.015$, $H/h = 0.11$)

Fig.6b Free surface elevation at $X/L=0.50$ over the crown
($h/gT^2 = 0.015$, $H/h = 0.11$)

The value of η_{rms} along the wave tank has been used to represent the wave energy and comparison has been made between its measured and computed values along the wave tank (Fig.7). The measured and computed values are in good agreement. A partial standing wave is formed offshore of the breakwater and nonlinear wave damping occurs across the crown leading to a small transmitted wave to the lee side.

Fig.7 water level variation along the wave tank ($h/gT^2 = 0.015, H/h = 0.11$)

The computed and measured values for the maximum water particle velocity components (U_m and W_m) along the crown of the breakwater are shown in Fig.8. While U_m has been used to denote the maximum horizontal porewater velocity over the crown, W_m has been used to express the maximum vertical seepage velocity along it. The results are compared for a wave height (H) of 3.0 cm and period (T) of 1.0 sec. It can be observed that the numerical model results agree qualitatively well with the experimental ones. However, the values computed by the numerical model seem to be higher than that in the experiment. The velocities have been measured in the experiment at a small distance over the crown but, in the BEM-FEM model, the velocities have been computed exactly on the crown surface. It has been found that the locations of the maximum horizontal and vertical velocities are located at the offshore crown corner of the breakwater. This is in agreement with earlier investigations that have also proved experimentally that the point of maximum wave force is at the same location (Mizutani et al., 1992).

Fig.8a Maximum horizontal porewater velocity along the crown ($h/gT^2 = 0.029, H/h = 0.11$)

Fig.8b Maximum vertical seepage velocity along the crown
($h/gT^2 = 0.029$, $H/h = 0.11$)

CONCLUSIONS AND PERSPECTIVES

- 1) A numerical model is presented which simulates the nonlinear interaction between free surface waves and a submerged permeable breakwater. Modified resistance coefficients have been developed from experimental measurements and improved the results of the BEM-FEM model.
- 2) The model accurately predicts the partial standing wave that is formed offshore of the breakwater and the damping which occurs along it causing a small wave to be transmitted to the lee of the breakwater. The model can accurately estimate the transmitted wave height resulting from the combined effects of reflection, shoaling and dissipation.
- 3) The numerical model has been shown to compute with good accuracy the wave kinematics inside and around the submerged breakwater. Therefore, this model can be used further for studying the stability of the armor of the breakwater.
- 4) The point of maximum velocity along the submerged breakwater is at the offshore corner of the crown for all wave conditions tested in this study. As a result, the location of the maximum wave forces on the armor units is also at the offshore crown corner.
- 5) The model may be used to optimize the submerged breakwater shape, size and properties for site specific design requirements.

CHAPTER 185

Regulation of Nearshore Circulation by Submerged Breakwater for Shore Protection

Hisamichi Nobuoka¹, Isao Irie², Hajime Kato¹ and Nobuo Mimura¹

Abstract

A submerged breakwater induces a circulation with onshore currents over the structure and offshore currents through gaps, resulting in sediment loss to the offshore region. A new submerged breakwater with inclined multiple blades is tested by laboratory experiments and numerical simulations. This breakwater can generate offshore currents over the structure and onshore currents through gaps suggesting onshore sediment supply.

1. Introduction

Submerged breakwaters and artificial reefs have been widely constructed to prevent coastal erosion without spoiling landscapes of coast. However, wave set-up induced in the onshore area of the structure by wave breaking often generates strong nearshore circulation. The directions of cross-shore currents of the circulation are onshore above the structures and offshore in their gaps (**Figure 1(a)**) (Browder, 1996; Uda, 1987).

These currents reduce the efficiency of shore protection, since the current crossing over the structure does not bring sediment onshore, while the offshore current takes sediment away to the offshore. If an opposite pattern of circulation, in which the direction of flow is onshore in the gaps of the structures (**Figure 1(b)**), can be formed, sediment will be supplied from offshore to onshore. In order to generate such current, it is need to develop a structure which dose not induce wave set-up in the onshore area. Authors have proposed such structures (e.g. Irie 1991).

This study aims at finding a technical solution which can meet the above requirement to control current's direction. To this end, a new

2 Dept. of Civil Eng. Faculty of Eng., Kyushu University, Hakozaki, Fukuoka, 812, Japan

submerged breakwater with multiple inclined blades shown in **Figure 2** is proposed.

In the study, experiments were performed to measure the wave set-up and patterns of the induced circulation around a structure in a wave flume and a wave basin. Numerical calculations using a two-dimensional model were also performed to simulate the nearshore currents around a structure. Finally, the functional capacity of these structures for shore protection was evaluated on the basis of the numerical simulation.

Figure 1 Patterns of nearshore circulation

2. Methods of Experiments for Wave Set-up and Currents

Experiments were performed to examine the distributions of wave height and wave set-up and set-down around breakwaters under the condition of the uniform water depth ($h=0.35\text{m}$) in a wave flume whose length, width and height were 35m, 0.3m and 0.5m respectively. The structures examined were an artificial reef and four types of new submerged breakwaters with multiple blades; a type of blades was upright, and the others were inclined offshore as shown in **Figure 3**. The angle of blades was 15° , 30° and 45° . The height (D), spacing of the blades (B) and total length of the body (WT) was $0.5h$, $2.0h$ and $6.0h$ respectively. Each structure was set in the flume at the point of 12m onshore from the wave maker. In each case, the condition of incident waves was 6.0cm in height, and 1.02, 1.27 and 1.83s in period. Fluctuations of water surface were measured around the structure at intervals of 7cm, i.e. $0.2h$.

Figure 3 Scale of multiple blades

Another experiments were performed to measure currents around the breakwaters in a wave basin with a uniform water depth ($h=0.1\text{m}$). The basin was 246cm long, 170cm wide and 30cm high, and was equipped with a wave maker, wave absorber and filter as shown in **Figure 4**. In the experiments, models of detached breakwater ($20\text{cm}\times 60\text{cm}$), artificial reef ($60\text{cm}\times 60\text{cm}$, 6.5cm high) and multiple blades ($60\text{cm}\times 60\text{cm}$, 6.5cm high, $\theta=30^\circ$, $B=2.0h$) were set in the center of the wave basin. The conditions of incident wave were 1.7cm in height and 1.1 and 0.76s in period.

To measure the patterns of currents, floats having a diameter of 1cm were used. The weight of the floats was adjusted so that they stayed in the surface layer and bottom layer respectively. The movement of the floats was recorded by a video camera, and traced at an interval of 5 or 20s.

Figure 4 Experimental wave basin

3. Wave Set-up and Set-down Around the Multiple Inclined Blades

Figure 5 shows the distributions of wave heights and mean water level around the artificial reef (a) and multiple blades inclined by 30° (b).

In the case of artificial reef, wave transmission coefficient is approximately 40% and standing waves is observed in the offshore side. On the other hand, for the multiple blades, the transmission coefficient is approximately 70% and no standing waves form. The coefficient changed from 60 to 70% with blade slant angle and wave period.

It was found by observation of the water motion that strong wave breaking occurred on the reef. On the other hand, at the top of the multiple blades, large eddies occurred. It can be concluded that the decreases in wave height were caused by wave breaking and reflection for artificial reef and eddy formation for multiple blades.

Regarding the mean water level distributions, wave set-up occurred in the onshore area in the case of reef. While, for the case of multiple blades, the mean water level decreased gradually in the onshore direction. Wave set-down occurred in the onshore area.

For all cases of blade's slope type and wave conditions, the mean water level is rather constant except just above the breakwater. Figure 6(a) shows the difference between the mean water levels of offshore and onshore sides around the five structures, respectively. Since the water depth is constant, it was taken as the reference level. The distribution of mean water level around the structure varies systematically depending on structure's type and the slope of the inclined blades. In the case of the reef, wave set-up occur in the onshore area. For the breakwaters with blades, the larger is the blade slope, the lower is the wave set-up in the onshore area. Even wave set-down takes place for the blade slopes of 30° and 45° .

(a) artificial reef

(b) multiple blades ($\theta = 30^\circ$, $T = 1.1s$)

Figure 5 Distribution of wave height and mean water level

Figure 6(a) Difference in mean water level around the structure

The results of the cases with different wave periods are shown in Figure 6(b). The horizontal axis is a wave period and the vertical the difference in mean water level. The same tendency as mentioned above was obtained; when the slant of blades is large, the wave set-down is also large. This tendency becomes more profound as the wave period becomes large.

Figure 6 (b) Difference of mean water level in all the case of multiple blades

4. Experimental Results on Nearshore Currents

Figure 7 (a),(b),(c) show the currents at surface layer around the detached breakwater, the reef and multiple blades inclined by 30°. The wave conditions are $H=1.7\text{cm}$ and $T=1.1\text{s}$. Filled dots in the figure indicate the location of floats at an interval of 5 or 20 seconds and the square in the center of figure shows the corresponding structure.

Around the detached breakwater (**Figure 7(a)**), the flow is so weak that a circulation is not very clear. At the side of the structure, onshore and offshore currents occur near the structure and far away from the structure.

For the case of the artificial reef (**Figure 7(b)**), a clear circulation is formed around the reef, in which currents flow in the onshore and offshore directions above the structure and on its both sides, respectively. The directions of the circulation at the bottom layer were same as that of the surface layer.

A completely opposite pattern of circulation is generated for the case of breakwater with inclined blades by 30° as shown in **Figure 7(c)**; the current flows to the shore through the gaps, and juts out over the blades. In the bottom layer except above the structure, the flow is very weak and goes toward onshore. The case with different wave condition, which is 0.76s in wave period, is shown in **Figure 7(d)**. Though a pattern of circulation around the multiple blades was not so clear, the pattern of currents was same as that in the case of wave period which was 1.1s.

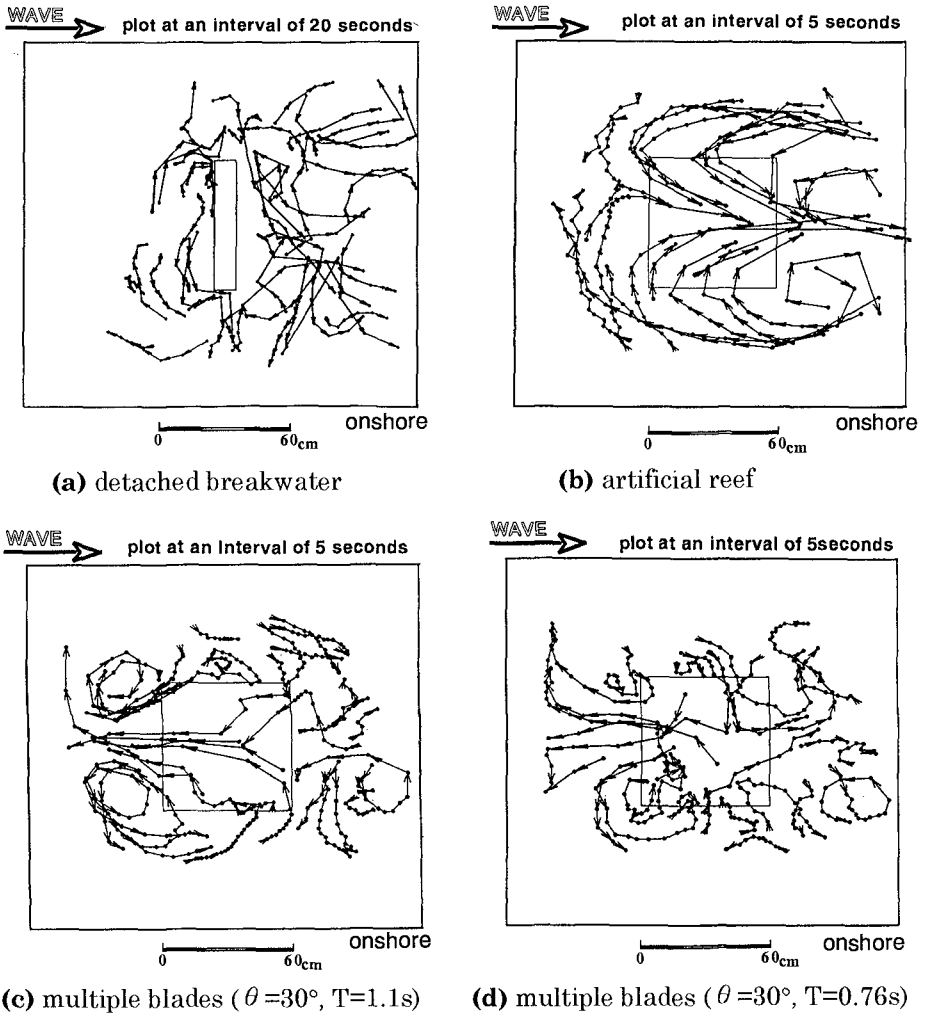

Figure 7 Nearshore currents around the structure (experiment)

5. Evaluation of Functional Capacity of Currents for Shore Protection

In order to study the currents around the submerged breakwaters in detail, a numerical model was developed.

5-1. Government Equation

Equations of conservation of mass and momentum (1), (2) and (3) for nearshore currents were used, with two additional terms to express special conditions imposed by the existence of the breakwater.

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial u (\bar{\eta} + h)}{\partial x} + \frac{\partial v (\bar{\eta} + h)}{\partial y} = 0 \quad (1)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + F_x - M_x + S_x + g \frac{\partial \bar{\eta}}{\partial x} = 0 \quad (2)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + F_y - M_y + S_y + g \frac{\partial \bar{\eta}}{\partial y} = 0 \quad (3)$$

where, u , v are x and y components of the velocity, $\bar{\eta}$ mean water level, F_x , F_y bottom friction, M_x , M_y horizontal mixing terms, and S_x , S_y radiation stress term. The bottom friction was formulated according to Longuet-Higgins(1970) with the Manning roughness coefficient being $0.013[\text{m}^{-1/3}\text{s}]$. These equations were calculated by ADI method.

5-2. Special Term

The one of special terms is needed to express the onshore momentum transport due to strong wave breaking above the reef. If this effect is not introduced, the reproduction of the flow is insufficient (Sasaki, 1990). In this study, this phenomenon was expressed by increasing the gradient of radiation stress at onshore side from wave breaking point.

The other special term is to express the mean resistance force of the inclined blades which appears as a residual stress over a period. This mean force was caused by the difference in the resistance force between the onshore and offshore directions. When the direction of water particle's motion is the same as the blade's inclination, the resistance force acting on the water mass is weak(**Figure 8(a)**). On the other hand, when the direction of flow is opposite to the blade inclination, the resistance force becomes strong(**Figure 8(b)**). Such a mechanism, therefore, can induce the difference of onshore and offshore resistance forces in a wave period. Since the offshore resistance force is stronger than onshore one, the blades exert offshore force on the water body and cause wave set-up on the offshore side.

Figure 8 Generation of the offshore residual resistance force

Figure 9 Balance of power around the multiple blades

It is assumed that the onshore and offshore resistance forces caused by blades are proportional to the square of the horizontal velocity of wave motion, and act in the direction opposite to the flow above the blades. It is also assumed that the resistance force integrated over the period of onshore or offshore flow is also proportional to the square of the maximum velocity in the corresponding period. The residual resistance force can be, therefore, evaluated by the difference in the square of maximum velocity. In this study, the horizontal maximum velocity was calculated by second-order stokes wave theory.

The three forces, which are the gradient of hydrostatic pressure, the gradient of radiation stress and the resistance force, balance near the multiple blades. This relation in area 1 shown **Figure 9** can be formulated as **Equation 4**.

$$g (\bar{\eta} + h) \frac{\Delta \bar{\eta}_1}{\Delta x} = - \frac{1}{\rho} \frac{\Delta S_{xx}}{\Delta x} + C_\alpha D \sum_1^N (u_{on(max)}^2 - u_{off(max)}^2) \quad (4)$$

The left hand side is the gradient of hydrostatic pressure. The first and the second terms in the right hand side are the gradient of the radiation stress in the water column on the blades and the mean resistance force in a wave period, respectively. C_α is a kind of resistance coefficient and was obtained by a least squares method for the cases of different blades angle.

Mean water level varied even in the offshore area of the structure, which is indicated as area 2 in **Figure 9**. It is assumed that the resistance force also acts this area. The balance of forces in area 2 is, therefore, formulated in the same way as Equation (4) using a coefficient of C_β instead of C_α , although the water depth is different from the area 1.

$$C_\alpha = -0.010 \times \theta - 0.016 \quad (5)$$

$$C_\beta = -0.013 \times \theta - 0.022 \quad (6)$$

here, the unit of θ is degree.

When the simulation of nearshore currents around the multiple blades was performed using the government equations with this resistance term, the velocities of flow became too strong. This is because the present model includes only the resistance force caused by wave motion, and does not take into account that by the currents. The coefficient of C_γ which modify the coefficient of C_α , C_β was evaluated so as to reproduce the currents well.

$$C_\gamma = 1.2 - 0.88 \times T \quad (7)$$

where, a range of a wave period, T , is from 0.76s to 1.1s for the water depth of 0.1m.

5-3. Results of Simulations for Nearshore Circulation

Figure 10(a) illustrates the currents around the detached breakwater. Very weak circulation flow occurred around the body.

For the case of artificial reef, a clear circulation was formed as shown in **Figure 10(b)**. The direction of circulation is onshore above the structure and offshore both sides of structure.

On the other hand, for the case of multiple blades, a completely opposite pattern of circulation was generated as shown in **Figure 10(c)**; the current flow to the shore through the gaps, and juts out over the blades. For the case with different wave period, the circulation was not much clear, but the same pattern appeared (**Figure 10(d)**).

These results of simulations show fairly good agreement with those obtained by experiments.

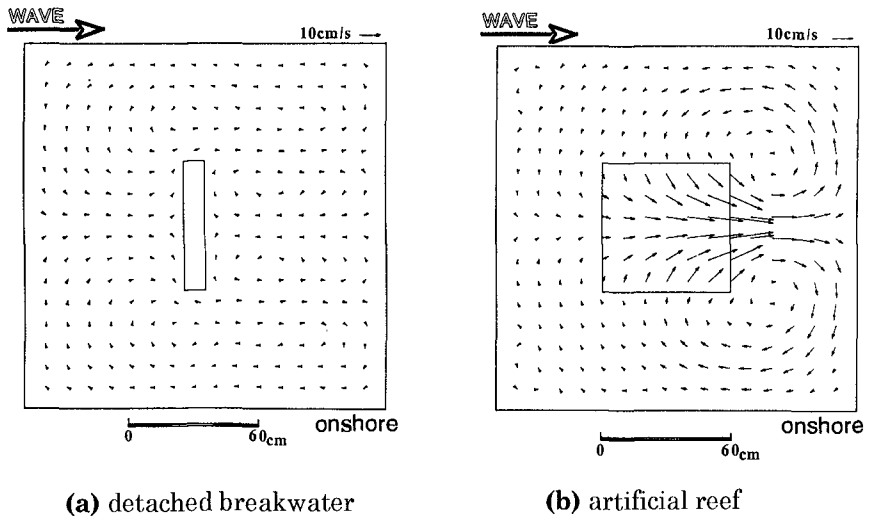

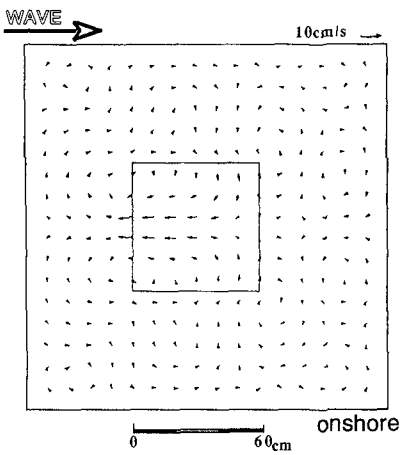

Figure 10 Nearshore currents around the structure (simulation)

5-4. Functional Capacity of Currents for Shore Protection

The effect of the induced currents for shore protection is evaluated on the basis of the result of the calculation. There are two disputed points; the one is wave set-up near shoreline, and the other is currents on the sides of breakwater. The examined structures were the detached breakwater, the artificial reef and the new submerged breakwater with multiple blades.

Wave set-up near the shoreline causes shoreline retreat, and the difference in wave set-up along the shoreline induces strong longshore currents which transport the sediments.

The wave set-up at line A-A' in **Figure 10(d)** are showed in **Figure 11**. The horizontal axis is long shore distance and the square of the center indicates the position of the structure. For the case of reef, highest wave set-up appears. On the other hand, for the case of multiple blades and detached breakwater, wave set-up was low, and the difference of mean water level in longshore direction was small, that indicates the beach would be protected.

The offshore currents on the side of the structure bring sediment offshore, resulting in shore erosion. The flow rates across the line B-B' in **Figure 10(d)** are indicated in **Figure 12**. The vertical axis shows the cross-shore flow rates; a positive value indicated the onshore flow rates.

In the cases with detached breakwaters and multiple blades inclined by 15° , no or little currents occurred, so there are no bars on the graph. The case of artificial reefs shows strong offshore currents. For the case of multiple blades, with the blade angle, the onshore currents become stronger. For the

case of multiple blades inclined by 45°, most strong onshore currents occur. It may be expected that the onshore currents supply sediment onshore.

Figure 11 Wave set-up near the shoreline

Figure 12 Cross-shore flow rates on the side of structure

6. Conclusions

This study confirmed the principle and effectiveness of a new type of breakwater with multiple blades to generate a preferable circulation pattern for preventing beach erosion. Three points should be emphasized as the conclusions of this study.

1. Wave set-down occurred in the onshore area of the new submerged breakwater with multiple inclined blades in laboratory experiments with a two-dimensional wave flume.
2. The direction of nearshore circulation around the multiple inclined blades is offshore above the structure and onshore on the sides of the structure. This pattern of the flows is opposite to that of nearshore circulation induced by artificial reefs.
3. The structure with multiple blades inclined by 45° caused the most strong onshore currents on the side of structure, which suggested that onshore transport of sediments was expected.

CHAPTER 186

Submerged breakwaters for the defence of the shoreline at Ostia Field experiences, comparison

by

Ugo Tomasicchio, Member ASCE ¹

Summary

An important study case with different defence structures and the results of the monitoring data of are reported. Field experiences are specially usefull to compare two soft structures used to defend the Lido of Ostia, i.e. the coastline of Rome at the mouth of river Tevere (Tiber)²

Introduction

Erosion phenomena along the almost 7500 km of the Italian coast are widespread and certainly have been increasing more and more during the last decades. The main causes of this aggravation are the large number of protection works against the landslides, the use of material from the river basins for building purposes and the construction of reservoirs for water supply.

Disappearance or reduction of the sandy beaches often determines a too heavy damage for the economy related to the tourism. This encourages the State or the local administrations to try to contrast the phenomena. A large number of defence interventions has been realized starting since the sixties and their importance and cost have been raising through the years. Adopted techniques have been paying an increasing attention to the results effectiveness and to the costs benefits optimization. For this last evaluation, the environmental parameters have assumed a big importance. In fact, it is clear that every defence intervention in areas which have particular tourist attractions can only be directed towards protection and, possibly, improvement of these amenities. During the recent years, the deeper attention for the environment has induced preference for soft structures like the beach nourishment and the submerged breakwaters. Even if the experience from the wide use throughout the sixties to the

¹ Politecnico di Bari, via Re David 200, 70125-Bari, Italy.

² Rome was for many centuries the *Caput Mundi* = Capital of the World (Tiber is the name in latin language; in the Roman time usual its pronunciation was Tiver, from wich many scholars consider to deduce the common name river).

eighties of the detached emerged breakwaters is only sufficient, this structure resulted to be effective for the defence of eroded beaches with a reasonable cost. A detached emerged breakwater interrupts the natural sediment longshore transport therefore the sand material which is entrapped in the sheltered area is subtracted to the downdrift coastline.

This phenomena, like the domino game, is visible at most of the Italian coasts and has given extension of this type of structure to very long coastlines (e.g. the Adriatic coastline).

Of course, their environmental result is not highly appreciated. In fact in addition to an inconvenience in the sometime wonderful seaweaves, the emerged breakwaters have often induced a worsening of the water quality in the protected area together with a strong and fast erosion phenomena at the openings between the barriers.

If the second effect, as well known, gives troubles to the swimmers, the first can induce the Health Authority to forbid the recreational use of the beach. If we realize that, generally, the defence work aim is to preserve the beach for a recreational use, the previous discussion shows, *ad abundantiam*, the unacceptableness of the emerged structures. In fact, during the Summer season, the water circulation, which is ensured only by the openings, is often insufficient for a tendentially eutrophic water. These are some of the reasons which have driven to the use of soft defence interventions, like the combination of a beach nourishment with the submerged breakwaters.

Sand material which is compatible for a beach nourishment can not easily be found in the Italian seas. Therefore, the required large volumes of necessary material for a beach nourishment are usually taken from quarries whose travel distance from the intervention area is giving sometime a too high cost. Use of the quarry must consider that the Italian territory is highly used for different purposes and, environmentally speaking, the areas still free of buildings are not less important and sometime they are in a preserved zone. On the other hand, the submerged detached breakwaters offer big benefits. They can be considered as soft structures; in fact, their environmental impact is soft (nature uses the coral reef) and they offer a low cost and effective defence of the beaches. The submerged breakwaters have been recreating sandy beaches which were completely lost with only a small negative impact on the adjacent coastline and, more important, without any reduction of the water circulation in the sheltered area during the summer. These benefits are attainable under the condition of a careful structure design. The design should consider the stability of the rubble mound, the transmission coefficient (which is related to the crest width, its submergence and wave climate) and the verification that the residual wave energy is not able to erode further the beach.

Many laboratory tests and field study have been carried out in Italy. The results from these studies allowed a verification of the indications published on this subject since the seventies and a better calibration of the relationships used for the design. Obviously, the field gives the best results for the interpretation of the phenomena and the calibration of the interventions.

The present paper aims to refer about and to discuss one of the most noising Italian defence work intervention. In particular, the purpose is to carry out a technical economical comparison between two different defence structures (beach nourishment

with reef and submerged breakwater) which have been built along two adjacent coastlines at Ostia (Roma). Their behaviour we compare. The first is an expensive - composite structure (beach nourishment and submerged barrier or reef defending a 3 km stretch). The second is a submerged rubble mound breakwater defending a 1 km long stretch. Results obtained suggest a preference for the second cheaper structure.

Fig. 1 The site of Lido of Ostia in front of Tirrenian sea

The littoral of Ostia

The littoral of Ostia extends itself to South-west and to South-east of the two mouths in which the sacred river Tevere forks itself, before flowing into the sea.

History says that the area around the river mouth has always been extending seaward.

The increment of the distance between the shoreline and the antique port of Ostia, the port of Rome at Empire time, was very rapid, causing not few problems to the transport from the Africa and Sicily regions of the provisions for the two millions of citizens.

Fig.2 (an old map of year 1680 by Mayer) shows the distance between the ports of Traiano and Claudio (Roman Emperors of the first century a.C.) and the sea. It's interesting to remember that the Port of Traiano and the next of Claudio were interested by silting up, soon after the end of their construction.

In fig. 3 (Caputo and al., 1992) the shoreline changes among 1873 and 1987 are represented. So, until year 1950, a shoreline advancement of about 2-3 m/y it has verified. No more accretion of the land area after 1950, due to the drastic reduction of the sediment transport from the river Tevere (use of material from the river basin for building purpose and the construction of about 20 reservoirs for water supply).

Fig. 2 Coastline as in old Map of Mayer (1680)

Fig. 3 Shoreline changes in the last century and in the last decades

Actually the river bed of the terminal zone has retreated, on the average, of 2 meters and the sediment transported by river has a very little size, not sufficient to stay in the inshore zone.

The result of this new situation was the erosion of the beach, in the left of the fig.3.

In the fig.4 the Lido of Ostia from the Nautical Map of 1983 is reported; in the same map four zones are distinguished (A, B, C, D) according to the years of the construction of the defence structures (the letters from A to C indicate the real time sequence of the building).

Fig. 4 Shoreline in a map of 1983. The four zones A,B,C,D.

Fig. 5 In the map of Consiglio Nazionale delle Ricerche, many results of study.

In the map (fig.5) many results of investigations and studies by National Research Council are presented: arrow shows the direction of the net longshore transport, as monitored by the sedimentologist research group.

Defence works in two last decades

To stop the shore erosion and its unacceptable effects, some defence structures were built, beginning from the years seventies; in the eighties was an hard structure consisted in a few segments of detached emerged rubble mound breakwaters (about one meter over the m.s.l.) founded in 2-3 meters depth with the crest 3-5 meters width.

Each one of the four zones (fig. 4) corresponds to a different defence structure used. The emerged detached breakwaters are in the **zone A**.

That hard structure, being the first structure downdrift to the mouth, was able to capture large volume of sediment transported by longshore and to enlarge the beach. Such design solution corresponds to the people request of that time.

Fig. 6 Aerial photo of zone A and cross section of the emerged segmented breakwater

Aerial photo (fig.6) shows the increase of land **area A** with the formation of the tombolos.

This result is good for the defence of the beach from the erosion but is not well accepted for the bathing use of the sea water in the tombolo areas. In fact, these areas are too receptive to the bacterial colonies, and so they are interdicted to the bathers like dangerous for their healthiness. (Italian law permits the water bathing use only if the number of the bacteria coli, per liter, is less than 100; for many other national laws - as in USA - is 500/liter). Also the emerged rubble mound breakwaters are very good sites for the development of the bacterial colonies (especially in the sea level exchange band by tide).

It's clear that each one structure, going from North to South, has conditioned the downside structure behaviour.

New design demands. Soft structures for the defence of the zones B and C.

In the second part of the years '80, the demand of more space for the recreational use of the beach increased very fast; moreover, the environmental culture was more developed in the people. Consequently, in order to prevent the erosive action of the sea in the littoral of Ostia, where the sediment balance is poor, to reduce the impact of the works on the environment, to limit the effects on the adjacent beaches, to ensure the exchange of protected areas, many technical solutions were investigated.

Mathematical and physical models were used to study the beach stability and to reduce the cost (first and of the maintenance) of the intervention.

The preference went, not without oppositions, to the soft structures, and mainly to the beach nourishment.

But, where to find the borrow areas for so large volume of suitable sand for an artificial beach, both from a quantitative as a qualitative by?

Many environmental investigations, supported by scientific criteria, were done; the search of the suitable sand was very difficult and the results suggest to take all the necessary materials from the land quarries (that means a greater cost of the intervention), relying the artificial beach nourishment and submerged rubble mound (a reef), as in fig. 7 for the **zone B**, 3000 m. long.

The width of the artificial beach in the design was of 40+90 m. (gravel and gross sand nourishment), while the crest of the reef was 15 m wide and 1,5 m deep under m.s.l. with the slopes $1/3$ seaside and $1/2$ landside on the bottom of about 4 m under m.s.l. (quarry stones among 5 and 1000 kg). The reef section hydraulic stability was tested in wave flume.

This solution was the more pleasant to the people of the bathers, but the question was: how will the reef be able to reduce significantly the wave energy and to maintain sufficiently stable that artificial beach through the years?

Due to the very high cost of the intervention, the Public Administration financed it as experimental project. Obviously a monitoring plan was also financed.

The construction was carried out 1989-1991 (not in the Summer season). But, already when the works were in progress and soon after, a not negligible erosion phenomenon started updrift (see aerial photos Fig. 9). The dimension of erosion pointed out the necessity of a periodic maintenance having a too high cost for the public administration.

So, in the 1992 decided to use a different cheaper soft structure to defend the neighbour new part of the coast, 700 m. long (zone C in fig. 8.). Fig. 8 shows also the cross section of the submerged breakwater used for the **zone C** and the aerial photos fig. 9 the shoreline exchanges between 1991 and 1995 years.

The depth of the crest of submerged barrier in this case was lowered only to 0,5 m under m.s.l., while the bottom is on 3 m about. In the zone C no artificial nourishment was done. Main reason of this decision was the reduced money availability. The first idea was to provide the artificial nourishment of the zone C, if necessary, in the future.

Fig. 7 Aerial photo of the zone B and cross section of the defence composite structure

Fig. 8 Aerial photo of the zone C and cross section of the defence structure

It can be also observed that between the zones B and C there is a big groyne (the inlet of the Canale dei Pescatori) that reduces significantly the sediment transport capacity of the natural drift. In spite of this, not few inspectors hoped too much in submerged breakwaters defence action.

Pay attention that we distinguish between submerged barrier, like breakwater, and reef; the first is able to reduce significantly the wave energy, the second can not (in the submerged breakwaters depth of the crest has to be not large than 50 cm.).

Fig. 9 *The Zone D - Works in progress*

Both the defence soft structures used for the zones B and C are able to assure the healthiness of waters in the protected areas.

In fact, thinking that the water transport by sea waves travels in maximum part on the surface, it means that a well designed submerged barrier can defend the shoreline stability by reducing the highest waves energy and can permit the transmission in protected area to the low waves mass transport (low waves and high temperatures are characteristic of Summer time in Italy) to assure a well exchange of water between offshore and inshore areas (id est the healthiness of recreational bathing water).

But, already at the end of the construction of the submerged rubble mound breakwater for the zone C, it was possible to see there a not little shifting of the shoreline seaward due to the natural sand capture.

Monitoring results

The aerial photos in fig. 10 show the shoreline exchanges of the artificial beach in the **zone B** between the years 1991-1995.

Cross sections (Fig. 11 and 12) northside and in the middle of the zone B taken in the year 1989 (before the works), in the 1992 (one year after the end of the works) and in the year 1995. Erosion action by waves is evident; southside is smaller due to long groin (at the inlet of the Canal).

Fig. 10 *In the aerial photographs the shoreline exchanges among 1985 - 1995 years*

The width of the emerged beach northside is reducing almost at the same size of the 1989; in all cases the erosion action by waves on the artificial beach is very clear both landside and seaside the reef.

As in Dean tests (1995), these results make evident that a similar reef can't defend the beach by waves and, also, breaking, does not reduce significantly the energy of waves passing in the area, increases the erosion in both sides; so, its presence can be, at the limit, dangerous rather than useful.

Viceversa, for the **zone C**, the defence utility of the submerged breakwater of the fig. 8 is demonstrated from the aerial photos in Fig. 10 and from the profiles of the cross section of Fig. 13.

No sand artificial nourishment was done in the zone C, so it's easily understandable that the submerged breakwaters can not only defend the coastline but it is able to capture the fine sediments by longshore drift and to assure them a dynamic sufficient stability.

These results have been observed also in not few field experiments (as at the mouth of Volturno river Napoli, like other example) and in laboratory tests (Chiaia and al., 1992). These results suggested to the public administration to continue in the defending of the **zone D** with the same structure as in zone C (works in progress).

Costs and benefits, comparison

First cost of the defence structure of the zone A (segmented detached emerged breakwaters) is the same of those of the zones C and D, fig. 9 (continuous submerged breakwaters), i.e. about 2 million US dollars/km.

Fig. 11 Zone B - Cross section in the north of zone B.

Fig. 12 Zone B - Cross section in the middle of zone B.

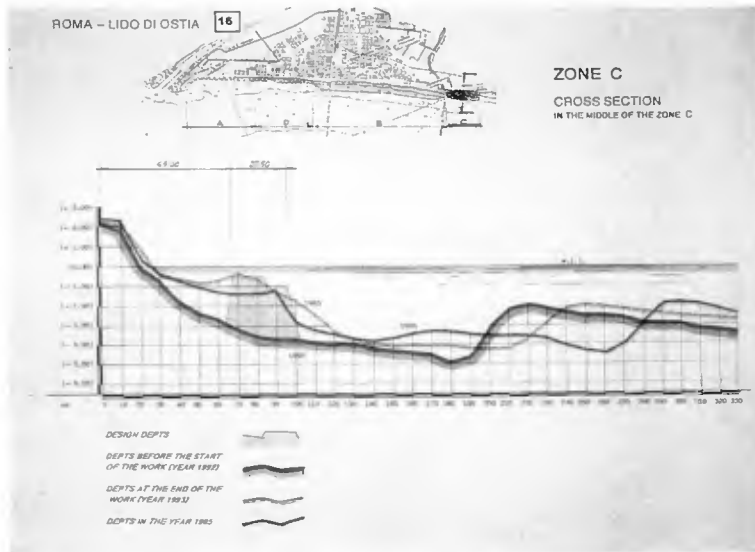

Fig. 13 Zone C - Cross section in the middle of zone C.

The barrier of the zone C is long 700 m, that of the zone D 1,300 m. For the nourishment of the zone B (3 km long), cubic meters 502,000 of fine sand and 880,000 of gravel mixed with coarse sand were used; the cross section volume of the stone reef in the zone B is very similar to that of the submerged breakwater in the zone C. So the first cost of the artificial beach in the **zone B** (artificial sand nourishment and stone reef) is very bigger (about 6.2 million US dollars/km) that the cost of the defence structure (only a submerged breakwater) in the **zone C** (about 2 million US dollars/km).

The monitoring control of the works suggests, also, a necessity of about 15,000 cubic meters/km of sand supply for the maintenance of the artificial beach in the zone B; none cost of the maintenance for the beach in the zone C, because there the nourishment is natural, i.e. it is due to the capture action of the downdrift sediment by the submerged breakwater. Comparison of the above results shows that in both cases of the two soft structures used for the zones B and C the principal scope of the defence from waves erosion has been obtained, also the healthiness of the bathing water was assured; moreover in the zone B a large artificial beach results (in the year 1995 the width was between 30 and 100 m. in going from north to south), while in the zone C the width of the natural beach was smaller (between 15 and 30 m.). It is interesting, also, to look at the favorable action of the special shape of the cross section of the submerged barrier used (two different steps to reduce the reflection of incident waves and, consequently, the energy of the breaking waves at the foot seaside of the barrier). Above the costs of both the soft structures are reported with the benefits for all the beach of very high tourist interest: the comparison is easy.

Fig. 14 Zone B - Before and after the works

Fig. 15 Zone C - Before and after the works

Considerations

The above experiences suggest the following considerations:

- a) both the soft structures have a very low environmental impact;
- b) well designed submerged breakwater is able to defend the coastline from erosion by seawaves, permits a sufficient water exchange between offshore and inshore areas during the summertime, can capture the sediment transport (when it there is) for a natural, low price and enough stable sand beach (pay attention that, for the Italian seas, the maximum spring-tide is generally about 30 cm);
- c) a reef does not assure the stability of the shoreline and increases the erosion landside due to the waves breaking on it (it's too much the energy of the highest waves that comes in the landside area);
- d) the costs of construction and maintenance of the defence soft structure, as in the example of the zone B, is very high and hardly supportable from the community. As benefits, it is a very acceptable soft structure, the area of emerged sand beach is large and better responds to the requests of the people for the recreational and bathing use. But, really, the defence structure is the coarse sand and gravel nourishment, while the effect of the reef is more negative than doubtfull. The laboratory tests demonstrate that an increase of the sand and gravel dimensions are more usefull to stabilize the beach (Aminti,1987).
- e) use of a submerged breakwater as in zone C and D has to be favourite when you want to defend from erosion the shoreline and also to build an artificial beach to reduce the sand supply necessity.
- f) In fact, it does not disturb the landscape scenery, permits to preserve the healthiness and the bathing use of the water in the protected area, assures a good

shoreline stability because it can reduce notably the energy of the highest erosive waves.

CHAPTER 187

WAVE TRANSMISSION AT LOW-CRESTED STRUCTURES

Kees d'Angremond¹, Jentsje W. Van Der Meer², Rutger J. De Jong³

Abstract

Existing data on wave transmission have been critically examined to obtain a homogenous data base. These data have been re-analyzed, and an expression has been derived relating the transmission coefficient to structural parameters and wave parameters.

Introduction

One of the main aims of breakwaters is improving the tranquility in designated areas to facilitate cargo handling or to protect natural shorelines. Economic considerations often indicate that the structural integrity of the breakwater shall be such that the structure is able to survive severe weather conditions without major damage. The functional requirements, however, do not always require that absolute tranquility is maintained under such extreme conditions. Since the volume of material involved in the structure (and thereby its cost) is proportional to the square of its height, it is worthwhile to consider the minimum crest level as carefully as the structural strength of the armor layer. Therefore it is necessary to give a good prediction of wave transmission of low-crested structures. This is the main reason for the continued attention for wave transmission at Delft University and Delft Hydraulics.

¹ Delft University of Technology, P.O. Box 5048, 2600 GA Delft, the Netherlands

³ MSc-Student, Faculty of Civil Engineering, Delft University of Technology, at present: Grabowsky and Poort, Consulting Engineers, The Hague, The Netherlands.

Run-up, Overtopping and Transmission

Before analyzing the phenomenon of wave transmission it may be wise to define the three related subjects, run-up, overtopping and transmission, since there seems to be a lot of misunderstanding about the meaning of these words.

Wave run-up is the phenomenon that when a wave approaches a sloping face, a wave tongue runs up the slope. The tongue reaches a maximum elevation above still water level, which is the run-up level. This is thus a vertical distance above the momentary sea level. When the crest of the slope is lower than the run-up level, the wave tongue will pass over the crest.

The average quantity of water passing over the crest is called wave transmission. It is expressed in m^3 per running meter crest per second, and it can therefore be compared with the specific discharge per unit width (q) in open channel flow. In case the area behind the sloping structure is dry land, the quantity of overtopping may be used to design the capacity of the drainage system.

In case the area behind the structure is a plane of water, the masses of water spilling over the crest from time to time will generate waves in the basin. These waves will generally be smaller than the waves at the outside of the structure. The ratio between the wave height behind the structure (H_t) and the wave height in front of the structure (H_i) is the transmission coefficient K_t .

The governing parameters related to transmission are: structural geometry, permeability, crest freeboard, crest width, surface roughness, water depth and the hydraulic parameters wave height and wave period. A definition sketch is given in Figure 1.

Figure 1. Definition Sketch

Existing Transmission Formulae

Two formulae describing wave transmission at low-crested structures have already been published by the authors in previous papers. In the first formula, derived

by Van der Meer (1990, a and b), the transmission coefficient was related to the crest freeboard R_c , divided by the incident significant wave height H_{si} .

$$K_t = 0.46 - 0.3 \frac{R_c}{H_{si}}$$

K_t is limited between 0.8 and 0.1.

Figure 2 shows an indication of the scatter obtained in this way. In particular, it is remarkable that the transmission coefficient does not reach the value 1 for relatively low structures, and that it remains quite above 0 for structures with a considerable relative freeboard.

Figure 2. Wave transmission versus relative crest height R_c/H_i

The second formula was derived by Daemen in his Master's thesis (Daemen 1991) and published by Van der Meer et al (1991). Daemen attributed part of the scatter to permeability of the armor layer, specifically for those structures that had a crest slightly above MSL. It was concluded that the scatter could be reduced by introducing a different dimensionless expression for the freeboard i.e. R_c/D_{n50} , in which D_{n50} is the nominal stone diameter of the armor layer.

Eventually, an expression was developed of the shape:

$$K_t = a \frac{R_c}{D_{n50}} + b$$

in which

$$a = 0.031 \frac{H_{si}}{D_{n50}} - 0.24$$

and

$$b = -5.42 s_{op} + 0.0323 \frac{H_{sj}}{D_{n50}} - 0.0017 \left(\frac{B}{D_{n50}} \right)^{1.84} + 0.51$$

Boundaries were set at $K_t \text{ max.} = 0.75$ and $K_t \text{ min.} = 0.075$, while the validity of the formulae was limited for $1 < H_s/D_{n50} < 6$ and $0.01 < s_{op} < 0.05$.

Daemen further noted that the data by Ahrens, based on the behavior of reef-type breakwaters were so much different that other formulae were required to describe transmission over such structures. A comprehensive analysis of the background of the tests by Ahrens justifies the separation of reef type structures from regular breakwaters. At the same time, Daemen suggested a modified expression valid for reef type breakwaters. The results obtained by Daemen for regular breakwaters are presented in Figure 3.

Figure 3. Calculated and measured transmission for conventional breakwaters (Daemen)

Although the result of Daemen looks quite promising considering the scatter, there is one obvious disadvantage: the formula is not valid for structures that have no characteristic diameter, or that have a low or zero permeability in the region around MSL. Examples of such structures are asphalt grouted breakwaters and groynes, caisson type breakwaters, and breakwaters with large solid superstructures. It was therefore decided to continue the work by Daemen and to try and find an expression for the transmission that is primarily based on the outer dimensions of the structure, with correction factors for roughness and permeability. Before starting the new analysis, it was decided to examine existing data sets critically to obtain a homogenous data base.

Existing Data Sets

Van der Meer and Daemen both used various sets of data that were gathered and published by various researchers. It was mentioned already that the test results by Ahrens were omitted by Daemen because of the completely different character of the reef type breakwater. The test series by Seelig (1980), Allsop (1983), Daemrich and Kahle (1985), Powell and Allsop (1985), Van der Meer (1988) and Daemen (1991) that had been used by both, van der Meer and Damen, were studied again for the present work, and new data from site specific model investigations by Delft Hydraulics (mainly carried out in 1993 and 1994) could be added. In these series also impermeable submerged breakwaters were included.

All data, however, have there specific character. Seelig used waves with an extremely large wave steepness of 0.10, which could not be reproduced in other laboratories due to wave breaking. Allsop restricted his studies to structures with a relatively high crest level. Daemrich and Kale used tetrapods as armor units, instead of quarry stone used by many other authors. Probably, the permeability is thus slightly larger, which results in a larger transmission. Powell and Allsop carried out their tests at extremely shallow water depths. Some of the recent investigations by Delft Hydraulics were also on armor layers with Tetrapods and Accropods, with consequences for the permeability. All authors are a little ambiguous about the definition of the crest level. This may explain systematic deviations between various data sets.

In spite of the inconsistency of the various data sets, all data, except those of Ahrens for reef type breakwaters were used. From the data sets, some tests were discarded, however, i.e. those sets with extremely steep or breaking waves ($s_{op} > 0.6$ and $H_{si}/h > 0.54$). Tests with $R_c/H_{si} > 2.5$ and with $R_c/H_{si} < -2.5$ were considered less relevant and therefore not taken into account either.

The complete set of data used during the present study is compiled in Figure 4, which gives the raw relation between R_c/H_{si} and K_t .

Figure 4. Homogenous Data on Transmission

Analysis

The analysis of data was taken up in a similar way as was done originally by van der Meer. This resulted in a relation of the form:

$$K_t = a \frac{R_c}{H_{si}} + b$$

in which

- a* determines the slope of the curve, and appears to be independent of any of the parameters considered, and
- b* determines the value of the transmission coefficient K_t when the relative crest height equals zero. This coefficient appears to be a function of crest width and breaker parameter.

Because of the trend in all data, the coefficient *a* could be set at -0.4. The coefficient *b* was expected to depend on crest width and breaker parameter ξ . It was attempted to find a dimensionless expression for the crest width by combining it with wave height and wave length respectively. Eventually, the best result was obtained by the expression

$$0.54 \left(\frac{B}{H_{si}} \right)^{-0.31}$$

The coefficient 0.54 in this expression could, however, not be considered a real constant yet. Because of the similarity between wave transmission and wave run-up, it was expected that the Iribarren parameter, $\xi = \tan \alpha / \sqrt{H/L}$ would play a role. It was found that the expression $(1 - e^{-0.5\xi}) * C$, (with $C = 0.64$) yielded optimum results.

The remaining scatter is due to the influence of the stone size D_{n50} . This influence becomes noticeable for values of $H_{si}/D_{n50} < 2$. The influence, however, is two-fold and works in different ways, depending on the crest level: small values of H/D indicate the presence of relatively large armor stones, which increase the permeability and thus increase the transmission by water flowing through the breakwater, but which increase the surface roughness at the same time and thus reduce transmission by water flowing over the breakwater. There were insufficient data to establish a final relation. Therefore, it is suggested to maintain the coefficient 0.64 for the time being. The deviation by this choice mainly influences the results for extreme values of K_t and thus of R_c/H_{si} (see figure 5).

Figure 5. Remaining scatter due to armor size

Conclusions

In conclusion, the expression proposed for permeable breakwaters is:

$$K_t = -0.4 \frac{R_c}{H_{si}} + \left(\frac{B}{H_{si}}\right)^{-0.31} * (1 - e^{-0.5\xi}) * 0.64$$

with limits for the value of K_t :
 $0.075 < K_t < 0.80$.

In a similar way, an expression for impermeable structures was derived:

$$K_t = -0.4 \frac{R_c}{H_{si}} + \left(\frac{B}{H_{si}}\right)^{-0.31} * (1 - e^{-0.5\xi}) * 0.80$$

with the same limits.

Measured and calculated results for compared for permeable and impermeable structures respectively. The results are presented in Figures 6 and 7. For permeable structures, the standard deviation σ was 0.060, resulting in a 90% confidence band of $K_t \pm 0.10$. For impermeable structures, the standard deviation was found to be 0.053, with 90% confidence level for $K_t \pm 0.087$.

Figure 6. Measured and calculated transmission permeable structures

Figure 7. Measured and calculated transmission impermeable structures

Recommendations

The main problem in finding a reliable expression for wave transmission is the fact that available data do not form a homogenous data base. Model tests have been carried out by several different laboratories, where it is not certain that always the same definitions have been used. This mainly applies to the crest level. Further, many model tests were carried out with emphasis on other aspects of structural behavior. It is therefore recommended that special tests be carried out with the main aim to establish a homogenous data base for transmission of permeable and non-permeable breakwaters.

CHAPTER 188

EFFECT OF SUBMERGED BREAKWATER ON PROFILE DEVELOPMENT

Martin D. Groenewoud¹, Jan van de Graaff², Edward W.M. Claessen³
and Stephan C. van der Biezen¹

ABSTRACT

The project “Dynamics of Beaches” is carried out by a network of six European Universities within the framework of the Human Capital and Mobility Program of the European Union. The aim of the project is to improve the existing knowledge on physical processes governing the nearshore zone due to effects of submerged breakwaters. Within the project hydrodynamic and morphological experiments have been carried out.

This paper discusses the results of the experiments that took place in a wave flume and the large wave basin at Delft University of Technology. The experiments were carried out with movable beds and varying wave conditions.

INTRODUCTION

Structural erosion and dune erosion during severe storm surges threaten large parts of coasts. Proper protection of threatened coasts is often an important aim in coastal engineering practice. Apart from this type of protection, sometimes new reclaimed areas have to be protected from attacks from the sea.

Coastal engineers must always select the proper protection method out of the many available methods; e.g., beach nourishments, series of groins, series of offshore breakwaters, submerged breakwaters, seawalls and revetments. In order to apply a specific method its physical effects on the surrounding area should be well known.

³ formerly Msc. student DUT

One of the promising methods of coastal protection is the use of submerged breakwaters. Within the framework of the Human Capital and Mobility program of the European Union six universities [Barcelona (Spain), Thessaloniki (Greece), Ghent (Belgium), Liverpool (U.K.), Cork (Ireland) and Delft (the Netherlands)] work together in solving some of the unknown aspects related to the use of submerged breakwaters along sandy coasts.

The primary aim of this project called "Dynamics of Beaches" is to obtain a valuable database which is available for further modelling studies.

In the research program many experiments in wave flumes and wave basins have been carried out by the partners with the main emphasis on the effects of a submerged breakwater on hydrodynamics. Table 1 gives an overview.

Laboratory	Facility	Bottom	Waves
Barcelona	Flume	Rigid	Irregular
Liverpool	Flume	Rigid	Regular/Irregular
Cork	Basin	Rigid	Irregular
Delft	Flume	Movable	Regular/Irregular
Delft	Basin	Movable	Regular

Table 1 Overview experiments "Dynamics of Beaches" project.

This paper discusses the results of the experiments in Delft with main emphasis on the wave flume experiments. First a general evaluation of the applicability of submerged breakwaters is given.

OBJECTIVES OF APPLICATION

The erosion of coasts can often be divided in two types of problems, viz.:

1 - Structural erosion

Structural erosion of a stretch of coast means that the stretch loses sediments at a regular basis. Typical for structural erosion is the fact that it is an irreversible process. In a certain cross-shore profile the amount of sediment diminishes as a function of time. Eventually all parts of the profile will suffer from this type of erosion.

Often a gradient in the longshore transport is the cause for this erosion. Fig.1 shows a simple schematization of the coast. If $S_b > S_a$ then the shoreline will retreat.

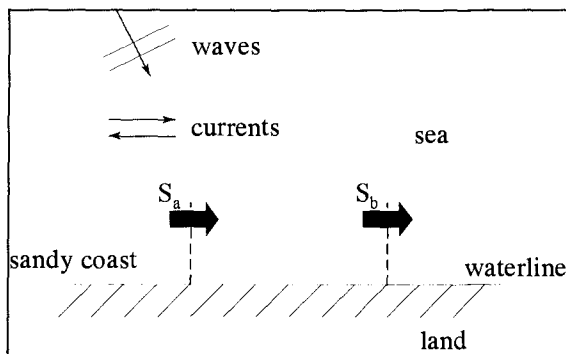

Fig.1 Longshore sediment transport

2 - Retreat of coastline during severe storm surges

A retreat of the (sandy) coast can take place during severe storm surges. Typical for this type of erosion is that it is a reversible process. Sediment is lost from the upper part of the profile to the shoreface, but will be transported in opposite direction again during calm weather conditions.

The second type of erosion should in principle not be battled by submerged breakwaters. During storm surges the combination of wave set-up, wind set-up and high (spring) tide leads to a high water level. The height of the submerged breakwater relative to water depth will become smaller. The influence of the breakwater will decrease at the time its presence is needed mostly. Therefore submerged breakwaters are not a proper solution to that kind of problem. It is stressed that of course the level of the crest is very important in this case.

Undesired structural erosion can be battled either by 'hard' or by 'soft' measures. 'Hard' measures are supposed to interfere with the sediment transports in such a way that the erosion is reduced or stopped at all. Well-known examples of such methods are: groins, offshore breakwaters, dikes etc. The erosion problem often is shifted to the adjacent leeside of the structure, which is a serious disadvantage of these types of countermeasures.

'Soft' measures (e.g. artificial nourishments) can avoid the disadvantage of leeside erosion. Nourishments, however, only treat the symptoms of the erosion; no permanent solution can be offered by these methods.

The general desire to solve erosion problems has stimulated the research of more structural solutions to the problem.

One of the promising methods is the use of submerged breakwaters. Basically the submerged breakwaters are supposed to reduce the wave heights landward of the structure. Because of this the wave-driven longshore current will be reduced. The decrease of the wave-driven longshore current will in principle lead to a reduction

of the longshore transport capacity. By fine-tuning the dimensions of the breakwaters (e.g. crest-height, gap size, orientation etc.) the desired reduction in transport capacity can be achieved. In other words, structural erosion can be avoided. More detailed descriptions of the effect of offshore breakwaters in general can be found elsewhere, e.g.: CUR, 1997; Pilarczyk and Zeidler, 1996.

The experiments as carried out in the framework of the 'Dynamics of Beaches' project are meant to increase the knowledge about the effects of submerged breakwaters on hydro- and morphodynamics.

THE DELFT EXPERIMENTS IN A WAVE FLUME

Experimental set-up

Several agreements concerning the experiments were made between the different partners of the Dynamics of Beaches project. Wave conditions and breakwater layout were in principle defined for a (fictitious) submerged breakwater at scale 1:1.

The experiments were carried out in one of the wave flumes of the Laboratory of Fluid Mechanics at Delft University of Technology (DUT). The dimensions of the wave flume are: length: 32.0 m; width: 0.8 m; height: 1.0 m.

The wave board is able to generate irregular waves. Because of the dimensions of the wave flume it was decided to perform the experiments at scale 1:15. Prototype wave conditions and breakwater layout were scaled down. Only the scaled parameters of the experiment will be mentioned in this paper.

The layout of the flume is shown in Fig.2. The layout of the cross-section of the submerged breakwater is presented in detail in Fig.3. According to the test programme the experiments were done with and without breakwater with a 1 in 15 slope and a movable bed. The bed consisted of sand with $D_{50} = 95 \mu\text{m}$ ($D_{10} = 76 \mu\text{m}$, $D_{90} = 131 \mu\text{m}$) which is relatively fine for sand along a beach. The purpose of using this type of sand is that the ratio between bed transport and suspension transport will be closer to the ratio that would occur if the experiments were performed at scale 1:1.

Because the erosion near the seaward toe of the breakwater was not a research topic, the first part of the slope is made out of concrete (see Fig.2). An advantage of a concrete slope seaward of the breakwater is that possible amounts of sediment transport over the breakwater can be measured very accurately.

Five different wave conditions with varying wave heights and wave periods (A through E, see Table 2) were defined in the Test Definition Report. By means of varying wave height and wave period the influence of these parameters on hydro- and morphodynamics can be investigated. One wave condition with regular waves was added (test F) to the program. In this way a coupling between the results of these 2DV tests and the 3D tests with regular waves can be made.

Fig. 2 Layout experiment (wave flume DUT).

All dimensions are in centimeters

Fig. 3 Layout of the breakwater in detail.

Six experiments were carried out without breakwater, each of them with one of the predefined wave conditions (A through F). The same strategy was repeated with the breakwater present. By using similar conditions for the tests with and without breakwater it is possible to make a true comparison between both situations.

Wave condition (irr. waves)	F/H _s (-)	H _s /L _{0p} (%)	T _p (s)	H _s (m)	h (m)	F (m)	H _s /L _p (%)
A	1.00	1.50	2.07	0.10	0.4	0.1	2.61
B	1.00	2.67	1.55	0.10	0.4	0.1	3.67
C	1.00	3.84	1.29	0.10	0.4	0.1	4.66
D	0.75	2.61	1.81	0.133	0.4	0.1	4.06
E	1.50	2.56	1.29	0.067	0.4	0.1	3.01
Wave condition (reg. waves)	F/H (-)	H/L ₀ (%)	T (s)	H (m)	h (m)	F (m)	H/L _p (%)
F	1.00	2.67	1.55	0.10	0.4	0.1	3.67

Table 2 Wave conditions

Each experiment lasted for 7.5 hours. The period of 7.5 hours was divided in four intervals with durations of respectively 0.5, 1.0, 2.0 and 4.0 hours.

The following types of measurements were carried out:

- wave height measurements (electrical resistance method)
- flow velocity measurements (electromagnetic fluid-velocity meters, (EMS))
- sediment concentrations measurements (transverse suction method with intake tubes)
- profile measurements (electronic profile follower)

The wave height, flow velocity and sediment concentration measurements were carried out during the different intervals at specific places (see Fig.4). Profile measurements were carried out between these intervals. Some of the results will be presented. (For a detailed description of measurements and results reference is made to Claessen and Groenewoud, 1995).

Fig.4 Cross-section of the flume and measuring positions

Analysis of results

As an example some of the results of the experiments with condition D ($H_s = 0.137$ m and $T_p = 1.81$ s) will be presented.

Profile measurements

The initial profile has a 1 in 15 slope. This relatively steep profile is far from equilibrium. Fast adaptations were therefore expected. After a test duration of 7.5 hours equilibrium is not yet reached. Aim of the tests was to see at what rate the adaptations would take place and what the influence of a submerged breakwater under varying wave conditions would be.

Fig.5 shows as an example the profile development of experiment D without breakwater. The other experiments without breakwater showed similar trends in profile development; erosion takes place around the shoreline and the sand is transported in offshore direction where a bar is formed. The size of the bar increases in time; the center of the bar moves seaward.

Fig.6 shows the profile development of experiment D with breakwater. Again, erosion around the waterline takes place. Part of the sediment settles against the breakwater. A bar in between the waterline and the breakwater is also formed.

Fig.7 compares the profiles after 7.5 hours of both experiments. The scourhole is less pronounced in case of the experiment with breakwater. The submerged breakwater clearly forms an obstacle for the sediment moving in seaward direction. Without the breakwater more sediment has moved in offshore direction.

Fig.8 shows the sediment transport through the vertical indicated in Fig.7. The transport in offshore direction was smallest for the experiment with breakwater. Other experiments gave similar results.

The experiments in the wave flume are strictly 2 dimensional. Therefore the mass flux due to (partly) breaking over the submerged breakwater has to return through the same cross-sections.

Fig.8 Comparison transport volumes through vertical ($x = 7.05\text{ m}$)

Simulation experiments with 2DV model

The experiments have been simulated with the computer programme Unibest- TC (Unibest is a program package of Delft Hydraulics). Measured wave heights and measured profile development have been compared with calculations.

Wave heights: measured and calculated

The results of the wave height measurements have been compared with calculations executed with Unibest-TC. The results of this comparison for experiment D are shown in Fig.9 and Fig.10. (In the figures the H_{rms} have been plotted).

For the situation with breakwater the Unibest-TC model calculates a sudden increase in wave height at the position of the breakwater. In reality the wave height and wave form will change less instantaneously as the effect of abrupt changes in the bottom profile.

Profile development: measured and calculated

Unibest-TC predicts the profile development for the situation without breakwater rather well (see Fig.11). Only the retreat of the waterline is not modelled satisfactory. This is due to the fact that the used equations are not valid near the waterline. The differences between measured and calculated development become larger with the breakwater present (see Fig.12). The calculated size of the scourhole lags behind in comparison to the measured development. Again, the retreat of the waterline is not modelled correctly.

Fig.9 Comparison measured and calculated wave heights experiment D with breakwater ($H_s = 0.137$ m, $T_p = 1.81$ s)

Fig.11 Comparison measured and calculated profiles experiment D without breakwater ($H_s = 0.137$ m, $T_p = 1.81$ s) after 7.5 hours wave action

Fig.12 Comparison measured and calculated profiles experiment D with breakwater ($H_s = 0.137$ m, $T_p = 1.81$ s) after 7.5 hours wave action

RESULTS OF THE 2DV MOVABLE BED TESTS IN BRIEF

In most cases the presence of the breakwater has reduced the sediment transports in offshore direction. In some cases there was a small amount of sediment transport over the breakwater in offshore direction. This sediment can be considered as lost.

The breakwater causes much dissipation of wave energy. The wave heights offshore have increased due to reflection against the breakwater.

High sediment concentrations were measured behind the breakwater caused by the increased turbulence as effect of wave breaking.

The experiments showed that with the used variety in wave conditions a change in wave height had much stronger effects on morpho- and hydrodynamics than a change in wave period.

The simulations with Unibest-TC showed that the wave height development along the profile is predicted quite well. The calculated profile development differed considerably from the measurements.

It has to be stressed that the experiments in the flume are strictly 2 dimensional. Therefore the mass flux in the top of the breaking waves has to return in the same cross-section. This also applies for waves breaking over the submerged breakwater.

3D MOVABLE BED TESTS

In order to investigate 3D effects near the gaps between submerged breakwaters, or at an end of a long submerged barrier, in the wave basin of the Laboratory of Fluid Mechanics at the Delft University of Technology a segmented type of submerged breakwater was focused upon. Small scale experiments were carried out with regular waves. The experiments were carried out in resemblance with experiments in the Hydraulics and Maritime Research Center in Cork, Ireland. Both universities used the same set-up, except that in Delft a movable bed was applied instead of a concrete slope.

Each experiment starts with the same initial profile, which is steeper than the theoretical equilibrium profile, and covers 7.5 hours of wave action. Three different mean wave heights H were applied: 0.08 m, 0.10 m and 0.12 m, defined at the seaward toe of the breakwater which had a crest submergence of 0.10 m. The mean wave period T was kept constant at 1.55 s. The sediment used in the basin was the same as used in the wave flume ($D_{50} = 95 \mu\text{m}$).

Experiments were carried out with and without breakwaters. The experiments without breakwaters show a slope adjusting offshore sediment transport, transforming the initial 1:15 slope into an ogee profile which tends to stability after 7.5 hours of wave exposure; a real equilibrium is, however, certainly not reached in 7.5 hours. The experiments were interrupted five times for profile monitoring, to visualize the profile development in time in five steps. For a wave height of 0.10 m, Fig.13 shows the final situation of the bed without breakwaters. The still water level is set at $z = 1.00$ m.

Repeating the tests with submerged breakwaters installed, the most noticeable observation is a strong offshore flow through the gaps between the breakwaters, apparently compensating for the mass flux over the breakwater crests. Fig. 14 shows the final situation of the bed with breakwaters.

The relatively high offshore velocities in the gaps lead to a profound sediment loss and a much larger retreat of the shoreline than observed without breakwaters. The same effect was found at Palm Beach, Florida, USA (Browder *et al.*, 1996). In an attempt to reduce beach erosion and wave impact on a protective seawall, an experimental submerged breakwater of 1,260 m length was installed in a water depth of approximately 3 m off the Town of Palm Beach, Florida. The profile data documented erosion in the entire monitored area with the greatest erosion landward of the submerged breakwater.

Fig.13 Final situation experiment without breakwaters

Fig.14 Final situation experiment with breakwaters

The current velocities measured relatively close to the bottom support the hypothesis that a surplus of water is built up landward of the breakwater. This can be seen from Figures 15 and 16.

Fig.15 Velocities and directions without breakwaters

Fig.16 Velocities and directions with breakwaters

In Figs.15 and 16 averaged current patterns relatively close to the bottom are given for the first 1.5 hours, with and without breakwaters. Although the vectors can only provide a rough indication of what the current pattern in the basin will be like, intercomparison of these figures clearly shows the influence of the breakwater segments. The offshore undertow, uniformly distributed over the width of the basin in Fig.15, is channelled towards the gaps between the breakwaters as shown in Fig.16.

It has to be stressed that a main objective of tests with a movable bed is to achieve a reliable data set for verification purposes of mathematical morphological models. This comparison has not yet been carried out.

CONCLUSIONS ON THE 3D MOVABLE BED TESTS

Submerged breakwaters seem to offer a number of advantages over conventional coastal protection structures. However, 3D experiments indicate that one should be careful when applying submerged breakwaters with gaps. 2DV experiments often stress the reduction of the offshore sediment transport by the breakwater. This seems to justify the conclusion that the submerged breakwater creates a perched beach. The present 3D results, however, prove that it is important to count for the consequences of gaps between the submerged breakwaters. These can lead to unexpected scouring.

Furthermore, from the 2DV tests it is found that the submerged breakwaters reduce the wave heights in the lee. This is in accordance with the 3D results. In the gaps, however, the waves can pass and diffract around the ends of the breakwater into the lee side of the breakwater. For this reason, the amount of wave energy at the lee side of the breakwater becomes larger than indicated by 2DV testing.

To summarize, introduction of 3D properties such as gaps between breakwaters and breakwater endings affect the performance of submerged breakwaters as follows:

- the wave energy transmitted to the lee side of the breakwaters is much greater than predicted by 2DV testing (Murphy *et al.*,1996),
- submerged breakwaters allow a mass transport over the crest. The return flow is concentrated in the gaps resulting in local high velocities,
- although submerged breakwaters create a perched beach in a 2DV situation (an infinitely long breakwater), a significant amount of sand is removed from behind the structures and transported through the gaps when applying segmented breakwaters,
- the *exposure ratio*, defined as the ratio of gap width to the sum of the breakwater length and gap width, has a significant influence on the morphodynamic processes occurring in the nearshore region.

The equilibrium state was not reached during the present experiments, so the resulting profile shape after 7.5 hours of wave exposure is still partly determined by the initial steep slope. Therefore, a long term prognosis about the efficiency of segmented submerged breakwaters can not be made on basis of the present results.

OVERALL CONCLUSIONS

Especially the 3D experiments have shown that one should be careful with applying submerged breakwaters. Submerged breakwaters do not seem to be good solutions for an arbitrary structural erosion problem.

The gaps in between of the breakwaters effect the hydro- and morphodynamics very strongly.

Further research is necessary to increase the knowledge about the influence of parameters like gap size (exposure ratio).

ACKNOWLEDGEMENT

The “Dynamics of Beaches” project is sponsored by the Human Capital and Mobility programme (Scientific and Technical Cooperation Networks) of the Commission of the European Union, Directorate General for Science, Research and Development, under contract CHRX-CT93-0392.

CHAPTER 189

CAUSE AND CHARACTERISTICS OF IMPACT PRESSURE EXERTED BY SPILLING AND PLUNGING BREAKERS ON A VERTICAL WALL

Seyed Ali Azarmsa ¹, Takashi Yasuda ², Hidemi Mutsuda ³

Abstract

Detailed measurements of spilling and plunging wave pressures on a vertical wall are carried out to identify and compare their characteristics. Kinematical differences between the spilling and plunging breakers enable us to investigate better the generation mechanism and characteristics of the impact pressure. Further, the reliability of numerically computed breaking wave pressure is investigated through the comparisons with the experimental results. It is made clear that the impact pressure can be well expressed in terms of internal kinematics of breaking waves.

Introduction

Impact pressure of breaking waves has been studied by many investigators, but for only plunging breakers (e.g. Bagnold, 1939; Kirkgoz, 1982; Chan and Melville, 1988; Cooker and Peregrine, 1990; Oumeraci et al., 1992; Hattori et al., 1994). Since the impact pressure exerted by a plunging breaker on a vertical wall usually takes place near the elevations where air is entrapped, some of the investigators related the cause of occurrence of the impact pressure to entrapped air dynamics, to reduced velocity of sound in a water-air mixture etc. and thus much less attention is paid on the role and contribution of the kinematics of water particles to the impact pressure.

Discussing different ideas about the generation mechanism of the impact pressure, Azarmsa et al., (1996a) made clear that generation of the impact pressure is independent of breaker type and showed that even spilling breakers exert the impact pressure on a vertical wall. Besides, they made clear that entrapped air

¹Doctoral Student, Dept. of Civil Engineering, Gifu University, Yanagido 1-1, Gifu, 501-11, Japan.

²Professor, ditto.

³Research Associate, ditto.

Figure 1: Experimental set-up.

does not play any role in generation of the impact pressure, although pressure oscillations are linked to entrapped air dynamics. Such conclusions turned our attention round from the entrapped air dynamics to the kinematics of the breaking waves as the key factor in generation of the impact pressure and related problems. To understand how the kinematics of breaking waves and the impact pressure are related, the internal kinematics of incipient breaking waves were computed numerically and applied to the calculation of the impact pressure in two different ways (Azarmsa et al., 1996a). The results indicated that both the horizontal and vertical components of velocity and acceleration of water particles should be considered in computations of the impact pressure.

In this study, spilling and plunging wave pressures exerted on a vertical wall are investigated to make clear the common and individual characteristics of the impact pressure exerted by these breakers. Moreover, the experimental and numerical results are compared to investigate the reliability of the vertical distribution of the maximum pressure computed on the base of the internal kinematics of breaking waves, as suggested by Azarmsa et al., (1996a). Further, since the internal kinematics of overturned waves is more critical than that of waves just at breaking, our attention is also focused on the pressure exerted by overturned waves. The results will be compared with the pressure exerted by waves which just break on the wall and the role of entrapped air will be discussed.

Experiments

Experiments were conducted in a 54m long, 1m wide, and 1m deep wave channel. A computer-controlled piston-type wave maker was used to generate the desired solitary waves.

Figure 1 shows a view of the wave channel and apparatus used for the experiments. A reef with the crown height of 9.0 cm was made of stainless steel plates and installed in the wave channel to make the generated solitary waves break. The dimensionless incident wave heights of generated spilling and plunging breakers are respectively ($H_1/h_1 = 0.24$) and ($H_1/h_1 = 0.55$), where $h_1 = 15\text{cm}$ is water depth in the wave channel. A vertical wall with 60.0 cm height and 2.0 cm thickness made of acrylic material was installed on the reef. In order to prevent probable vibrations of the vertical wall from transferring to the pressure trans-

ducers, the transducers were set not to the acrylic wall but to a rigid steel frame which was directly fixed to side walls of the wave channel. An acrylic frame was used to hold the transducers in a vertical slit which was already prepared in the wall so that the transducers were not in contact with the vertical wall. The small space less than 0.1 cm between the acrylic frame and the vertical wall was coated by gum tape.

Pin point pressure transducers with operational capacity of 500 gf/cm^2 and overload capacity of 120 % were used for pressure measurements. Natural frequency of the pressure transducers are 10 KHz. Adaptors filled with silicon grease were used with the pressure transducers. Each adaptor had a pin hole of only 0.5 mm in diameter which enabled us to measure pressure very locally. Pressure data were recorded and digitized with 20 KHz sampling frequency which was adequate for being able to record the peak pressure during the impact and to collect sufficient numbers of data around the peak, as the shortest pressure rise time was 0.4 ms.

The spilling and plunging wave pressures were measured in detail at various elevations (spaced 5 mm apart, above the wave through level, here S.W.L.) and for different wall locations in their breaking zones. Since the breaking point varies with the breaker type, we were obliged to locate the wall in two different areas on the reef to measure pressure in the breaking zones of the spilling and plunging breakers. Hence, for the purpose of comparison, dimensionless relative distance of the wall from the breaking point, $\delta x/h_1$, is adopted to show the wall location in the breaking zone.

Numerical Simulations

Fully nonlinear BIM is used to compute the spilling and plunging wave profiles, the associated water particle velocities and accelerations, and the exerted pressure on a vertical wall installed in their breaking zones. Computations are made for the same incident waves and bottom topography used in the experiments. Details of the computational approaches, the concepts used for pressure computations and the computed free surface profiles of the spilling and plunging breakers (in the absence of the wall) at different stages of overturning process are presented in previous work of Azarmsa et al. (1996a).

Figure 2 indicates how the spilling and plunging wave profiles vary during the collision with a vertical wall modeled at different locations on the reef. When these breakers collide with a vertical wall at a location before the breaking point (**Fig. 2 (a)**), their horizontal momentum smoothly converts into the vertical momentum and as a result, water rises up the wall. For the wall at the breaking point (**Fig. 2 (b)**), the front face of both the breakers converges toward a point on the wall. The elevation of the focus of the front face of the plunging breaker on the wall is only a little higher than the elevation of the incident wave crest. But since the slope of the front face of the spilling breaker is milder than that of the plunging breaker, the water line at the wall can considerably rises up the wall

before that the wave crest could make a contact with the wall. As a result, the elevation of the focus of the front face of the spilling breaker on the wall is much higher than the elevation of the incident wave crest. **Figure 2** (c) indicates that collision of the plunging breaker with the wall at a location after the breaking point results in entrapping air. However, air is not entrapped between the front face of the spilling breaker and the wall, as expected.

Pressure Time Histories

In order to investigate the characteristics of the plunging and spilling wave pressures, detailed measurements of pressure in both horizontal and vertical directions were carried out and variation of pressure time history with wall locations in the breaking zone and elevations along the wall are investigated.

a) Plunging Breaker

Pressure records on the wall installed in a location very near to the breaking point ($\delta x/h_1 = -0.13$) are shown in **Fig. 3** (a). The pressure measured near the still water level is very similar to the standing wave pressure and characterized by long pressure rise time and low maximum pressure value. However, as the elevation increases, the dimensionless value of maximum pressure exerted on the wall becomes larger so that $p_{max}/\omega_0 H_1 > 15$ is observed at the elevation of $z/h_1 = 0.52$ just below the wave crest. Comparisons among the pressure time histories measured between the elevations $z/h_1 = 0.42$ and 0.52 reveal that although the pressure rise times in these records are very short and more or less the same, the maximum pressure values and the pressure fall times differ from case to case.

Figure 3 (b) illustrates the pressure time histories recorded on the wall installed at the breaking point ($\delta x/h_1 = 0.00$). Comparisons between **Fig. 3** (a) and (b) reveal that for only a small (2.0cm) change in the wall location, the pressure time histories measured at the elevations of $z/h_1 = 0.42, 0.45$ and 0.52 have considerably changed. The maximum pressure value has increased more than twice at the elevations of $z/h_1 = 0.42$ and 0.45 , but it has decreased at the elevation of $z/h_1 = 0.52$.

In fact, when the wall is located at the location of $\delta x/h_1 = -0.13$ violent vertical motion of the water on the wall prevents the wave crest from making a direct impact on the wall and causes the water particles near the wave crest to move upward. However, change of the wall location from $\delta x/h_1 = -0.13$ to the breaking point ($\delta x/h_1 = 0.00$) allows the wave to deform more before colliding with the wall. As a result, the wave front face becomes nearly vertical and the wave crest makes a direct impact on the wall just before that the water rising on the wall reaches the wave crest elevation. Therefore, change in the wall location allows a change in direction of movement of the water particles near the wave crest from an upward direction to a nearly horizontal one. Moreover, the water jet observed by video camera just starts forming at the breaking point. In other

Figure 3: Time histories of the plunging wave pressure recorded on the wall at different locations.

words, the velocity and acceleration of water particles which are near the wave crest and form the jet have also increased. Therefore, it can be concluded that the reason why both of the pressure intensity and the elevations at which high pressures take place change sensitively with the wall locations should be closely related to the rapid change in the wave kinematics.

Time histories of the pressure exerted on the wall installed at two different locations after the breaking point are shown in **Fig. 3** (c) and (d). Pressure time histories measured on the wall at different elevations, especially those near the still water level are characterized by low frequency oscillations which are supposed to be excited due to the dynamics of air entrapped between the curved front face of a plunging breaker and a vertical wall. Entrapped air also makes the pressure rise time become longer. Comparisons between **Fig. 3** (b) and (d) reveal that although the pressure rise time becomes longer due to the entrapped air influence, the maximum pressure value remains in the same order or becomes even larger (e.g. at the elevation of $z/h_1 = 0.41$, **Fig. 3** (d)) than those measured at the breaking point ($\delta x/h_1 = 0.00$). This confirms that the maximum pressure value does not necessarily change inversely with the pressure rise time, as mentioned before. Moreover, the impact pressure occurs in a wider area on the wall at the location of $\delta x/h_1 = 0.47$. Comparisons between the pressure time history recorded at the elevation of $z/h_1 = 0.41$ (**Fig. 3** (d)) and the pressure records on the wall at the breaking point (**Fig. 3** (b)) reveal that the overturned waves may exert even stronger impacts on the wall than the waves which just break on the wall with an almost vertically fronted face (see also **Fig. 6** (c) and (e)). As long pressure rise time, multiple peaks and low frequency oscillations following the peaks reveal and also as seen in **Fig. 2**, a big amount of air is entrapped between the front face of the overturned wave which collides with the wall at the location of $\delta x/h_1 = 0.47$. Therefore, occurrence of such a high impact pressure may be related to the velocity and acceleration of water particles which their values have also become larger, in comparison with their values at the breaking point. As a result, it can be concluded that although the entrapped air is generally supposed to reduce the intensity of the impact pressure, it does not necessarily control the occurrence of high impact pressures.

b) Spilling Breaker

Figure 4 (a) indicates that for a wall location close to the breaking point ($\delta x/h_1 = -0.27$), the pressure recorded at and near the still water level is similar to the standing wave pressure. However, as the elevation increases, the pressure rise time becomes shorter and the maximum value of pressure increases so that it exceeds the value of $7\omega_0 H_1$ at the elevation of $z/h_1 = 0.47$.

The pressure time histories recorded at the breaking point (**Figure 4** (b), $0.33 < z/h_1 < 0.47$) are characterized by short rise time and high peak value. The pressure time history recorded at the elevation of $z/h_1 = 0.43$ reveals that even the spilling breaker exerts the impact pressure on the wall. This indicates

a) Near breaking ($\delta x/h_1 = -0.27$)

b) Breaking point ($\delta x/h_1 = 0.00$)

c) After breaking ($\delta x/h_1 = 0.67$)

d) After breaking ($\delta x/h_1 = 1.47$)

Figure 4: Time histories of the spilling wave pressure recorded on the wall at different locations.

Figure 5: Oscillations in the time history of the spilling wave pressure.

that occurrence of the impact pressure is independent of breaker type, as concluded by Azarmsa et al., (1996a). Since a spilling breaker does not entrap an air pocket (as previously seen in **Fig. 2**), this result also indicates that the impact pressure may be generated even in the absence of entrapped air. As the elevation increases (above the elevation of $z/h_1 = 0.43$), the maximum value of pressure decreases, although the pressure rise time remains short.

The results shown in **Fig. 4** (c) and (d) make clear that as well as a plunging breaker, a spilling breaker also exerts the impact pressure on a vertical wall at a location after the breaking point. As seen previously (**Fig. 3**(c)), low frequency oscillations which demonstrates presence of an entrapped air pocket are observed in the time histories of the plunging wave pressure. In contrast, very high frequency oscillations are detected in the time histories of the spilling wave pressure. To see better these oscillations, one of these records is shown in **Fig. 5** in a smaller time scale. Frequency of these oscillations is more than 1.6 KHz which is much higher than the frequency of oscillations observed in the time histories of the plunging wave pressure (reported here or those reported in the literature). Besides, these oscillations are damped in less than 4ms. Therefore, it seems that these oscillations are excited by some small air bubbles temporarily entrapped between the unstable wave front and the vertical wall or resulted from partial compression and expansion of the air between the wall and upper side of the wave front when it is forced to go out rapidly (see wave profiles of the spilling breaker while colliding with a wall at a location after the breaking point, **Fig. 2** (c)).

Comparisons between the spilling (**Fig. 4**) and plunging (**Fig. 3**) wave pressures exerted on the wall in the after breaking area ($\delta x/h_1 > 0.00$) reveal that

air pocket entrapped by the plunging breaker causes the pressure rise time to increase. From the comparisons, it is also understood that for the records with almost the same maximum pressure values, the pressure rise times are different and vice versa, as also mentioned before. Therefore, it can be concluded that the maximum pressure value does not necessarily obey an inverse relation with the pressure rise time, although some empirical formulas for the peak value of pressure have been based on such an assumption (e.g. Weggel and Maxwell; 1970, Kirkgoz; 1990, Hattori et al.; 1994).

Vertical Distribution of the Maximum Pressure

The study of vertical distribution of the maximum pressure is important not only for evaluating the critical force and momentum working on the structure during the wave impact but also for investigating the localized characteristics of the impact pressure which may be the cause of the local damages in a vertical structure.

To derive the vertical distribution of the maximum pressure, the maximum pressure values of repeated tests carried out under the identical initial experimental conditions are averaged and normalized by $\omega_0 H_1$ at each measuring point. **Figures 6 and 7** respectively show the obtained results for the plunging and spilling breakers at different wall locations in their breaking zones. At each measuring point, the range of pressure variation and the mean value for repeated experiments are illustrated by the interval between two bars and open circle, respectively. From the comparisons, it is found that for both the breakers the peak value of pressure exerted on the wall increases as the wall is shifted more from the before breaking area ($\delta x/h_1 < 0.00$) toward the breaking point ($\delta x/h_1 = 0.00$).

At the breaking point ($\delta x/h_1 = 0.00$), both the experimental and numerical results are illustrated. The solid circle indicates the calculated peak value of the pressure resulted from the direct impact of the free jet on the wall. This value is calculated on the base of horizontal momentum and inertia of the jet (Azarmsa et al., 1996 (a)). The solid line represents vertical distribution of maximum pressure computed directly from the BIM by considering both of the horizontal and vertical components of water particle kinematics. Agreement between the experimental result and the numerical one using the BIM (the open circles and the solid line) reveals that vertical distribution of both the plunging and spilling wave pressures can be computed under the assumption of irrotational flow in the incompressible and inviscid fluid. Moreover, the difference between the peak values of the pressure resulted from each of the computational concepts (the solid circle and line) indicates the significant contribution of vertical velocity and acceleration of water particles in generation of the impact pressure.

As seen, both the breakers exert the impact pressure on the wall not only at the breaking point but also in the after breaking area ($\delta x/h_1 > 0.00$). From the comparisons, it is also found that as the wall is moved from the breaking point toward the after breaking area, size of the area on the wall subjected to

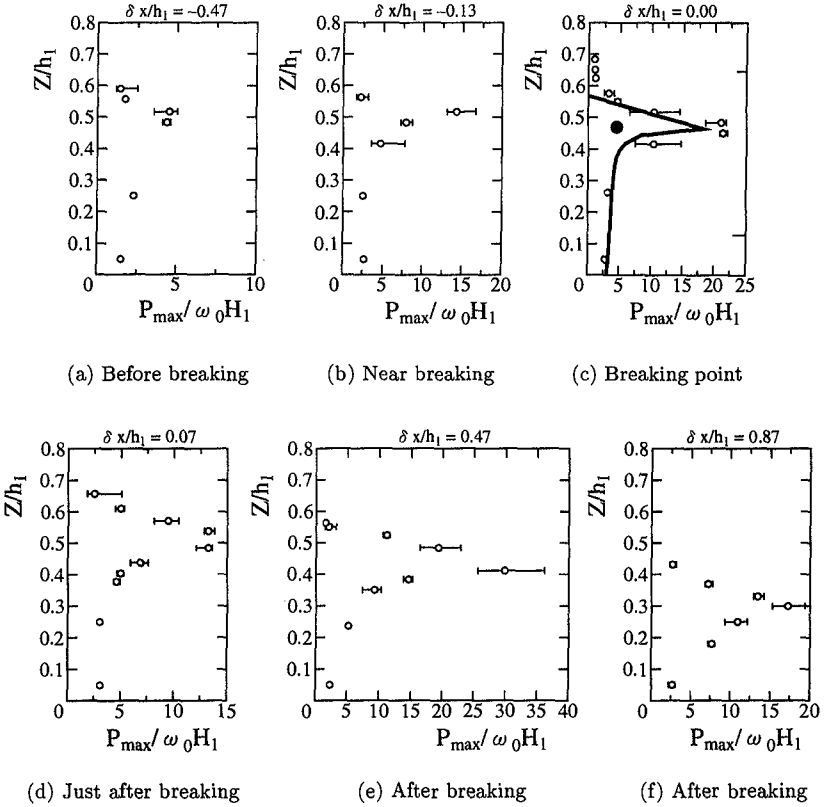

Figure 6: Vertical distribution of the maximum pressure exerted by the plunging breaker on the wall at different locations.

high pressures becomes larger and reach to its largest value at the location of $\delta x/h_1 = 0.47$ for the plunging breaker and $\delta x/h_1 = 1.47$ for the spilling breaker. Therefore, it can be concluded that the total force exerted on the wall in the after breaking area should be the largest. On the other hand, comparisons between Fig. 6 and Fig. 7 reveal that size of the impact zone for the spilling breaker is smaller than that for the plunging breaker. This is because size of the jet (which contains water particles of the most critical kinematics) excited by a spilling breaker is much smaller than that by a plunging breaker. From the comparisons, it is also found that the ranges of pressure variation for the repeated experiments are larger for the spilling breaker. The reason why in the impact zone the spilling wave pressure varies more sensitively with the repeats of the experiments is also related to the fact that size of the jet excited by a spilling breaker is small. In fact because of the smallness of the jet size, the elevation at which the impact pressure is exerted on the wall may change owing to a small

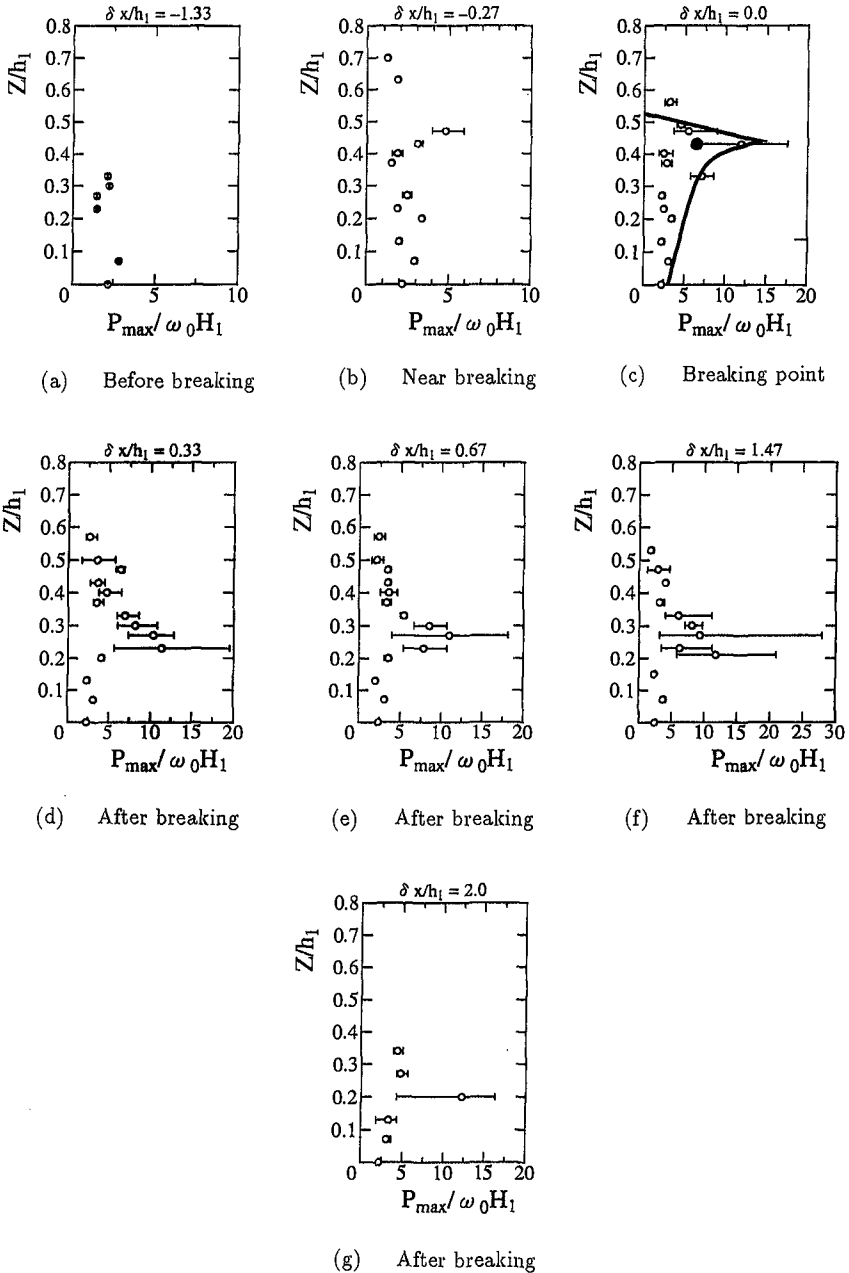

Figure 7: Vertical distribution of the maximum pressure exerted by the spilling breaker on the wall at different locations.

Figure 8: Variation of the peak value in the vertical distribution of maximum pressure with wall locations.

change in the collision condition of a spilling breaker with a vertical wall and as a result, a fixed pressure transducer may or may not be affected by strong impact pressure, from one to another repeat of the experiments. Therefore, it can be concluded that the variability of the maximum pressure in repeated tests is not only due to the randomness and dynamics of entrapped air, but also may be because of the size and elevation of the jet at the instant of collision.

For both of the breakers, variation of the peak value in the vertical distribution of the maximum pressure with wall locations is shown in **Fig. 8**. The results for the plunging breaker reveal that pressure exerted by an overturned wave may be even higher than that by a wave just breaking on the wall with an almost vertically fronted face. The reason may be related to the fact that kinematics of an overturned wave is more critical than the kinematics of the same wave just at the breaking point. In contrast, the pressure peaks recorded for the spilling breaker at different wall locations near the breaking point and in the after breaking area are almost the same. This is not unexpected because the kinematics of the spilling breaker does not change so much during the overturning process. **Figure 8** also reveals that the obtained values for the spilling breaker are smaller than those for the plunging breaker. Since there is a big difference between the spilling and plunging breakers with regard to the volume of entrapped air, if the impact pressure is related to the reduced velocity of sound in a water-air mixture (Schmidt et al., 1992; Hattori, 1994; Peregrine and Topliss, 1994), the pressure exerted by the spilling breaker is expected to be higher (see discussion made by Azarmsa et al., 1996a). However, the results of this study make clear that occurrence of the impact pressure can not be related to the water hammer effect even if the reduced velocity of sound in a water-air mixture is used.

Conclusions

The results of this study clearly show that different types of breaking waves at different steps of their overturning process exert the impact pressure on a vertical structure. It is made clear that occurrence of the impact pressure can not be related to the water hammer effect, even if the reduced velocity of sound in a water-air mixture is used. Besides, it is shown that although the entrapped air reduces the intensity of the impact pressure, it does not necessarily control the occurrence of high impact pressures. Further, it is made clear that occurrence of the impact pressure is closely related to the internal kinematics of breaking waves. Therefore, the condition under which the impact pressure may occur is not critically dependent on wave geometry, entrapped air dynamics and so on. In other words, the structures subjected to the breaking waves quite frequently experience the impact pressure. As a result, even if the impact pressure is supposed to cause local damage in the structure, after sufficient number of repeats of the event at different elevations the stability of the structure may be threaten in whole.

CHAPTER 190

DYNAMIC RESPONSE OF VERTICAL ELASTIC WALLS TO BREAKING WAVE IMPACT

Masatato Hattori¹ and Nobuaki Tsujioka²

Abstract

Experiments were focused on deflection responses of the wall member of upright structures to impulsive wave forces. The experiments revealed that the wall deflection response depends on wave loading modes as well as on natural frequency of the wall member system, f_{NW} . Single degree-of-freedom model of transient impact shows that the peak wall deflection is given as a function of the ratio between rise time of wave force τ_F and f_{NW} , representing characteristics of the wave load and the wall member. The measured peak deflection agrees well with the predicted by the model. In addition, the model indicates that with decreasing natural frequencies of the wall system, the wave load mode brought about greater peak deflections changes from the mode of short duration force to that of long-lasting force.

Introduction

Steep breaking waves impinging onto upright structures bring about high impact forces of short duration. It has been considered that such impact forces are not the cause of sliding and/or overturning of massive structures. On the other hand, some studies (e.g., Weggel and Maxwell, 1970; Mogridge and Jamieson, 1980) pointed out a possibility that the impact force will cause a cumulative and local damage due to shear and fatigue failures to the structure. As a result of successive attacks of the breaking wave, such damage grows likely into a sudden breakdown of the structure.

1 Professor, Department of Civil Engineering, Chuo University, Bunkyo-ku, Tokyo 112, Japan.

2 Graduate-Student, ditto.

The failure processes, therefore, seem to be relevant to deflection responses of the wall member to the impact.

Many studies have been conducted to provide functional information on the stability of upright structures. In contrast with this, as far as we know, only three previous studies (Witte, 1988; Kirkgöz, 1990; Hattori, 1994) have discussed dynamic responses of the vertical wall to impact wave pressures. Therefore, more precise studies are requested to deepen our understanding of the deflection response of elastic walls, as the first step toward the explication of failure processes of the wall member.

Accordingly, we conducted a series of comprehensive experiments with the following objectives;

- (1) to build up the reliable data base of deflection responses of the vertical wall due to impulsive wave forces for designing the structures,
- (2) to examine influences of the wave loading mode and the physical property of elastic walls on the wall deflection response, and
- (3) to discuss a critical condition, producing the greatest wall deflection, based on a single degree-of-freedom model of transient impact.

Experimental setup and Measurements

Figure 1 shows the general arrangement of experimental setup. Experiments were conducted in a glass-walled wave flume, 0.30 m wide, 0.55 m high, and 20 m long, in which a steel plane beach of 1/20 slope was installed. Regular waves were produced by a reflection-absorbing wave maker of flap-type, controlled by a programmed analogue signal yielding a regular wave train. Vertical wall complex was mounted rigidly on a plastic mound with a foreshore slope of 1/10. Except for the wall complex, the experimental setup and measuring techniques used in this study are basically the same as those used in the previous study (Hattori et al. 1994).

Fig. 1 General arrangement of the experimental setup. (units: m)

Vertical wall is composed of two parts, the rigid wall of 10 mm-thick steel plate (0.30 m wide and 0.50 m high) and the square elastic wall as shown in Fig. 2. The elastic wall is a thin plate fully fixed each side with rigid steel frames, and it is

inlaid into the lower section of the rigid wall. Taking into account influences of the wall physical property on the deflection response, we used three elastic plates with different properties (Table 1).

Fig. 2 Wave tank cross-section showing the location of rigid and elastic walls. (units: mm)

Table 1 Physical properties of the elastic plates.

Plate	Thickness (mm)	Density (g/cm ³)	E (KN/m ²)	f _{NW} (Hz)	
				in air	in water

	0.5	9.0	1.0 × 10 ⁸	290	100
Polyvinyl chloride	0.5	1.14	1.6 × 10 ⁷	300	59

E: Modulus of elasticity.

In this study, the wall deflection response will be examined in terms of the natural frequency of the elastic wall system, f_{NW} , as a relevant parameter representing dynamic characteristics of the elastic wall. Taking account of added mass effect of ambient water in front of the wall, the natural frequency (first mode) of wall deflection system (abbreviated to W-D system) were calibrated by a pendulum test with changing the water depth in front of the wall. As an example, the natural

frequency of 1 mm-thick spring metal plate wall is given by Fig. 3, as a function of the relative water depth d_w/h_a (d_w : water depth at the wall, and h_a : elastic wall height).

Fig. 3 Natural frequency of the spring metal wall. (1.0 mm-thick)

When pressure transducers are installed on the elastic wall, the output signals are usually contaminated by wall oscillations (Hattori, 1994). To avoid such undesirable effect, eight semi-conductor type transducers (10 mm ϕ , and natural frequency: 3 KHz) were deployed on the rigid wall (Fig. 2). Impact pressures were recorded on digital recorders over six wave periods at a sampling frequency of 5 KHz. The time history of the wave force per unit wall width, $F^*(t) [=F(t)/\gamma H_B^2]$, was computed by depth integration of the pressure time histories. γ is the specific weight of water, and H_B is the breaking wave height.

Wall oscillations excited by wave impact were detected by an accelerometer (natural frequency: 3 KHz) setting up at the elastic wall center (Fig. 2). Using time series data of the wall oscillations, the wall deflection at the wall center $\delta(t)$ was computed by means of a step by step integration of a linear acceleration method.

Experimental Results and Discussions

The wall deflection response depends closely on the magnitude and the rise time of impact forces (Hattori, 1994). Accordingly, we classify the wave loading into the three following modes (Hattori et al., 1994), according to the relationship between the wave force oscillation frequency f_{FO} and the natural frequency of W-D system f_{NW} . That is,

- (1) Single peaked load (S-P LOAD) with very short duration: $f_{FO} \gg f_{NW}$,

- (2) Damped pressure oscillation load A (D-P-O LOAD A): $f_{FO} > f_{NW}$, and
 (3) Damped pressure oscillation load B (D-P-O LOAD B): $f_{FO} < f_{NW}$.

Time history records of the wave force and the wall oscillations were examined by the aid of a frequency spectral analysis. The time history records taken from a breaking wave collision are transient data that result from short duration nonstationary phenomena with a clearly defined beginning and end. Hence, frequency spectra of these data will be analyzed by means of techniques commonly used for stationary data.

Figure 4 shows a typical experimental result obtained from the S-P LOAD, an extremely high peak pressure of $p_p=1030 \text{ N/m}^2$ [$p_p^* (=p_p/\gamma H_B)=80.1$] occurs at just above the still water level (pressure records not shown). Fig. 4 (A) is time history records of the wave force and the wall oscillations of spring metal of 1-mm thick. $t^* [= t/(H_B/C_S)]=0$ on the time axis refers to the time of the peak wave force. $C_S (=1500 \text{ m/s})$ is the sound velocity in water. Three video still pictures on the top of Fig. 4 provide a sequential change of impinging wave shape, at three different instants marked by thick arrows on the top of the time history records.

Fig. 4 (B) shows a comparison between the computed frequency spectra of the wave force and the wall oscillation data. From a comparison between time histories of the wave pressures (not shown) and the wave force (Fig. 4 (A)), we find that despite the peak wave pressures produced by S-P LOAD are extremely high magnitude, the maximum wave force does not attain a high magnitude ($F_M=1030 \text{ N/m}$), because of narrow region of the high peak pressures and of subtle time gaps between the peak pressures.

Just after impact, the wall starts to oscillate and keeps on oscillating with a natural frequency of the W-D system even after damping down the wave impact. In Fig. 4 (B), no any spectral peak appears on the frequency spectrum of wave force. In contrast with the wave force, on the frequency spectrum of wall oscillations, a distinct spectral peak is found at a frequency of 278 Hz correspond to the natural frequency of W-D system, in which the wall is almost in water (see Fig. 3, $d_w/h_a=0.9$).

Under D-P-O LOAD A, a thin air pocket is trapped between the wall and breaking wave front at impact, results in the wave force oscillations with higher frequencies than the natural frequency of the W-D system. Owing to short duration time of the wave force, the maximum wave force ($F_M=1720 \text{ N/m}$) is larger than that of S-P load (Fig. 4 (A)). Consequently, as seen in Fig. 5 (A), the spring metal wall of 1.0 mm-thick can not response to very rapid changes of the impact force and keeps to oscillate with its own natural frequency, even after the wave force oscillations damp down. The computed frequency spectrum of wave force record indicates a distinct spectral peak at a frequency of 479 Hz, while that of wall oscillation record shows the only peak at a frequency of 288 Hz, corresponds to the natural frequency of W-D system (see Fig. 3, $d_w/h_a=0.81$).

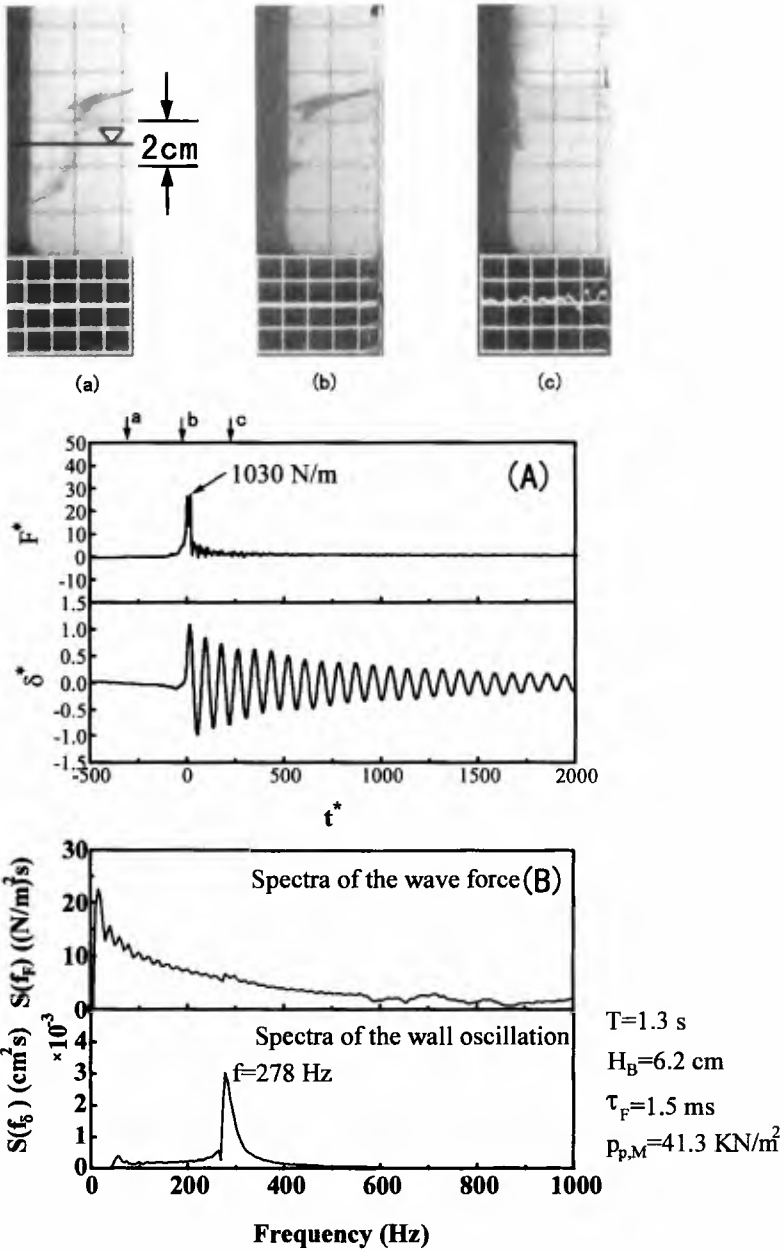

Fig. 4 Time history records of frequency spectra of the wave force and the wall deflection. (S-P LOAD)

Fig. 5 Time history records and frequency spectra of the wave force and the wall deflection. (D-P-O LOAD A)

Figure 6 shows the time history records taken from D-P-O load B and these computed frequency spectra. The D-P-O LOAD B occurs when a larger air pocket is trapped at impact. Therefore, the peak pressure magnitudes decrease and the pressure rise times increase. These wave loading characteristics are clearly reflected in the wave force record (Fig. 6 (A)). The wave force record also displays a regularly damped oscillations, while the wall oscillation record indicates a rather complicated behavior owing to collisions of irregular wave front of impinging breakers on the wall, as seen in the still pictures on the top of Fig. 6 (A). Frequency spectrum of the wave force record indicates that the wave force oscillates with a frequency of 186 Hz. On the other hand, the wall oscillations are composed of two dominant components in frequency, the natural frequency f_{NW} of 479 Hz (see Fig. 3) and the frequency of 186 Hz, identical with the wave force oscillations. The wall oscillations with 186 Hz frequency attenuate rapidly with the wave force oscillations. It seems that the small spectral peak at 250 Hz indicates the occurrence of the free oscillation of second mode of W-D system.

From the experimental results, we notice the following facts;

- (1) When frequencies of the wave force oscillations are higher than the natural frequency of the W-D system (S-P LOAD and D-P-O LOAD A), the only wall oscillation with the natural frequency of W-D system is excited just after the wave impact. On the other hand, D-P-O LOAD B excites wall oscillations with two dominant components in frequency, the wave force oscillation and the natural oscillation of W-D system. In either case, the wall keeps on oscillating with the natural frequency even after the impact force damp down.
- (2) The natural frequency of W-D system changes with the contact length of entrapped air pocket with the wall, depends on the wave loading mode (see Fig. 3). Then, the contact length is measured from still video pictures taken at the instant of a wave impact, and the natural frequency of W-D system is estimated by using the pendulum test result. It is found that the natural frequency is almost the same as the measured one.
- (3) Wave pressure records taken from the D-P-O LOAD display regular pressure oscillations with almost the same changes in magnitude and in phase (not shown). A thinner air pocket entrapped at impact brings about a higher peak pressure of short duration and results in pressure oscillations with a higher frequency (Hattori et al., 1994). As the result, maxima of the wave force due to D-P-O LOAD tend to be larger than that due to S-P LOAD, which produces very high peak pressures over narrow zone near the still water level. On the basis of the measured pressure record, Figures 7 (a) and (b) show relations of $\dot{p}_{P,M} \sim \dot{\tau}_P$ and $\dot{F}_M \sim \dot{\tau}_F$. $\dot{p}_{P,M}$ ($= \dot{p}_{P,M}/\gamma H_B$) is the maximum peak pressure, and $\dot{\tau}_P$ ($= \dot{\tau}_P/(H_B C_S)$) and $\dot{\tau}_F$ ($= \dot{\tau}_F/(H_B C_S)$) are the rise time of wave pressure and wave force. The variation trend of \dot{F}_M with $\dot{\tau}_F$ is similar to that of $\dot{p}_{P,M}$ with $\dot{\tau}_P$. However, we notice that maxima of the wave force due to D-P-O LOAD (open triangles) tends to be greater than that due to S-P LOAD. This is a very important evidence for designing the structure.

Fig. 6 Time history records and frequency spectra of the wave force and the wall deflection. (D-P-O LOAD B)

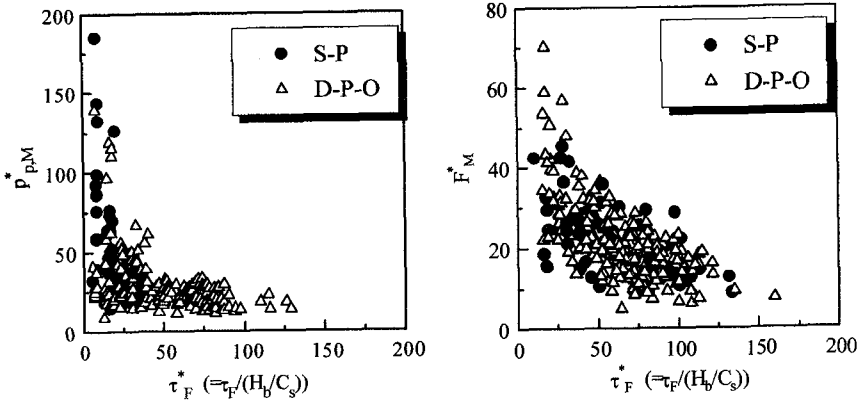

Fig. 7 Relation of $p^*_{P,M} \sim \tau^*_P$ and $F^*_M \sim \tau^*_F$.

(4) As seen in Fig. 4 (A) of the S-P LOAD, the wall oscillations lasting for a long time are gradually damped and maintains a almost constant frequency. This implies that both the fluid damping and the added mass due to the impinging water mass do not practically affect the wall deflection response to a transient impact.

Single Degree-of-Freedom Model for Transient Impact

In the following, we will discuss the wall deflection as a transient phenomenon caused by a wave impact of short duration. Based on the experimental results, assume that any damping and added mass effects caused by the water mass colliding on the wall can be neglected.

We use a single degree-of-freedom model of transient impact, in which the wall at rest is subjected a force input $F(t)$ and produces a wall deflection response $\delta(t)$. The equation governing the deflection response of the elastic wall system without damping (Fig. 8) is given by Eq. (1).

Fig. 8 Wall deflection system for transient impact.

$$m \frac{d^2\delta(t)}{dt^2} + k\delta(t) = F(t) , \tag{1}$$

where m is the wall mass including the virtual mass of impinging water, k is the spring constant, and t is the time. The input force $F(t)$ is assumed by a form of isosceles triangle with the height of F_M and the base of 2τ (Fig. 8). With the initial conditions of

$$\delta = d\delta(t)/dt = 0 : \text{at } t = 0, \tag{2}$$

the relative wall deflection δ/δ_s is obtained as Eqs. (3) to (5). δ_s is the wall deflection due to the maximum wave force F_M as a static load, distributed uniformly on the wall center elevation.

$$\delta/\delta_s = (t/\tau) - (\sin f_{NW}t / \sin f_{NW}\tau) ; (0 \leq t \leq \tau) \tag{3}$$

$$= (2\tau-t)/\tau + [2\sin f_{NW}(t-\tau) - \sin f_{NW}t] / \sin f_{NW}\tau ; (\tau \leq t \leq 2\tau) \tag{4}$$

$$= [2\sin f_{NW}(t-\tau) - \sin f_{NW}t - \sin f_{NW}(t - 2\tau)] / \sin f_{NW}\tau ; (2\tau \leq t) \tag{5}$$

, in which $f_{NW} = (1/2)(k/m)^{1/2}$: the natural frequency of the wall system. From Eqs. (3) to (5), we calculate the gain factor of wall deflection, $\delta_M^* (= \delta_M/\delta_s)$ and the relative lag time $\Delta t_\delta^* (= \Delta t \cdot f_{NW})$ between the maximum force F_M^* and peak deflection δ_M^* (Fig. 9), as a function of the relative rise time $\tau_F^* (= \tau_F \cdot f_{NW})$.

Variations of the gain factor δ_M^* and the lag time Δt_δ^* in terms of τ_F^* are shown in Fig. 9. The single degree-of-freedom model indicates that the largest peak wall deflection due to a given wave force attains 1.5 times as much as the static wall deflection, when the relative rise time $\tau_F^* = 0.45$, and that the peak wall deflection always appears after occurrence of the maximum wave force.

Fig. 9 Variations of δ_M^* and Δt_δ^* .

Figures 10 and 11 show respectively a comparison between the measured and predicted gain factor for 1 mm-thick spring plate and 0.5 mm-thick PVC plate walls.

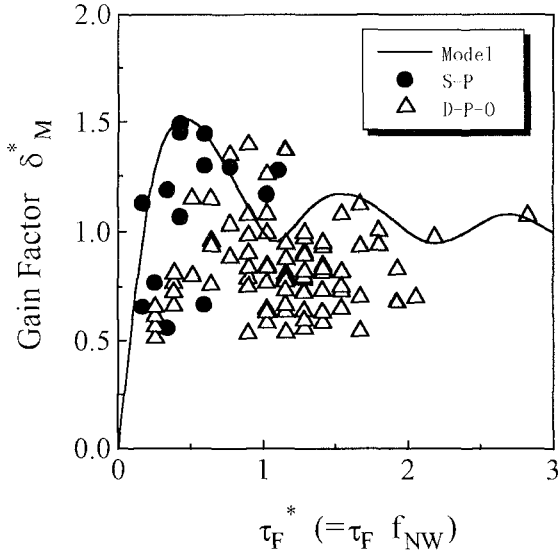

Fig. 10 Gain factor of the wall deflection.
(1.0 mm-thick spring plate wall)

Fig. 11 Gain factor of the wall deflection.
(0.5 mm-thick PVC plate wall)

The solid line represents the model prediction. Although the experimental points are widely scattered owing to variability of the impact processes, the model agrees reasonably well with upper bounds of the experimental points. In case of the spring metal wall ($f_{NW}=557$ Hz in air), the large gain factor within range of $0 \leq \tau \leq 1$ is produced by the S-P LOAD (solid circles). On the other hand, in case of PVC plate ($f_{NW}=300$ Hz in air), the large gain factor within the same range appears under the D-P-O LOAD condition (open triangles).

Due to the three-dimensionality of the wave impact process, the convergent crest of breaking waves does not always hit simultaneously the rigid and elastic walls. As the result, we could not obtain reasonably good results on the variation of the delay time Δt^*_δ with the relative rise time τ^*_F .

Conclusions

We conducted laboratory experiments focused on wall deflection responses of the wall member of upright structures to impulsive wave forces. The wall deflection response relates closely not only to the wave load mode, the magnitude and the rise time of impact forces, but also to the natural frequency of the wall deflection system. The single degree-of-freedom model of transient impact describe well the wall deflection process. In addition, the experiments point out an very important fact that the wave force produced by single-peaked load is lower than that by the damped-pressure-oscillation load, such as D-P-O LOAD A. The main findings are as follows;

- (1) Both S-P LOAD and D-P-O LOAD A, $f_{FO} \gg f_{NW}$ and $f_{FO} > f_{NW}$, excite the wall oscillations only with the natural frequency of the W-D system. Such wall oscillations continue for a long time even after the wave impact damp down.
- (2) The wall oscillations due to the D-P-O LOAD B, $f_{FO} < f_{NW}$, consist of the two components in frequency, correspond to the wave force oscillations and the natural oscillations of W-D system.
- (3) The single degree-of-freedom model of transient impact describes well the wall deflection response and is verified by comparisons of the experiments. The gain factor of the wall oscillation δ^*_M is a function of the relative rise time τ^*_F , and the peak value of δ^*_M attains 1.5, when $\tau^*_F = 0.45$.

CHAPTER 191

WAVE TRANSMISSION PAST VERTICAL WAVE BARRIERS

David L. Kriebel¹ and Chad A. Bollmann²

Abstract

Three theories for predicting regular wave transmission past vertical wave barriers are evaluated using three sets of experimental data. The three theories are: (1) the power transmission theory of Wiegel (1960), (2) and modified power transmission theory that includes effects of wave reflection, and (3) the eigenfunction expansion theory of Losada et al. (1992). Under deep and near-deep water conditions - which are typical of most design conditions - the theory of Wiegel is found to over predict wave transmission under most circumstances. The modified power transmission theory provides better agreement with the data. The eigenfunction method provides good agreement for deep wave barrier drafts but overestimates transmission for shallow drafts.

Introduction

For more than 30 years, estimates of wave transmission past vertical wave barriers (vertical wall breakwaters, sometimes called wave screens, wave fences, skirt breakwaters, or curtain walls) have been based primarily on the theory and experimental data published by Wiegel (1960). The "Wiegel Theory" has been adopted as the recommended practice by both the Army Corps of Engineers (1984) in the *Shore Protection Manual* and by the Naval Facilities Engineering Command (1982) in the *Coastal Protection Design Manual 26.2*. While other theories have been published since then, none has been as widely adopted for design purposes and none has been accompanied by new experimental data.

Despite the widespread use of the Wiegel theory, questions have arisen recently³ concerning its accuracy. Wiegel himself recognized that the theory was not physically rigorous and he considered it a first approximation based on some limiting assumptions (Wiegel, 1995, personal communication). In general, a comparison of Wiegel's theory to his own data shows that his theory tends to overpredict wave transmission under deep water conditions and underpredict transmission as the relative water depth became more shallow. Since most wave barriers are built in deep or near-deep water conditions, use of this theory in design may produce deeper wave barrier drafts, at greater cost, than would actually be required to achieve some desired level of wave transmission.

Recently, several more sophisticated theories for wave transmission have been proposed based on numerical solutions of the boundary value problem for waves interacting with a vertical barrier. Liu and Abbaspour (1982) developed a numerical solution based on the boundary integral equation method, while both Losada, Losada, and Roldan (1992) and Abul-Azm (1993) developed numerical solutions based on the method of eigenfunction expansion. Compared to Wiegel's simple theory, these theories are more difficult to apply because they require complex matrix solutions. In addition, the numerical solutions have not been widely or rigorously verified through comparison to measurements.

In this paper, we evaluate three different theories for predicting the transmission of regular waves past wave barriers and we then compare these theories to some new experimental data for wave transmission past vertical wave barriers. The three theories that are evaluated include: (1) the original power transmission theory of Wiegel, (2) the eigenfunction expansion theory of Losada et al. and Abul-Azm, and (3) a modified power transmission theory which was developed in the course of this study. This modified theory is, like the original Wiegel theory, based on the wave power transmission past the wave barrier and, like the Wiegel theory, predicts the wave transmission is a simple closed-form equation. Unlike the original derivation, however, the modified theory accounts for the effects of partial wave reflection from the barrier and this results in different (lower) transmission than is predicted by the Wiegel theory

These theories are then evaluated using laboratory data from three different sources. This includes the original Wiegel data as well as additional laboratory tests data published by Peratrovich, Nottingham & Drage, Inc. (1992) based upon tests conducted by the British Columbia Research Corporation (BCRC). The third set of data was then collected as part of this study and is based on experiments conducted at the U.S. Naval Academy Hydromechanics Laboratory (NAHL).

³ Based on discussions at a Wave Barrier Design workshop, held by Peratrovich, Nottingham & Drage, Inc. in Seattle, Washington, on April 24-25, 1995

Definition of a Vertical Wave Barrier

A definition sketch of a vertical wave barrier is shown in Figure 1. The wave barrier consists of an impermeable vertical wall with a draft or penetration, w , in water of depth d . The wave field consists of incident regular waves with height H_i and frequency σ , along with transmitted waves of height $H_t = K_t H_i$, and reflected waves of height $H_r = K_r H_i$, where K_t and K_r are the transmission and reflection coefficients. The water depth is assumed uniform on both sides of the wall so that the wave length, L , and the wave group velocity, C_g , are equal on both sides. If we define the wavenumber as $k = 2\pi/L$, then the wave transmission is fundamentally dependent on two dimensionless variables: the relative water depth kd and the relative barrier penetration kw .

Figure 1. Definition sketch of wave interaction with a vertical wave barrier.

Wiegel Power Transmission Theory

The Wiegel theory is based on the concept that wave motions behind the wall (downstream) are related to the wave power transmission below the wall. Wave power is computed as the depth-integrated product of wave induced dynamic pressures, p , and wave-induced horizontal fluid velocities, u , time-averaged over one wave cycle. Wiegel then assumed that the net wave power transmitted behind the wall (over the full depth) was equal to the fraction of the incident wave power below the bottom of the wall as

$$\frac{1}{T} \int_0^T \int_{-d}^0 p_i u_i dz dt = \frac{1}{T} \int_0^T \int_{-d}^{-w} p_i u_i dz dt \tag{1}$$

Substituting the expressions for dynamic pressure and horizontal fluid velocity from linear wave theory and carrying out the integration then leads to the solution for the transmission coefficient given by Wiegel (1960) as

$$K_t = T_F^{1/2} \tag{2}$$

where we introduce the *transmission function*, T_F , which is given by

$$T_F = \frac{2k(d-w) + \sinh 2k(d-w)}{2kd + \sinh 2kd} \tag{3}$$

Modified Power Transmission Theory

In the modified power transmission theory, the same basic approach is used but the effects of wave reflection are also considered. This time, the dynamic pressures below the barrier are assumed to be given to first order by the sum of incident and reflected pressures, $p_i + p_r$. Because pressures are additive, the net pressure acting on a vertical plane below the wave barrier is greater than that assumed by Wiegel. In a similar way, the horizontal fluid velocities below the wave barrier are modified by reflection. However, the effective velocity is $u_i - u_r$, and is reduced from that assumed by Wiegel.

Based on the above arguments, the transmitted wave power downstream can be equated to the net wave power transmitted under the barrier as

$$\frac{1}{T} \int_0^T \int_{-d}^0 p_i u_i dz dt = \frac{1}{T} \int_0^T \int_{-d}^{-w} (p_i + p_r) (u_i - u_r) dz dt \tag{4}$$

Substituting the expressions for dynamic pressures and horizontal fluid velocities from linear wave theory and canceling common terms then gives:

$$K_t^2 = (1 - K_r^2) T_F \tag{5}$$

By including the effect of the reflected wave, the solution given above contains two unknowns and cannot be solved without introduction of another relationship between K_t and K_r . Since equation (5) implicitly assumes that there are energy losses in the system, the necessary relationship is one that guarantees conservation of fluid mass, or continuity of the fluid velocities, below the wave barrier as $u_t = u_i - u_r$. Ignoring any phase shifts that may occur across the wall, and assuming that velocities are described by linear wave theory, the matching condition requires that

$$K_t = 1 - K_r \quad (6)$$

Substitution of equation (6) into equation (5) then gives the following solution for transmission coefficient from the modified power transmission theory:

$$K_t = \frac{2 T_F}{1 + T_F} \quad (7)$$

where the transmission function T_F is defined in equation (3). Because of the inclusion of the effects of wave reflection, equation (7) predicts wave transmission coefficients that are smaller than those predicted by the Wiegel theory in equation (2). This may be seen most readily in equation (5) where it is clear that the effect of wave reflection (with reflection coefficient K_r greater than zero but less than one) is to decrease the wave transmission compared with that predicted by Wiegel.

The modified power transmission theory is, like the Wiegel theory, an approximation of the actual wave transmission process. From a theoretical standpoint, the method appears inconsistent because the usual balance of incident, reflected, and transmitted wave energy is not preserved. In addition, the modified theory, like the Wiegel theory, produces inconsistent results when taken in shallow water limit. However, the method is intended as a simple engineering solution and, as will be shown, it provides significantly better results when compared to measured wave transmission than the Wiegel theory for most conditions of interest.

Eigenfunction Solution

Because of the theoretical limitations of the power transmission theories, it is next of interest to consider mathematically exact solutions for linear water wave interaction with a thin vertical barrier. Such a solution has been given by both Losada et al. (1992) and Abul Azm (1993) based on eigenfunction expansion methods and their solution will be further considered here. In this paper, the method will only be presented in a summary form and the reader is referred to the original papers for a more thorough description of the method.

The eigenfunction expansion method involves solution for the velocity potentials on the upwave side (wavemaker or incident wave side) and on the downwave side (transmitted wave side) of the wave barrier. These upwave and downwave potentials must then be appropriately matched at the location of the wave barrier ($x=0$). Following Dalrymple and Martin (1990), these potentials must be harmonic in time with frequency σ and must have a spatial dependence (in x and z) given by

$$\Phi_{up} = Z_1 e^{-ik_1 x} + \sum_{n=1}^N R_n Z_n e^{ik_n x} \quad \Phi_{dn} = Z_1 e^{-ik_1 x} - \sum_{n=1}^N R_n Z_n e^{-ik_n x} \quad (8)$$

Equation (8) automatically satisfies the requirement that the velocities must be matched at all elevations on and below the barrier. In this form, the first term in each velocity potential is the incident progressive wave mode while the terms in the summation includes both the scattered progressive wave ($n=1$) and the evanescent wave modes ($n > 1$), all with unknown complex amplitudes R_n .

The functions Z_n in equation (8) describe the depth-dependence of the wave modes and are given by

$$Z_n = \frac{i g H_i}{2 \sigma} \frac{\cosh k_n (d+z)}{\cosh k_n d} \quad (9)$$

The wavenumbers k_n are given by the solution of the dispersion equation

$$\sigma^2 = g k_n \tanh k_n d \quad (10)$$

where the first (real) root is the linear progressive wavenumber, $k_1 = k$, and where there are then an infinite set of imaginary roots for $n > 1$.

The solution for the complex amplitudes R_n must satisfy two additional physical requirements: (a) the velocities must be zero on both sides of the barrier in the upper region where $-w < z < 0$, and (b) the velocity potentials (or equivalently the dynamic pressures) must match in the gap below the barrier where $-d < z < -w$. As a result, two distinct equations (from upper and lower regions) are obtained - the so-called dual-series relationships noted by Dalrymple and Martin (1990) - and both must be satisfied simultaneously to find the unknowns R_n .

It may then be shown that two equivalent methods may be used to satisfy the matching conditions: one through a least squares procedure and the other through a more direct procedure. In the first approach, used by Losada et al. (1992) and Abul-

Azm (1993), the matching conditions are first applied locally, retaining the vertical (z) dependence. The resulting dual series relationships are then combined and re-written as one mixed boundary condition which must equal zero over the full depth. This combined function is then solved in a least-squares sense in which the square of the function is minimized. In a second approach, used in this paper, the matching conditions are applied and are again combined into one mixed boundary condition. This combined function is then, however, multiplied by the orthogonal functions Z_n and depth-integrated over the full depth. This results in a single matrix equation that can be solved directly without the need a least-squares solution.

Following the second method, the mixed boundary condition to be satisfied, denoted $G(z)$ as in Losada et al. (1992), is defined for the upper and lower regions as follows. In the upper region, the horizontal velocities ($u = \partial\Phi/\partial x$) are set equal to zero at the wave barrier ($x=0$) resulting in

$$G(z) = -k_1 Z_1 + \sum_{n=1}^N R_n k_n Z_n = 0 \quad -w < z < 0 \quad (11)$$

In the lower region, the velocity potentials from equation (8) are matched directly under the wall ($x=0$) as

$$Z_1 + \sum_{n=1}^N R_n Z_n = Z_1 - \sum_{n=1}^N R_n Z_n \quad (12)$$

Following cancellation of the leading terms, and after multiplying by k_1 to make equation (12) dimensionally consistent with equation (11), the remaining portion of the mixed boundary condition is obtained as

$$G(z) = 2 k_1 \sum_{n=1}^N R_n Z_n = 0 \quad -d < z < -w \quad (13)$$

The mixed boundary condition $G(z)$ can then be satisfied in the usual way by employing the orthogonality properties of the depth-dependent eigenfunctions Z_n from equation (9) as

$$\int_{-d}^0 G(z) Z_m dz = 0 \quad (14)$$

This yields the following set of matrix equations which must be solved for the unknown amplitudes R_n

$$\sum_{n=1}^N R_n (2 k_1 X_{nm} + k_n Y_{nm}) = k_1 Y_{1m} \quad (15)$$

where the functions X_{nm} and Y_{nm} are defined by Losada et al. (1992) and are given by

$$X_{nm} = \int_{-d}^{-w} Z_n Z_m dz \quad (16)$$

$$Y_{nm} = \int_{-w}^0 Z_n Z_m dz \quad (17)$$

Once the matrix in equation (15) is solved for the unknowns R_n , the transmission coefficient is obtained from the first term, R_1 . The reflection and transmission coefficients for the progressive wave modes are given by

$$K_r = |R_1| \quad K_t = |1 - R_1| \quad (18)$$

Numerical computations have shown that the solution obtained by employing the orthogonality properties of the eigenfunctions is numerically equivalent to that obtained by Losada et al. (1992) using the least-squares solution procedure. It is noted, however, that the matrix in equation (15) is somewhat easier to solve than that given by Losada et al. in that it has stronger diagonal dominance.

Comparison to Data

The three theories for wave transmission past vertical wave barriers are now compared to available laboratory data for regular waves. Two sources of published data were considered: (1) the data given by Wiegel (1960) and (2) the data given by Peratovich, Nottingham, and Drage (1992) from tests conducted at the British Columbia Research Corporation (BCRC). These data were then supplemented by additional data collected in the Naval Academy Hydromechanics Laboratory (NAHL).

The NAHL tests were conducted in a wave tank 120 feet (36.6 m) long, 8 feet (2.43 m) wide, and 5 feet (1.52 m) deep. A thin rigid wall (2 inches or 5 cm thick) was placed about 60 feet (18.3 m) from the wavemaker. The wall was supported at the sides of the tank and was also backed by an aluminum frame to prevent deflection of the wall. With the fixed water depth, four wall penetrations were tested producing four values of the relative wall penetration, w/d , was 0.4, 0.5, 0.6, and 0.7.

In these experiments, 80 tests were performed with regular waves. The wave periods varied from 0.9 sec to 2.5 sec and wave heights ranged from 1 in (2.5 cm) to almost 9 inches (23 cm). Combinations of these parameters were used to obtain values of wave steepness, H_s/L , between 0.01 and 0.06 with most tests being in the range of 0.02 to 0.04. Incident waves were measured with a fixed wave gage near the wavemaker while transmitted waves were measured with the fixed gage located about 15 feet (4.6 m) behind the wall. In all tests, a series of 5 to 10 waves of uniform height was generated and measurements were limited to exclude any effects of wave reflection from the beach landward of the wall or from the wavemaker.

Figures 2a through 2h present comparisons of measured and predicted transmission coefficients for regular waves. Each figure represents a specific relative water depth, d/L . Transmission coefficients are then plotted as a function of the relative wall penetration, w/d . Note that in some cases where more than one source of data is used, the relative water depths were approximated in order to compare the various theories and data sets on the same graph. As an example, in Figure 2b, tests conducted by Wiegel used a relative depth of 0.68, while tests conducted by BCRC used a relative depth of 0.73. Theoretical results were based on an approximate average value of $d/L=0.70$.

Figures 2a, 2b, and 2c show measured and predicted wave transmission for deep water conditions where the relative depth is about 0.5 or higher. In these figures, it is evident that the Wiegel theory overestimates the wave transmission while the modified theory provides much better predictions at all values of relative depth and wave barrier penetration. For those cases where the penetration reached one-third to one-half of the water depth, wave reflection from the wave barrier is expected to have been most pronounced. It is for these conditions that the differences between the two theories are particularly large and the modified theory, which includes the effects of wave reflection, provides a significant improvement. The eigenfunction solution overestimates the transmission for small wall penetrations but then agrees with the modified theory and predicts the transmission quite well for deeper wall penetrations.

All other cases shown in Figure 2 represent intermediate or transitional water depths. In Figures 2d, 2e, and 2f it is evident that the modified theory yields improved prediction of wave transmission for most wave barrier penetrations when compared to the Wiegel theory. For barrier penetrations of 0.2 or less (wave barrier penetrations just below the wave trough level), both theories underpredict the measured wave transmission. For cases of deeper penetration, the Wiegel theory again tends to overestimate transmission while the modified theory is more accurate. In these cases, the eigenfunction solution again overestimates transmission for small wall penetrations and agrees with the modified power transmission theory - and with the data - at larger wall penetrations.

In Figures 2g and 2h, the relative depth is fairly shallow (though still greater than the normal limit between intermediate and shallow water wave conditions) and results of the three theories are mixed. Of the two power transmission theories, the Wiegel theory generally provides better predictions than the modified theory. Unlike the deep water conditions, the Wiegel theory no longer overestimates transmission and, in fact, has a tendency to underestimate transmission. The modified theory consistently underestimates the transmission more severely. In these "shallow water" conditions, the eigenfunction theory tends to overestimate the transmission at all values of wall penetration until the wall penetration is over 90 percent of the water depth.

Conclusion and Discussion

Results presented in this paper indicate that for most conditions of interest in engineering design - for deep water conditions with large wave barrier penetration (typically to mid-depth or deeper) - the Wiegel theory generally overestimates wave transmission while both the modified power transmission theory and the eigenfunction expansion theory produce more accurate predictions with little bias toward over or under-prediction of wave transmission. Neither the modified power transmission theory nor the eigenfunction expansion method produce improved estimates of wave transmission under all conditions, however. In near-shallow water, the modified theory tends to underestimate wave transmission while, for these same relative depth conditions, the eigenfunction method tends to overestimate wave transmission.

One puzzling feature of the results in Figure 2 is the degree to which the modified power transmission theory agrees with the complete eigenfunction solution for certain conditions, namely for deep water and large wall penetrations. This can be explained by considering the first term in the eigenfunction expansion. From equation (15), if $n=m=1$, the leading-order behavior of the eigenfunction solution is

$$R_1 = \frac{Y_{11}}{2X_{11} + Y_{11}} \quad (19)$$

The integrals Y_{11} and X_{11} may be expressed in terms of the transmission function, T_F , in equation (3) and it can be shown that $X_{11} \approx T_F$ and $Y_{11} \approx 1 - T_F$. As a result, the leading-order wave transmission from the eigenfunction solution can then be obtained from equation (11) in the following form

$$K_t = 1 - R_1 = \frac{2T_F}{1 + T_F} \quad (20)$$

This result is identical to that obtained from the modified power transmission theory in equation (7). The modified power transmission theory is therefore consistent with

the leading-order behavior of the progressive wave modes in the eigenfunction solution and is valid for conditions where the evanescent wave modes are not expected to be significant.

For conditions where the evanescent modes are important (small wave barrier penetrations), the eigenfunction solution tends to overestimate wave transmission and is less accurate than would be expected. The reason for this appears to be that frictional losses become important due to flow separation at the bottom of the wave barrier. In the NAHL tests, both dye studies and velocity measurements using an acoustic doppler velocimeter confirmed the presence of a large vortex at the bottom of the wall. The inclusion of friction in the eigenfunction solution dramatically improves its predictive ability and this will be the subject of future work.

CHAPTER 192

PHYSICAL STUDY OF THE NATURE OF HIGH PEAK WAVE PRESSURES

Jordan Marinski¹

ABSTRACT

In order to investigate the generation mechanism of high peak wave pressures on vertical/steep walls two physical experiments are carried out on a specially constructed research apparatus. It is found from present experiments that the enclosed air volume as a physical medium under compression could not be a cause for the high peak short-period wave pressures. The wave breaking on a vertical wall is accompanied by cumulating of the wave energy and its redistribution on the smaller area of the wall and conditions for shock wave are created after the collision of the streams.

INTRODUCTION

During the breaking of a wave on vertical/steep walls or elements very short-period peak pressures have been recorded. There are experimental data which prove their importance about coastal and harbours works stability,(OUMERACI et al., 1992). But in the literature there are different and inconsistent physical hypotheses which should explain one and the same phenomenon - high peak pressure generating mechanism. These hypotheses have become a physical basis of different formulas for calculation of the wave loading on vertical walls or elements used in the designing and building of vertical structures. In this way insufficient study of the nature of high peak pressures has contributed to many failures of the vertical structures.

1) Assoc. Professor, Bulgarian Academy of Sciences, Institute of Water Problems, Acad. G.Bonchev street, Block 1, 1113 Sofia, Bulgaria.

The aims of this experimental study are: 1) to model breaking wave impact out of wave flume if we accept in advance that those basic assumptions of BAGNOLD, (1939) for the appearance of this type of high pressures are truth, namely a) the wave motion turns into translational motion; b) shortly before the impact the wave front is vertical and smooth; 2) to learn the quantitative effects of a entrapped air volume on the impact parameters.

PROCEDURE

The reasons to be investigated high peak pressures out of wave flume are: 1) the experiments carried out in a wave flume show that such kind of breaking wave impact, when the high peak short-period pressure appears, repeats very rarely even if there are the same wave parameters and the same geometry of the bottom at the approach of waves; 2) it is not possible to give in advance one exactly fixed air volume on the wall and to study its quantitative effect during breaking wave impact in a wave flume.

The experimental study is carried out on a specially constructed research apparatus, Fig. 1.

Fig. 1 Experimental set-up

One of the arms of "U"-shaped pipe is made of Plexiglas and has rectangular cross-section, which allows visual observation of the impact of the water column on a flat solid plate. Under the plate a water-air-outflow opening is left. Its dimensions are chosen in such a way that two requirements are met : 1) water column cross section remains the same until reaching the impact plate with velocity values from 0,8 to 1,5 m/s; 2) the spreading of a water hammer pressure is avoided.

The water column motion is a uniformly accelerated motion due to the head which is created beforehand by changing the pressure in one of the arms and instantly following equalising of that pressure. With this preliminary created head the water column velocity is regulated and it could reach the value of 1,5 m/s. At such velocity values in a wave flume, the high peak pressures at wave height of 6-10 cm has been registered, by SMIRNOFF, (1955) and RUNDGREN, (1958). The liquid

mass taking part in the impact is 7,65 kg. The experiment is filmed by a high speed camera (4000 frames per second).

The research working program includes the following two physical experiments:

EXPERIMENT A: *Quantitative study of the entrapped air volume effect on the impact parameters: p , dp/dt and t , where p - hydrodynamic pressure; dp/dt - rate of pressure change; t - rise time.*

The air quantity is given preliminary. Under the impact plate in the side outlet plane a replaceable water-and airtight "threshold" is fixed. Its height D is given beforehand and varies from $0,06 H$ to $0,22 H$, where H is the width of the water column, Fig.2.

Fig.2. Air entrapment on the impact plate

In this way an air cushion with thickness equal to the threshold height and with a rectangular cross-section equal to that of the water column is created. The thickness of air cushion is as follows: $D = 0,06 H$; $D = 0,11 H$; $D = 0,16 H$; $D = 0,22 H$. The pressures are measured in two locations by membrane resistor transducers (gauges) whose natural frequency is 2000 Hz and operating pressure range of up to 100 kN/m^2 . The area of the membrane is 1 cm^2 .

EXPERIMENT B: *Modelling of the wave front surface F motion during the breaking wave impact on a wall.*

The shape and velocity of the oncoming wave are known from the experiments in wave flume, (DENNY, 1951). By changing the geometry of the profile of the approach before the impact plate an analogous kinematic profile can be achieved. The pressures are measured in two locations before the entrapment of air cushion (G_1) and in the location of the air entrapment (G_2).

RESULTS**EXPERIMENT A**

The recorded impact characteristics are shown in Fig.3.

Fig.3. Effect of thickness of the entrapped air volume on impact parameters

The results could be divided in three different groups:

1. The effect of an air volume at $D/H \leq 0,06$
2. The effect of an air volume at $0,06 < D/H < 0,22$
3. The effect of an air volume at $D/H \geq 0,22$

1. $D/H \leq 0,06$. Compression of very thin air cushion.

During the impact the very thin air cushion is broken by the liquid to many small bubbles, which in practice do not reduce the kinetic energy of the water column. The pressure gauges do not catch the air compression of the small bubbles and register the impact pressure of the jets when the water gets in touch with the gauge membrane. Such insignificant small air quantities practically does not affect the character and the magnitude of the pressures.

2. $0.06 < D/H < 0.22$. *Compression of thin air cushion.*

The rate of pressure change clearly shows two physical processes from which the maximum pressure value has been formed. The first part of the pressure is generated as a results from the air compression, but the second is indicated at the time of contact between the liquid and the impact plate. The rate of pressure change at the time of the contact of the liquid with plate is four times bigger than the one with the air compression. However, unlike the first case, during the compression of the continuous thin air cushion a loss of kinetic energy is almost not observed, Fig. 3. The resulting magnitude of the peak pressure in spite of the compression is increasing, Fig. 4

Fig. 4. Effect of dimensionless thickness (D/H) on magnitude of impact pressure

3. $D/H \geq 0.22$. *Compression of air cushion*

At this thickness of the air cushion the pressure is due only to the air compression. Here the kinetic energy of running water is being reduced by the compression of the air cushion. The pressure magnitude is decreasing, Fig. 4. The rate of pressure change with air compression is nearly 4 times less of the same with a direct impact of the liquid.

From the experimental study described above the following conclusion about the quantity influence of the air volume could be made:

- 1). The pressure from the air compression is negligibly small with insignificant air volumes due to breaking of the air cushion into bubbles.
- 2). When the air cushion keeps continuous before it is broken, the pressure from the air compression is added to the pressure from direct liquid impact.
- 3). At bigger air volumes the water column does not reach the plate during the impact and the air cushion acts as a damper.

EXPERIMENT B

The research apparatus allows the motion of the wave front, which surface is designated here as F , to be simulated before and during the impact. By changing the geometry of the profile of approach before the impact plate and using a high speed camera a kinematical profile analogous to that of the wave front surface F motion in a flume (DENNY, 1951) is achieved, Fig. 5.

Fig. 5. Modelling of the wave front surface F motion

The Gauge 1 registers the pressure at the location where the water flow is deviated and accelerated upwards without air entrapment.

The Gauge 2 records the pressure where the air is entrapped, Fig. 6.

Fig. 6. Pressure-time records during the impact; G1: striking water column; G2: shock wave

The shape of the pressure curve obtained from Gauge 2 exactly repeats the records of high pressures in a wave flume made by numerous researchers (BAGNOLD, 1939; RUNDGREN, 1958; GODA & HARANAKA, 1967; PARTENSCKY, 1987; KIRGOZ, 1982; TAKAHASHI et al. 1994).

At the location of the entrapment of the air a counter stream appears and a free fluid issuing is strongly hampered. These conditions are of crucial importance for a shock wave to be created. It is confirmed from the record of Gauge 2 shown in Fig. 6 and after a comparison between the impact parameters from experiment A and experiment B, shown in Table 1.

Table 1. Comparison of impact parameters obtained from experiments A & B

Type of impact	u m/s	p kN/m ²	t s	dp/dt (tgφ) -
with air compression	1	24	0,02	0,14
water jet (column)	1	30	0,004	1
collision of streams and jets (shock wave)	1	65	0,0008	15

EXPLANATION OF THE GENERATION MECHANISM OF HIGH PEAK WAVE IMPACT PRESSURES

The physical experiments help to be established the following:

1. The enclosed air volume as a geometric space and a physical medium with density considerably smaller than that of water allows the focusing of the kinematical parameters vectors of the flowing liquid around the gas-liquid interface F.

2. The velocity values calculated using the data obtained with high speed camera are an experimental proof about the cumulative character of the wave flow rate during the breaking against the wall. The velocity of stream at the time of spilling on the plate is twice as much as the surface F velocity before its reaching the barrier. In physics the cumulative principle with water current motion is known, (LAVRENTIEV and SHABAT, 1977), (SLOBODETSKI and ASLAMAZOV, 1980). Its theoretical basis with waves breaking against a wall could be illustrated. If a water jet strikes a flat plate with velocity c, Fig. 7, the velocity values of both spilling jets on the plate are the same equal to c:

$$c_1 = c_2 = c \quad (1)$$

and it is not dependent on the angle of attack θ .

Fig. 7. Impact of a jet on a fixed flat plate

Now let examine this water mass of the wave which strikes the wall as it is shown in Fig. 8.

Fig. 8. Impact of a wave on a vertical wall

The velocity value of the front of wave respectively the water surface F before the impact u and the angle of attack between the wave front and the wall plane are known. Let find the stream velocity v with which it is spilling on the wall.

The velocity u could be shown by the vector equation

$$\vec{u} = \vec{u}_1 + \vec{u}_2 \tag{2}$$

where \vec{u}_1 is the velocity component that is paralleled to the wave front and \vec{u}_2 is the velocity of the cross point P of the wave front line and the wall line.

During the impact on the wall the velocity of the spilling stream is equal to the sum of both velocities

$$v = u_1 + u_2 \quad (3)$$

knowing that $c_1 = c_2 = c$.

The component velocities u_1 and u_2 could easily be found, ($u \perp u_1$).

Therefore $u_1 = u \cdot \cot\alpha$ and $u_2 = u/\sin\alpha$. Substituting these values in Eq. 3 gives

$$v = u \frac{1 + \cos\alpha}{\sin\alpha} \quad (4)$$

With small values of α , (such are made in practice) theoretically the velocity could reach values many times bigger than the velocity of the wave front before its contact with the wall. The same is the case considering the kinetic energy. The ratio of the energy per unit volume of such spilling stream on the wall $\rho v^2/2$ to the energy of moving water in the wave $\rho u^2/2$ is more than 1. When $\alpha = 10^\circ$, $v = 11u$, $\rho v^2/2 / \rho u^2/2 = 120$; at $\alpha = 2^\circ$, $v = 57u$, $\rho v^2/2 / \rho u^2/2 = 3200$.

3. Due to the entrapped air space and the field of the velocities (as well as field of the accelerations) the wave energy is being distributed on a smaller area on the wall which is proved from both gauges indications. The cumulative character of the water stream motion on the wall contributes to the wave energy convergence. The stream which is moving vertically upward has started from the lower part of the wave. The counter stream is created by the impact of the wave crest. No matter the mass in the central part of wave (say in the form of striking jets) reaches the wall before or after the collision of these two streams. The possibility for spilling of water streams and jets disappears and after their collision a zone of high shock hydrodynamic pressure is created at the location of the entrapped air cushion.

CONCLUSIONS

1. The wave breaking on a vertical wall is accompanied by cumulation of the wave energy and its redistribution on the smaller area of the wall, and conditions for a shock wave are created at the collision of the streams and jets.
2. The closed air volume as a physical medium under compression could not be a cause for the high peak short-period wave pressures.

ACKNOWLEDGEMENT

The experiments were carried out in Moscow Civil Engineering Institution, Department "Water resources and harbours" founded by Professor N. N. Dzhunkovski. The author wish to express his sincere gratitude to the Institution and

to the Department for their financial support and personally to Professor Gleb Smirnoff who was the initiator of this study.

CHAPTER 193

A Design Short-Crested Wave Force Model for Vertical Deep-Water Breakwaters

S.-Y. Tzang¹ and S.-R. Liaw²

Abstract

Fenton's short-crested wave force approximations were modified for designing a vertical breakwater in deep water regions. The theoretical water surface profiles and depth-distributions of hydrodynamic pressure in front of a vertical breakwater were first evaluated with field wave conditions of height $H_b=10\text{m}$ and period $T=9.6\text{s}$ at depths d from 20m to 40m. The calculations immediately illustrated characteristics of residual pressures at wave crest and exponentially decreasing profiles under design water level. As d increased, wave crest height decreased as well and the crest pressure deviations became negligible while overestimated pressure force by assuming linear under-water pressure distributions became more significant. Through appropriate modifications, a design wave force model were proposed and compared with Goda's design formulae for standing waves. Results clearly displayed that 45° incident short-crested waves could induce greater total wave forces on a vertical breakwater than those by Goda's formulae at the same depth. Differences became greater at $d=40\text{m}$ by about 12% ~ 17% for $T=10\text{s}$ and 17% ~ 29% for $T=18\text{s}$ based on Fenton's 2nd and 3rd-order approximations.

Introduction

Currently in many countries, up-surgng economic developments have made breakwaters, which were used to be constructed at water depths around 20m, now tend to be installed at water depths of more than 40m. For example in Japan, several port engineering require rather deep water breakwaters such as those in port Kamaish (deepest depth of 63m) etc.(Tanimoto & Takahashi, 1994). Similar challenges are also about to be encountered in Taiwan for its deep-water port projects in the near future. Thus, studies on the complex wave characteristics before a breakwater and

¹ Associate Professor, Dept. of Harbor and River Eng. National Taiwan Ocean University, Keelung, Taiwan 202, R.O.C.

² Chief Engineer, Harbor & Coastal Eng. Dept., China Eng. Consultants, Inc. 20th Fl., 185 Hsin-Hai Rd. Sec. 2, Taipei, Taiwan, R.O.C

related engineering techniques have become an urgent task.

In marine environments, waves generally attack breakwaters obliquely rather than normally resulting in a short-crested wave system (Jeffrey, 1924; Chappellear, 1961). It has been a common engineering assumption adopted for design purposes that normal incident wave forces are greatest than short-crested wave forces, e.g. Goda's formulae (1972, 1985). In fact, this is not always true as pointed out previously that short-crested waves could induce greater wave forces on vertical walls than standing waves (Silvester, 1974; Roberts and Schwartz, 1983). These findings simply suggested that in certain conditions Goda's formulae for standing waves might under-estimate the resulting total wave forces and the designed breakwaters are more susceptible to catastrophic damages during storm attacks.

Goda's Design Wave Force Formulae

As schematically represented by Figure 1 for a composite breakwater, Goda defined wave crest height η_c and wave pressures P_i at specified positions as follows :

Figure 1. Definition Sketch of Goda's Design Standing Wave Pressures

Wave crest elevations

$$\eta_c = 0.75(1 + \cos \beta) \lambda H_{\max} \quad (1)$$

η_c : upper limit of wave pressure above design water level (DWL)

β : angle between incident wave and the normal of breakwaters

λ : pressure dissipation ratio (=1.0 for current paper)

Wave-induced pressures

$$P_1 = \frac{1}{2}(1 + \cos \beta)(\alpha_1 + \alpha_2 \cos^2 \beta) \lambda W_0 H_{\max} \quad ; \quad P_2 = \frac{P_1}{\cosh(2\pi h / L)}$$

$$P_3 = \alpha_3 P_1 \quad ; \quad P_u = \frac{1}{2}(1 + \cos \beta) \lambda \alpha_1 \alpha_3 w_0 H_{\max}$$

$$\alpha_1 = 0.6 + \frac{1}{2} \left[\frac{4\pi h / L}{\sinh(4\pi h / L)} \right]^2 \quad ; \quad \alpha_2 = \min \left\{ \frac{h_b - d}{3h_b} \left(\frac{H_{\max}}{d} \right)^2, \frac{2d}{H_{\max}} \right\} \quad (2)$$

$$\alpha_3 = 1 - \frac{h'}{h} \left[1 - \frac{1}{\cosh(2\pi h / L)} \right]$$

P_1, P_2, P_3, P_u : max. pressures at DWL, sea bed, caisson bottom and up lift pressure;

h, h', d : water depths from DWL to sea bed, caisson bottom, and rubble mound;

η_c, h_c : elevation of wave crest and caisson top above DWL;

$\alpha_1, \alpha_2, \alpha_3$: coefficients for pressure calculation.

For a vertical breakwater, it is shown that $h=d$ and $P_2=P_3$ while Eq.(1) and Eq.(2) confirm that Goda assumed maximum wave force by standing waves and those by obliquely incident waves decreased by a factor of $\cos\beta$.

Fenton's short-crested wave force theory

Based on Hsu et al's (1979) approximations of short-crested waves, Fenton (1985) further studied the surface wave profile, wave pressure and resulting total forces on a vertical wall. The short-crested wave system can be defined in Figure 2.

Figure 2. Definitions of A Short-Crested Wave System

As expressed in Figure 2, an obliquely incident wave and its reflected wave from a vertical wall can generate a short-crested wave system. Thus, short-crested waves are essentially three dimensional rather than the two dimensional standing waves, which approach a breakwater normally. According to Fenton in the case of total reflection, short-crested wave height H_{sc} is exactly equal to twice of the incident wave height H_D . Represented by Cartesian coordinates, the governing equation for the velocity potential ϕ simply satisfies the Laplace equation :

$$\nabla^2 \phi = \phi_{xx} + \phi_{yy} + \phi_{zz} = 0 \quad (3)$$

Solving with dynamic and kinematic boundary conditions on surface, at sea bed and on breakwater, Fenton derived a 3rd-order approximations with a variable $\delta = \frac{1}{2} k H_{sc}$ (H_{sc} : short-crested wave height) as expressed, respectively below :

Surface water profile :

$$k \eta(x, y, z, t) = \sum_{i=1}^3 \frac{\delta^i}{(i-1)!} \sum_{j=0}^i \cos j(mkx - \omega t) \sum_{l=0}^i B_{jil} \cos lnky + O(\delta^4) \quad (4)$$

Hydrodynamic pressure :

$$\frac{kp(x, y, z, t)}{\rho g} = -kz + \sum_{i=1}^3 \frac{\delta^i}{(i-1)!} \sum_{j=0}^i \cos j(mkx - \omega t) \sum_{l=0}^i C_{jil}(z) \cos lnky + O(\delta^4) \quad (5)$$

Total wave pressure force :

$$\begin{aligned} \frac{P^*}{\rho g d^2} &= \delta F_{11} \cos(mkx - \omega t) + \delta^2 [F_{20} + F_{22} \cos 2(mkx - \omega t)] \\ &+ \frac{1}{2} \delta^3 [F_{31} \cos(mkx - \omega t) + F_{33} \cos 3(mkx - \omega t)] + O(\delta^4) \end{aligned} \quad (6)$$

The dimensionless coefficients B_{ij} , C_{ij} , F_{ij} and the listed variables are all defined in Fenton (1985). To examine the short-crested wave characteristics before a vertical breakwater, both Fenton's 2nd and 3rd-order approximations shall be evaluated with field wave conditions and then modified for design applications. The results will also be compared with Goda's formulae to manifest the under-estimation of wave forces by standing wave theory in deeper water regions.

Wave Characteristics before A Deep-Water Vertical Breakwater

Both wave crest elevations and wave pressure at specified depths were first studied with a set of in-situ design wave conditions at installation depths of 20, 25, 30, 35, and 40m, respectively. The incident design wave height H_b is 10 meters, wave period T is 9.6 seconds and steady current along the breakwater is neglected in this paper. The seabed slope is assumed to be 1/50 for applying Goda's formulae and only incident angles $\theta=0.01^\circ$ and 45° were considered. Results calculated with water density $\rho=1.03 \text{ g/cm}^3$ and gravity acceleration $g=9.806 \text{ cm/s}^2$ are summarized in Table 1, where the shadowed areas denote results for $\theta=45^\circ$ by both approximations.

Water surface profiles

For water surface profiles, it is seen in Table 1 that short-crested wave crest heights η_c are decreasing with water depth and higher for normal incidence at each depth. The values at wave crest are exactly the same for both approximations but the phase variations of surface profiles are slightly different as illustrated in Figure 3. From both Table 1 and Figure 3, it is noted that short-crested η_c of both normal and oblique incidence are always smaller than those by Goda's formulae except for the case at $d=20\text{m}$. In fact, Goda's formulae gave a constant value of 15m regardless of the water depth and are even higher than short-crested waves by 1m to 2.9m at $d=40\text{m}$ for $\theta=0.01^\circ$ and 45° , respectively by different approximations.

Wave pressure depth distributions

Contrary to η_c , Table 1 shows that at each depth waves with the same height and period imposed greater maximum pressures for $\theta=45^\circ$ than those for normal incidence. This is clearly demonstrated by the phase variations of the wave pressure at half depth and seabed by both approximations as shown in Figure 4 and Figure 5, respectively. It is seen in both figures that maximum wave pressures of $\theta=45^\circ$ are greater than those of $\theta=0.01^\circ$ and maximum standing wave pressures occurred at phases deviated from phase of zero (wave crests) due to double hump structure. For waves of $\theta=45^\circ$, pressures at DWL and at seabed derived by 2nd-order approximation are all greater than those by 3rd-order approximation but the differences became quite small as water depth increased. By 2nd-order approximations, the residual errors of water pressure at wave crest tend to diminish with increasing depths except for the cases of $\theta=0.01^\circ$. This suggests that in deeper waters Fenton's approximations are more applicable due to negligibly small residual crest pressures and thus, resulting total wave pressure force on a vertical breakwater can be reasonably derived.

where

θ : incidence angle; k : wave number; η_c : wave crest elevation (unit: m); *: same as left

P_{crest} : wave pressure at η_c ; P_1, P_2 : wave pressure (phase $t/T=0$) at DWL & seabed

$P_{1\text{max}}, P_{2\text{max}}$: maximum wave pressure at DWL & seabed (unit: kN/m^2)

d/L : relative water depth; H_{sc}/L : short-crested wave steepness; δ : expansion parameter

Figure 6 and Figure 7 display both onshore and offshore pressures at different depths by both approximations, respectively. From the figures and Table 1, it is found that the residual errors at wave crest P_{crest} for 45° incident short-crested waves altogether decreased towards a theoretical zero to satisfy the Bernoulli assumptions at free surface boundary. The values decrease from 85 to -2 kN/m^2 by 2nd-order approximations and from -75 to -14 kN/m^2 by 3rd-order approximations at depths of 20m to 40m. For results by 2nd-order approximations, the deviations at wave crest seem more significant for normal incident waves than obliquely incident waves and pressure changes at DWL with depths were more notified than those by 3rd-order approximations. Being supported by negligible discrepancies between the two approximations at deep depths, it seems reasonable to apply either of the two approximations to estimate wave forces on a deep-water vertical breakwater.

Resultant wave forces estimations

Compared with the results by Goda's formulae, Table 1 shows that short-crested wave pressures of 45° incidence at DWL and seabed by both approximations were similarly greater than those by Goda's except at depth of 20m. The differences were gradually enlarged with increasing water depth at both locations, implying that Goda's formulae tend to under-estimate the resulting total pressure forces for obliquely incident waves on a deep water vertical breakwater. This is demonstrated with the calculated wave forces summarized in Table 2, in which numerical values were derived by summations of the approximated pressures directly from Eq.(6) at discretized depths. The reasons for utilizing discrete summations were mainly due to the avoidance of the residual effects of the surface errors on the resulting integration of Eq.(6) and the merits of estimations of wave forces between any two depths. Taking Figures 6 and 7 for illustrations, the pressure distributions above DWL were seen to be similarly linear for most depths but the surface residual errors would certainly cause calculated wave forces to be less reliable. If we correct this error by constraining the values of P_{crest} to be theoretically zero thus, wave forces can simply be calculated with known values of η_c and maximum pressure at DWL P_{1max} . However, this correction had resulted in an error equal to the triangle area with coordinates of $(P_{1max}, 0, P_{crest})$ and its magnitude is simply equal to $1/2 \times P_{crest} \times \eta_c$. Shown in Table 2, we notify the decreasing trends of the errors with increasing water depths since P_{crest} became much smaller as displayed in Figure 6 and 7. As a result, we found from Table 2 that errors are decreasing in deeper water by both approximations for 45° incident waves. However, the results for normal incidence have not shown similar tendency, rather are still significant at $d=30\text{m}$ and 40m , implying more attentions should be taken when applications.

On the other hand, the pressure force below DWL is simply the summation of the pressure force per unit depth. Usually for engineering applications as schematically shown in Figure 1 by Goda, the total on and off-shore pressure forces are derived by the magnitude of the area with linear distribution between P_1 and P_2 . The calculations are simple but may result in a significant error in resulting wave forces, especially for a deep water breakwater. As summarized in Table 2, the differences

between linear assumptions and the derived theoretical curves were exactly the shadowed areas shown in Figure 6 and 7. In this paper, the theoretical under-water total forces were approximated by summations of 20 trapezoidal pressure forces and more divisions can only slightly change the results. Obviously, linear assumptions of the pressure depth distributions result in an overestimation of the total force (the shadowed area), which became greater with increasing water depth. For 45° incident waves, Table 2 shows that for on-shore pressure force the over-estimations due to linear assumptions were about 10% at $d=20\text{m}$ to 19% at $d=40\text{m}$ greater than those due to theoretical profiles. They became even greater for the cases with normal incident waves, e.g. 46% and 26% for both 2nd and 3rd approximations. Overall, the over-estimations calculated by both approximations became closer in deep waters. This trend was also true for off-shore pressure force calculations. Therefore, linear assumptions always resulted in over-estimations and were more significant with increasing water depths. Besides, both approximations gave closer values at $d=40\text{m}$ than at $d=20\text{m}$, confirming the application of either of the two perturbed approximations in deeper water will not make much differences to each other.

Figure 8. Definition Sketch for Design Short-Crested Wave Force Model

A Design Short-Crested Wave Force Model

According to above discussions, for a deep-water vertical breakwater we propose a design force model based on Fenton’s short-crested wave theory as schematically displayed in Figure 8. This model assumes that the residual surface pressure (on-shore) are negligible and set to be zero at the elevation of η_c . The pressures increase linearly to the maximum pressure at DWL (P_{1max}) such that the total wave pressure force above DWL is equal to the summation of each component pressure forces in the enclosed triangle area. The under water pressure force for both on and off-shore directions is the summation of the discrete unit pressure force derived directly from the theory for avoiding the over-estimations due to linear approximations. As a result, the total on and off-shore wave pressure forces at each depth calculated by this design model were summarized in Table 2. Table 2 illustrated that by this design wave force model the results were slightly different from those by Eq. 6 at water depths.

Comparisons of total pressure forces with depth

The comparisons with Goda’s formulae will mainly focus on the on-shore total

Note : the shadowed areas denote the calculations by the 3rd-order approximations

wave pressure forces in the following sections. The short-crested wave pressure forces were derived according to Figure 8 and standing wave pressure forces were based on Figure 1. From Table 2, the calculated total pressure forces by short-crested wave model were always greater than Goda's results, even though the over-estimation due to linear short-crested wave pressure distribution under DWL had been excluded. As water depths increased, the trends of depth distribution of wave pressure were opposite for both approximations and resulting total wave forces by 2nd-order were also greater than those by 3rd-order but the differences became smaller in deeper waters. At water depth of 40m, for example, the 45° incident short-crested waves could impose 10% to 14% greater pressure forces than standing waves on a vertical breakwater. Based on the findings and Table 2, it is expected that short-crested wave forces could still be significantly greater than standing waves forces at water depths over 40m. It is clearer that Goda's formulae tend to under-estimate total pressure forces especially for a deep-water vertical breakwater. Therefore, the traditional acknowledgment of standing waves to be the maximum imposing loading on a vertical breakwater should be corrected for future engineering practices.

Applications to short-crested swells

To further demonstrate the differences between current model and Goda's formulae, we shall briefly examine the variations of total wave pressure forces with longer waves at depth of 40m. The wave height is the same as discussed above but wave periods will be 10, 12, 14, 16, and 18 seconds, respectively. Results calculated by both short-crested wave approximations were summarized in Table 3. Figure 9 displays the phase variation of maximum on and off-shore pressure depth distributions by the 2nd-order approximations. It is observed from Table 3 that wave crest elevations η_c were only slightly increasing with wave periods and standing η_c are all higher than short-crested η_c but the differences decreased with longer wave periods. Figure 9 shows that the surface residual pressures were relatively small and Table 3 confirms the same trend for 3rd-order approximations. Besides, at this depth the curvature of the under-DWL on and off-shore pressure depth distributions were more significant for shorter-period waves by both approximations. Thus, the over-estimation by linear assumptions of the on-shore pressure depth distributions became less important such as were about 17.3% for T=10s to 6.1% for T=18s, respectively for 2nd-order approximations. But the variances in total wave forces derived according to Figure 8 between the two approximations became more significant with longer wave period. From Table 3, the total wave forces by 2nd-order were greater than those by 3rd-order approximations by about 4.4% for T=10s to 9.8% for T=18s. As a result for 45° incident short-crested waves acting on a vertical breakwater in such conditions, the total wave forces calculated by current model became greater with period than those by Goda's. For 3rd-order approximations, the trend could grow up about from 12% for T=10s to 17% for T=18s and became even more significant for those by 2nd-order approximations. The comparisons clearly suggest that the design forces could be under-estimated by Goda's formulae, especially in deep waters.

Conclusions and Suggestions

The evaluations with $\theta=45^\circ$ incident waves of $H_D=10\text{m}$ and $T=9.6\text{s}$ show that both Fenton's 2nd and 3rd-order approximations can be reasonably applicable at deep depths due to more negligible residual pressures at wave crest. Modified from the theory, present short-crested wave force model for deep-water vertical breakwaters defines maximum wave pressure P at DWL and linear distribution of P to zero pressure at wave crest. The resulting wave pressure forces are simply the summations of pressure distributions derived according to theoretical approximations at discrete depths. Linear assumptions for pressure depth distribution under DWL result in greater over-estimated total wave forces with increasing water depth or shorter waves. Differences between 2nd and 3rd-order approximations always become negligible as water depth increased but more significant for longer waves or for $\theta=0^\circ$. For $\theta=45^\circ$ and $T=9.6\text{s}$, the over-estimations by 3rd-order approximations could amount about from 5% to 18% at $d=20\text{m}$ to 40m but then decrease to 6% for $T=18\text{s}$ at $d=40\text{m}$. For current wave conditions, Goda's formulae for standing waves under-estimate the total pressure forces than short-crested waves of $\theta=45^\circ$ by at least 10% at depth of 40m and up to 17% or 28% for waves of $T=18\text{s}$ derived by 3rd-order and 2nd-order approximations, respectively.

It is recommended that more studies on the applications of the current model to field conditions to be carried out for further design needs of deep-water breakwaters. Three-dimensional hydraulic model tests are considered necessary for decisive selection between the two approximations. Further extension to establish a similar model for composite breakwaters will be very valuable for engineering practices.

CHAPTER 194

New design methods for wave impact loadings on vertical breakwaters and seawalls

Allsop N.W.H.,¹ McKenna J.E.,² Vicinanza D.³ & Whittaker T.T.J⁴

ABSTRACT

This paper discusses wave impacts on vertical and composite breakwaters and related coastal structures. It describes types of vertical walls in use, with particular reference to older walls that may be much more influenced by wave impacts. Methods to estimate wave forces are identified. Analysis of performance suggests that these under-predict wave impact loads, and cannot identify combinations of geometry and wave conditions which lead to impacts.

Comprehensive 2-dimensional hydraulic model tests have been conducted using random waves to measure wave pressures (and other responses) on a wide range of simple and composite vertical walls. The test results have been used here to:

- Identify the ranges of geometry and wave conditions which lead to wave impacts;
- Develop a simple method to estimate wave forces under impact conditions.

Analysis of % of impacts has defined a new design diagram to identify wave conditions and wall / mound geometries which cause impacts. These results are intended for engineers analysing vertical or composite walls in deep water, in harbours, or along the shoreline.

1. VERTICAL WALLS

Seawalls or breakwaters around the world have often been built with vertical or steep faces formed by small blocks joined together. The structure relies on its weight to resist sliding or overturning forces, and on the bonding or jointing of the blocks to maintain its monolithicity. The integrity of blockwork walls depends on their resistance to local pressures or pressure gradients. Modern structures may be formed from larger elements, perhaps full-depth cellular caissons filled with sand or rubble, and founded on rubble. A few modern structures use concrete blocks bonded or keyed together, or thin concrete elements.

Much of the historical and experimental information discussed in this paper has been presented in the comprehensive research report by Allsop et al (1996a).

Construction of breakwaters, piers, and seawalls

Unless founded directly onto rock, vertical breakwaters or piers built before about 1900 used rubble slightly below low water, and surmounted by blockwork walls. Hewn stones were laid in bond, generally slightly off vertical. Blocks were originally laid dry, or in lime / pozzolanic mortar. Cement mortars were used after about 1900, and concrete blocks after about 1880. Tensile, bending, or shear loads were transferred between adjoining blocks, or courses of blocks, by iron cramps, keys or joggle joints between blocks.

Concrete blocks were used at North Tyne in 1855 (Fig 1), for Dover breakwater, 1866, and at Cork in 1877. Concrete bags formed a foundation at Fraserburgh in 1877, and for Ardrossan Pier in 1892. Concrete filling was used for the later stages of Alderney breakwater 1849-1866, Aberdeen south breakwater, 1873; North Pier at Aberdeen, and the Fraserburgh breakwater, both in 1877. The Italian engineer Coen Cagli re-introduced vertical wall breakwaters to Italy after a visit to Britain in 1896 where he saw blockwork breakwaters at Dover, Sunderland, North Tyne, Peterhead, and Wick.

Figure 1 North Tyne Breakwater

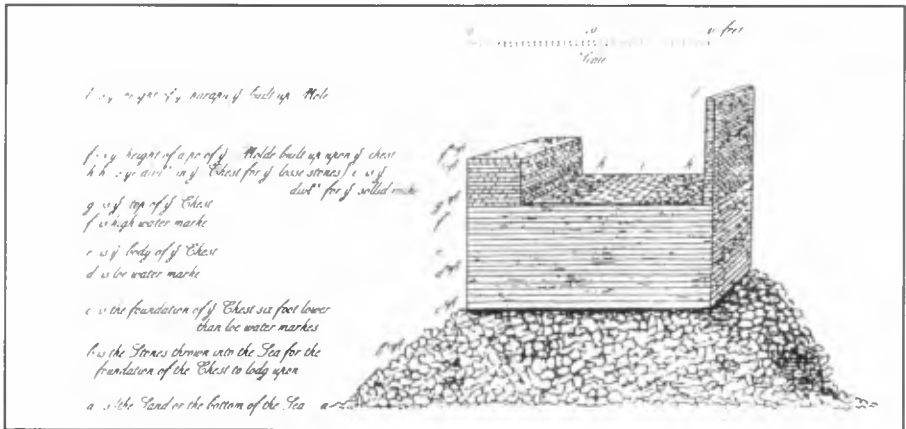

Figure 2 Timber caisson used for the Greate Mole at Tangier, 1677

Caissons were rarely used in the UK before 1900, but construction of the Greate Mole at Tangier by British engineers using caissons in 1660s is described by Routh cited by Allsop et al (1996a). The Mole was started with rubble foundations placed ahead of blockwork in August 1663, but only reached 350m by August 1668 due to adverse wave conditions; loss of

fill into the sand; diversion of the workforce to other (military) duties; difficulties in obtaining materials; and significant delays in payment for work completed. Construction re-started in April 1670 with the blockwork walls damaged and breached by storms. A new construction was copied from Genoa using "great wooden chests" bound in iron, and filled with stones and mortar. After much debate, some reported in Samuel Pepys' diaries, wooden caissons of 500 to 2000 tons were towed out from England, and sunk onto the foundation filled with stone bound in mortar (Fig 2). Progress was quicker with the new construction and suffered less delay than the blockwork sections. In 1680 however, peace was concluded, and the breakwater was then destroyed lest it provide shelter to a later enemy.

The development of many harbours around the UK between 1850 and 1900, and their survival, have reduced the need for new harbours around the UK, so relatively few have been constructed since 1900. Vertical breakwater exceptions to this are at the new marina harbour at Brighton protected by circular caissons based on those used at Hanstholm in Denmark; and the vertical wave screen breakwaters at Sutton Harbour, Plymouth, and Cardiff Barrage.

Performance in service

The life of a breakwater may be considered in three periods: construction; initial service; and extended service (often well beyond that used in design life calculations). Most damage occurs early in its life, even during construction, so most breakwaters which survive the first 5 years without damage are likely to survive the next 40-50 years. This simplification however ignores steady or accelerated deterioration which may lead to sudden failures in later life.

Stevenson describes construction at Wick started in 1863 using dry-placed blocks of 5 to 10 tons. During storms in 1870, about 115m was destroyed, presumably by breaching the wall. This section was then rebuilt using cement to bond the block facing, and iron dowels between courses. A storm in February 1872 gave impact pressures so severe that facing stones were shattered, although Stevenson does not identify whether this was by direct wave impact, or by stones from the mound being hurled against the face. In December 1872 a section of blockwork bonded together and estimated as weighing 1350 tons slid into the harbour. This was followed in 1873 by movement of another section of 2600 tons.

During construction of Catania breakwater in Sicily in 1930, large blocks slid backwards into the harbour under wave attack. The damage was repeated in 1933 when much of the upper part of the breakwater slid backwards, due to a lack of horizontal connectivity between layers. Later structures in Italy included connections to resist horizontal forces, but few if any existing structures were re-appraised or strengthened, and collapses continued at Genoa in 1955, at Ventotene in 1966, Palermo in 1973, Bari in 1974, and Naples in 1987.

Mutsu-Ogawara port on the Pacific coast of Japan was under construction in 1991, when it was hit by waves of $H_s=9.9\text{m}$, substantially above the 1:50 year design condition of $H_{so}=7.6\text{m}$. Damage was particularly severe where mounds of armour intended to cover the front face were incomplete and/or had already been damaged. Waves tripped over the part-height mounds causing impact forces so severe that two 24m long caissons suffered significant structural damage, one of them losing most of its upper part.

Sakata port is on the Japan Sea, less exposed than the Pacific coast. Even so, waves during winter 1973 / 74 reached $H_{so}=7.2\text{m}$ and exceeded $H_{so}=4.5\text{m}$ on 4 other occasions. In depths no more than 9-10m, these conditions would have reached or exceeded the breaking limit. Nearly all 39 caissons, each 20m long and 17m deep, slid during these storms, some by 4m.

In December 1990, a small breakwater was damaged at Amlwch, North Wales. It is about 60m long, slightly curved in plan, and is constructed using concrete blocks in slices on mass concrete on the rockhead. The outer end of the breakwater was slid backwards by about 0.3, cracking the crown wall in three places. Wave conditions are estimated as $H_{so} \geq 4\text{m}$, with

$T_m=9s$. The foreshore is very steep, approximately 1:13, falling outside of any established design method. The depth at the toe probably reached at least 11-14m. Allsop & Vicinanza (1996) estimated inshore wave conditions limited by depth to $H_{s0}=4m$ at MHWS, but reducing to $H_{s0}=3.6m$ at MLWS. Using the method of Vicinanza et al (1995), F_h was calculated as 1040kN/m at MHWS. With no up-lift force for blocks direct on concrete, and $\mu=0.5$, these give a factor of safety of $F_s = 0.9$ at high water, contrasted by predictions using Goda which give $F_s = 1.2$ at high water, and $F_s = 2.3$ at low water.

In late October 1966, the blockwork breakwater of Porthcawl in South Wales lost its capping wall over a length of about 55m, again probably due to a single direct wave impact.

These examples demonstrate that wave impact forces are very high, and the more recent damage suggest that predictions of wave loadings / responses remain very uncertain. As many blockwork walls approach 150 years old, and the potential for local or catastrophic collapse increases, it becomes more important to re-examine wave load prediction methods.

2. WAVE LOADINGS ON VERTICAL AND COMPOSITE WALLS

The main loadings acting on these types of walls arise from: direct wave pressures; up-lift forces; quasi-hydrostatic forces from internal water pressures; and geotechnical forces / reactions from backing or supporting materials. These structures resist wave and geotechnical forces essentially by their own weight, and by friction with the underlying materials. Interlock or bonding forces between component elements maintain continuity and avoid movement or loss of elements and/or fill.

The simplest failure mode for monolithic vertical structures is sliding under direct wave forces, primarily under horizontal loads, but also influenced by up-lift forces. Failure by overturning may be examined by assuming rotation about the rear heel of the caisson / wall, but the point of rotation depends upon bearing capacity and geotechnical characteristics of the mound / foundation. Analysis of foundation failures has been discussed by de Groot et al (1995), and constitutes a major part of the MAST III research project PROVERBS. Blockwork breakwaters may also fail by loss of integrity where a block is removed (seaward) by net suction forces, followed perhaps by progressive damage and then catastrophic collapse.

It is often convenient to treat wave pressures / forces on these structures as quasi-static / pulsating; of dynamic / impulsive or impact, see also Figure 4 in Section 3.

Quasi-static or pulsating wave pressures change relatively slowly. A wave impinges directly against the structure applying a (quasi-) static pressure difference. The obstruction of wave momentum causes the water surface to rise up, increasing the force on the wall. The net force is related closely to the peak water level, and can be estimated using simple methods. Most design methods assume static loadings, and simple equilibrium conditions.

Dynamic or impact pressures arise where the wave breaks directly onto the structure. Impact pressures are substantially greater than pulsating pressures, and of much shorter duration. The processes of wave breaking are not well understood and the occurrence of breaking cannot be predicted with reliability, so these pressures are extremely difficult to calculate, and have historically not been used in design calculations. Schmidt et al (1992) remind us that there are still two attitudes to impact loadings. The first simply assumes that impact pressures are not important and need not be adopted in design. The second is to skip the problem of evaluating impact loads by assuming that the structure can be designed so that impacts will not occur. A third (newer) approach is to conduct dynamic analysis of the structure, its foundation, and the loads. This requires high levels of data on wave loadings, and on the geotechnical response characteristics of structure / mound / foundation, but is likely to become more frequently used.

These problems are compounded by uncertainties in defining conditions that lead to impacts. Schmidt et al (1992) and Oumeraci (1994) define 7 breaker classifications in terms of H_b/d , but the breaker height H_b is extremely difficult to predict, so these classifications are of limited use. Klammer et al (1996) define 2 types of plunging and a "flip-through" breaker, but then derive a suggested force formula for all three types lumped together.

Goda (1985) described rules to identify whether particular structures or sea states will cause impulsive wave conditions, and that method is re-interpreted as Figure 3.

Wave force prediction methods

Hiroi's simple formula gives a uniform wave pressure p on the front face up to $1.25H$ above still water level where H the wave height, and $p = 1.5\rho_w gH$. Sainflou's method calculates a maximum pressure, p_1 , at static water level, tapering to zero at $H + \delta_0$ above SWL, and reducing linearly with depth from p_1 to p_2 at the rubble base. The Shore Protection Manual (1984) however suggests that Sainflou's method may over-estimate wave forces for short non-breaking waves, and uses Miche-Rundgren formulae to derive the clapotis height from which an (assumed) linear hydrostatic pressure is calculated. For long waves of low steepness, the SPM recommends Sainflou's method.

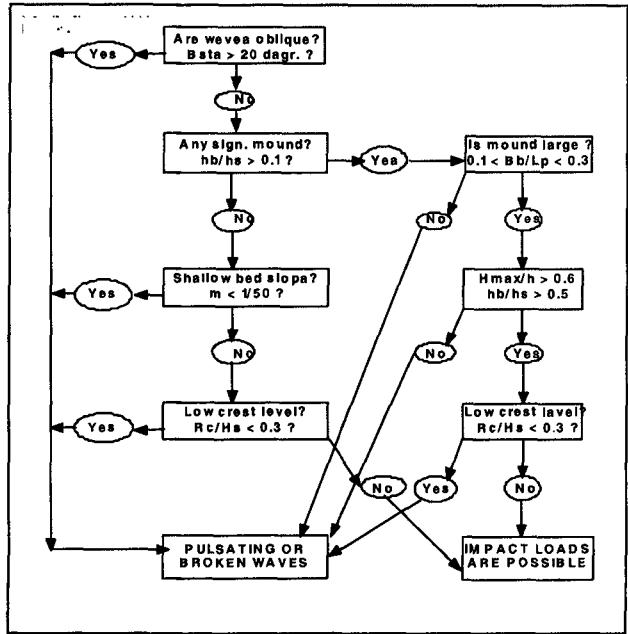

Figure 3 Impact breaking conditions, derived from Goda (1985)

Goda's method

The most widely used prediction method for wave forces on vertical walls was developed by Goda (1985), primarily to calculate horizontal forces for concrete caissons on rubble mound foundations, and calibrated against laboratory tests and back-analysis of historic failures. This method assumes wave pressures on the front face are distributed trapezoidally, reducing from p_1 at s.w.l. to p_2 at the caisson base. Above s.w.l. pressure reduces to zero at the (notional) run-up height $\eta^* = 1.5H_{max}$, where H_{max} is taken as $1.8H_b$. The method describes impulsive and deflected wave components by coefficients α_1 , α_2 , and α_3 . The effect of relative depth to wave length on the pulsating component is represented by α_1 ; the effect of impulsive breaking due to the mound is represented by α_2 ; and α_3 accounts for the relative crest level and relative depth over the toe. The depth h is taken at the mound toe, and d over the mound at the front face of the caisson, but h_b is taken $5H_b$ seaward.

The caissons on rubble foundations considered by Goda had natural periods around 0.1 to 0.3s. When subjected to loads of much shorter durations, the effective load is smaller than the applied load. Thus for the short peak pressures caused by wave impacts, Goda's formula

does not give actual pressures, but equivalent static loads for the dynamic system of caisson, mound and foundation. Goda noted that impulsive pressures caused by waves which break onto the wall may rise to $p=10\rho_w gH$, but judged that vertical breakwaters would not be designed to be exposed to direct impulsive pressures.

Wave impact force predictions

In Europe, engineers observed the effects of very large forces on some walls, and noted very short impacts coupled with very large pressures. Bagnold postulated a model of air compressed by the exchange of wave momentum, see Klammer et al (1996) for a simple description. At maximum pressure, all the wave momentum has been converted to pressure over the impact rise time. This approach however required identification of the thickness of the air pocket, and of the virtual length of the water piston, neither of which could be measured. Minikin's (1963) used Bagnold's model to develop to estimate impact pressures caused by waves breaking directly onto a wall, and therefore addressed the problems of impact pressures. The resulting expression for p_{max} may be written:

$$p_{max} = \frac{1}{2} C_{mk} \pi \rho_w g H_{max} (1+d/h) (d/L) \quad (1a)$$

where C_{mk} is defined to fit Rouville's data, accounting for typical sizes of air pocket. Minikin suggests $C_{mk}=2$, which is then cancelled within eqn. 1a to give the simpler version used in the British Standard, BS6349 Pt1, BSI (1984):

$$p_{max} = \pi \rho_w g H_{max} (1+d/h) (d/L) \quad (1b)$$

Unfortunately, this expression was re-written by Minikin with $\pi\rho_w g$ replaced by $2.9!$ This (mis)-use of dimensioned coefficients was later compounded by the Shore Protection Manual, and others. The total horizontal force may be written in dimensionally correct terms:

$$F_{hmax} = \frac{1}{2} C_{mk} \pi \rho_w g H_{max} d \left\{ (1+d/h) H/(3L) + 1/(2\pi) + H/(8\pi d) \right\} \quad (1c)$$

Many versions of Minikin's formula for total force, except that used by BSI (1984), included a factor of 101 replacing πg , but without qualification on the units. In imperial units this becomes more serious when later authors imply that $\pi g = 101$ can be used in other units than f.p.s, and have thus propagated the erroneous version of Minikin's formulae ever since! In practice the SPM version of Minikin's method gave so much greater pressures than other formulae that its use for calculations in practical design has been limited. Goda writing on wave force formulae in 1990 summarises the prevalent view on Minikin's method as "can be considered to belong to a group of pressure formulae of historical interest".

Takahashi extended Goda's method to include effects of breaking wave impacts. This was obtained by re-analysing tests of caissons sliding under wave impacts (regular waves), together with data on caisson movements at Sakata Port. The modification is applied by changing the α_2 coefficient to be the maximum of α_2 or a new impulsive coefficient α_1 , itself given by coefficients representing the effect of wave height on the mound, and mound shape.

Other methods for impact pressures

Partenscky quoting Oumeraci has used results from the large wave channel at Hannover / Braunschweig (GWK) to suggest that impact pressures of very short durations (0.01 to 0.03s) may be calculated the breaking wave height, and a coefficient K_1 given in terms of the air content a_o of the breaking wave.

Blackmore & Hewson conducted field measurements at four sea walls in the UK, from which they developed a model based on momentum exchange. Impact pressures p_i depend on the shallow water wave velocity, v_o ; the wave period, T ; and an aeration factor, λ , which depends on the roughness of the foreshore. A value of $\lambda = 0.3$ is recommended for a rough and rocky seabed, and $\lambda = 0.5$ for a regular seabed. Breaking wave heights are indirectly considered by using shallow water wave velocities calculated from the breaking water depth, h_b , and breaking wave height, H_b .

More recently, Klammer et al (1996) have developed a method to predict wave impact forces based primarily on solitary waves, but with some (rather tenuous) comparisons with data from random wave tests in the Large Wave Flume at Hannover / Braunschweig.

3. DESIGN OF MODEL STUDIES

3.1 Test structures and facility

Hydraulic model tests were conducted to measure wave pressures / forces on a range of simple vertical and composite wall configurations, using the Deep Random Wave Flume at Wallingford, which is 52m long and operates with water depths between 0.8m and 1.75m. The flume is configured to reduce reflection of waves from the test section in absorbing side channels. The bathymetry approaching the test section was formed to 1:50. The main caisson was formed as a hollow box with pressure transducers mounted flush with the front face and the underside. The design / construction of the model caissons, the measurement systems, and the test programme, have been described fully by Allsop et al (1996a).

Figure 4 Wave pressure events from Test 10003 on Structure 1

The geometric and wave parameters that influence wave forces include: wave heights, H_{so} and H_b ; water depth in front of the structure, h_b ; crest freeboard, R_c ; wave steepness, s_{mo} ; wave length at structure toe, L_s ; water depth over mound at wall, d ; berm height, h_b ; berm width, B_b , and front slope of mound, α ; and the depth of embedment of caisson into mound, h_b-h_c . Systematic variations would have required more than 1 year testing, so drastic reductions were made by concentrating on the most important dimensionless parameters, particularly the relative wave height, H_b/d , berm length, B_b/L , and berm height, h_b/h_s .

For the simple wall, the parameters varied were the waves and water depth. The crest level was not changed. For composite walls, the main change was the relative height / depth of the mound in front of the wall, by varying the height of the mound, and the water level. The other changes were to the width of the berm (3 widths) and the front slope angle of the mound (1:1.5, 1:3 with most tests using 1:2). Eleven structures were tested in this study. Structure 0 was a simple vertical wall. The main composite walls were Structure 1 with a small mound; Structures 2 or 3 with intermediate mounds; and Structures 9 and 10 with large mounds.

Wave steepnesses of $s_{mo} = 0.02, 0.04$ and 0.06 were used for relative wave heights of $H_b/h_s = 0.1 - 0.6$, but restricted to $0.15 - 0.4$ for some structures. Up to 5 water levels were used.

Pressures / forces were measured by pressure transducers in the front and lower faces of the caisson. These gave high resolution measurements to about 8m (fresh) water head, and a maximum pressure before damage equivalent to 15m.

The sampling rate was 400Hz, and data were collected from 16 pressure transducers for 500 waves for each test. Oumeraci et al (1994) suggest reduction factors for impact pressures sampled at 400Hz may give under-estimates of maximum pressures by up to 50%, but the reduction for horizontal force is limited to 20%. At these rates, the total impulses are not significantly affected.

Figure 5 Weibull probabilities of horizontal forces, pulsating, and (few) impacts

4. RESULTS

In excess of 1 million waves were sampled in 217 tests. Pressures measured by a transducer at static water level are shown in Figure 4 for about 9 waves on Structure 1 with a low rubble mound. This shows some impact events; and others with substantially smaller pressures with much longer rise times, pulsating events. During other tests, severe impacts up to $p=40\rho_w g H_s$ were noted. Previous studies had suggested that severe impacts might be very variable, but repeated tests confirmed that these impacts were repeatable.

Simple vertical walls

In the first analysis, horizontal forces (and uplift where applicable) were calculated for each force event. The statistical distribution of horizontal forces were then plotted on Weibull axes for each test. Examples for simple vertical walls subject to waves of $H_s/h_s=0.3$ and 0.4 in Figure 5 show the start of impacts (about 2%) where the highest forces for $H_s/h_s=0.4$ start to deviate (upwards) from the linear Weibull line for the pulsating condition for $H_s/h_s=0.3$. Overall forces are not greatly increased by these impacts, but $F_{h99.6\%}$ and $F_{h1/250}$ are increased significantly. These increases further as waves approaches the breaking limit for shallow bed slopes around $H_s/h_s = 0.55$ to 0.6.

Figure 6 Influence of H_{st}/d on $P_{i\%}$ for simple walls

For the simple wall tests, impacts ($P_{i\%}$) are plotted against H_{si}/d (equal to H_s/h_s for simple walls) in Figure 6. Impacts start at $H_{si}/d > 0.35$, suggesting this simple limit for onset of impacts. $H_s/h_s=0.35$ is lower than the simple rule for wave breaking over shallow bed, but it is reasonable to expect some larger waves to break at conditions below $H_{si}/d=0.55$.

These limits identify different types of wave / structure interaction, but do not predict forces. Horizontal forces non-dimensionalised as $F_{h1/250}/\rho_w g d^2$ have been plotted against H_{si}/d in Figure 7. Force predicted by Goda's method are also shown, illustrating relatively good agreement for relatively small waves in the region $H_{si}/d \leq 0.35$, but significant errors for those waves which cause impacts, $H_{si}/d > 0.35$.

Figure 7 Dimensionless force against H_{si}/d for simple walls

Composite structures

Responses of composite structures are more complex, being influenced by the height, width and slope of the rubble berm, as well as by relative water depth and wave conditions. The first task was to separate data by the relative berm height, h_b/h_s into "low" and "high" mounds. Low mounds are described by $0.3 < h_b/h_s < 0.6$, and high mounds by $0.6 \leq h_b/h_s < 0.9$. These limits are not themselves of much significance, but give convenient divisions between regions of different response characteristics.

Low mounds.

$0.3 < h_b/h_s < 0.6$

For low mounds, the onset of breaking and hence of impact conditions is shifted by the presence of the mound to $H_{si}/d=0.65$, see Figure 8. For higher waves, $0.65 < H_{si}/d \leq 1.3$, the nearness of breaking and effect of the mound combine to increase $P_{i\%}$. The dimensionless forces in Figure 9 fit surprisingly well the simple prediction method in eqn. (2) derived initially for simple walls only.

Figure 8 Influence of H_{si}/d on $P_{i\%}$ for low mounds

$$F_{h1/250}/(\rho_w g d^2) = 15 (H_{si}/d)^{3.134} \quad \text{for } 0.35 < H_{si}/d < 0.6 \quad (2)$$

High mounds. $0.6 \leq h_p/h_s < 0.9$.

Wave loads are again pulsating for high mounds with smaller waves ($0.3 < H_{sr}/d < 0.6$). Here Goda's equations give conservative predictions for horizontal wave forces. Then as wave heights increase, more waves break on the structure, and the situation becomes more complex. For small waves, $0.3 < H_{sr}/d < 0.55$, the loading conditions are primarily pulsating, and for larger waves, $0.65 < H_{sr}/d < 1.3$, primarily impacts.

Within the last zone examined here, covered by the largest waves tested $0.65 < H_{sr}/d < 1.3$, the influence of berm width expressed as B_{eq}/L_p is substantially more important. For short berms, given by $0.08 < B_{eq}/L_p < 0.14$, the waves are still pulsating with few if any impacts, and again Goda's method can be used to estimate wave forces. At the opposite end with long berms given by $B_{eq}/L_p > 0.4$, wave breaking occurs over the berm before the wall, and wave loads on the wall are due to broken waves. Again the use of Goda's method gives a safe estimation of forces, even though the process under broken waves will be rather different.

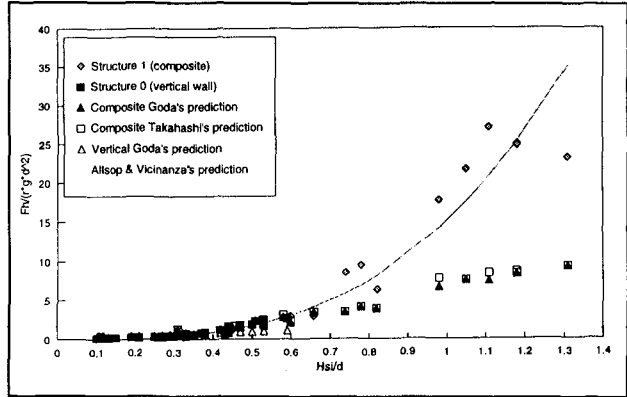

Figure 9 Dimensionless force against H_{sr}/d for low mounds

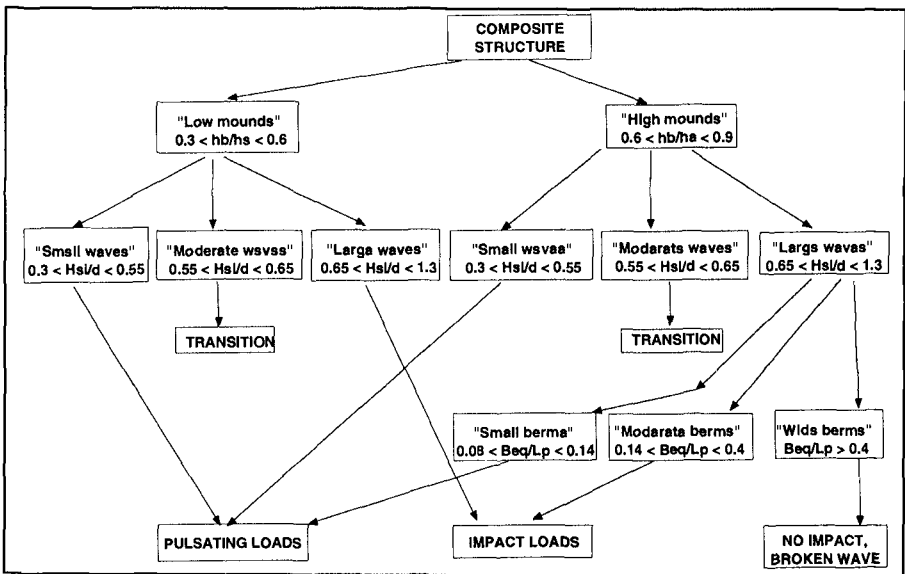

Figure 10 Decision chart for impacts on simple or composite walls

The overall picture of the different loading conditions over these regions is summarised in a type of flow chart in Figure 10. This was developed first by Allsop et al (1996c) and refined by Allsop et al (1996a). The parameter regions are divided by the relative berm height h_b/h_s , the relative wave height H_w/d , and the relative berm length B_{eq}/L_p . This chart represents a considerable simplification of the overall processes, but renders decisions on the type of wave loading substantially more tractable.

5. POSITION AND VARIATIONS OF IMPACTS

The major emphasis so far has been the extreme pressures / forces which determine overall stability of the structure. Data on local pressures and pressure gradients are also needed in any analysis of potential local damage or instability of blockwork.

Distribution of pressures

Goda's method assumes that wave pressures are distributed trapezoidally over the front face. For pulsating conditions this assumption is reasonably well-supported, but for impact conditions, agreement is much less good. For $H_w/d=0.4$ on the same simple wall, the peak pressures in Figure 11 are much more severe. The peak is greater than predicted, and here is slightly above the water level.

Figure 11 Vertical distribution of pressures, $H_w/d=0.4$, simple wall

Increasing impacts increase overall forces, but also substantially increases local pressure gradients, illustrated dramatically in Figure 12 where the difference between these tests is in the effective berm width, B_{eq} . The most uniformly distributed pressures occur for the simple wall, and for the composite structure with moderate berm, 3. Structures 4 and 7 have only slightly larger berms, yet the local pressures and pressure gradients increase significantly. Here increasing the berm width has initiated the breaking process, giving greater impact forces for greater relative berm width, and dramatically greater peak pressures.

Figure 12 Effect of berm width on distribution of pressures, high mounds

Pressure gradients

Pulsating wave conditions give relatively low absolute values of wave pressure, so pressure gradients seldom exceed values of $dp/dz > 1$. The situation is however dramatically different for impact conditions, even on simple walls where peak local pressure gradients in these tests varied over $dp/dz=2$ to 70. These increased slightly for low mounds to $dp/dz=5$ to 90, and for high mounds to $dp/dz=2$ to 80. The mean value of these results, the standard deviations (s.d.) and coefficients of variation are summarised below:

Structure	range	mean (dp/dz)	s.d. (dp/dz)	coef. varn.
Vertical	2 - 70	13.2	15.9	1.19
Low mound	5 - 90	29.5	25.9	0.879
High mound	2 - 80	21.6	17.5	0.814

For impact waves, the greatest relative local pressure measured in these tests was given by:

$$p_{max} / (\rho_w g H_w) \leq 50 \tag{3a}$$

and the steepest pressure gradient was given by:

$$\max (dp / dz) \leq 90 \tag{3b}$$

6. DISCUSSION ON SCALE EFFECTS

Use of model tests should always include analysis of scale effects, particularly where key responses are influenced by the scale of the tests. Analysis of pressure measurements at laboratory scale here has not explicitly assumed any scale conversion, but use of parameters scaled by Froude implies that pressures measured here can be scaled by Froude unless corrected. Wave impacts in small scale hydraulic model tests are however greater in magnitude, but shorter in duration than their equivalents at full scale in sea water, so simple Froude scaling will over-estimate prototype loads, but under-estimate their durations.

New work discussed by Allsop et al (1996a, b) and Howarth et al (1996) has been used to develop a simple correction method for impact pressures. Measurements of wave impact pressures on concrete armour units on a prototype breakwater have been compared with measurements of equivalent pressures in laboratory tests at 1:32 scale in fresh water. These were used to calculate pressure impulse estimated by peak pressure multiplied by the rise time Δt . Values of this pressure impulse were compared at the same exceedance levels and show extremely close agreement over the regions of probability of interest, 90-99.9% non-exceedance.

Extreme impact pressures from field and model have then been compared by Allsop et al (1996a, b), see Figure 12, and these show that model results need to be corrected by factors between 0.45 to 0.40 for non-exceedances levels of 90 - 99.9%. It should however be borne in mind that the relatively slow rate of sampling

Figure 13 Weibull probabilities of impact pressures, field and model

used in the Wallingford / Belfast / Sheffield tests may imply that some peak pressures could have been under-estimated by up to 50%, so any scale correction to reduce predicted pressures should be used with care.

ACKNOWLEDGEMENTS

This work is based on studies completed at HR Wallingford for the Construction Sponsorship Directorate of the UK Department of Environment, under research contracts PECD 7/6/263, PECD 7/6/312, and CI 39/5/96; with support from the MCS project of the European Union's MAST II programme under contract MAS2-CT92-0047, and the PROVERBS project in MAST III under contract MAS3-CT95-0041.

Substantial additional support to the testing and/or data analysis has been given by the Queen's University of Belfast; the Department of Hydraulics of the University of Naples; and the University of Sheffield. Funding support for visiting researchers at Wallingford from TECHWARE, the international exchange programme of the University of Naples, and the Department of Education NI is also gratefully acknowledged.

The senior author acknowledges considerable assistance from his colleagues at Wallingford; advice by Mike Chrimes, librarian of the Institution of Civil Engineers; Gerald Müller of Queen's University of Belfast for discussions on wave impacts and advice on measurement devices; Mario Calabrese of University of Naples for assistance in the development of the initial flow diagram dividing parameter regions and pulsating / impact responses; and Andreas Kortenhaus of University of Braunschweig for advice on analysis and event definitions. The senior author is also grateful to the Port and Harbour Research Institute in Japan and JISTEC for supporting participation in the 1994 Wave Barriers workshop.

Abstract

Froudian scaling laws are often used to convert model wave impact pressures to prototype scale. However, although many model studies have been performed in the past, the effects of scale on the magnitude and duration of wave impact pressures have yet to be determined.

Wave impact pressures were monitored on a Cob armoured breakwater at LaCollette Harbour, Jersey, UK, throughout the Winter of 1993/94. In addition, a 1:32 scale model of the prototype breakwater was constructed at the University of Bristol and subjected to a similar wave climate as was measured at prototype scale. A comparison of the pressures measured at the 2 scales has allowed the scale effects present in the wave impact process to be determined.

Introduction

Wave impact loading has long been of interest to designers and researchers, as it can be the most severe form of loading on coastal structures (e.g. Rouville 1938). Despite this, there is still considerable uncertainty about the magnitude of these loads and the physical processes which govern them. Although many model studies have been carried out, the scale effects present in the impact process remain uncertain.

Traditionally, Froudian scaling is used to convert model wave loads to prototype scale, as it is generally accepted that wave loads are gravity dominated. However, during the wave impact process the compressibility of the wave front may be the

dominating factor in determining the magnitude of the pressure generated (Führböter 1988, Kamel 1970). Many researchers have recognised that small scale experiments may overestimate the pressures measured at prototype scale when Froudian similarity is used. Very little research, if any, has adequately shown this to be the case by carrying out experiments at model and prototype scales and comparing the results.

In this study, impact pressures were measured on a typical hollow cube armour unit (a Cob unit) at LaCollette Harbour, Jersey. In addition, a 2-dimensional model of the breakwater at LaCollette Harbour was constructed at 1:32 scale in the small wave flume at the University of Bristol. The wave and tidal conditions measured at LaCollette Harbour were recreated as closely as possible in the laboratory. Any differences in the pressures measured at model and prototype scales are likely to be due to the scale effects present in the impact process.

Prototype pressure measurement

LaCollette breakwater was constructed in the early 1970s, and forms part of the outer coastal defence of St. Helier Harbour, Jersey. The breakwater is protected by Cob armour units, placed in a single layer, protecting a rubble core. The main axis of the breakwater runs WNW to ESE, and is subjected to wave loading from the South-west. A typical cross-section of the breakwater is shown in Figure 1.

Figure 1: Typical cross-section of LaCollette Breakwater, Jersey, UK

Wave impact pressures were measured at 8 points on the surface of a single unit on row 5 of the breakwater. The unit was chosen as it received wave impact loading on every tide whilst being far enough up the breakwater slope to be relatively unaffected by the toe beam. Data Instruments AB pressure transducers were used to measure impact pressures. The transducers were placed flush with the surface of the Cob unit to ensure that the pressures measured were the same as those experienced by the unit. The pressures were sampled at 500Hz, which was adequate to ensure the vast majority of impact pressures were accurately captured. Wave height and tidal level were measured at the breakwater toe.

The long logging periods and the high sampling rates involved in measuring wave loads on a prototype breakwater can mean a huge volume of data can be collected, with relatively few impact 'events' occurring during that time. Intelligent monitoring techniques were used in an attempt to limit the volume of data stored whilst retaining all significant impact data. This was achieved by sampling pressure data for 1 hour as the tidal level increased towards the instrumented unit, and for 1 hour as the tidal level fell back below the unit. The logging period was sufficiently long to ensure that all impacts which occurred on the instrumented unit were measured. An analysis program was then implemented to detect the wave impacts measured during the logging period and to determine the magnitudes and rise times of the pressures. The details of each impact were then stored in a text file with the time and the tidal level at the time of impact. This process greatly reduced the amount of data stored whilst retaining all useful impact pressure information.

Pressure and wave data was monitored almost continuously between November 1993 and February 1994.

Model Pressure Tests

A 2-dimensional model of the LaCollette breakwater was constructed at 1:32 scale. A 1:50 slope was constructed in front of the breakwater, representing the average slope of the bathymetry at Jersey. Impact pressures were measured on the top limb of the Cob unit, as this was the position at which the largest pressures at prototype scale were measured. The pressure on the top limb was sampled at 10kHz. This is a faster sampling rate (to scale) than that used at prototype scale, as it has previously been found that wave impact pressures measured in the laboratory, using fresh water, can have an extremely short duration (e.g. Oumeraci 1993, Kirkgöz 1995). The pressure transducer used was the EP-101W-50 transducer supplied by Entran Ltd., chosen for its excellent frequency response and small size. The diameter of the sensing face roughly represented the diameter of the prototype scale transducer used in Jersey. The size of the sensing face of a pressure transducer is likely to affect the magnitude and rise time of the impact pressure measured, resulting in smaller magnitude, longer duration pressures being recorded. If accurate scaling between model and prototype scales is to be achieved it is likely that the linear dimensions of the transducer face should be subject to the same scale factor as the rest of the

model. If inappropriate transducers are used then the effects of scale in the impact process may not be detected (e.g. Führböter 1986).

The model breakwater was subjected to similar random wave conditions as those measured at LaCollette Harbour. The waves were always applied normal to the breakwater, which was not necessarily the case for the prototype structure. Despite this, it is thought that the waves applied to the model were a good representation of the prototype wave climate.

Prototype results

The site deployment at LaCollette Harbour was extremely successful. More than 4000 impact pressures above 1m head of water were recorded, with more than 3000 impacts measured on the vertical face of the top limb. Figure 2 shows pressures measured on instrumented unit caused by a typical wave - transducer 6 was situated on the vertical face of the top limb. In this case transducer 6 has measured an impact pressure equivalent to 3.5m head of water, whilst the other transducers have measured 'quasi-hydrostatic' pressures. The impact pressures measured exhibited typical wave impact features: a rapid rise in pressure (with a rise time generally below 30ms) as the wavefront impinged on the unit, followed by a longer duration pressure formed as the unit is submerged.

Figure 2: Typical pressure traces measured at prototype scale

All the impact pressures measured throughout the winter on the vertical face of top limb are plotted against probability of non-exceedence in Figure 3. The pressures followed a log-normal distribution very closely. The largest pressure measured was 14.6m head of water. The excellent correlation with a log-normal distribution suggests that more extreme impact pressures may be accurately predicted by extrapolating the graph.

Figure 3: Log-normal distribution of impact pressure, prototype

The distribution of the rise times measured for each impact, plotted on log-normal axes, is shown in Figure 4. It can be seen that impact rise time follows a log-normal distribution well. Approximately 30% of the impact pressures measured had a rise time less than 10ms.

Figure 4: Log-normal distribution of impact pressure rise times, prototype

Model Test Results

The pressure transducer used in the model test programme performed excellently, and was found to be capable measuring the very rapid impact pressures found at small scales. The impact pressures measured exhibited similar features as those found at prototype scale. A typical impact pressure is shown in Figure 5. The pressure rise times were often very short, with many impacts being lower than 0.5ms.

Figure 5: Typical impact pressure trace at model scale

The pressures measured during each test were plotted on statistical axes. It was found that a log-normal distribution accurately described the impact pressures measured in each test. The rise times of all the impact pressures measured during the test programme are shown in Figure 6. Log-normal axes have been used. It can be seen that the impact pressure rise times are accurately described by a log-normal distribution. It can also be seen that approximately 50% of the pressures measured exhibited a rise time of less than 1ms. A small number of impacts, approximately 1%, had a rise time of less than 0.1ms, equal to the sampling interval used throughout the test programme. Ideally, a higher sampling frequency would have been used so that even the most rapid impact pressures that occurred could have been accurately captured. However, an increase in the sampling rate would have led to increases in the already large volume of data recorded, and in any case the percentage of impact pressures which were affected by the sampling rate was small.

Figure 6: Log-normal distribution of impact pressure rise times, model

Scale Effects

The breakwater at LaCollette Harbour was modelled as closely as possible at 1:32 scale. The wave conditions measured at Jersey were reproduced accurately in the laboratory. The size of the pressure transducer was scaled as accurately as possible from prototype to 1:32 scale. Hence it can be assumed, with reasonable confidence, that any differences in the impact pressures measured at model and prototype scales are due to the scale effects present in the impact process.

It has generally been predicted by previous researchers (e.g. Führböter 1984) that Froudian scaling *overestimates* the magnitude of prototype impact pressures and *underestimates* their rise times. These results have been found in this research. It may be expected, therefore, that the magnitude of wave impact impulses will scale relatively accurately using Froudian scaling, since impulse is assumed to be the product of pressure magnitude and rise time.

Impulse data collected at model and prototype scale, scaled to prototype using Froudian scaling, is shown in Figure 7. The impulses are plotted on log-normal axes. It can be seen that for low probabilities of non-exceedence the values of model and prototype impulses differ significantly, with the model results underestimating the impulses measured at prototype scale. For more extreme impulses, however, the model and prototype data correlate well, suggesting that for the most severe impact events Froudian scaling can reasonably be used to predict prototype impulses from small scale data. Impulse is related to the wave momentum destroyed in the impact process. Wave momentum can be accurately scaled using Froudian similarity, and hence the value of impulse in the impact process can be modelled using Froudian

scaling. The difference in data at small values of impulse may be caused by the higher sampling rate (to scale) used in the laboratory, which allowed impact pressures with an extremely short rise time to be measured.

Figure 7: Comparison of impact impulses using Froudian scaling

Figure 8: Comparison of pressure magnitudes using Froudian scaling

The distribution of all the impact pressures measured at prototype and model scale is shown in Figure 8. The model pressures have been scaled to prototype using Froudian similarity. It can be seen that the pressures at both scales follow a log-normal distribution extremely well. The distribution of pressures both start at 1m head of water as this was used as the threshold pressure magnitude for both scales. The pressures measured in the laboratory were generally larger than those measured at prototype scale. Although the magnitude of the pressures are different, the excellent correlation in the type of distribution data from both scales follow suggests that very similar processes are present at both scales.

The difference in the maximum pressures likely to occur at model and prototype scales increases as the likelihood of occurrence decreases. This is illustrated below:

Probability of non-exceedence, %	Model pressure, m	Prototype pressure, m	P_{model}/P_{proto}
50	2.13	1.68	1.27
90	6.35	3.26	1.80
99	18.1	7.20	2.51
99.9	40.4	12.50	3.24

As the impacts become more severe then the model pressures increasingly overestimate the magnitude of the pressure which will occur at prototype scale. The prototype and model pressures may be related, once Froudian scaling has been used, by the empirical equation:

$$\frac{P_{prototype}}{\rho g} = \left(\frac{P_{model}}{\rho g} \right)^{0.684}$$

It may be suggested that as the impact loading becomes more severe the effect of wave compressibility dominates over Froudian (gravity) forces. Hence, the increasing differences between model and prototype pressures is due to the increasing effect of wavefront compressibility on the impact process.

The largest non-dimensionalised pressure *likely* to occur in 100 waves, denoted by $P_{100}/\rho g H_s$, has been used to compare results from different model tests as well as being used in the prototype analysis. The value of $P_{100}/\rho g H_s$ is a good measure of the severity of wave impact loading, as it is a function of both the frequency of occurrence and the statistical distribution of the pressures measured. The effect of the still water level on the value of $P_{100}/\rho g H_s$ is shown in Figure 9. It can be seen that, for both scales, the most severe wave impacts occur when the still water level is below the level of the transducer. The pressures measured in the laboratory are much greater than those measured at prototype scale at this still water level, suggesting that compressibility effects are most important for the most severe

loading. As the water level rises towards the transducer then the pressures become less severe, with the pressures measured at both scales converging. This suggests that compressibility effects are less than Froudian effects for less severe impact pressures.

Figure 9: $P_{100} / \rho g H_s$ vs. relative water depth, h_t

It has been suggested previously (e.g. Oumeraci 1991) that impact pressures measured at small scales tend to have shorter rise times than would have been predicted using Froudian scaling. Figure 10 shows the percentage of impacts which occurred for given rise times. The data has been scaled to prototype scale using Froudian similarity. The results from both scales can be directly compared as the same definition of an ‘impact event’ was used at both scales. It can be seen from Figure 10 that a much higher proportion of impact pressures measured at 1:32 scale have short rise times compared to those measured at prototype scale.

Figure 10: Comparison of impact pressure rise times using Froudian scaling

Figure 10 shows that great care must be taken when performing model wave impact tests. For example, it may be decided in the design of a coastal structure that impact pressures with a rise time below 5ms (for example) need not be considered, as it might be assumed that pressures of a shorter duration will have little effect on the prototype structure. However, Figure 10 shows that if model tests were carried out to determine the pressures likely to occur at prototype scale, rise times of less than this value (scaled down using Froudian scaling laws) should be considered. The short rise times which occur at small scales represent longer duration pressures at prototype scale which may be structurally important.

Conclusions

It has been shown that the physical effects present in model wave impact tests are similar to those found at prototype scale. For example, typical impact pressure traces are similar, the relationship between impact severity and still water level is similar, and pressures from both scales accurately follow a log-normal distribution. However, significant scale effects present in the wave impact process have been found:

The use of Froudian scaling to convert model impacts to prototype scale is likely to overestimate the pressures which will occur on the structure by up to 500%. The

error in the predicted pressures increases as the severity of the impact loading increases.

The rise times of impact pressures are underestimated at model scales if Froudian similarity is used. The reduced compressibility of the wavefront at model scale leads to sharper impact pressures with short rise times and large magnitudes. The reduction in compressibility is caused by less air entrainment present in the model waves, which in turn is caused by the use of fresh water in the laboratory as well as differences in the Weber number at the two scales.

Impact impulses scale reasonably well when Froudian scaling is used. The impulse generated in the impact process is principally related to the momentum of the wave, which may be accurately scaled using Froudian similarity.

A relationship between model and prototype pressures has been deduced. This allows Froudian scaling to be used to convert model data to prototype scale, as long as the appropriate adjustment is made to take scale effects into account.

CHAPTER 196

WAVE IMPACT LOADING OF VERTICAL FACE STRUCTURES FOR DYNAMIC STABILITY ANALYSIS - PREDICTION FORMULAE -

P. Klammer¹, A. Kortenhaus², H. Oumeraci³

ABSTRACT

Based on impulse theory and experimental investigations on breaking wave kinematics and impact loads, prediction formulae for impact forces have been derived for vertical face breakwaters and further monolithic structures where wave effects dominate design considerations. Hydraulic model tests have been performed to obtain the water mass involved in the impact process and to verify the theoretical results obtained from theory.

INTRODUCTION

The results of the re-analysis of vertical breakwater failures (*Oumeraci, 1994*) have highlighted the importance of breaking waves and the subsequent destructive potential of impact loads. One of the principal lessons drawn from these failures consists in the urgent need to supplement the present static design approach by dynamic stability analysis. For this purpose, the impact loads induced by breaking waves on vertical breakwaters must be specified. It is the main purpose of this paper to develop an approach for the prediction of the impact load as needed for dynamic analysis of caisson breakwaters and further monolithic structures where wave effects dominate design considerations.

For this purpose, a formula for the impact force will be derived using impulse theory and solitary wave theory. Missing parameters were obtained from PIV measurements (particle image velocity) conducted at the University of Edinburgh. The obtained formulae will be compared to hydraulic model tests performed in the Large Wave Flume of Hannover (GWK).

THEORETICAL BACKGROUND

A breaking wave impinging on a vertical wall generally induces impulsive pressures on the wall which are difficult to predict in terms of their magnitude as well as in terms of their spatial and temporal distribution (Fig. 1).

Fig. 1: Impact loading of vertical structure - definition sketch

The forward momentum of a fluid mass m hitting a wall with a horizontal velocity u will induce a force impulse (Fig. 1):

$$\int_0^{t_r} F_h(t) \cdot dt = m \cdot u \tag{1}$$

where t_r is the rise time up to the peak force $F_{h,max}$ and $F_h(t)$ is the horizontal force-time function. Assuming a linear temporal increase of the force $F(t)$, Eq. (1) yields:

$$\frac{1}{2} F_{h,max} \cdot t_r = m \cdot u \tag{2}$$

thus leading to the peak force:

$$F_{h,max} = 2 \cdot \frac{m \cdot u}{t_r} \tag{3}$$

Most of the difficulties encountered in applying Eq. (3) for the prediction of impact forces originate from the lack of information on the magnitude of the fluid mass m which is involved in the impact process and which accounts only for a small portion of the total mass M of the breaking wave impinging on the wall

$$m = k \cdot M \tag{4}$$

Assuming that the actual wave at breaking may be approximated by a solitary wave, its total mass M is given by the following relationship (Munk, 1949):

$$M = \rho \cdot \sqrt{\frac{16}{3} \cdot H_b \cdot d_b^3} \quad (5)$$

where ρ is the density of the fluid; H_b is the wave height at breaking and d_b is the water depth at the breaking point.

The maximum horizontal velocity approximates to (Munk, 1949):

$$u = \sqrt{g \cdot (d_b + H_b)} \quad (6)$$

and with the corresponding breaking criterion:

$$\frac{H_b}{d_b} = 0.78 \quad (7)$$

Eq. (6) yields:

$$u = \sqrt{g \cdot d_b \cdot (1 + 0.78)} \approx 1.33 \cdot \sqrt{g \cdot d_b} \quad (8)$$

and Eq. (5) yields:

$$M = \rho \cdot \sqrt{\frac{16}{3} \cdot H_b \cdot \left(\frac{H_b}{0.78}\right)^3} \approx 3.35 \cdot \rho \cdot H_b^2 \quad (9)$$

The forward momentum of the fluid mass m involved in the impact process is obtained from Eqs. (4), (8) and (9) to:

$$m \cdot u = (k \cdot M) \cdot u \approx 4.47 \cdot k \cdot \rho \cdot H_b^2 \cdot \sqrt{g \cdot d_b} \quad (10)$$

Considering Eq. (3) the dimensionless peak force is obtained as a function of the dimensionless rise time:

$$\frac{F_{h, \max}}{\rho \cdot g \cdot H_b^2} = k \cdot 8.94 \cdot \left(\frac{\sqrt{d_b/g}}{t_r} \right) = k \cdot 8.94 \cdot \left(\frac{t_r}{\sqrt{d_b/g}} \right)^{-1} \quad (11)$$

The nondimensional parameter k which represents the portion of the total mass of the breaking wave involved in the impact process has to be determined experimentally for each breaker type. According to *Bagnold (1938)* k is approximately 0.2. It can be concluded from Eq. (11) that the following issues will have to be further investigated:

- *Breaker types*: Breaker types have to be classified with respect to the loading induced in order to check the applicability of the proposed formula (impact loading and non impact loading)
- *Wave height H_b* : If H_b is not measured a method must be developed to determine the wave height at the breaker point taking into account the presence of the structure.
- *Mass parameter k* : for each loading case k has to be calculated from hydraulic model tests (see Eq. (4)).
- *Rise time t_r* : the determination of rise time t_r is dependent on the breaker type.

- *Occurrence frequency of relative horizontal force*: one of the two related parameters (relative horizontal force or relative rise time) in Eq. (11) must be taken from statistical analyses of hydraulic model tests.

(a) Typical Breaker Types

Model tests in the wave flume at the University of Edinburgh were conducted to experimentally define the water mass m involved in the impact process under different loading case conditions (Oumeraci *et al.*, 1995). In these tests velocity profiles for the following breaker types could be determined:

- well developed plunging breaker with large entrapped air-pocket
- plunging breaker with small entrapped air-pocket
- "flip-through" breaker

A rough classification of wave loading is given in Fig. 2 which distinguishes between 'pulsating' loads and impact loads. For the latter which is induced by waves plunging on the structure the Goda method (Goda, 1985) is not applicable (Takahashi *et al.*, 1993). The proposed method was therefore developed for this type of loading (Fig. 2c).

Fig. 2: Classification of wave loading

(b) Estimation of Incident Wave Heights

Wave breaking can be taken into account by a formula given in Oumeraci *et al.*, 1993 in which the total reflection of the structure and its influence on wave breaking is considered:

$$H_b = L_b \cdot \left[0.1025 + 0.0217 \left(\frac{1 - C_r}{1 + C_r} \right) \right] \cdot \tanh \left(2 \pi \frac{d_b}{L_b} \right) \quad (12)$$

In Eq. (12) d_b is the water depth at the breaking point of the wave, L_b is the wave length of the breaking wave and C_r is the reflection coefficient of the structure. The significant wave height can be calculated by a comparison between H_d (calculated from shoaling) and H_b in which H_d may not exceed H_b .

The water depth in front of the structure can be regarded as the governing parameter for the magnitude of the resulting wave height H_b . It can be assumed that a relatively short berm in front of the structure ($B_b/L \leq 0.15$) will have only a small influence on wave breaking. Therefore, it would not be correct to use the water depth d in front of the structure as an input ($d = d_b$) for Eq. (12). On the other hand using the water depth hs (Fig. 1) at the toe of the berm would certainly overestimate the breaker height as the influence of the berm on the breaking would be neglected. It is assumed that the berm width B_b , the wave length L and the slope of the berm 1:m ($m = \cot \alpha$) will influence the breaking of waves. Therefore an effective water depth d_m can be derived which takes into account the aforementioned parameters (Fig. 1):

$$d_m = d + B_{rel} \cdot m_{rel} \cdot (hs - d) \quad (13)$$

In Eq. (13) B_{rel} is the part of the berm width which influences the effective water depth:

$$B_{rel} = \begin{cases} 1 & \text{for } B_b/L > 1 \\ 1 - 0.5 \cdot B_b/L & \text{for } B_b/L \leq 1 \end{cases} \quad (14)$$

The parameter m_{rel} in Eq. (13) is a part of the slope of the berm which influences the effective water depth and is assumed to be:

$$m_{rel} = \begin{cases} 1 & \text{for } m < 1 \\ m^{-0.5} & \text{for } m \geq 1 \end{cases} \quad (15)$$

For solitary waves the effective water depth d_m is very close to the depth hs ($d_m = hs$), so that $B_{rel} = 1$ and $m_{rel} = 1$. This is confirmed by comparing the calculated wave height using Eq. (12) and this assumption with measurements in the Large Wave Flume of Hannover (GWK) (Fig. 3).

A relatively good agreement between measured and calculated values is also obtained for regular and random wave tests.

(c) Experimental Determination of Mass Parameter k

The basic concept for the evaluation of water mass m involved in the impact process is illustrated in Fig. 4. The impulse of a water mass m with a horizontal velocity $v(z)$ at a height z above the berm can be calculated as follows (Fig. 4a):

$$v(z) \cdot dm(z) = v(z) \cdot [\rho \cdot l(z) \cdot dz] \quad (16)$$

Fig. 3: Calculated vs measured wave height H_b for solitary waves

Fig. 4: Principal determination of wave induced loading

The vertical component of the velocity can be neglected. This impulse (Eq. (16)) is equal to the pressure impulse $dI = p(t) \cdot dt$ at the wall measured at a height z above the berm during the period t_1 to t_2 (Fig. 4b):

$$p(t) \cdot dt = [\rho \cdot l(z) \cdot dz] \cdot v(z) \tag{17}$$

Both the velocity (Fig. 4d) and the pressure distribution (Fig. 4e) were measured over the full height of the wall. From those, it is possible to determine the mass distribution for the respective breaker type (Fig. 4c).

The calculation of water masses involved in the impact process was performed according to the height of the pressure cells 6-12 at seven locations (Fig. 4a). The measured pressure distributions were integrated from time t_1 to the time of the maximum t_{max} (Fig. 4b) and from time t_1 to the time of maximum wave run-up at the wall t_2 (Fig. 4b). These values were multiplied by the horizontal velocities obtained from the PIV measurements.

Finally, the mass parameter k could be estimated for different breaker types (Tab. 1) (see also Fig. 4):

Tab. 1: Mass parameter and impulse ratio for different breaker types

Loading case	Breaker type	Mass parameter k [%]	Impulse ratio ^{*)} I_{rFh}/I_{dFh} [%]
2	Well developed plunging breaker with much air enclosed	11	9
3	Plunging breaker with little air enclosed	16	15
4	flip-through breaker	28	21

*) I_{rFh}, I_{dFh} : definition see Fig. 4

In Tab. 1 the experimentally determined mass parameter k (11-28%) are in the same order of magnitude as the average value $k \approx 0.2$ proposed by *Bagnold (1938)*.

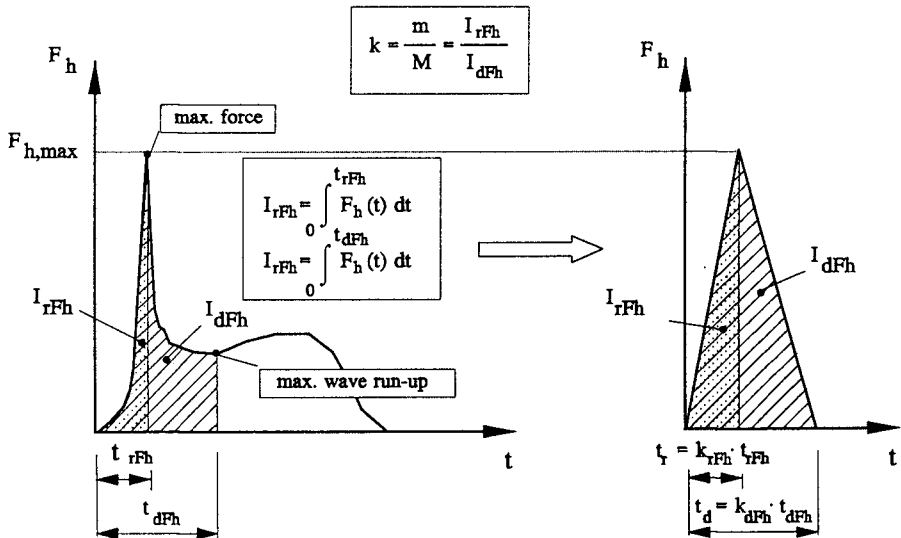

Fig. 5: Substitution of the real force history by an equivalent triangular force

Fig. 5 (left side) illustrates a typical horizontal force history induced by a wave impinging on the wall. The maximum load is reached after a time t_{rFh} and the maximum wave run-up after a time t_{dFh} . At that time it is assumed that the total mass M of the breaking wave has transferred its impulse I_{dFh} to the wall whereas the mass m inducing the impact transfers its impulse I_{rFh} to the wall over a duration t_{rFh} . Subsequently, the mass parameter k can be verified by the ratio of I_{rFh} and I_{dFh} as given in Fig. 5.

This force impulse ratio calculated for the same PIV tests as those used for the determination of k leads to results also given in Tab. 1. A comparison between the values of the PIV tests and the impulse ratio clearly shows that the latter are slightly smaller.

(d) Temporal Development of Horizontal Force

The theoretical approach is based on the assumption of a linear rise of the horizontal force to the maximum load (Fig. 5). Actually the shape of this force increase is strongly dependent on the breaker types.

Therefore two factors k_{rFh} and k_{dFh} are introduced which account for the different geometries of load histories in the case of breaking waves. The factor k_{rFh} is the value that has to be multiplied with the rise time t_{rFh} in order to obtain a triangle with the same area (force impulse). For the horizontal force this can be calculated as follows (Fig. 4):

$$k_{rFh} = \frac{2 \cdot I_{rFh}}{F_{h, \max} \cdot t_{rFh}} \quad \text{with } k_{rFh} < 1 \quad (18)$$

For k_{dFh} a similar approach yields:

$$k_{dFh} = \frac{2 \cdot \Delta I_{dFh}}{F_{h, \max} \cdot \Delta t_{dFh}} \quad \text{with } k_{dFh} < 1 \quad (19)$$

where the portion of impulse ΔI_{dFh} is defined as:

$$\Delta I_{dFh} = \int_{t_{rFh}}^{t_{dFh}} F_h(t) dt \quad (20)$$

(e) Prediction Formula for Impact Loading of Vertical Structures

Using the results derived in the previous sections Eq. (11) may be rewritten as:

$$\frac{F_{h, \max}}{\rho \cdot g \cdot H_b^2} = 8.94 \cdot \frac{k}{k_{r, Fh}} \cdot \left(\frac{t_r}{\sqrt{d_b/g}} \right)^{-1} \quad (21)$$

where k and $k_{r, Fh}$ are obtained from PIV tests:

- well developed plunging breaker: $k = 0.10$; $k_{r, Fh} = 0.80$
- plunging breaker: $k = 0.15$; $k_{r, Fh} = 0.80$
- 'flip-through': $k = 0.20$; $k_{r, Fh} = 1.00$

Since a distinction between these three loading cases based on simple parameter analysis is not yet available it is proposed to select a conservative value for $k = 0.20$ and $k_{r, Fh} = 0.80$, thus resulting in the following prediction formula:

$$\frac{F_{h,\max}}{\rho \cdot g \cdot H_b^2} = 2.24 \cdot \left(\frac{t_r}{\sqrt{d_b/g}} \right)^{-1} \quad (22)$$

This prediction formula can be compared with measurements obtained from GWK tests (Fig. 6) which are described in more detail in *Kortenhaus et al. (1994)*.

Fig. 6: Comparison of prediction formula to large-scale measurements (random waves)

It can be seen from Fig. 6 that the prediction formula in Eq. (22) represents approximately the upper envelope to the random wave test results. This was to be expected as a conservative approach was used where solitary wave theory was used. Therefore, for solitary waves the prediction formula better fits the data obtained from the model tests (Fig. 7). However, the large scatter in the data can be explained as follows:

- breaking processes at a vertical wall are extremely stochastic which can only be approximated by the aforementioned approach;
- the sampling frequency of the pressure transducers used in the tests was not high enough leading to errors in both defining the rise time and the maximum load;
- sampling noise during the measurements cause some problems in defining the zero crossings which are essential in defining the accurate rise times.

The relation between rise time t_r and total duration t_d of the load (both for triangular load geometries) can also be taken from large-scale measurements:

$$t_d = t_r + 0,35 \cdot \left(1 - \exp(-20 \cdot t_r) \right) \quad (23)$$

Fig. 7: Comparison of prediction formula to large-scale measurements (solitary waves)

Fig. 8: Total duration t_d vs rise time t_r for random waves in large-scale model tests

(f) Statistical Distribution for Relative Horizontal Forces

In order to apply the prediction formula (Eq. (22)) a statistical distribution function for relative horizontal forces $F_h / \rho \cdot g \cdot H_b^2$ is needed. Such a distribution function has been developed by modifying the standard Weibull distribution (Weibull, 1951) as follows:

$$F(x) = 1 - \exp\left[-\gamma \cdot (\ln x - \beta)\right]^\alpha \quad x > 0 \tag{24}$$

In Eq. (24) α , β and γ are the parameters of the modified Weibull functions where $F(x)$ is the distribution function. Fig. 9 shows the non exceedance probabilities of relative horizontal forces taken from large-scale measurements with random waves.

Fig. 9: Statistical distribution function of relative horizontal forces

Assuming a non exceedance value a relative horizontal force can be read from Fig. 9 or calculated by Eq. (24). In this approach no scale effects are considered but will have to be investigated further.

(g) Temporal Development of Pressure Distribution

For dynamic analyses it is very often necessary to apply pressure distributions at the front face of the structure instead of horizontal forces. Therefore, a pressure distribution has to be suggested. In Fig. 10 the temporal development of a typical pressure distribution for a well developed plunging breaker is shown over 30 time steps with the maximum impact force indicated in the centre of the figure.

It can be seen from Fig. 10 that the pressure distribution changes its shape significantly with time. Furthermore, the peak pressure close to the design water level (DWL) is very high at the time of the maximum force. As a result of the analysis of several distributions similar to that shown in Fig. 10 a very simplified pressure distribution at the time of peak force occurrence is proposed for design purposes in Fig. 11.

In Fig. 11 the height of the pressure distribution η^* above DWL is dependent on the wave height H_b and can be derived as follows:

$$\eta^* = 0.8 \cdot H_b \tag{25}$$

Fig. 10: Pressure distribution for a 'well developed plunging breaker'

Fig. 11: Pressure distribution for breaking waves

In Eq. (25) H_b is the wave height of the breaking wave which can be taken from Eq. (12). The pressure head at the berm p_b can be approximated by:

$$p_b = 0.45 \cdot p_{max} \tag{26}$$

where p_{max} is the pressure at DWL. Therefore, p_{max} can be calculated from the horizontal force history by:

$$p_{max}(t) = \frac{F_h(t)}{0.4 d_b + 0.3 d_b + 0.4 H_b} = \frac{F_h(t)}{0.7 d_b + 0.4 H_b} \tag{27}$$

(h) Dynamic Load Factor

For practical design it might be desirable to use a static approach. This can be obtained by assuming an equivalent static load inducing the same response of the structure. The ratio between equivalent static and dynamic load, called dynamic load factor D, must be determined (*Oumeraci and Kortenhaus, 1994*).

DESIGN CONCEPT

For breaking waves at a structure prediction formulae have been developed in the previous sections. Therefore, an overall deterministic design concept can be derived which is principally summarized in Fig. 12.

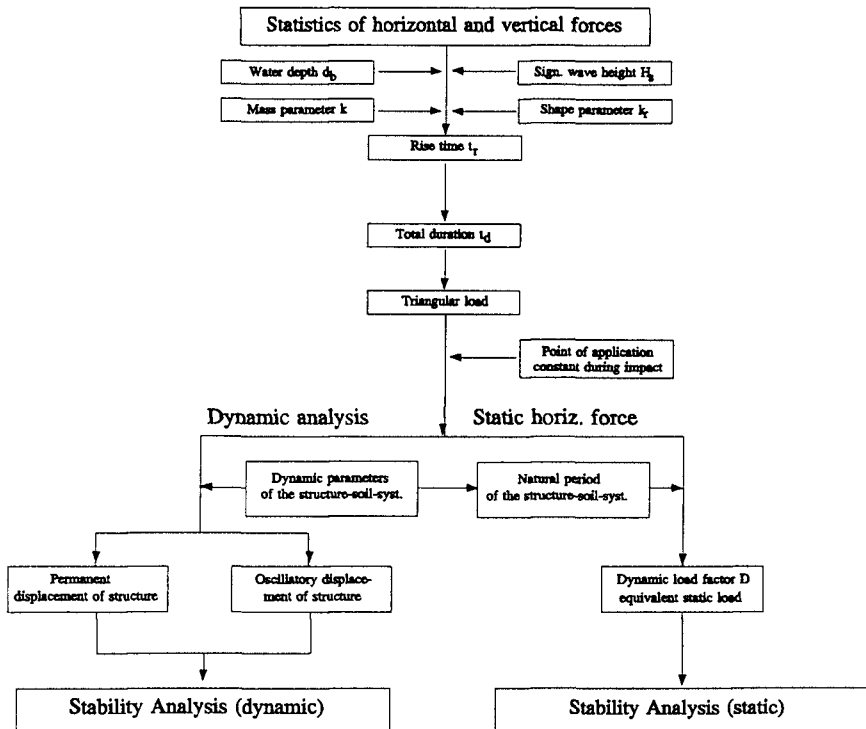

Fig. 12: Design concept for breaking wave loads

CONCLUDING REMARKS AND FUTURE WORK

Based on impulse theory and experimental investigations on breaking wave kinematics and impact loads, prediction formulae for impact forces have been derived for vertical face breakwaters.

Hydraulic model tests have been performed to assess the water mass involved in the impact process and to verify the results obtained from theory. It was found that the proposed formula represents the upper envelope of the measured values.

The ongoing and future research work is directed towards further improvement of the proposed prediction formulae. This will be particularly achieved by a better definition of the mass parameter k and of the pressure distribution for each breaker type. Moreover, a similar approach will also be developed for the uplift pressures and forces induced by breaking waves.

CHAPTER 197

Analysis on the Interaction of Waves with Flexible Floating Structure by BE-FE Combined Method

Xiaodong Liu ¹ and Shigeki Sakai ²

Abstract

A numerical method is developed to analyze the dynamic responses of large-scale floating structures to waves. A boundary element method is applied to evaluate the fluid motion and a finite element method to analyze the response of structure. The BEM and FEM are combined to solve the wave-structure interaction problem by satisfying the continuity of the pressure and displacement on the fluid-structure interface. The unknown time-dependent boundary conditions on the free surface and the interface are evaluated by a time-stepping procedure, which gives a time domain solution. An implicit scheme ensures the calculation precision.

1. Introduction

In the analysis of floating structure, the dynamic responses of structure to waves are the most important factor. A small-scale floating structure can be analyzed as a rigid body. However, for a large-scale floating structure like floating pier, floating bridge or floating airport, the elastic deformation can not be ignored, and then the effect of flexibility should be considered in the wave-structure interaction.

In the previous studies, the wave-induced deformation of floating structure is calculated by the radiation-diffraction theory, in which the velocity potentials are expressed as a linear summation of incident, radiation and diffraction waves. This theory is available for the

1 Graduated Student, Dept. of Civil and Environmental Eng., Iwate University, 4-3-5 Ueda, Morioka, 020 Japan
2 Associate Professor, Dept. of Civil and Environmental Eng., Iwate University, 4-3-5 Ueda, Morioka, 020 Japan

analysis of periodic waves, however it is difficult to solve the problem with non-periodic waves, such as the random waves in actual seas. In the present study, a numerical approach is developed to simulate the interaction of floating structure with arbitrary waves.

In order to examine the validity and applicability of the proposed numerical implementation, the calculated results are compared with experimental data.

2. Numerical analysis

2.1 Governing equation and boundary conditions

The coordinate system of two-dimensional numerical flume is defined in Figure 1. The water depth is uniform. The waves generated on the wave maker boundary propagate in x direction, and pass through under the elastic structure, which is floating on water surface and can move freely in the vertical direction. A numerical wave filter is set up on the other end of water flume to absorb the waves. The property of fluid and the condition on fluid-structure interface are assumed as follows: (1)the fluid is incompressive and inviscid; (2)the flow is irrotational; (3)structure moves with fluid inseparably and satisfies both of the Bernoulli's equation and the bending equation of structure.

Figure 1. Definitions

According to assumption (2), a velocity potential ϕ will satisfy the following governing equation in the domain Ω :

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial z^2} = 0 \quad \text{in } \Omega \quad (1)$$

Assuming that the waves excited on free surface is of small amplitude, the boundary conditions can be described as

$$\frac{\partial \phi}{\partial x} = V_n \quad \text{on } S_1 \quad (2)$$

$$\frac{\partial \phi}{\partial n} = 0 \quad \text{on } S_b \quad (3)$$

$$\frac{\partial \phi}{\partial n} = \frac{\partial z}{\partial t} \quad \text{on } S_f, S_s, S_2 \quad (4)$$

$$\frac{\partial \phi}{\partial t} + gz + \frac{p}{\rho} = 0 \quad \text{on } S_f, S_s \quad (5)$$

$$\frac{\partial \phi}{\partial t} + gz + \mu \phi - \int_{x_1}^x \phi \frac{\partial \mu}{\partial x} dx = 0 \quad \text{on } S_2 \quad (6)$$

$$\frac{\partial \phi}{\partial x} = -\frac{1}{\sqrt{gd}} \frac{\partial \phi}{\partial t} \quad \text{on } S_3 \quad (7)$$

where, t is time and n means the outward normal direction on boundary. (2) gives the water particle velocity of waves generated on wave maker boundary, and (3) is the impermeability condition on bottom boundary. (4) and (5) are the kinematic and dynamic conditions on the free surfaces and the interface. (6) is the dynamic condition on the free surface of the wave filter and (7) is the Sommerfeld equation on the outside boundary of the wave filter.

2.2 Boundary integral equations

As the velocity potential ϕ is a harmonic function, the Laplace equation in domain Ω can be derived as the boundary integral equation by using Green's equation.

$$c^*(\chi_l)\phi(\chi_l) = \int_{s(\chi)} \left[\frac{\partial \phi(\chi)}{\partial n} G(\chi, \chi_l) - \phi(\chi) \frac{\partial G(\chi, \chi_l)}{\partial n} \right] ds \quad (8)$$

$$G(\chi, \chi_l) = -\frac{1}{2\pi} \log|\chi - \chi_l|$$

where, $\chi = (x, z)$ and $\chi_l = (x_l, z_l)$ are the position vector on boundaries at the points of consideration and application respectively, and $c(\chi_l)$ is the parameter corresponding to the configuration of boundaries.

By substituting (2), (3), (4) and (7) into (8), the

relation between the unknowns of the velocity potential ϕ on all boundaries and the variable z on the free surface and the interface can be expressed by the following integral formulation.

$$c^*(\chi_l)\phi(\chi_l) = -\int_S \phi \frac{\partial G}{\partial n} ds + \int_{S_f, S_s, S_2} \frac{\partial z}{\partial t} G ds + \int_{S_1} V_n G ds + \int_{S_3} \left(\frac{\partial \phi}{\partial x} \right) G ds \quad (9)$$

On the right side of the above equation, the third term is known by giving the normal water particle velocity of waves on wave maker boundary. The fourth term is treated by the transformed Sommerfeld condition on the outside boundary of wave filter, which will be explained in part 2.4. The second term is the unknown time-dependent part including free surfaces and structure surface. To obtain the solution that satisfies equation (9), it is necessary to utilize the dynamic boundary conditions.

The dynamic boundary condition on free surface S_f is described by imposing $p=0$ into equation (5)

$$\frac{\partial \phi}{\partial t} + gz = 0 \quad \text{on } S_f \quad (10)$$

where z is the displacement measured from the equilibrium water surface.

The dynamic boundary condition on the free surface of wave filter is shown in equation (6). If $\mu = \partial \mu / \partial x = 0$, it will be identical with the general form, like equation (10).

The dynamic condition on structure surface is introduced in part 2.3 in detail.

2.3 Finite element analysis of structure

The flexible floating structure is considered as a plate with unit width, in which the effect of axis force is neglected. By discretizing the continuous body into elements, and converting the distribution force acting on each element into the concentrated force acting on the nodal points, the finite element analysis can give the solution of structure deformation from the dynamic condition on fluid-structure interface by satisfying the continuity of the nodal displacement.

The dynamic equilibrium equations for a finite element

system in motion can be written in matrix form

$$[M]\ddot{\{V\}} + ([K] + [K_d])\{V\} = \{F\} \quad (11)$$

where, $[M]$: the assembled mass matrix of structure
 $[K]$: the assembled stiffness matrix
 $[K_d]$: the converted coefficient matrix of the hydrostatic restoring force
 $\{V\}$: the displacement vector
 $\{F\}$: the external force vector

The mass matrix and stiffness matrix are calculated by the general approach of finite element method. The hydrostatic restoring force ($\rho g v(x)$), which is proportional to the displacement $v(x)$ of structure, is a distribution force along elements. By changing the distribution force into the equivalent concentrated forces at nodal points, the coefficient terms corresponding to the displacement can be described in the form of the element coefficient matrix $[K_d]^e$, which is

$$[K_d]^e = \frac{\rho g l}{420} \begin{bmatrix} 156 & 22l & 54 & -13l \\ 22l & 4l^2 & 13l & -3l^2 \\ 54 & 13l & 156 & -22l \\ -13l & -3l^2 & -22l & 4l^2 \end{bmatrix} \quad (12)$$

where, ρ is water density, g is the acceleration due to gravity, and l is the length of element. The coefficient matrix of the complete element assemblage is obtained by the direct addition of the element coefficient matrices similar to the assemblage of stiffness matrix.

Moreover, the fluid pressure ($p = -\partial\phi/\partial t$) that acts on floating body is a distribution force varying with the velocity potentials. It is also needed to convert the distribution force into the equivalent concentrated forces at nodal points. And then, the external force vector $\{F\}$ can be obtained by adding the nodal forces to the corresponding points.

In dynamic analysis, the equilibrium equations (11) are solved by using the Newmark integration scheme.

2.4 Wave filter boundary condition

In order to decrease the reflection waves from the far end of flume, a numerical wave filter proposed by Ohyama et al(1985) is employed to absorb the waves. The numerical wave filter consists of a sponge layer for absorbing the energy of incident waves and a Sommerfeld boundary for radiating the incoming waves. The sponge layer can be effectively used to absorb the component waves within a wide period range. But if the wave length is larger than the width of sponge layer, the efficiency of the sponge layer decreases. Therefore, the Sommerfeld condition applied on the outside boundary of the sponge layer can absorb the wave energy of long period waves.

Assuming that the attenuation coefficient μ in the sponge layer distributes linearly in horizontal direction and imposing eq.(6) to eq.(7), the boundary condition on S_3 that satisfies the continuity of velocity and pressure can be derived as follow

$$\frac{\partial \phi}{\partial x} = -\frac{1}{\sqrt{gd}} \left(\frac{\partial \phi}{\partial t} + \mu \phi - \int_{x_1}^{x_2} \phi \Big|_{on S_2} \frac{\partial \mu}{\partial x} dx \right) \quad \text{on } S_3 \quad (13)$$

2.5 Time-stepping procedure

The velocity potential ϕ on the discrete nodal points along all the boundaries and the nodal displacements on free surface and fluid-structure interface are time-defendant variables. The time under consideration is subdivided into the constant time intervals Δt , the motions of fluid and floating body can be described by a time-stepping scheme, in which a solution is established at each time step. Assuming that the velocity potential and its time derivatives at time t , denoted by $\phi^k, \dot{\phi}^k$ and $\ddot{\phi}^k$, respectively, are known, and that $\phi^{k+1}, \dot{\phi}^{k+1}$ and $\ddot{\phi}^{k+1}$ at time $t + \Delta t$ are unknown, the relation of the unknowns at time step $k+1$ and the knowns at time step k on nodal point i can be expressed by the constant-average-acceleration scheme, as follow.

$$\phi_i^{k+1} = \phi_i^k + \Delta t \dot{\phi}_i^{k+1} = \phi_i^k + \Delta t \dot{\phi}_i^k + \frac{\Delta t^2}{4} (\ddot{\phi}_i^k + \ddot{\phi}_i^{k+1}) \quad (14)$$

$$\dot{\phi}_i^{k+1} = \frac{2}{\Delta t} (\phi_i^{k+1} - \phi_i^k) - \dot{\phi}_i^k \quad (15)$$

$$\ddot{\phi}_i^{k+1} = \frac{4}{\Delta t^2} (\phi_i^{k+1} - \phi_i^k) - \frac{4}{\Delta t} \dot{\phi}_i^k - \ddot{\phi}_i^k \quad (16)$$

At the nodal point i on free and interface boundaries, the displacement, velocity and acceleration at step $k+1$ can be also expressed in the similar relation equation in terms of the previous solutions.

In the time-stepping calculation employed in this paper, at first, ϕ_i^{k+1} is predicted in relation (14), in which $\Delta\phi_i^{k+1}$ is approximately evaluated by the solution of the previous time step in relation (17).

$$\Delta\phi_i^{k+1} \approx \Delta t \dot{\phi}_i^k + \frac{\Delta t^2}{2} \ddot{\phi}_i^k \quad (17)$$

And then, the vertical velocity and displacement on free surface and interface are calculated from the boundary integration equation (9). The velocity potential ϕ_i^{k+1} required can be evaluated by the dynamic conditions of eq.(6),(10) and (11). For one step's calculation, it repeats until the relative error between ϕ_i^{k+1} evaluated and that predicted is smaller than a given value. The solution is given by an implicit method.

3. Calculated and experimental results

3.1 Experimental equipment

The wave flume used for the present experiments is 26m long, 0.8m wide and 1m deep, as illustrated in figure 2. The water depth is 60cm. A wave generator is placed at one end of the flume. The wave generator has an absorbing system so that any reflected waves from the floating structure will not be reflected by the paddle of the wave maker. At the other end a wave absorber is installed to decrease wave reflection. Three kinds of

Figure 2. Experimental equipment

polyethylene plates with thickness 5mm, 10mm and 20mm are used as the model floating structure. The density of polyethylene plate is 0.941 and its elastic modulus is about 450 MPa. The wave profiles in the front open water are measured by two wave gauges. The vertical displacements of the floating body are measured at 20 points along the center of the flume by using an array of ultra-sonic sensors.

3.2 The numerical wave flume

The definition of the numerical two-dimensional wave flume is shown in figure 3. In the discretization of all boundaries, the element length on floating structure is 0.1m, 0.2m on free surface and 0.5m on the bottom. The calculation starts with a still water as the initial condition, and waves are produced by giving the water particle velocity and elevation on wave maker boundary. The step-by-step calculation proceeds with the time intervals of 1/100 wave period and the relative error 0.01 for each calculation step.

Figure 3. Definition of the numerical wave flume

3.3 Deformation of water surface and structure

Fig.4 shows an example of the calculated wave profile and the structure deformation at $t=24s$ after the waves are generated from a still water condition. In this case, the structure is 20mm thick and the wave period is 1.2 second. It can be seen clearly that the wavelength under the structure increases and the wave height (structure deformation amplitude) decreases significantly.

In figure 5, the time histories of deformation at several nodal points are plotted. The top one and the bottom one are in front and rear open waters respectively, and that in the middle part are on floating structure. In this figure, the vertical axis gives the value of vertical deformation and the horizontal axis is time.

Figure 4. Deformation in open water and structure

Figure 5. Time history deformation

The waves in front open water become stable, and then are influenced by the reflection waves due to the motion of floating body. For the deformation of structure, the amplitudes are large at both ends and small in structure. The motion of structure become stable after five waves pass through the structure. The variation of water surface elevation in front of wave filter is in steady state, therefore the waves are absorbed in the wave filter and the motion of floating structure is not influenced by the reflection waves.

3.4 Structure displacement response

Figure 6 shows the vertical deformation amplitude of structure with the thickness of 20mm and the wave periods of 0.8s and 1.4s. In this figure, the experimental data are the average values of wave heights measured by the time history deformation at the five waves that are in steady state. The amplitudes decrease significantly near the edge of the structure. This phenomenon is attributed to the energy conversion when the fluid motion changes into the structure-fluid combined motion. Both of the measured and the calculated results show that the deformation amplitudes exit the modes which depend on the length of structure and the period of incident waves, and they agree with each other very well.

Figure 6. Deformation amplitude of structure

Figure 7 shows the changing rates of deformation amplitudes when waves propagate into structure by energy conservation method, potential matching method, the present method and experiments, respectively. The amplitude changing rates by the present method are calculated by evaluating the average amplitudes excluding the values near the edges of structure. The amplitude variations at structure edge based on the present method coincide with the measured data well.

3.5 Moment response

Figure 8 shows the response of bending moment for 20mm-thick floating structure. The peaks exist at several places and the mode observed depends on the incident wave periods. The longer the wave period becomes, the

lower the order of mode is and the greater the bending moment becomes.

Figure 7. Comparisons of the amplitude changing rates at the edge of floating structure

Figure 8. Moment response

4. Conclusions

The numerical approach proposed in the present study simulates the interaction of waves and flexible floating structure by employing BEM for evaluating the fluid motion and FEM for calculating the deformation of floating structure. By satisfying the continuity of the pressure and displacement on the fluid-structure interface, the BEM and FEM are combined to solve the interaction problem. The proposed method is of the following advantages: (1) The dynamic responses of structure to waves are calculated in a time-stepping procedure, which gives a time-domain solution; (2) The velocity potential is not expressed by any assumed function and is evaluated numerically. Therefore, the present method can be easily applied to any wave condition including random waves just by giving the values of incident waves on the wave maker boundary of the numerical wave flume; (3) The unknown time-dependent boundary conditions on the free surface and fluid-structure interface are evaluated by an implicit predictor-corrector scheme, which ensures a calculation precision.

The comparisons between the calculated and experimental results show that the present method is effective to the dynamic response analysis of flexible floating structures to waves.

CHAPTER 198

Design wave height related to structure lifetime

Zhou Liu¹ Hans F. Burcharth²

Abstract

The determination of the design wave height (often given as the significant wave height) is usually based on statistical analysis of long-term extreme wave height measurement or hindcast. The result of such extreme wave height analysis is often given as the design wave height corresponding to a chosen return period. Sometimes confidence band of the design wave height is also given in order to include various sources of uncertainties.

In this paper the First Order Reliability Method (FORM) is used to determine the design wave height corresponding to a certain exceedence probability within the structure lifetime. This includes the statistical vagrancy of nature, sample variability and the uncertainty due to measurement or hindcast error. Moreover, based on the discussion on the statistical vagrancy of nature, a formula for the calculation of encounter probability is presented.

1 Introduction

The determination of the design wave height (often given as the significant wave height) is usually based on statistical analysis of long-term extreme wave height measurement or hindcast. The sources of uncertainty contributing to the uncertainty of the design wave height are (Burcharth 1992):

- 1) Statistical vagrancy of nature, i.e. the extreme wave height X is a random variable.
- 2) Sample variability due to limited sample size.
- 3) Error related to measurement, visual observation or hindcast.
- 4) Choice of distribution as a representative of the unknown true long-term distribution
- 5) Variability of algorithms (choice of threshold, fitting method etc.)
- 6) Climatological changes

The sources 1, 2 and 3 and their influence on the design wave height will be discussed in this paper.

¹Ph.D., Department of Civil Engineering, Aalborg University, Denmark

²Professor, dr.techn., Department of Civil Engineering, Aalborg University, Denmark

We use an example to demonstrate how the design wave height is determined. The data consist of 17 most severe storms in a period of 20 years for a deep water location. The Gumbel distribution curve in Fig.1 is obtained by fitting these 17 wave data to a Gumbel distribution.

Fig.1. Design wave height.

If the design level for the design wave height is a return period of 100 years, i.e. $T = 100$, the design wave height is $x^{100} = 12.2 \text{ m}$, which means that on average this 12.2 m design wave height will be exceeded once in every 100 years.

The design wave height can be better described by the use of encounter probability, i.e. the probability that the design wave height will be exceeded within the structure lifetime. For example if the structure lifetime L is 25 years, the encounter probability of the design wave height x^{100} is

$$p = 1 - \exp\left(-\frac{L}{T}\right) = 22\% \tag{1}$$

Eq (1) is derived as eq (11) in section 2.

This means that the 12.2 m design wave height will be exceeded with 22% probability within a structure lifetime of 25 years.

If the sample variability is included, the design wave height x^{100} becomes a random variable. The distribution of the design wave height x^{100} , which is usually assumed to follow the normal distribution, can be obtained by numerical simulation, cf. Fig.1. If the upper bound with 90% confidence is taken as the design level, the design wave height is 14.8 m. What is the exceedence probability of the 14.8 m design wave height within the structure lifetime ? It cannot be calculated straight away but it might be guessed that it is

$$p = 1 - 0.9 (1 - 0.22) = 30\%$$

In this paper the First Order Reliability Method (FORM) is used to determine a design wave height corresponding to a certain exceedence probability within a specified structure lifetime. This includes the statistical vagrancy of nature, sample variability and the uncertainty due to measurement/hindcast error. Moreover, based on the discussion on the statistical vagrancy of nature, a formula for the calculation of encounter probability is presented.

2 Design wave height related to the statistical vagrancy of nature: Encounter probability

Even if we had an infinite quantity of historic true wave data and knew the related distribution precisely, there would still be uncertainty as to the largest wave which will occur during any period of time - simply due to the statistical vagrancy of nature. In this case the design wave height related to structure lifetime is characterized by the encounter probability, i.e. the probability that the design wave height will be exceeded within the structure lifetime.

Assume that the number of the extreme events is N within the structure lifetime L . X^1 denotes the maximum value in these N independent trials. Then the distribution function of X^1 is

$$F_{X^1}(x) = P(X^1 < x) = (F_X(x))^N \quad (2)$$

Note that F_{X^1} can be interpreted as the non-occurrence of the event ($X > x$) in any of N independent trials.

Assuming that the number of the extreme events $N = \lambda L$, where the sample intensity λ is

$$\lambda = \frac{\text{number of extreme events}}{\text{number of years of observation}} \quad (3)$$

From the definition of the return period T

$$T = \frac{1}{\lambda (1 - F_X(x))} \quad (4)$$

we get from eq (2)

$$F_{X^1}(x) = (F_X(x))^{\lambda L} = \left(1 - \frac{1}{\lambda T} \right)^{\lambda L} \quad (5)$$

The encounter probability of x , i.e. the probability that x will be exceeded within the structure lifetime L , is

$$p = 1 - F_{X^1}(x) = 1 - \left(1 - \frac{1}{\lambda T} \right)^{\lambda L} \quad (6)$$

For the case where $\lambda = 1$, eq (6) becomes

$$p = 1 - \left(1 - \frac{1}{T}\right)^L \quad (7)$$

However, the number of the extreme events within the structure lifetime N is also a random variable. N is usually assumed to follow the Poisson distribution

$$P(N = n) = \frac{(\lambda L)^n}{n!} \exp(-\lambda L) \quad n = 0, 1, 2, \dots \quad (8)$$

The probability of the event ($X^1 < x$ or $\bar{X} < x$) within the structure lifetime is

$$\begin{aligned} F_{X^1}(x) &= P(X^1 < x) = \sum_{n=0}^{\infty} [P(N = n) F_{X^1}(x, n)] \\ &= \sum_{n=0}^{\infty} \left[\frac{(\lambda L)^n}{n!} \exp(-\lambda L) (F_X(x))^n \right] \\ &= \sum_{n=0}^{\infty} \left[\frac{(\lambda L F_X(x))^n}{n!} \exp(-\lambda L) \right] \\ &= \exp(-\lambda L) \sum_{n=0}^{\infty} \left[\frac{(\lambda L F_X(x))^n}{n!} \right] \\ &= \exp(-\lambda L) \exp(\lambda L F_X(x)) \\ &= \exp[\lambda L (F_X(x) - 1)] \end{aligned} \quad (9)$$

Inserting eq (4) into eq (9) is obtained

$$F_{X^1}(x) = \exp\left(-\frac{L}{T}\right) \quad (10)$$

The encounter probability of x within the structure lifetime is

$$p = 1 - F_{X^1}(x) = 1 - \exp\left(-\frac{L}{T}\right) \quad (11)$$

Eq (11) is not only simpler than eq (6), but has stronger theoretical background as well because it treats N as a random variable.

3 Design wave height related to the statistical vagrancy of nature, sample variability and measurement/hindcast error

To exemplify the discussion, it is assumed that the extreme wave height follows the Gumbel distribution

$$F = F_X(x) = P(X < x) = \exp\left(-\exp\left(-\frac{x-B}{A}\right)\right) \quad (12)$$

where X is the extreme wave height which is a random variable, x a realization of X , A and B the distribution parameters.

Due to the sample variability and measurement/hindcast error, the distribution parameter A and B become random variables, and the maximum wave height within the structure lifetime, X^1 , becomes a conditional random variable $X^1|_{A,B}$. The probability of $X^1 > x_0$ within the structure lifetime is

$$P(X^1|_{A,B} \geq x_0) = P(x_0 - X^1|_{A,B} \leq 0) \quad (13)$$

Now consider the failure function

$$g(x^1, a, b) = x_0 - X^1|_{A,B} \quad \begin{cases} < 0 & \text{failure} \\ = 0 & \text{limit state} \\ > 0 & \text{no failure} \end{cases} \quad (14)$$

It can be seen that the failure probability of the failure function is actually the exceedence probability of the design wave height x_0 within the structure lifetime.

By the use of the Rosenblatt transformation, the Hasofer and Lind reliability index β for the failure function can be estimated by the First Order Reliability Theory (FORM). The failure probability, i.e. the probability of $X^1 > x_0$ within the structure lifetime, is calculated by

$$P(X^1|_{A,B} \geq x_0) \approx \Phi(-\beta) \quad (15)$$

where Φ is the standard normal distribution. The procedure for the calculation of β is detailed in the Appendix.

4 Numerical simulation of σ_A and σ_B

The only unknown in the calculation of β is the distribution of A and B .

Due to the sample variability, i.e. the influence of limited number of data, the distribution parameters A and B , estimated from a sample, are subject to an uncertainty.

Wave data set contains measurement/hindcast error. Measurement error is from malfunction and non-linearity of instruments, such as accelerometer and pressure cell, while hindcast error occurs when the sea-level atmospheric pressure fields are converted to wind data and further to wave data. The accuracy of such conversion depends on the quality of the pressure data and on the technique which is used to synthesize the data into the continues wave field. Burcharth (1986) gives an overview on the variational coefficient C (standard deviation over mean value) of measurement/hindcast error.

In order to account for the sample variability and measurement/hindcast error, A and B are assumed to follow the normal distribution. The mean values μ_A

and μ_B are obtained by fitting the data to the distribution by one of the fitting methods, such as maximum likelihood method or the least square method. The standard deviations σ_A and σ_B are obtained by numerical simulations, taking into account the sample variability and the hindcast error, as explained as follows:

A sample with size N is fitted to the Gumbel distribution

$$F_X(x) = P(X < x) = \exp\left(-\exp\left(-\left(\frac{x-B}{A}\right)\right)\right) \quad (16)$$

The obtained distribution parameters A_{true} and B_{true} are assumed to be the true values. Numerical simulation is applied to get the standard deviations of the estimators A and B , taking into account the sample variability corresponding to the sample size N . The procedure is as follows:

- 1) Generate randomly a number between 0 and 1. Let the non-exceedence probability F equal the number. the single extreme data x is obtained by

$$x = F_X^{-1}(F) = A_{\text{true}} [-\ln(-\ln F)] + B_{\text{true}} \quad (17)$$

- 2) Repeat step 1) N times. Thus we obtain a sample belonging to the distribution of eq (16) and the sample size is N .
- 3) Fit the sample to the Gumbel distribution and get the new estimated distribution parameters A and B .
- 4) Repeat steps 2) and 3), say, 10,000 times. Thus we get 10,000 values of A and B .
- 5) Calculate the standard deviations σ_A and σ_B .

In order to include the measurement/hindcast error it is assumed that the hindcast error follows a normal distribution. The following step can be added after step 1).

- 1*) Generate randomly a number between 0 and 1. Let the non-exceedence probability F be equal to the number. The modified extreme data x_{modified} is obtained by

$$x_{\text{modified}} = x + C x \Phi^{-1}(F) \quad (18)$$

where Φ is the standard normal distribution and C is the coefficient of variation of the measurement/hindcast error. C ranges usually from 0.05 to 0.2 as suggested by Burcharth (1986).

5 Examples

The deep water wave data presented in Fig.1 is used as an example to demonstrate the determination of the design wave height and the influence of sample variability and measurement/hindcast error.

The data set consists of 17 significant wave heights corresponding to the 17 most severe storms in a period of 20 years, i.e. $\lambda = 17/20$. By fitting a Gumbel distribution to the extreme data we obtain the distribution parameters $A = 1.73$ and $B = 4.53$, cf. Fig.1.

If only the statistical vagrancy of the nature is considered, i.e. A and B are exact values, the wave height corresponding to any return period can be found from the graph. The 100 year return period significant wave height is 12.2 m, which by use of eq (11) is found to correspond to 22% exceedence probability within 25 year structure lifetime.

Sample variability

Taking into account the sample variability, the distribution parameters A and B become random variables. Their distributions shown in Fig.2 are obtained by the Monto-Carlo simulation as explained in section 4.

Fig.2. Distribution of the Gumbel parameters A and B by sample variability (N=17).

The probability density and the non-exceedence probability of the maximum significant wave height within any structure lifetime can be estimated by FORM. Fig.3 shows the results for a structure lifetime of 25 years. The figure includes for comparison also graphs where the sample variability is omitted. These graphs are obtained by eq (11).

Fig.3. Distribution of maximum significant wave height (sample size $N=17$).

If the design level is the significant wave height corresponding to 22% exceedence probability within 25 years ($T = 100$ years), it can be seen from Fig.3 that the design wave height with consideration of the sample variability is 12.7 m, which is a little larger than the value without the consideration of the sample variability (12.2 m). It can also be seen that the design wave height of 14.8 m (upper bound with 90% confidence, cf. Fig.1) corresponds to 9% exceedence probability within 25 years, not 30% as guessed in Section 1.

In the case of a bigger sample size, e.g. $N = 100$, there is almost no difference between the design wave height with and without sample variability, cf. Fig.4. For comparison the same λ value is applied.

Fig.4. Distribution of maximum significant wave height (sample size $N=100$).

Table 1 shows the design wave height corresponding to different sample size. Sample size ∞ means that there is no sample variability. Keep in mind that a

typical sample size is about 20, it can be said that sample variability has some limited influence on the design wave height.

Table 1. Significant wave height corresponding to $p = 22\%$ within $L = 25$ years

sample size	10	17	50	100	∞
H_s (m)	13.0	12.7	12.4	12.3	12.2
relative difference	6.5%	4%	1.6%	0.8%	0

Measurement/hindcast error

The same procedure can be applied to further include the measurement/hindcast error.

The variational coefficient of the extreme data listed in Table 2 is taken from Burcharth (1986). Data based on visual observation from ships should in general not be used for determination of design wave height because ships avoid poor weather on purpose. With the advances in measuring techniques and numerical models, generally the C value has been reduced to app. 0.1 or less.

Table 2. Coefficient of variation for significant wave height (Burcharth 1986).

Methods of determination	Coefficient of variational
Accelerometer buoy	
Pressure cell	0.05 - 0.1
Vertical radar	
Horizontal radar	0.15
Hindcast, SPM method	0.15 - 0.2
Hindcast, numerical	0.1 - 0.2
Visual observation	0.2

In Fig.5 the coefficient of variation C of the extreme data due to measure-

ment/hindcast error is assumed a typical value of 0.1.

Fig.5. Distribution of maximum significant wave height ($N = 17, C = 0.1$).

In Table 3 is given values extracted from Fig.5 corresponding to an exceedence probability of $p = 22\%$.

Table 3. Significant wave height corresponding to $p = 22\%$ within $L = 25$ years

Case	H_s (m)	Remarks
Statistical vagrancy	12.2 m	
Statistical vagrancy + sample variability	12.71 m	sample size $N = 17$
Statistical vagrancy + sample variability + hindcast error	12.75 m	sample size $N = 17$ variational Coeff. $C = 0.1$

It can be seen from Fig.5 and Table 3 that the influence of measurement/hindcast error on the design wave height is very small.

6 Conclusions

The paper concentrates on the exceedence probability of the design wave height within the structure lifetime (encounter probability).

If only the statistical vagrancy of the nature is included, a new and simple encounter probability formula is derived which takes into account the randomness of the extreme events within the structure lifetime.

If other uncertainties should be considered, the paper shows that the reliability theory can be applied to determine the encounter probability of the design wave height. A practical example shows that normally sample variability has little influence on the design wave height, while the influence of measurement/hindcast errors is almost negligible.

Appendix: Estimation of reliability index β

The followings explain the procedure for the calculation of β .

From eq (9) is obtained

$$\begin{aligned}
 F_{X^1}(x^1) &= \exp[\lambda L (F_X(x^1) - 1)] \\
 &= \exp\left[\lambda L \left(\exp\left(-\exp\left(-\left(\frac{x^1 - B}{A}\right)\right)\right) - 1\right)\right] \tag{19}
 \end{aligned}$$

which can be rewritten as

$$x^1 = A \left[-\ln \left(-\ln \left(1 + \frac{\ln F_{X^1}(x^1)}{\lambda L} \right) \right) \right] + B \tag{20}$$

X^1 can be converted to the standard normal distributed random variable U^1 by

$$\Phi(u_1) = F_{X^1}(x^1) \tag{21}$$

Inserting eq (21) into eq (20) is obtained

$$x^1 = A \left[-\ln \left(-\ln \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \right) \right] + B \tag{22}$$

The failure function becomes

$$g(u_1, a, b) = x_0 - A \left[-\ln \left(-\ln \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \right) \right] - B \tag{23}$$

The normal random variables A and B are converted into the standard normal distributed random variables U_2 and U_3 respectively

$$\frac{A - \mu_A}{\sigma_A} = u_2 \quad \frac{B - \mu_B}{\sigma_B} = u_3 \tag{24}$$

Insert eq (24) into eq (23) is obtained

$$\begin{aligned}
 g(u_1, u_2, u_3) &= x_0 - (\mu_A + \sigma_A u_2) \left[-\ln \left(-\ln \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \right) \right] \\
 &\quad - (\mu_B + \sigma_B u_3) \tag{25}
 \end{aligned}$$

The differentiations of the failure function are

$$\begin{aligned}
 a_1 &= \frac{\partial g}{\partial u_1} = \frac{(\mu_A + \sigma_A u_2) \phi(u_1)}{\ln \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \lambda L \Phi(u_1)} \\
 a_2 &= \frac{\partial g}{\partial u_2} = -\sigma_A \left[-\ln \left(-\ln \left(1 + \frac{\ln \Phi(u_1)}{\lambda L} \right) \right) \right] \\
 a_3 &= \frac{\partial g}{\partial u_3} = -\sigma_B \tag{26}
 \end{aligned}$$

where ϕ is the density function of the standard normal distribution.

The iterative procedure for calculation of β is

- 1) Select trial values : $u^* = (u_1^*, u_2^*, u_3^*)$.
- 2) Insert u^* into eq (26) and get (a_1, a_2, a_3) .
- 3) Determine a better estimate of u^* by

$$u_i^* = a_i \frac{\sum_{i=1}^3 (a_i u_i^*) - g|_{u^*}}{\sum_{i=1}^3 a_i^2}$$

- 4) Repeat steps 2) and 3) to achieve convergence.
- 5) Calculate β by

$$\beta = \left(\sum_{i=1}^3 (u_i^*)^2 \right)^{\frac{1}{2}}$$

Coastal Engineering 1996

Proceedings of the
twenty-fifth international conference

September 2-6, 1996
The Peabody Hotel
Orlando, Florida

Held under the auspices of the
Coastal Engineering Research Council of the
American Society of Civil Engineers

Edited by Billy L. Edge

Published by the

ASCE *American Society
of Civil Engineers*

345 East 47th Street
New York, New York 10017-2398

Abstract:

This proceedings contains over 370 papers presented at the 25th International Conference on Coastal Engineering which was held in Orlando, Florida, 2-6 September, 1996. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation, erosion and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering.

CONTENTS

Part I Characteristics of Coastal Waves and Currents

CHAPTER 1	
Experimental Study of Breaking Waves over a Shoal	2
<i>Arun Chawla, H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 2	
A Method for Estimating Standardized Bimodal Directional Spectra	16
<i>Ryuichi Fujiwara, Masahiko Isobe</i>	
CHAPTER 3	
The Effects of Currents on Estimations of Directional Wave Spectra	30
<i>Yasuyuki Nakagawa, Hiroichi Tsuruya, Noriaki Hashimoto</i>	
CHAPTER 4	
A Method for Estimating Directional Spectra in a Field of Incident and Reflected Waves	43
<i>Hiromune Yokoki, Masahiko Isobe</i>	
CHAPTER 5	
Active Absorption of Multidirectional Waves	55
<i>Hemming A. Schaffer, Jesper Skourup</i>	
CHAPTER 6	
Time-Averaged Wave Field Evolution in Coastal Zone	67
<i>Jianlu Xu, Rodney J. Sobey</i>	
CHAPTER 7	
Quality Control of GEOSAT Wave Data for Engineering Applications	81
<i>M. Siddabathula, Vijay G. Panchang</i>	
CHAPTER 8	
Boussinesq Type Equations with High Accuracy in Dispersion and Nonlinearity	95
<i>P.A. Madsen, B. Banijamali, H.A. Schaffer, O.R. Sorensen</i>	
CHAPTER 9	
Wave Kinematics Computations Using Boussinesq Models	109
<i>J. Bosboom, G. Klopman, J.A. Roelvink, J.A. Battjes</i>	
CHAPTER 10	
Effects of Mode Truncation and Dissipation on Predictions of Higher Order Statistics ...	123
<i>James M. Kaihatu, James T. Kirby</i>	
CHAPTER 11	
Field Observation of Movement of Sand Body Due to Waves and Verification of Its Mechanism by Numerical Model	137
<i>Takaaki Uda, Yoshimichi Yamamoto, Naoki Itabashi, Kosuke Yamaji</i>	

CHAPTER 12	
Wave Groups in the Surf-Zone: Model & Experiments	151
<i>J. Veeramony, I. A. Svendsen</i>	
CHAPTER 13	
Simulation of Propagating Nonlinear Wave Groups	165
<i>Paul de Haas, Maarten Dingemans, Gert Klopman</i>	
CHAPTER 14	
Cross-Shore Momentum Flux Due to Shear Instabilities	175
<i>Ad Reniers, Jurjen A. Battjes</i>	
CHAPTER 15	
Modelling Post-Wave Breaking Turbulence and Vorticity	186
<i>T.C.D. Barnes, M. Brocchini, D.H. Peregrine, P.K. Stansby</i>	
CHAPTER 16	
A Turbulent Flow Model for Breaking Waves	200
<i>Nguyen The Duy, Tomoya Shibayama, Akio Okayasu</i>	
CHAPTER 17	
Turbulence Structures in the Surf Zone	214
<i>T.R. Haydon, D.B. Hann, P. Davies, C.A. Greated, T.C.D. Barnes</i>	
CHAPTER 18	
Experiments on Design Wave Height in Shallow Water	221
<i>J. William Kamphuis</i>	
CHAPTER 19	
Time-Dependent Quasi-3D Modeling of Breaking Waves on Beaches	233
<i>Entin A. Karjadi, Nobuhisa Kobayashi</i>	
CHAPTER 20	
Models of Wave Height and Fraction of Breaking Waves on a Barred Beach	247
<i>Yoshiaki Kuriyama</i>	
CHAPTER 21	
A Parametric Model for Random Wave Deformation by Breaking on Arbitrary Beach Profiles	261
<i>Hyuck-Min Kweon, Yoshimi Goda</i>	
CHAPTER 22	
Generation Characteristics of Wave Sounds as a Factor of Beach Amenity	275
<i>Hitoshi Murakami, Sadahiko Itoh, Yoshihiko Hosoi, Hideo Araki and Tsuyoshi Koyabu</i>	
CHAPTER 23	
Measurements of Wave Breaking in the UK Coastal Research Facility	286
<i>Howard N. Southgate, Stuart Stripling</i>	
CHAPTER 24	
A New Type Breaker Forming a Giant Jet and Its Decaying Properties	300

CHAPTER 25	
Wave Climate Cycles and Coastal Engineering Practice	314
<i>Douglas L. Inman, Scott A. Jenkins, M. Hany S. Elwany</i>	
CHAPTER 26	
Stability of Design Wave Estimates	328
<i>Jan Rossouw, Josep R. Medina</i>	
CHAPTER 27	
An Evaluation of Two Wave Forecast Models for the South African Region	340
<i>M. Rossouw, D. Phelp</i>	
CHAPTER 28	
A Comprehensive Wind, Wave, and Current Measurement Program in the South China Sea	354
<i>Jagat N. Sharma, S. Tryggestad, J. Bian</i>	
CHAPTER 29	
Wave Height and Period Distributions from Long-Term Wave Measurement	368
<i>Chung-Chu Teng, Ian M. Palao</i>	
CHAPTER 30	
Interference of Small Structures in the Vicinity of Large Structures	380
<i>Subrata K. Chakrabarti, Sumita Chakrabarti</i>	
CHAPTER 31	
Wave Dynamics at Coastal Structures: Development of a Numerical Model for Free Surface Flow	389
<i>Zoheir A. Sabeur, N. William H. Allsop, Robert G. Beale, John M. Dennis</i>	
CHAPTER 32	
Scale Effects in Oxygenation in the Breaker Zone of Coastal Structures	403
<i>V.K. Tsoukala, C.I. Moutzouris</i>	
CHAPTER 33	
Wave Actions on a Vertical Cylinder in Multi-Directional Random Waves	415
<i>Yu-xiu Yu, Ning-chuan Zhang, Qun Zhao</i>	
CHAPTER 34	
Wind/Wave Relation and the Pressure Gradient Effect	429
<i>Spiros M. Gouloumis</i>	
CHAPTER 35	
Non-Reflected Multi Directional Wave Maker Theory and Experiments of Verification ..	443
<i>Kazunori Ito, Hidehiro Katsui, Masashi Mochizuki, Masahiko Isobe</i>	
CHAPTER 36	
Fifty Years of Wave Growth Curves	457
<i>Paul C. Liu</i>	

CHAPTER 37	
Development of a Third Generation Shallow-Water Wave Model with Unstructured Spatial Meshing465
<i>Michel Benoit, Frederic Marcos, Francoise Becq</i>	
CHAPTER 38	
New Optimization Method for Paddle Motion of Multi-Directional Wavemaker479
<i>Akira Matsumoto, Minoru Hanzawa</i>	
CHAPTER 39	
Generation of Second-Order Long Waves by a Wave Group in a Laboratory Flume and Its Control493
<i>M. Mizuguchi, H. Toita</i>	
CHAPTER 40	
Kinematic Predictions in Large Shallow Water Waves502
<i>Susan Smith, Christopher Swan</i>	
CHAPTER 41	
Fetch Limited Spectral Evolution in Finite Depth Water516
<i>I.R. Young, L.A. Verhagen</i>	
CHAPTER 42	
Measurement of Breaking Waves Using Particle Image Velocimetry527
<i>Kuang-An Chang, Philip L.-F. Liu</i>	
CHAPTER 43	
Computation of the Near-Bottom Kinematics of Shoaling Waves537
<i>Luc Hamm</i>	
CHAPTER 44	
Formulation and Validation of Vertically 2-D Shallow-Water Wave Model551
<i>Bradley D. Johnson, Nobuhisa Kobayashi, Daniel T. Cox</i>	
CHAPTER 45	
Particle Velocity Distribution in Surface Waves565
<i>Geir Moe, Oivind A. Arntsen</i>	
CHAPTER 46	
A Comparison of Analysis Methods for Wave Pressure Data575
<i>Murray Townsend, John D. Fenton</i>	
CHAPTER 47	
A Nonlinear Model for Wave Propagation589
<i>Ting-Kuei Tsay, Philip L.-F. Liu, Nan-Jing Wu</i>	
CHAPTER 48	
Application of a Digital Particle Image Velocimetry (DPIV) System to Breaking Waves in the Surf Zone602
<i>Kenneth R. Craig, Robert J. Thieke</i>	

CHAPTER 49	
Wave Gauging Networks Worldwide - An Overview616
<i>J. Michael Hemsley</i>	
CHAPTER 50	
Improvement of Submerged Doppler-Type Directional Wave Meter and its Application to Field Observations629
<i>Noriaki Hashimoto, Masao Mitsui, Yoshimi Goda, Toshihiko Nagai, Tomoharu Takahashi</i>	
CHAPTER 51	
Comparison of Directional Wave Data Quality from Two Different Monitoring Systems .	.643
<i>Lihwa Lin, Sidney Schofield, Hsiang Wang</i>	
CHAPTER 52	
The Digital Simulation of Non-Linear Random Waves657
<i>Kyungmo Ahn</i>	
CHAPTER 53	
The “SWAN” Wave Model for Shallow Water668
<i>N. Booij, L.H. Holthuijsen, R.C. Ris</i>	
CHAPTER 54	
Generation Depths from Water Wave Data677
<i>J. Ernest Breeding, Jr.</i>	
CHAPTER 55	
Wave Climate Assessment in the South Aegean Shelf689
<i>Spiros Christopoulos, Christos Solomonidis</i>	
CHAPTER 56	
Sea State Parameterisation Using Empirical Orthogonal Functions703
<i>Witold Cieslikiewicz, Jerzy Graff</i>	
CHAPTER 57	
Fully Nonlinear Properties of Periodic Waves Shoaling over Slopes717
<i>Stephan T. Grilli, Juan Horrillo</i>	
CHAPTER 58	
Water Wave Fluctuations Induced by Irregular Bathymetry731
<i>Lulin Guo, Robert A. Dalrymple</i>	
CHAPTER 59	
Integral Control Data Assimilation in Wave Predictions743
<i>L.H. Holthuijsen, N. Booij, M. van Endt, S. Caires, C. Guedes Soares</i>	
CHAPTER 60	
Two-Dimensional Analysis of Wave Transformation by Rational-Approximation-Based, Time-Dependent Mild-Slope Equation for Random Waves754
<i>Toshimasa Ishii, Masahiko Isobe, Akira Watanabe</i>	

CHAPTER 61	
Nonlinear Wave Transformation Due to a Submerged Breakwater	767
<i>Masahiko Isobe, Akira Watanabe, Shogo Yamamoto</i>	
CHAPTER 62	
Observed and Modeled Wave Results from Near-Stationary Hurricanes	781
<i>Charles L. Vincent, Robert E. Jensen</i>	
CHAPTER 63	
Estimation of Persistence Statistics of the Waves Observed on Japanese Coast in the Light of Recent Studies	794
<i>Hajime Kato, Hisamichi Nobuoka</i>	
CHAPTER 64	
Probabilistic Modeling of Long-Term Wave Climate	808
<i>V.M. Leyden, W.R. Dally</i>	
CHAPTER 65	
Monte Carlo Simulation for Nearshore Wave Statistics in Southern California	822
<i>Chia-Chi Lu, R. Rea Strange III</i>	
CHAPTER 66	
Bottom Friction Dissipation in the Belgian Coastal Regions	836
<i>Weimin Luo, Jaak Monbaliu, Jean Berlamont</i>	
CHAPTER 67	
Weakly non-Gaussian Model of Wave Height Distribution for Nonlinear Random Waves ..	850
<i>Nobuhito Mori, Takashi Yasuda</i>	
CHAPTER 68	
An Attempt at Applying the Chaos Theory to Wave Forecasting	864
<i>Takao Ohta, Akira Kimura</i>	
CHAPTER 69	
Transition of Stochastic Characteristics of Waves in the Nearshore Zone	878
<i>David J. Robillard, Michel K. Ochi</i>	
CHAPTER 70	
Monitoring and Modelling on Shallow Water Wave Propagations in “El Saler” Beach ..	889
<i>Jose C. Santos, Jose M. de la Pena, Jose Lozano</i>	
CHAPTER 71	
Intercomparison of Parameter Estimation Methods in Extremal Wave Analysis	900
<i>Masataka Yamaguchi</i>	
CHAPTER 72	
Influences of Spectral Shapes on the Statistical Properties of Simulated Random Waves ..	914
<i>John Z. Yim, M.-Y. Lai</i>	
CHAPTER 73	
Second-Order Interaction between Random Wave and Submerged Obstacle	927

CHAPTER 74	
A Uniform Mild-Slope Model for Waves over Varying Bottom941
<i>Libang Zhang, Billy L. Edge</i>	
CHAPTER 75	
Bragg Reflection of Shallow-Water Waves on a Sloping Beach955
<i>Yong-Sik Cho, Jong-In Lee, Jong-Kyu Lee</i>	
CHAPTER 76	
Reflection Analysis with Separation of Cross Modes968
<i>John Gronbech, Thomas Jensen, Henning Andersen</i>	
CHAPTER 77	
Wave Runup on Beaches981
<i>John P. Ahrens, William N. Seelig</i>	
CHAPTER 78	
Field Study on Wave Run-Up on Seadykes994
<i>Joachim Grune</i>	
CHAPTER 79	
Wave Run-Up on Revetments with Composite Slopes1008
<i>Zeya Wang, Joachim Grune</i>	
CHAPTER 80	
Landward Transport of Spray Generated from a Wave Absorbing Sea Wall1022
<i>Misao Hashida, Nobuhiro Matsunaga, Isao Irie</i>	
CHAPTER 81	
Irregular Wave Kinematics from a Pressure Record1034
<i>Christopher H. Barker, Rodney J. Sobey</i>	
CHAPTER 82	
Nonlinear Refraction-Diffraction of Surface Waves over Arbitrary Depths1048
<i>Serdar Beji, Kazuo Nadaoka</i>	
CHAPTER 83	
Boussinesq Equations with Improved Doppler Shift and Dispersion for Wave/Current Interaction1060
<i>Qin Chen, Per A. Madsen, Ole R. Sorensen, David R. Basco</i>	
CHAPTER 84	
The Propagation of Water Waves in Prismatic Channels1074
<i>Li Li, Robert A. Dalrymple, Jeffrey M. Mlynarski</i>	
CHAPTER 85	
A Statistical Approach for Modeling Triad Interactions in Dispersive Waves1088
<i>Y. Eldeberky, V. Polnikov, J. A. Battjes</i>	

CHAPTER 86	
A Fully Nonlinear 3D Method for the Computation of Wave Propagation	1102
<i>Andrew B. Kennedy, John D. Fenton</i>	
CHAPTER 87	
A Fourth Order Boussinesq-Type Wave Model	1116
<i>Mauricio F. Gobbi, James T. Kirby</i>	
CHAPTER 88	
Fast Methods for Computing the Shoaling of Nonlinear Waves	1130
<i>J.D. Fenton, A.B. Kennedy</i>	
CHAPTER 89	
Structure of Frequency Domain Models for Random Wave Breaking	1144
<i>James T. Kirby, James M. Kaihatu</i>	
CHAPTER 90	
A Hamiltonian Model for Nonlinear Water Waves and Its Applications	1156
<i>A.K. Otta, M.W. Dingemans, A.C. Radder</i>	
CHAPTER 91	
The Role of Wave-Induced Shear Stresses in the Momentum Balance Equations	1168
<i>Francisco J. Rivero, Agustin S.-Arcilla</i>	
CHAPTER 92	
Nonlinear Wave Dynamics in the Surf Zone	1178
<i>O.R. Sorensen, P.A. Madsen, H.A. Schaffer</i>	
CHAPTER 93	
A Boussinesq Breaking Wave Model with Vorticity	1192
<i>I.A. Svendsen, Ke Yu, J. Veeramony</i>	
CHAPTER 94	
Roller Contributions as Inferred from Inverse Modelling Techniques	1205
<i>D.J.R. Walstra, G.P. Mocke, F. Smit</i>	
CHAPTER 95	
Wave-Current Interaction in Inlets	1219
<i>Michael J. Briggs, Zeki Demirebilek, Debra R. Green</i>	
CHAPTER 96	
Wave Climate of Large Reservoirs and a Revised Wave Hindcast Formula	1233
<i>Pierre Dupuis, Jean-Pierre Tournier, Octave Caron</i>	
CHAPTER 97	
Spectral Modelling of Current Induced Wave-Blocking	1247
<i>R.C. Ris, L.H. Holthuijsen</i>	

Part II Long Period Waves, Storm Surges and Wave Groups

CHAPTER 98	
Uncertainties in the Validation of Harbor Wave Models	1256
<i>Zeki Demirbilek, Bingyi Xu, Vijay Panchang</i>	
CHAPTER 99	
Field Measurements and Numerical Modeling of Harbor Oscillations During Storm Waves	1268
<i>W.M. Jeong, J.W. Chae, W.S. Park, K.T. Jung</i>	
CHAPTER 100	
Performance of a Resonator Designed by the Wave Filter Theory - Applicability to a Harbor	1280
<i>Takayuki Nakamura, Hitoshi Mochizuki, Satoshi Morita</i>	
CHAPTER 101	
The Generation of Waves by a Landslide: Skagway, Alaska - A Case Study	1293
<i>Fredric Raichlen, Jiin Jen Lee, Catherine Petroff, Philip Watts</i>	
CHAPTER 102	
Laboratory Experiment on Long Wave Generation by Time-Varying Breakpoint	1307
<i>Satoru Nagase, Masaru Mizuguchi</i>	
CHAPTER 103	
Laboratory Experiments on Generation of Long Waves in the Surf Zone	1321
<i>Akio Okayasu, Teruki Matsumoto, Yasuyuki Suzuki</i>	
CHAPTER 104	
Generation of Infragravity Waves	1335
<i>A. R. van Dongeren, I.A. Svendsen, F.E. Sancho</i>	
CHAPTER 105	
Responses of Coastal Topography to Sea-Level Rise	1349
<i>Nobuo Mimura, Eiichi Kawaguchi</i>	
CHAPTER 106	
Numerical Study of Low Frequency Surf Zone Motions	1361
<i>H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 107	
Neptune - An Integrated Approach to Determining NW European Coastal Extremes ...	1375
<i>Jerzy Graff, Witold Cieslikiewicz</i>	
CHAPTER 108	
A Stochastic Typhoon Model and Its Application to the Estimation of Extremes of Storm Surge and Wave Height	1389
<i>Yoshio Hatada, Masataka Yamaguchi</i>	

CHAPTER 109	
Design of Vertical Walls Against Storm Surge	1403
<i>A. Kortenhaus, C. Miller, H. Oumeraci</i>	
CHAPTER 110	
Nearshore, Wave and Topographic Effects in Storm Surges	1417
<i>Gary Watson, Takao Yamashita</i>	
CHAPTER 111	
The Swash Zone: A Focus on Low Frequency Motion	1431
<i>Adam M. Shah, J. William Kamphuis</i>	
CHAPTER 112	
The Development of an On-Line, Interactive, Tsunami-Information Resource	1443
<i>Benjamin Cook, Catherine Petroff</i>	
CHAPTER 113	
Long Wave Runup on Coastal Structures	1452
<i>Utku Kanoglu, Costas Emmanuel Synolakis</i>	
CHAPTER 114	
Offshore Tsunami Profiles Observed at the Coastal Wave Stations	1465
<i>Toshihiko Nagai, Noriaki Hashimoto, Kazuyoshi Shimizu, Fujio Kitamura</i>	
CHAPTER 115	
A Realistic Model for the 1992-96 Tidal Waves	1478
<i>Srinivas Tadepalli, Costas Emmanuel Synolakis</i>	
CHAPTER 116	
Long-Period Oscillations in a Harbour Caused by Typhoon	1491
<i>Wataru Kioka</i>	
CHAPTER 117	
Estimation of Wave Groups Parameter from Wave Climate Statistics	1503
<i>Satoshi Nakamura</i>	

Part III Coastal Structures

CHAPTER 118	
Reflection Coefficients of the Step-Shaped Slit Caisson on the Rubble Mound	1516
<i>Sung Mo Ahn, Ryuichi Fujiwara, Hiroshi Matsunaga, Katsuhiko Kurata, Shohachi Kakuno</i>	
CHAPTER 119	
Berm Breakwater Trunk Exposed to Oblique Waves	1528
<i>A. Alikhani, G.R. Tomasicchio, J. Juhl</i>	
CHAPTER 120	
Interaction Between Main Armour and Toe Berm Damage	1542
<i>P. Aminti, A. Lamberti</i>	

CHAPTER 121	
Stability of Artificial Roughness Elements and Run-Up Reduction	1556
<i>M. Klein Breieler, K.W. Pilarczyk</i>	
CHAPTER 122	
Wave Induced Velocities at a Rubble Mound Breakwater	1569
<i>Bruno Brunone, Giuseppe R. Tomasicchio</i>	
CHAPTER 123	
Natural Periods of Armor Stones	1583
<i>Fred E. Camfield</i>	
CHAPTER 124	
Reliability Based Optimal Design of Vertical Breakwaters Modelled as a Series System of Failure	1589
<i>E. Christiani, H.F. Burcharth, J. Dalsgaard Sorensen</i>	
CHAPTER 125	
Overall Slope Stability Analysis of Rubble Mound Breakwaters	1603
<i>Julien De Rouck, Luc Van Damme</i>	
CHAPTER 126	
Interactions in the Stability of Toe-Berm and Main-Armour for Rubble-Mound Breakwaters: An Experimental Study	1617
<i>Philippe Donnars, Michel Benoit</i>	
CHAPTER 127	
Potential Uses for the Rapidly Installed Breakwater System	1631
<i>Jimmy Fowler, Donald Resio, Michael Briggs, Cheryl Pollock</i>	
CHAPTER 128	
Stability of Reshaping Breakwaters with Special Reference to Stone Durability	1640
<i>P. Frigaard, T. Hald, H.F. Burcharth, Sigurdur Sigurdarson</i>	
CHAPTER 129	
Field Investigations on Wave-Dissipating Concrete Blocks Covering Vertical Wall Breakwater	1652
<i>Michio Gomyoh, Kazuhiko Sakai, Tomotuka Takayama, Kojiro Suzuki, Shigeo Takahashi</i>	
CHAPTER 130	
New Stability Formula for Wave-Dissipating Concrete Blocks Covering Horizontally Composite Breakwaters	1665
<i>Minoru Hanzawa, Hirokazu Sato, Shigeo Takahashi, Kenichiro Shimosako, Tomotsuka Takayama, Katsutoshi Tanimoto</i>	
CHAPTER 131	
Breakwater Stability under Regular and Irregular Wave Attack	1679
<i>Thomas Jensen, Henning Andersen, John Gronbech, Etienne P.D. Mansard, Michael H. Davies</i>	
CHAPTER 132	
Roundhead Stability of Berm Breakwaters	1693

CHAPTER 133	
Improvement of Composite Breakwater on Solid Bottom Against Severe Tsunamis	1707
<i>Yoshiaki Kimura, Hideo Kondo, Shinji Kuwabara, Akira Kawamori</i>	
CHAPTER 134	
Hydraulic Stability Analysis of Leese Slopes of Overtopped Breakwaters	1721
<i>M.D. Kudale, N. Kobayashi</i>	
CHAPTER 135	
Influence of the Core Configuration on the Stability of Berm Breakwaters	1735
<i>Nikolay Lissev, Alf Torum</i>	
CHAPTER 136	
Model Study of Reservoir Riprap Stability	1748
<i>Etienne P. D. Mansard, Michael H. Davies, Octave Caron</i>	
CHAPTER 137	
Prototype Measurements of Wave Pressures on a Wave Screen: Comparison to Physical and Analytical Models	1762
<i>F.L. Martin, M. A. Losada, C. Vidal, J.L. Diaz Rato</i>	
CHAPTER 138	
Velocity Field Measurements over Breakwater Heads under 3D Waves	1776
<i>Yoshiharu Matsumi, Akira Kimura, Kenichi Ohno</i>	
CHAPTER 139	
Wave Climate Simulation and Breakwater Stability	1789
<i>Josep R. Medina</i>	
CHAPTER 140	
Incipient Motion of Breakwater Armor Units	1803
<i>J. A. Melby, N. Kobayashi</i>	
CHAPTER 141	
Overtopping Reduction in Crownwall Design	1816
<i>Jose Luis Monso, Alfonso Vdaor, Cristina Cadevall, Cristina Garcia</i>	
CHAPTER 142	
Stable Profiles of Reshaping Breakwaters with a Berm Below the Water Level	1826
<i>C.I. Moutzouris</i>	
CHAPTER 143	
Experiments on a Non-Wave Overtopping Type Seawall	1840
<i>Keisuke Murakami, I. Irie, Y. Kamikubo</i>	
CHAPTER 144	
A Condition and Performance Rating System for Breakwaters and Jetties	1852
<i>John Oliver, Don Plotkin, John Lesnik, Douglas Pirie</i>	

CHAPTER 145	
Wave Overtopping and Stability of Armor Units under Multidirectional Waves	1862
<i>T. Sakakiyama, R. Kajima</i>	
CHAPTER 146	
Numerical Modeling of Breach Growth in a Sanddike	1876
<i>Guis S. Stelling, Willem T. Bakker, Christine van Kuik, Christel Somers</i>	
CHAPTER 147	
Aging and Stability of Placed Block Revetments	1888
<i>Theo Stoutjesdijk, Hans Johanson, Mark Klein Breteler</i>	
CHAPTER 148	
Experimental Analysis of the Settlement Failure Mechanism Shown by Caisson-Type Seawalls	1902
<i>Shigeo Takahashi, Kojiro Suzuki, Katsumasa Tokubuchi, Ken-ichiro Shimosako</i>	
CHAPTER 149	
Full Scale Measurements of Wave Attenuation Inside a Rubble Mound Breakwater . . .	1916
<i>Peter Troch, Marc De Somer, Julien De Rouck, Luc van Damme, Dierik Vermeir, Jean-Pierre Martens, Conan van Hove</i>	
CHAPTER 150	
Numerical Modelling of Wave Interaction with Dynamically Stable Structures	1930
<i>Marcel R.A. van Gent</i>	
CHAPTER 151	
Monitoring of Zeebrugge Breakwaters	1944
<i>Luc van Damme, Julien de Rouck</i>	
CHAPTER 152	
Influence of Rock Shape and Grading on Stability of Low-Crested Structures	1957
<i>Jentsje W. van der Meer, W.H. Tutuarima, G. Burger</i>	
CHAPTER 153	
Toe Stability of Rubble Mound Breakwaters	1971
<i>Ton van der Meulen, Gerrit J. Schiereck, Kees d'Angremond</i>	
CHAPTER 154	
Seawall Effects on Historically Receding Shorelines	1985
<i>Bryan N. Jones, David R. Basco</i>	
CHAPTER 155	
Control of Wave Propagation Angle by Tapered-Submerged Breakwater	1998
<i>Satoshi Takewaka, Isao Irie</i>	
CHAPTER 156	
Multidirectional Wave Loads on Vertical Breakwaters	2008
<i>Claudio Franco, Jentsie W. Van der Meer, Leopoldo Franco</i>	

CHAPTER 157	
Modelling the Impact of Detached Breakwaters on the Coast	2022
<i>K.J. Bos, J.A. Roelvink, M.W. Dingsmans</i>	
CHAPTER 158	
Evaluation of Beach Modelling Techniques Behind Detached Breakwaters	2036
<i>Philip Axe, Suzana Ilic, Andrew Chadwick</i>	
CHAPTER 159	
Numerical Modelling of Bed Evolution Behind a Detached Breakwater	2050
<i>Philippe Pechon, Charles Teisson</i>	
CHAPTER 160	
Combined Diffraction and Transmission of Water Waves around a Porous Breakwater	
Gap	2063
<i>Xiping Yu, Hiroyoshi Togashi</i>	
CHAPTER 161	
Prediction of Wave Reflection from Rock Structures: An Integration of	
Field & Laboratory Data	2077
<i>Mark A. Davidson, Paul A.D. Bird, David A. Huntley, Geoff N. Bullock</i>	
CHAPTER 162	
Performance Evaluation of Buoy-Membrane Wave Barriers	2087
<i>M.H. Kim, B. L. Edge, S.T. Kee, L. Zhang</i>	
CHAPTER 163	
An Improved Design Method for the Riprap of Earthfill Dams of Large Reservoirs ...	2101
<i>Jean-Pierre Tournier, Pierre Dupuis, Raymond Ares</i>	
CHAPTER 164	
Geotextile Systems in Coastal Engineering - An Overview -	2114
<i>Krystian W. Pilarczyk</i>	
CHAPTER 165	
Groynes on the East Frisian Islands: History and Experiences	2128
<i>Hans Kunz</i>	
CHAPTER 166	
Permeable Pile Groins	2142
<i>Thomas Trampenau, Frank Goricke, Arved J. Raudkivi</i>	
CHAPTER 167	
The Effect of Groundwater on Scour Near Structures	2152
<i>John H. Loveless, Geoffrey T. Grant, Robert I. Karlsson</i>	
CHAPTER 168	
Abrasion of Steel Pipe Piles by Sediment Motion in Coastal Zones	2166
<i>Gaku Matsuoka, Shinichi Ito, Toshihiko Yamashita, Hiroshi Saeki, Yoshihisa Kariyazono, Koichi Sato</i>	

CHAPTER 169	
A Viscous Rotational Model for Wave Overtopping over Marine Structure	2178
<i>Fei Zhuang, Jiin-Jen Lee</i>	
CHAPTER 170	
Overtopping of Waves at a Wall: A Theoretical Approach	2192
<i>M. Jervis, D.H. Peregrine</i>	
CHAPTER 171	
Wind Effects on Runup and Overtopping of Coastal Structures	2206
<i>Donald L. Ward, Jun Zhang, Christopher G. Wibner, Charles M. Cinotto</i>	
CHAPTER 172	
Wave Overtopping of Vertical Structures Including Wind Effect	2216
<i>Johannes P. de Waal, Patrick Tonjes, Jentsje W. van der Meer</i>	
CHAPTER 173	
Bridge Pier Scour Assessment for the Northumberland Strait Crossing	2230
<i>C.D. Anglin, R.B. Nairn, A.M. Cornett, L. Dunaszegi, J. Turnham, G.W. Annandale</i>	
CHAPTER 174	
Wave Setup at River Entrances	2244
<i>David J. Hanslow, Peter Nielsen, Kevin Hibbert</i>	
CHAPTER 175	
Scour at Coastal Inlet Structures	2258
<i>Steven A. Hughes, J. William Kamphuis</i>	
CHAPTER 176	
Probability Distribution of the Maximum Wave Height along a Sea Wall with Finite Width	2272
<i>Akira Kimura, Takao Ohta</i>	
CHAPTER 177	
Beach Response in Front of Wave-Reflecting Structures	2284
<i>Roy C. Seaman, Tom O'Donoghue</i>	
CHAPTER 178	
Fundamental Characteristics of Wave Transformation around Artificial Reefs	2298
<i>Toshio Aono, Eric C. Cruz</i>	
CHAPTER 179	
Performance of a Submerged Breakwater for Shore Protection	2312
<i>Albert E. Browder, Robert G. Dean, Renjie Chen</i>	
CHAPTER 180	
Nonlinear Wave Transformation over a Submerged Triangular Breakwater	2324
<i>Lifen Dong, Akira Watanabe, Masahiko Isobe</i>	
CHAPTER 181	
Breaking Limit, Breaking and Post-Breaking Wave Deformation Due to Submerged	

Structures2338
<i>Koichiro Iwata, Koji Kawasaki, Do-Sam Kim</i>	
CHAPTER 182	
Italian Experience on Submerged Barriers as Beach Defence Structures2352
<i>Alberto Lamberti, Alessandro Mancinelli</i>	
CHAPTER 183	
Resonant Reflection and Refraction-Diffraction of Surface Waves Due to Porous Submerged Breakwaters2366
<i>Hajime Mase, Akira Kimura, Hiroshi Sakakibara</i>	
CHAPTER 184	
BEM-FEM Combined Analysis of Nonlinear Interaction between Wave and Submerged Breakwater2377
<i>N. Mizutani, W.G. McDougal, A.M. Mostafa</i>	
CHAPTER 185	
Regulation of Nearshore Circulation by Submerged Breakwater for Shore Protection ..	.2391
<i>Hisamichi Nobuoka, Isao Irie, Hajime Kato, Nobuo Mimura</i>	
CHAPTER 186	
Submerged Breakwaters for the Defence of the Shoreline at Ostia - Field Experiences, Comparison2404
<i>Ugo Tomasicchio</i>	
CHAPTER 187	
Wave Transmission of Low-Crested Structures2418
<i>Kees d'Angremond, Jentsje W. van der Meer, Rutger J. De Jong</i>	
CHAPTER 188	
Effect of Submerged Breakwater on Profile Development2428
<i>Martin D. Groenewoud, Jan van de Graaff, Edward W.M. Claessen, Stephan C. van der Biezen</i>	
CHAPTER 189	
Cause and Characteristics of Impact Pressure Exerted by Spilling and Plunging Breakers on a Vertical Wall2442
<i>Seyed Ali Azarmsa, Takashi Yasuda, Hidemi Mutsuda</i>	
CHAPTER 190	
Dynamic Response of Vertical Elastic Walls to Breaking Wave Impact2456
<i>Masatao Hattori, Nobuaki Tsujioka</i>	
CHAPTER 191	
Wave Transmission Past Vertical Wave Barriers2470
<i>David L. Kriebel, Chad A. Bollmann</i>	
CHAPTER 192	
Physical Study of the Nature of High Peak Wave Pressures2484
<i>Jordan Marinski</i>	

CHAPTER 193	
A Design Short-Crested Wave Force Model for Vertical Deep-Water Breakwaters	2494
	<i>S.-Y. Tzang, S.-R. Liaw</i>
CHAPTER 194	
New Design Methods for Wave Impact Loadings on Vertical Breakwaters and Seawalls . .	2508
	<i>N.W.H. Allsop, J.E. McKenna, D. Vicinanza, T.T.J. Whitaker</i>
CHAPTER 195	
Scale Effects of Wave Impact Pressures on Cob Armour Units	2522
	<i>M.W. Howarth, N.W.H. Allsop, A.M. Vann, R.J. Jones, J.P. Davis</i>
CHAPTER 196	
Wave Impact Loading of Vertical Face Structures for Dynamic Stability	
Analysis - Prediction Formulae -	2534
	<i>P. Klammer, A. Kortenhaus, H. Oumeraci</i>
CHAPTER 197	
Analysis on the Interaction of Waves with Flexible Floating Structure	
by BE-FE Combined Method	2548
	<i>Xiaodong Liu, Shigeki Sakai</i>
CHAPTER 198	
Design Wave Height Related to Structure Lifetime	2560
	<i>Zhou Liu, Hans F. Burcharth</i>
CHAPTER 199	
Wave Impact Beneath a Horizontal Surface	2573
	<i>D.J. Wood, D.H. Peregrine</i>
CHAPTER 200	
Wave Impulse Prediction for Caisson Design	2584
	<i>Michael J.A. Walkden, Peter J. Hewson, Geoffrey N. Bullock</i>
CHAPTER 201	
Wave Overtopping Rate and Reflection Coefficient for Obliquely Incident Waves	2598
	<i>Yoichi Moriya, Masaru Mizuguchi</i>
CHAPTER 202	
Sediment Transport and Wave Reflection near a Seawall	2612
	<i>Jonathon R. Miles, Paul E. Russell, David A. Huntley</i>

Part IV Coastal Processes and Sediment Transport

CHAPTER 203	
Wave Energy Dissipation in Kelp Vegetation	2626
	<i>Alfonse Dubi, Alf Torum</i>
CHAPTER 204	
Experimental Study on the Effect of Gravity Drainage System on Beach Stabilization . .	2640
	<i>Hiroi Kanazawa, Fumihiko Matsukawa, Kazumasa Katoh, Iwao Hasegawa</i>

CHAPTER 205	
Field Experiment on the Effect of Gravity Drainage System on Beach Stabilization . . .	2654
	<i>Kazumasa Katoh, Shin-ichi Yanagishima</i>
CHAPTER 206	
On the Change of Velocity Field in Nearshore Zone Due to Coastal Drain and the Consequent Beach Transformation	2666
	<i>Michio Sato, Tadahiro Fukushima, Ryuichiro Nishi, Masahiko Fukunaga</i>
CHAPTER 207	
Evaluation of a Beach Dewatering System: Nantucket, USA	2677
	<i>William R. Curtis, Jack E. Davis, Ian L. Turner</i>
CHAPTER 208	
Sediment Transport Processes at Ocean Beach, San Francisco, California	2691
	<i>Robert T. Battalio, Dilip Trivedi</i>
CHAPTER 209	
Two Treatments of Shore Erosion in Extreme Floods on U.S. Great Lakes	2705
	<i>Robert J. Hallermeier</i>
CHAPTER 210	
Long-Term Beach Response to Shore Stabilization Structures on the Oregon Coast . . .	2718
	<i>G.E. Hearon, W.G. McDougal, P.D. Komar</i>
CHAPTER 211	
Profile Volumes as a Measure of Erosion Vulnerability	2732
	<i>Timothy W. Kana, Ram Krishna Mohan</i>
CHAPTER 212	
Breach Growth: Experiments and Modelling	2746
	<i>Harry de Looff, Henk J. Steetzel, Arie W. Kraak</i>
CHAPTER 213	
The Impact of an Extreme Event on the Sediment Budget: Hurricane Andrew in the Louisiana Barrier Islands	2756
	<i>Jeffrey H. List, Mark E. Hansen, Asbury H. Sallenger, Jr., Bruce E. Jaffe</i>
CHAPTER 214	
Beach Maintenance Strategies, a Comparison for a Recreational Beach	2770
	<i>M. Pluijm, G. Kant, R. Noltén, A.P. de Looff</i>
CHAPTER 215	
Littoral Impact of Ocean City Inlet, Maryland, USA	2779
	<i>Julie Dean Rosati, Bruce A. Ebersole</i>
CHAPTER 216	
Extreme Water Levels, Wave Runup and Coastal Erosion	2793
	<i>P. Ruggiero, P.D. Komar, W.G. McDougal, R.A. Beach</i>

CHAPTER 217
A Morphological “Mixed-Type” Model for the Ebro Delta Coast2806
Agustin Sanchez-Arcilla, Jose A. Jimenez

CHAPTER 218
Sea Dike Erosion and Coastal Retreat at Nam Ha Province, Vietnam2820
Ton That Vinh, G. Kant, Nguyen Ngoc Huan, Z. Pruszek

CHAPTER 219
Beach Profile Analysis around Indian River Inlet, Delaware, U.S.A2829
Kirk F. Bosma, Robert A. Dalrymple

CHAPTER 220
Improved 3-D Beach Evolution Model Coupled with the Shoreline Model (3D-SHORE) .2843
Takuzo Shimizu, Takahiro Kumagai, Akira Watanabe

CHAPTER 221
Evaluation of Shoreface Nourishments by Line Modelling2857
*Martin D. Groenewoud, Willem T. Bakker, Jan van de Graaff, Ruud Spanhoff,
Christian Laustrup*

CHAPTER 222
Beach Monitoring Program of Valencia (Spain)2871
Jose Serra, Josep R. Medina

CHAPTER 223
Bar Migration and Duneface Oscillation on Decadal Scales2884
Marcel J.F. Stive, Jorge Guillen, Michele Capobianco

CHAPTER 224
Morphological Development of the Terschelling Shoreface Nourishment in Response to Hydrodynamic and Sediment Transport Processes2897
P. Hoekstra, K.T. Houwman, A. Kroon, B.G. Ruessink, J.A. Roelvink, R. Spanhoff

CHAPTER 225
Justification for Beach Nourishment2911
John G. Housley

CHAPTER 226
Beach Nourishment Versus Shore Protection Structures2918
*Alexander Khabidov, Yuri Bazhenov, Marina Glodenis, Nadya Ivanova, Liya Kaskevitch,
Oleg Rybak, Valery Savkin, Anatoly Trizno, Grigory Zelensky, Veniamin Yedapin*

CHAPTER 227
Comparison of Beach and Shoreface Nourishment Torsminde Tange, Denmark2927
Christian Laustrup, Holger Toxvig Madsen, Per Sorensen, Ida Broker

CHAPTER 228
Mathematical and Physical Modeling of Beach Nourishment Projects2941
W. Eric Rogers, Paul A. Work

CHAPTER 229	
Coastal Zone Dynamics during Artificial Nourishment	2955
<i>Elzbieta Zawadzka</i>	
CHAPTER 230	
Dune Damage Curves and Their Use to Estimate Dune Maintenance Costs	2969
<i>David R. Basco, Cheol S. Shin</i>	
CHAPTER 231	
Hurricane Opal Induced Changes on Natural and Nourished Beaches, West-Central Florida	2982
<i>Richard A. Davis, Jr., Ping Wang</i>	
CHAPTER 232	
Modelling Sand Transport and Profile Evolution on Macrotidal Beaches	2994
<i>Paul R. Fisher, Tim J. O'Hare</i>	
CHAPTER 233	
Beach Evolution Under Random Waves	3006
<i>Patrick Holmes, Thomas E. Baldock, Ray T.C. Chan, M. Ahmad L. Neshaei</i>	
CHAPTER 234	
Beach Profile Surveys Along the U.S. Pacific Coast 1945-1947	3020
<i>Nicholas C. Kraus, Robert L. Wiegel, Willard N. Bascom</i>	
CHAPTER 235	
Mechanism and Calculation of Sand Dune Erosion by Storms	3034
<i>Ryuichiro Nishi, Nicholas C. Kraus</i>	
CHAPTER 236	
Simulation of Coastal Profile Development Using a Boussinesq Wave Model	3048
<i>K.A. Rakha, R. Deigaard, P.A. Madsen, I. Broker, J.K. Ronberg</i>	
CHAPTER 237	
Cross-shore Sediment Transport and Beach Deformation Model	3062
<i>RattanapitikonWinyu , Tomoya Shibayama</i>	
CHAPTER 238	
Experimental Study on Sediment Transport in Surf and Swash Zones Using Large Wave Flume	3076
<i>Takao Shimizu, Masaaki Ikeno</i>	
CHAPTER 239	
The Influence of Long Waves on Macrotidal Beach Morphology	3090
<i>David J. Simmonds, Tim J. O'Hare, David A. Huntley</i>	
CHAPTER 240	
Mathematical Models for Waves and Beach Profiles in Surf and Swash Zones	3104
<i>Akira Watanabe, Mohammad Dibajnia</i>	

CHAPTER 241	
Comparisons of Erosion Models for Storms at Ocean City, Maryland	3115
<i>Jie Zheng, Robert G. Dean</i>	
CHAPTER 242	
Measurements of Wave Generated Bedforms	3129
<i>Christopher D. Jette, Daniel M. Hanes</i>	
CHAPTER 243	
Field Measurement of Bed Roughness for Waves on an Offshore Reef	3143
<i>Raymond C. Nelson</i>	
CHAPTER 244	
Effect of Wave-Induced-Pressure on Seabed Configuration	3155
<i>Tetsuo Sakai, Hitoshi Gotoh</i>	
CHAPTER 245	
The Measurement of Bed Form Shapes in Hydraulic Models	3169
<i>Ian E. Shepherd</i>	
CHAPTER 246	
Asymmetric Boundary Layer Flow above Sand Ripples under Progressive Waves	3183
<i>Takao Toue, Kazuo Nadaoka, Hidehiro Katsui</i>	
CHAPTER 247	
Undertow Profiles in the Bottom Boundary Layer under Breaking Waves	3194
<i>Daniel T. Cox, Nobuhisa Kobayashi</i>	
CHAPTER 248	
A Comparison of Field Observations and Quasi-Steady Linear Shear Instabilities of the Wave Bottom Boundary Layer	3207
<i>D.L. Foster, A.J. Bowen, R.A. Beach, R.A. Holman</i>	
CHAPTER 249	
Wave Boundary Layer Flows and Pore Pressures in Permeable Beds	3219
<i>H.H. Hwung, K.S. Hwang, B.H. Lee</i>	
CHAPTER 250	
Backfilling of Trenches Exposed to Waves	3231
<i>Jacob Hjelmager Jensen, Jorgen Fredsoe</i>	
CHAPTER 251	
A Closed-Form Solution for Turbulent Wave Boundary Layers	3244
<i>Magnus Larson</i>	
CHAPTER 252	
Observed Suspended Sediments in Storm Conditions	3257
<i>J.J. Williams, C.P. Rose, P.D. Thorne, L.E. Coates, J.R. West, P.J. Harcastle, J.D. Humphery, S.P. Moores, D.J. Wilson</i>	

CHAPTER 253	
Ebb Tidal Delta Evolution of Coastal Inlets	3270
<i>Michael R. Dombrowski, Ashish J. Mehta</i>	
CHAPTER 254	
Adjustments toward Equilibrium of a Large Flood -Tidal Delta after a Major Dredging Program, Tauranga Harbour, New Zealand	3284
<i>Terry Healy, Joseph Mathew, Willem de Lange, Kerry Black</i>	
CHAPTER 255	
Laboratory Mobile Bed Model Studies on Ebb Tidal Shoal Evolution	3295
<i>Xu Wang, Lihwa Lin, Hsiang Wang</i>	
CHAPTER 256	
Interaction of the Colorado River Project, Texas, with Longshore Sediment Transport ..	3309
<i>Daniel J. Heilman, Billy L. Edge</i>	
CHAPTER 257	
A Comprehensive Field Study of Tidal Inlet Processes at Ponce de Leon Inlet, Florida ..	3323
<i>Gary L. Howell</i>	
CHAPTER 258	
Transport of Fluid Mud Generated by Waves on Inclined Beds	3337
<i>Thijs van Kessel, C. Kranenburg, J.A. Battjes</i>	
CHAPTER 259	
Wave on Pebble Beach and Deformation of Pebble Beach	3349
<i>Ichiro Deguchi, Masanobu Ono, Toru Sawaragi</i>	
CHAPTER 260	
Wind-Induced Waves and Currents in a Nearshore Zone	3363
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroshi Kawakami</i>	
CHAPTER 261	
Predicting Large-Scale, Cross-Shore Sediment Movement from Orbital Speeds	3378
<i>Edward B. Hands, John P. Ahrens, Donald T. Resio</i>	
CHAPTER 262	
Small-scale Morphology Related to Wave and Current Parameters Over a Barred Beach	3391
<i>A.F. Garcez Faria, E.B. Thornton, T.P. Stanton</i>	
CHAPTER 263	
Prediction of Shoreline Change Considering Cross-Shore Sediment Transport	3405
<i>Yoshimichi Yamamoto, Kiyoshi Horikawa, Katsutoshi Tanimoto</i>	
CHAPTER 264	
The Influence of Rollers on Longshore Currents	3419
<i>Daniel A. Osiecki, William R. Dally</i>	

CHAPTER 265	
Velocity Field Measurements in a “Coastal Buffer Zone”	3431
<i>Hiroshi Yagi, Hirofumi Hinata, Kazuo Nadaoka</i>	
CHAPTER 266	
Development of Underwater Beach Profile by Monochromatic and Random Waves ...	3442
<i>Karsten Peters, Jurgen Newe, Hans-H. Dette</i>	
CHAPTER 267	
Turbulent Stresses in the Surf-Zone: Which Way Is Up?	3453
<i>John W. Haines, Guy Gelfenbaum</i>	
CHAPTER 268	
Asymmetric and Irregular Wave Effects on Bedload: Theory Versus Laboratory and Field Experiments	3467
<i>Leszek M. Kaczmarek, Rafal Ostrowski</i>	
CHAPTER 269	
Kinematics and Shear Stresses from Combined Waves and Longshore Currents in the UK Coastal Research Facility	3481
<i>Richard R. Simons, Ruairi D. MacIver, Wameidh M. Saleh</i>	
CHAPTER 270	
Movable Bed Roughness in the Flow of Irregular Waves and Currents Over Movable Beds	3495
<i>Zai-Jin You, Peter Nielsen</i>	
CHAPTER 271	
Seabed and Foundation Response to Wave Loading	3507
<i>Michael H. Davies</i>	
CHAPTER 272	
Interannual Shoreline Variations at Duck, NC, USA	3521
<i>Nathaniel Plant, Rob Holman</i>	
CHAPTER 273	
Long Term Behaviour of the Sediment Volume inside a Tidal Basin after Poldering ...	3534
<i>Ernst Schroeder, Roland Goldenbogen, Hans Kunz</i>	
CHAPTER 274	
Wave Groups in a Barred Nearshore	3546
<i>B. Boczar-Karakiewicz, W. Romanczyk, J.L. Bona, B. Greenwood</i>	
CHAPTER 275	
Coastal Morphodynamic Instabilities	3560
<i>Albert Falques, Amadeu Montoto, Vicente Iranzo</i>	
CHAPTER 276	
On Validation of a Sand Waves and Sand Banks Model	3574
<i>Suzanne J.M.H. Hulscher</i>	

CHAPTER 277	
Transverse Bars in Duck, North Carolina	3588
<i>Kathryn M. Konicki, Rob A. Holman</i>	
CHAPTER 278	
On the Systematic Offshore Decay of Breaker Bars	3600
<i>Kathelijne M. Wijnberg</i>	
CHAPTER 279	
Longshore Bed-Load Transport	3614
<i>Jesper S. Damgaard, Richard L. Soulsby</i>	
CHAPTER 280	
Design Capacity of a Longshore Current Recirculation System for a Longshore 	
Sediment Transport Laboratory Facility	3628
<i>David G. Hamilton, Julie D. Rosati, Jimmy E. Fowler, Jane M. Smith</i>	
CHAPTER 281	
Influence of Nearshore Hardbottom on Regional Sediment Transport	3642
<i>Paul C.-P. Lin, R. Harvey Sasso</i>	
CHAPTER 282	
Improvement of the Most Accurate Longshore Transport Formula	3652
<i>J.S. Schoonees, A.K. Theron</i>	
CHAPTER 283	
Cross-shore Structure of Longshore Currents during Duck94	3666
<i>Falk Feddersen, R.T. Guza, Steve Elgar, T.H.C. Herbers</i>	
CHAPTER 284	
Three-Dimensional Hydrodynamics on a Barred Beach	3680
<i>Tae-Myoung Oh, Robert G. Dean</i>	
CHAPTER 285	
Rip Current Generation on a Plane Beach	3694
<i>D.A. Suriamihardja, Yoshito Tsuchiya</i>	
CHAPTER 286	
Nearshore Placement of Sand	3708
<i>Scott L. Douglass</i>	
CHAPTER 287	
Influence of Nearshore Berm on Beach Nourishment	3722
<i>Paul A. Work, Emre N. Otay</i>	
CHAPTER 288	
Accuracy of Sand Volumes as a Function of Survey Density	3736
<i>Jennifer L. Irish, W. Jeff Lillycrop, Larry E. Parson</i>	
CHAPTER 289	
Shoreline Analysis Using Digital Photogrammetry	3750

CHAPTER 290	
Application of Satellite Images to the Detection of Coastal Topography	3762
<i>Ji Wu, Jea Tzyy Juang</i>	
CHAPTER 291	
Sediment Transport in Swash Zone under Obliquely Incident Waves	3770
<i>Toshiyuki Asano</i>	
CHAPTER 292	
Sheet Flow Modelled As Pure Convection	3784
<i>Stephen Clark, Peter Nielsen</i>	
CHAPTER 293	
A Transport Rate Formula for Mixed-Size Sands	3791
<i>Mohammad Dibajnia, Akira Watanabe</i>	
CHAPTER 294	
Modelling of 3D Sediment Transport in the Surf Zone	3805
<i>Berry Elfrink, Ida Broker, Rolf Deigaard, Erik Asp Hansen, Peter Justesen</i>	
CHAPTER 295	
A Numerical Model of Sheet Flow Sediment Transport	3818
<i>Sadakazu Katori, Masaru Mizuguchi, Akira Watanabe</i>	
CHAPTER 296	
Numerical Modeling of Nearshore Morphological Changes under a Current-Wave Field	3830
<i>Taerim Kim, Hsiang Wang</i>	
CHAPTER 297	
An Analysis of Particle Saltation Dynamics	3846
<i>Michael R. Krecic, Daniel M. Hanes</i>	
CHAPTER 298	
Sediment Movement and Stress Condition in Sea Bed	3860
<i>Yoshihiko Maeno, Motoyasu Ishikawa, Kozo Bando, Yoshinobu Akiyama, Kouichi Yabe</i>

CHAPTER 199

Wave impact beneath a horizontal surface.

D.J.Wood [†] and D.H.Peregrine [‡]

Abstract

Many coastal structures and natural coasts have openings, overhangs and projections which are open to impact by incident water waves. The sudden impact of a wave on a rigid surface leads to a rapid rise of pressure and consequent violent water motions. We consider the wave impact on the underside of a projecting surface. The example discussed is that of a flat deck close to the mean water level. A pressure-impulse approach is used, which has the advantage that given a solution for one problem it is possible to select pressure-impulse contours which give the solution to related problems. The pressure gradient on the underside of the deck is especially strong near the seaward edge of the impact region, so this is a region where any projections on the structure's surface may be subject to strong shearing forces. On the other hand the maximum pressure-impulse is at the landward end of the impact zone, it is here that the deck is most likely to be 'blown' upward.

Introduction

There are a number of circumstances in which the effect of the upward impact of a wave beneath a rigid horizontal surface needs to be estimated. For offshore oilrigs the lack of good estimates of such upward impacts leads to designs where the main platform of rigs is built to be out of reach of 'green water'. This may not be an option for some coastal structures, including piers and jetties, and temporary works in inter-tidal zones. Here we present pressure-impulse calculations for an impact on a horizontal surface near the surface of water of finite depth. For convenience we refer to the rigid surface as a deck.

In studies of wave impact on a wall Bagnold (1939) was the first to note that although pressure measurements show great variability between nominally identical wave impacts the integral of pressure over the duration of the impact,

[†]Ph.D. student, School of Mathematics, University of Bristol, University Walk, Bristol, BS8 1TW, UK, (*Deb.Wood@bristol.ac.uk*)

[‡]Professor of Applied Mathematics, School of Mathematics, University of Bristol, (*D.H.Peregrine@bristol.ac.uk*)

the pressure-impulse, is a more consistent measure of wave impact. This has been exploited theoretically by Cooker and Peregrine (1990 a,b, 1992, 1995) who show that the pressure-impulse and its distribution is not sensitive to the shape of the impacting water except in a region very close to the structure. Chan (1994) and Losada, Martin, and Medina (1995) show good agreement with experiment for wave impact on a wall.

Mathematical model

The geometrical simplifications we make may be seen in figure 1. The water is taken to be of finite depth $CD = a$, and to impact the horizontal deck BC of length L with an upward velocity V . The free surface outside the deck is taken to be flat, as BA , and to stretch to infinity. However, as indicated below alternative surface shapes are easily found by choosing different contours of pressure-impulse. The boundary conditions on CD given in figure 1 indicate that the problem can be reflected in the vertical plane of CD , corresponding to impact on a horizontal surface of length $2L$ with a central plane of symmetry.

Figure 1: The problem to be solved.

Let the pressure be $p(x, y, t)$, then the pressure-impulse is

$$P(x, y) = \int_{t_b}^{t_a} p(x, y, t) dt \tag{1}$$

where t_a and t_b are the times after and before impact respectively, such that the time interval (t_b, t_a) is short compared with all other time scales in the problem. The main approximation is that during this short time the fluid motion changes so rapidly that the equation of motion may be approximated by

$$\frac{\partial \mathbf{u}}{\partial t} = -\frac{1}{\rho} \nabla p \tag{2}$$

where $\mathbf{u}(x, y, t)$ is the velocity field, and ρ the density which is assumed to be constant and uniform. The neglect of the convective terms $(\mathbf{u} \cdot \nabla) \mathbf{u}$ is consistent except in any small region near the impact where jets may form.

Integration of (2), with respect to time, yields

$$\mathbf{u}_a - \mathbf{u}_b = -\frac{1}{\rho} \nabla P \quad (3)$$

Incompressibility gives $\nabla \cdot \mathbf{u}_a = \nabla \cdot \mathbf{u}_b = 0$. Therefore we find

$$\nabla^2 P = 0 \quad (4)$$

in the region of the water.

The boundary condition at the free surface is that the pressure must be constant and continuous therefore $P = 0$. At the walls and on the bed, the normal velocity must be zero before and after impact, therefore using equation (3), $\partial P / \partial n = 0$, where n is the normal direction. As the water meets the deck BC, the water has vertical velocity V , which could be any function of x , and after impact the water has zero vertical velocity. Therefore, again using equation (3), we have $\partial P / \partial n = V$. For simplicity, we choose V to be constant. We make the problem dimensionless by choosing units for which $V = 1$ and $L = 1$.

Infinite depth solution

The problem of a wave hitting upwards under a deck jutting out from a wall, is mathematically equivalent to a plate dropping onto a body of water and setting the water in motion. Also when considering solving Laplace's equation we can use the direct analogy with the velocity potential of irrotational flow. If we consider the complex potential for a flow past a plate then we just need a change of reference frame to find the complex potential of a moving plate in a stationary fluid. With a complex potential $w = \phi + i\psi$, then $\partial \phi / \partial x = 0$ on $x = 0$, and $\partial \phi / \partial y = 1$ along the plate. These are the conditions that are required by P , and so the lines of constant pressure-impulse are given by lines of constant ϕ . The solution may be found in Lamb (1932, section 71), and in Milne-Thompson (1962, section 6.3), for a fluid flowing past an ellipse. If we allow one of the semi-axes to shrink to zero then we have a plate instead of an ellipse in the flow. Finally choosing the plate to be perpendicular to the flow, the length of the plate to be 2, and the velocity 1, we get an expression for the complex potential of a stream flowing past a plate:

$$w = -\sqrt{1 - z^2} \quad (5)$$

where the origin is taken to be the centre of the plate.

If we subtract the complex potential for a stream from this expression we have the potential for a moving plate. As the velocity of the stream is $(0, -1, 0)$, we must therefore subtract iz to get:

$$w = -iz - \sqrt{1 - z^2} \quad (6)$$

This solution is symmetric about the centre of the plate. This means that we can consider a line drawn perpendicular to the plate from the centre of the plate, to be a wall, bringing us back to the original problem of the water hitting a deck jutting out from a wall. Hence we have an expression for the pressure-impulse:

$$P = \text{Re}(-iz - \sqrt{1 - z^2}) \quad (7)$$

This is the infinite depth solution. Figure 2 shows contours of pressure-impulse. The total impulse on the deck is $\pi/4$, in dimensional terms $\pi \rho V L / 4$.

Figure 2: Infinite depth solution. Total impulse on deck (0,1) is $\pi/4$.

Infinitely long deck.

As a becomes small the effect of the free surface on the solution under the plate becomes small. This means it is possible to solve in that region by neglecting the condition at the free surface. Hence we solve Laplace's equation on a strip where $\partial P/\partial y = 1$ along the top, $\partial P/\partial n = 0$, where n is the normal direction, along the left-hand edge and bottom.

The solution is given by:

$$P = \frac{1}{2a} [y^2 - x^2] + K \tag{8}$$

where K is a constant which depends on the behaviour of P near $x = 0$, where this approximation fails. Figure 3 shows the case when $a = 0.1$, and K is set to zero.

Figure 3: Analytic solution when a is small. ($a = 0.1, K = 0$)

In practice the 'filling flow' solution of Peregrine and Kalliadasis (1995) may be more relevant to this case.

More general solution

Consideration of the boundary conditions in Figure 1, or the solution (7) shows that at B there is a square root singularity. This singularity causes problems for many numerical solution methods. However, one way to eliminate the problem of the singularity is to map the original problem using conformal maps as follows. First map to a half-space, then use another conformal map to perform a shift and stretch so that by using a final conformal map we can bend the problem back to a semi-infinite strip but with the boundary conditions shifted round to a convenient position, i.e. shift the boundary conditions on the deck round to the vertical wall.

Let the original plane in which the problem is posed be the z plane. The first map we need is $w = u + iv = \cosh(\pi z/a)$. This gives the problem shown in figure 4. As we only use conformal maps P continues to satisfy Laplace's equation throughout.

Figure 4: The problem in the w -plane after the first complex map.

Figure 5. The final problem to be solved in the ζ -plane, where $F(\eta) = -\sin(\pi\eta/a)/(M\sqrt{b^2-1})$ with $b = [\cos(\pi\eta) - N]/M$.

We then use a translation and magnification to shift B to -1 , and C to 1 . The map required is $h = f + ig = Mw + N$ where $M = 2/(\cosh(\pi/a) - 1)$ and $N = M + 1$. The last step is to map this problem back to the strip. The final map required is $\zeta = \xi + i\eta = a \cosh^{-1}(h)/\pi$. This gives the problem as shown in figure 5, in a form with the singularity eliminated by being placed at a corner.

We solve Laplace's equation in this region by separation of variables. Let $P = f(\eta)g(\xi)$, giving $f'' = -\alpha^2 f$ and $g'' = \alpha^2 g$, where α is a constant. Solving for f , using the boundary condition that $f = 0$ at $\eta = a$, and $\partial f/\partial \eta = 0$ at $\eta = 0$, gives $f = A \cos(\alpha_n \eta)$ where $\alpha_n = (n + 1/2)\pi/a$. We now solve for g , using the condition that $P \rightarrow 0$ as $\xi \rightarrow \infty$. This gives $g = Re^{-\alpha_n \xi}$. Hence we have an expression for the pressure-impulse:

$$P = \sum_n A_n e^{-\alpha_n \xi} \cos(\alpha_n \eta) \quad (9)$$

Finally we use the condition that $\partial P/\partial \xi = -\sin(\pi \eta/a)/(M\sqrt{b^2-1})$, where $b = [\cos(\pi \eta) - N]/M$ along $\xi = 0$ to get expressions for the A_n . Using this condition we get:

$$-\sum_n A_n \alpha_n \cos(\alpha_n \eta) = -\frac{\sin(\pi \eta/a)}{M\sqrt{b^2-1}} \quad (10)$$

The final step is to multiply both sides by $\cos(\alpha_m \eta)$, and integrate along the line $\xi = 0$ to get:

$$A_m = \frac{2}{\alpha_m a} \int_0^a \frac{1}{M} \frac{\sin(\pi \eta/a) \cos(\alpha_m \eta)}{\sqrt{b^2-1}} d\eta \quad (11)$$

Similar results can be found for any velocity distribution $V = V(x)$.

Results and discussion

The integral in (11) is evaluated by using a numerical routine. For the cases of $a = 0.5$ and $a = 2.0$ taking thirty terms in the sum, gives an accuracy of 4 and 12 decimal places respectively. The distribution of pressure-impulse in the water beneath the deck is shown for deck width to depth ratios of 0.5, 1.0 and 2.0 in figures 6, 7 and 8 respectively. The values of the total impulse on the deck and on the wall beneath each deck are given in each caption.

In figures 6, 7 and 8 note the differing contour intervals, and the increasing impulse on the deck as the water depth a is decreased. The value of total impulse on the deck is given as a function of a in figure 9. This trend is for the impulse from impact of a given velocity and area to increase as the body of impacting water becomes more confined. The same trend is described by Cooker and Peregrine (1995) for impact on an interior wall of a rectangular box and by Topliss (1994) for impact within a circular cylinder. Consideration of flow in the most confined circumstances, as a becomes small, has given the concept of 'filling flows' (Peregrine and Kalliadasis, 1995). Further, an estimate of how the compressibility of dispersed air bubbles, such as those entrained in waves during breaking, may soften wave impact is given in Peregrine and Thais (1996).

The results are in dimensionless units, for practical use the dimensional pressure-impulse is needed; that is

$$P^*(x^*, y^*) = \rho VLP(Lx, Ly), \quad (12)$$

Figure 6: Pressure-impulse contours with $a = 2.0$. Total pressure-impulse on the deck and wall respectively are 0.81 and 1.02

Figure 7: Pressure-impulse contours with $a = 1.0$. Total pressure-impulse on the deck and wall respectively are 0.92 and 0.74.

Figure 8: Pressure-impulse contours with $a = 0.5$. Total pressure-impulse on the deck and wall respectively are 1.193 and 0.44.

where * denotes the dimensional quantities. Whilst ρ and L will generally be known, V the vertical velocity of impact will need to be estimated. A simple method of estimating V is to first estimate how high a wave would be in the absence of the deck. Suppose it would have a height ΔH above the deck level. In simple projection of a particle this would require a velocity of $\sqrt{2g\Delta H}$. This is a reasonable, somewhat conservative, estimate for V .

Figure 9: Total impulse on deck against depth a .

Note, the above solutions are not appropriate for impact from jets, e.g. see Cooker and Peregrine (1995), where the semi-infinite rectangular impact on a wall is equivalent to half of a plane jet and section 3.5 gives the solution for a circular jet. However, the solutions can be used for waves which are not nearly level with the deck as the figures indicate. By subtracting the appropriate constant from P , any of the contours of P can be chosen as an alternative free surface. Although such a surface tends downward rather than towards a horizontal level, this is not of great significance as long as the shape within roughly unit distance is appropriate. See Cooker and Peregrine (1995) for some examples.

Clearly the results presented here can be used to estimate the impulse and the spatial distribution of a wave impact. In addition, as illustrated by Cooker and Peregrine (1992) it is possible to estimate the impulse on smaller bodies on and near the wave impact area. The impulse may be derived from the local pressure-impulse gradient. Figure 10 shows the local gradient along the surface of the deck, and figures 11 and 12 show the gradient down the wall and along the bed respectively for a selection of values of a . On the wall and the bed the pressure gradient is tangential since $\partial P/\partial n = 0$. However, on the deck where the impact occurs $\partial P/\partial n \neq 0$ so that there is also a component of impulse perpendicular to the deck and downward.

Consideration of the gradient of pressure-impulse gradient near the edge of the deck shows alarmingly high values because the mathematical solution has a singularity at the edge of the deck. Clearly a better approximation is needed

Figure 10: $\frac{\partial P}{\partial x}$ along the deck.

Figure 11: $\frac{\partial P}{\partial y}$ along the left hand wall.

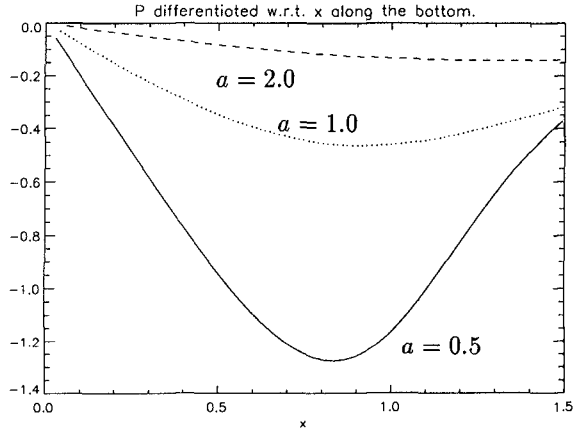

Figure 12: $\frac{\partial P}{\partial x}$ along the bottom.

there. One simple way of obtaining more realistic values is to consider how the solution is obtained for the infinite-depth case, $a = \infty$. There, the solution for the flow past a plate is used. This solution is a limit of flow past an ellipse. Thus a somewhat better solution could be obtained from the flow past a slender ellipse. In any case, it seems reasonable to conclude that attachments beneath a deck are vulnerable to especially large impact forces if they are near the edge of the deck, or the edge of the impact zone.

Three-dimensional effects

All the above work assumes uniformity perpendicular to the (x, y) plane, or some rigid boundaries parallel to that plane. In practice this is unlikely, and three-dimensional effects may be important. That is the impact area on the deck, rather than being a long strip of finite width L , should be taken as a finite area of an appropriate shape. This aspect of the problem is under study. For the present, we just note that for infinite depth solutions, a solution for impact on an elliptic area can readily be found from the potential flow round an ellipsoid.

Conclusions

A readily evaluated solution is presented for the pressure-impulse from waves hitting a deck from below. It is found that the impulse is greater if the water is shallow.

The same results may be useful for estimating the effects of upward impact by liquid confined within a container.

CHAPTER 200

WAVE IMPULSE PREDICTION FOR CAISSON DESIGN

Michael J.A. Walkden¹, Peter J. Hewson² and Geoffrey N. Bullock³

Abstract

Problems associated with the measurement of wave impact pressures are described and the poor comparison between the results of previous studies is outlined. It is argued that the force impulse form and magnitude are more relevant parameters for caisson design than maximum impact pressures. Data from small and large scale laboratory measurements are used to develop a simplified design approach for caisson breakwaters based on the limited magnitude of the force impulse. Comparison between large scale data and predictions based on small scale results show reasonable agreement.

Introduction

The form of breakwater selected for a particular site depends upon many physical, economic and political factors. Rubble mound constructions are popular in shallow water because they have proved reliable and easy to repair but they are expensive in deep water. Due to the growth of ocean going vessels and the associated need to provide mooring facilities in deeper water there is increasing interest in vertically sided breakwaters. Historically these have had a masonry construction, although in recent decades cellular caissons have provided a preferred alternative. The most common failure mode of caisson breakwaters has been sliding due to the impact of breaking waves (Oumeraci, 1994, Franco, 1994). Such impacts are highly complex events which can not yet be described theoretically. Small scale laboratory wave impacts are therefore a valuable source of information for both designers and those seeking to improve design methods. Due to the sensitivity of breaker shape to wave and physical boundary conditions and the transient and localised nature of impact pressures, results are frequently test specific. If this problem was successfully addressed then confidence in predictions of prototype loading conditions based on such small scale laboratory tests would be greatly enhanced.

Scatter of impulse pressures

Even the pressures generated by nominally identical consecutive breakers of a monochromatic wave train are only predictable in a statistical sense. Hayashi and Hattori, (1958) stated that "The initial shock pressure varies so enormously from test to test that it almost seems to have nothing to do with our theoretical considerations". There are many possible reasons for this, some due to random fluctuations in wave form, others due to test conditions and procedures.

Denny (1951) investigated high frequency random fluctuations in the wave form and took measurements of peak pressure from waves of various heights with two different levels of disturbance. This showed that the distribution of peak pressures normalised to wave height was identical for waves of different heights and similar disturbance, but for waves with less disruption, the distribution included much higher relative pressures. This effect may be due to differences in entrapped aeration, variations in the velocity field or some other process. The degree of disturbance and therefore the degree of pressure attenuation will depend on test facilities such as the wave generator and absorption system, and test procedures such as whether a solitary or regular wave train is tested, and how long the water is left to calm between tests.

Variation in pressure records between experiments will be compounded by effects specific to the wave channel and others resulting from the choice of equipment and procedure. The breaker shape depends, for the two dimensional case, mainly on the incident wave conditions, period, height and depth, and the physical boundary conditions mainly foreshore topography and permeability. Any difference in these between tests could be expected to alter impact pressures. The characteristics of the pressure transducers and their position are also significant because peak pressures are generally highly transient and localised. The number of transducers, their size and positions are significant to the spatial resolution, whilst frequency response and sample rate influence temporal resolution.

Impulse repeatability

The wide variation in peak pressure was first addressed by Bagnold who noted that the pressure rise impulse (see Figure 1) was far more repeatable. This observation was used to develop a concept of an 'effective length' of a piston like body of fluid extending horizontally into the wave from the front face. Because it was believed that the generation of the impulse was caused by momentum focusing through the pocket, it was the pocket dynamics and essentially its thickness which determined the impulse duration. Bagnold was unable to prove his model by measuring the air pocket. Also it is now known that an air pocket is not a necessary condition for the occurrence of an impulse load. The work has since been developed by other researchers, including Kirkgoz who measured a similar effective length for flat fronted waves as Bagnold found for air pocket waves, although with wide variation, and Weggel, *et al* (1970) who tried to show, but were unable to establish, that effective length varied with wave steepness.

Figure 1. Definition of pressure rise impulse (shaded area)

P_{max} and T_{pr}

The consistency of wave pressure impulse has often been expressed as a relationship between the maximum impact pressure P_{max} , and the time for the pressure to rise to it, T_r of the form;

$$P_{max} = K \cdot T_{pr}^H$$

where K is a constant. Published examples include;

$P_{max} = 232T_{pr}^{-1}$, Weggel *et al*, (1970).

The upper envelope of 12 laboratory 2D measurements with a beach slope 1/20 and a discontinuous wave wall. Regular waves were used to form one breaker type, the heights and periods are not specified although the steepness is given as 70 mm/sec. Six pressure transducers were used which were located 19 mm apart. No information is provided on their characteristics or sample rate or the measures taken to ensure a calm water surface.

$P_{max} = 250T_{pr}^{-0.9}$, Kirkgoz (1990).

The best fit line to 70 laboratory 2D measurements with a beach slope of 1/10 and a continuous wave wall. Regular waves were used in still water depth of 0.61 m with an average height of 0.259 m and a 2 second period, these conditions produced plunging breakers. 10 pressure transducers with a 19 mm active surface diameter at 30 mm centres were sampled at 40 kHz. 1 hour was left between each test to allow the water surface to calm.

$P_{max} = 261T_{pr}^{-0.65}$, Witte.

The upper limit function to approximately 100 laboratory 2D events with a beach slope of 1/6. Regular waves of height 0.25 m and period 2 seconds were generated in a still water depth of 0.61 m (depth at wall 0.16 m). 25 waves were generated per train to prevent re-reflection. Steep, vertical and air pocket breaker types were examined. 14 pressure transducers with a minimum gap of 0.015 m and surface diameter of 3.7 mm were sampled at 62.5 kHz.

$P_{max} = 400T_{pr}^{-0.75}$, Hattori *et al*, (1994).

The upper limit function to a large number of laboratory events including a range of breaker shapes. The beach slope was 1:20 and the water depth at the wall was 50 mm. Regular wave trains were generated with an energy absorbing paddle with heights which varied from 40 to 120 mm and periods of 1.5, 1.7 and 2.0 seconds. Six pressure transducers were sampled at 5 kHz and located at 10 mm centres around still water level.

$P_{max} = 485T_{pr}^{-1}$, Weggel *et al*, (1970).

The test conditions were as described above, except the wave steepness was 17.9 mm/sec.

$P_{max} = 3100T_{pr}^{-1}$, Blackmore and Hewson (1984).

The upper limit function to approximately 80 full scale marine wave impacts on a sea wall. The wave heights ranged from 0.8 to 1.3 m with periods of from 2.67 to 8.5 seconds. The waves had mostly broken at impact. Seven 25 mm diameter pressure transducers were positioned at around 1 m intervals.

These functions appear because, as Bagnold noted, the pressure impulse is limited, if P_{max} is large, then T_{pr} tends to be small and *vice versa*. There are too many variables between each test to determine the effect of each on K and H although there seems to be some relationship between K and the size of the wave. For example the constant of 3100 calculated from the prototype sea wave impacts of Blackmore and Hewson is significantly higher than those derived from the laboratory data. The fact that this relationship between P_{max} and T_{pr} has been different in each case is probably due, at least in part, to the difficulties of recording consistent impact pressures between tests.

This pressure impulse appears to be a more consistent feature of impact loading than the pressure maxima, it may therefore be a more reliable basis for design if the structure response to the impulse is properly understood.

Structural Dynamics.

Structural response to loading is fundamentally important to design. Goda used a dynamic model to develop his method for breakwater design (Goda, 1974 and 1994) which has since become the standard in many countries. Oumeraci and Kortenhaus (1994) created a similar model which was calibrated with near prototype measurements recorded in the Grosser Wellen Kanal (GWK), see below. This was used to show how the structure responded to different force time histories. It was demonstrated that, for impacts without significant air pocket generated force oscillations, the dynamic response could be accurately predicted by simplifying the force time history to a triangular impulse described by the maximum force, F_{max} , the impulse duration, T_d and the rise time T_r . The results were presented in the form of dynamic amplification factors, ratios of force maxima to the equivalent static load which would have caused the same displacement (F_{stat}). The dynamic amplification factors depend upon the ratios of T_d and T_r to the natural period (T_n) of the structure

in question. In this way structural dynamic response can be accounted for and the problem for the designer is reduced to ensuring integrity under a known static load.

There are a series of problems to be overcome before adopting this approach. The form and magnitude of the force impulse has to be determined from the incident wave conditions and the physical boundary conditions. At present this can only be achieved through physical model tests. The natural variation in the magnitude and form of the impulses measured during such tests must therefore be accounted for and a reliable and appropriate method of scaling must be determined.

Scale effects

A comparison of similar wave impacts at significantly different scales have been conducted by Sakakiyama (1994) for the case of a submerged breakwater in front of a vertical wall, and by Fuhrboter (1986) for sloping revetments. To the authors knowledge no such data has been published for the case of a vertical wall experiencing direct wave breaking. The case for the existence of scale effects appears to be that field measurements provide relatively smaller peak impact pressures than have been measured in the laboratory and scaled with the Froude law. Aeration is often suggested as a probable cause although it seems probable that the above mentioned difficulties associated with measuring consistent impact pressures are at least partly responsible.

Aeration

Entrained aeration has a strong effect on the compressibility characteristics of water. It affects the rate of momentum exchange between the wave and wall (Blackmore and Hewson, 1984) and reduces the speed of sound in the fluid, altering the propagation of pressure waves (Topliss, 1994, Griffiths, 1994). It depends strongly on the chemistry and biology of the water. Bubbles of air in fresh water tend to be formed larger than in sea water due to increased surface tension, they also coalesce more readily and burst more easily at the surface. No direct measurements have yet been made of breaker aeration so its effects can only be assumed, however it has been shown that artificial aeration can reduce impact pressures (Crawford *et al*, 1994, Walkden *et al*, 1995).

If entrained aeration does affect impact pressures this does not necessarily mean that the impulse magnitude is affected. The force impulse represents the momentum of a proportion of the wave. Although aeration reduces water density, the wave mass remains essentially the same due to bulking. Also the wave kinematic pattern is probably not strongly effected, there is therefore reason to believe that the wave impulse might be reasonably independent of entrained aeration and so possibly free of associated scale effects.

Physical experiments

Measurements of wave impact forces were conducted at both small and near prototype scale in order to develop a way of accounting for wave impulse loading, for

impacts without significant air pocket oscillations. The following subjects were investigated;

The magnitude and form of the force impulse,

Linearisation of the impulse,

The significance of K and H,

Scale effects,

Transformation from dynamic loads to equivalent static loads.

University of Plymouth (UoP) small scale wave impact tests

Experiments were conducted in a 20 m long, 1.2 m deep and 0.9 m wide flume fitted with an energy absorbing wedge type wave paddle (Bullock and Murton, 1989).

Waves shoaled over a 1:4.5 sloping impermeable foreshore and broke onto a vertical wall made of 25 mm acrylic sheet. Five sealed gauge Kulite type 219 pressure transducers with an active surface diameter of 18 mm were used to record the pressures at the wall at 2 kHz. Three of these had a pressure range of from 0 to 100 kN/m², the others were designed for pressures of up to 400 kN/m². The transducer centres were 40, 55, 70, 90 and 110 mm above the toe of the wall, although during experiments the transducer at 90 mm was damaged. Data was recorded on a P.C. by means of a Microlink logger. Video records were made of each test.

GWK large scale wave impact tests

Experiments were conducted in Europe's largest wave flume, the GWK. The physical boundary conditions were not geometrically similar to those of the UoP flume but it was felt that adequately similar breaker geometry would be attainable. The GWK is a large concrete 'U' channel, with its base at ground level, internally it is 324 m long, 5 m wide and 7 m deep. Waves broke onto a sand filled concrete caisson mounted on a rubble foundation over a shallow sloping sand bed. Instrumentation was mounted on and built into a spar which was then attached to the caisson face. Four Kulite type 219 pressure transducers were installed which had a pressure range of 0 to 400 kN/m² (see above). They were positioned at 200 mm increments, 0.72 to 1.32 m from the top of the rubble mound. An additional pressure record was made with one of the transducers belonging to the Franzius Institut which was already built into the caisson and located 0.54 m above the rubble mound. Cabling was contained within the spar to protect it from the impacting waves. Pressures were recorded at 2 kHz. Video records of each test from two static and one mobile camera provided information on the breaker forms. Thirty eight tests were conducted in total in water depths ranging from 3.1 m to 3.3 m, including regular and pseudo random wave trains and solitary waves. Wave heights ranged from 0.5 to 1.1 m with periods from 3.5 to 5.5 seconds.

Results

Due to space limitations only the results from two tests will be shown, one conducted in the UoP flume, and one carried out in the GWK. In the former case 350 waves of height (H) 0.11 m, period 1.25 s and 79 mm water depth at the wall, broke with a near vertical, slightly overhanging wave front.

Figure 2. Maximum impact pressures from one transducer (UoP Data)

The data shown in Figure 2 illustrates the typically large spread in P_{max} . The mean value is 13.4 kN/m^2 , with a range from 2.3 kN/m^2 to 58.6 kN/m^2 . If this test had been conducted in order to model a design wave impact it might be concluded that the design event may produce a pressure maxima of anything from $2.13 \rho g H$ to $54.3 \rho g H$. It is not clear how such results should be interpreted.

Figure 3. Typical force time history, the shaded area represents the impulse (UoP data)

In order to obtain the impulses, the force time histories were first calculated by spacewise integration of the pressures. The impulse is a dynamic load involving rapid variations in force, therefore a simple low pass filter was used to remove the quasi

static force component, see Figure 3. The distribution of the impulse was found to be compact, Figure 4 shows the results from the UoP test, normalised to the total momentum exchange caused by the wave at the wall. This implies that accounting for the impulse magnitude, with for instance a statistical confidence limit, may be fairly straightforward.

Figure 4. Frequency distribution of force impulse normalised to total momentum (Impulse momentum fraction, UoP data)

Partly because of this consistency, if the data is represented in the $F_{max} T_d$ domain it clusters around a similar function to those found in the $P_{max} T_{pr}$ domain, as shown in Figure 5.

Figure 5. Relationship between maximum dynamic force and impulse duration

The values of F_{max} and T_d in Figure 5 are not suitable to be used to predict the structure response following the method described by Oumeraci and Kortenhuis. This is because the impulse is linearised to a triangle with base T_d and height F_{max} . Some of the data shows both a high peak force and a long duration which if used as a basis for linearisation results in an unrealistically high impulse magnitude and an over-prediction of structure response. This is because the form of the impulse tends to be concave as the force drops, as can be seen in Figure 3. In order to realistically predict structure response the magnitude of the impulse must be correct.

Figure 6. Method of processing the linearised force impulse

It was therefore decided to process the values of F_{max} and T_d to parameterise both the magnitude and the form of the impulse. Figure 6 demonstrates the method which was used. $T_{d.eq}$ and $F_{max.eq}$ are equivalent values which were calculated so that the area of the triangle they described is equal to the impulse magnitude, and the triangle they form is similar to the original linearised impulse. An alternative more ideal approach might account for the relationship between removed impulse frequencies and the natural frequency of the structure. The data in Figure 7 has been processed in this way.

The power of $T_{d.eq}$ in the best line fit in Figure 7 (shown with the dashed line) found through least squares regression, is 0.92. It can be seen that $T_{d.eq}^{-1}$ also provides a good fit. If the latter value is used then the constant assumes the value 16.3 and has units of Ns/m run or impulse per metre and is twice the average impulse magnitude. This data can now be used to account for dynamic response in the way Oumeraci and Kortenhuis suggest because both the impulse magnitude and its form are parameterised by $F_{max.eq}$ and $T_{d.eq}$.

Comparison with large scale test results

Similarity of physical boundary conditions between the large and small scale experiments was not possible. The small scale foreshore was impermeable and had a

regular slope, whereas the large scale foreshore was permeable and included a berm. If the incident wave conditions were geometrically similar then the breaker shapes would not be and no comparison between the results would be meaningful. It was therefore decided to base a scale comparison on the breaker shape and the wave momentum. The video records were used to match similar breaker shapes at small and large scale, then the wave momenta were used to obtain the scale ratio. The average momentum measured for the UoP waves was 39.2 Ns/m run and for the GWK data, 4545 Ns/m run, which provides a length scale of 6.7.

Figure 7. Impulse momentum and shape parameterised by F_{eq} and T_{eq}

Figure 8. Comparison between scaled UoP data and GWK data

The values of $F_{max.eq}$ and $T_{d.eq}$ measured in the UoP flume were scaled according to Froude and compared to values obtained from the GWK test in Figure 8. The match is not perfect but when the lack of boundary condition similarity is considered the results might be considered close.

Figure 9. Equivalent static load function calculated from the dynamic amplification factors of Oumeraci and Kortenhaus, 1994. It is assumed that $T_n = 0.1$ and $T_r = 0$

In Figure 9 the dynamic force function $F_{max.eq} = 1900/T_{d.eq}$ has been multiplied by a dynamic amplification function to obtain the equivalent static load function. The maxima of this (in this case 45 kN/m run) might be considered the largest equivalent static force the impulse can generate and therefore the design load for this breaker.

Conclusions and discussion

- (I) Maximum impact pressures are highly variable and difficult to compare between tests. This is due to differences in test procedure and conditions as well as natural random scatter.
- (II) The magnitude of the force impulse is more consistent and more relevant to structural stability than a transient and localised pressure maxima.
- (III) The form of the force impulse is highly variable, this may be due to aeration effects, variations in breaker kinematics or some other unknown effect.
- (IV) Clustering occurs in the $F_{max} T_d$ domain due to points (II) and (III). This can be described with the dynamic force function $F_{max} = K \cdot T_d^H$, where K is a constant.
- (V) If the impulse is linearised to parameterise its magnitude and form by $F_{max.eq}$ and $T_{d.eq}$ then K is twice the mean impulse area, and H assumes the value -1.
- (VI) Scale effects can be reduced if experiments are conducted in large flumes however unless sea water is employed, similarity in aeration characteristics and therefore compressibility can not be assumed.

(VII) It was not possible to properly assess scale effects on the impulse because of a lack of geometric similarity, however a reasonably close comparison between large scale results and predictions based on small scale tests was obtained suggesting that scale effects on the impulse may be minimal.

(VIII) If T_r is assumed to be zero, and the structure natural frequency is known, then the maxima of the product of the dynamic force function and a dynamic amplification function might be considered the maximum static load for design purposes.

The analysis and interpretation presented is highly simplified and is intended to illustrate the basis of an approach. Areas of necessary further development include;

(I) Allowing non zero rise times.

The rise time can be measured fairly simply and used to select a more appropriate, dynamic amplification function. The ratio T_r/T_d may be affected by scale.

(II) Accounting for significant air induced force oscillations.

The entrapment of a long and large oscillating air pocket is recognised as resulting in a significant and dangerous loading condition. It is probably a relatively rare event because it requires a normal direction of approach and a relatively clean wave form. A similar danger may arise due to group dynamics of bubble clouds.

(II) The mean dynamic force function was used to predict equivalent static loads. For design purposes the loading should be calculated on the basis of the worst case with a chosen probability of occurrence within the design life. If the model test conditions have been chosen to represent events with a known return period then the smooth distribution of measured impulses should allow a confident estimate of a realistic design impulse magnitude.

(III) The method of impulse definition.

The use of a low pass filter to define the impulse seems to work well. The cut off frequency should be decided upon with a consideration of the way the structure will respond to that frequency. Similarly the process of obtaining $T_d.eq$ and $F_{max.eq}$ could be developed with more consideration of the structure dynamics.

(IV) Directionality.

The waves angle of approach has not been dealt with although its inclusion may be relatively straightforward. This method is based on momentum transfer at the plane of the caisson face which might be expected to vary relatively simply with angle of approach.

(V) Accounting for the structure response.

The conversion of dynamic loads to equivalent static loads has been based on the dynamic amplification factors published by Oumeraci and Kortenhaus (1994). These were derived by reducing the description of the caisson motion to a simplified single degree of freedom model. This was intended to "constitute a useful guide for judgement in developing design load specifications". There are many limitations which have been discussed in their paper regarding their model and modelling of structural dynamics in general. In the light of their comments it would be preferable, though more complex, to use a numerical model rather than a dynamic amplification function to account for structure response.

(VI) Assessment of the effect of breaker shape on the impulse momentum fraction. This varies with breaker type so it will reach a measurable maxima at some breaking condition. This might be multiplied by the design wave momentum in order to calculate a worst case impulse momentum. From this the constant K is obtained, and so the dynamic load function is known. The effect of variations in the incident wave and physical boundary conditions on the impulse momentum fraction should be easier to assess than for impact pressure maxima because of its more compact distribution. It is also far less sensitive to the characteristics of measurement equipment and test procedures. For these reasons scale effects may be also be easier to assess.

The main advantage of this approach is that it provides a means of interpreting the results of physical model tests in a way which is meaningful for structural design. This means that nature can be left to resolve the complexities of the breaker shape, a problem which can not yet be fully solved through numerical modelling.

Future work

Measurements of entrained and entrapped air are in progress at the University of Plymouth in order to examine their effect on the impulse form and magnitude and wave impact pressures. This work is being conducted both in the laboratory and in the field (Crawford, *et al* 1994, Walkden, *et al*, 1995 and Bird *et al*, 1997). It is hoped that the results will help explain the distribution of data along the dynamic load function, provide insights into the relationship between entrapped air and the force impulse and provide data with which to test possible scale effects.

Acknowledgements

The work described in this paper was in part carried out under contract MAS2-CT92-0047 of the European Union's Marine Science and Technology Programme. This, together with co-operation and facilities made available by the Franzius Institut, Universitat Hannover and the Technischen Universitat Braunschweig are gratefully acknowledged.

CHAPTER 201

WAVE OVERTOPPING RATE AND REFLECTION COEFFICIENT FOR OBLIQUELY INCIDENT WAVES

Yoichi MORIYA¹ and Masaru MIZUGUCHI²

Abstract

Recently, wave overtopping over a vertical wall for normal incidence were treated analytically on the basis of the wave energy flux concept (Mizuguchi, 1993). In this study, the Mizuguchi's model for normal incidence is extended to oblique incidence. Incident wave angle effect on the wave overtopping rate is investigated. Validity of the extended model is checked experimentally. Satisfactory agreement between the extended model and the experimental results was found for the wave overtopping rate.

1. Introduction

Wave overtopping for oblique incidence has been studied experimentally in several papers. The influence of the incident wave angle on wave overtopping tests over a vertical wall was studied by using regular waves by Inoue and Tuchiya (1971) or using irregular waves by Takayama et al. (1984). Recently, several model tests have been performed, for example, de Waal and van der Meer (1992) ; Juhl and Sloth (1994), and so on. However, the quantitative estimation of wave overtopping rate does not agree among the previous studies. The disagreement partly comes from the varying wave height in front of the wall.

Recently, for normal incidence, a set of simple equation to estimate the wave overtopping rate over a vertical wall and the reflection coefficient were derived

(Mizuguchi, 1993). The model, which does not include any experimental constants, is based on the energy flux concept with an assumption of partially standing waves. The validity of the model was confirmed by experiment (Yokoyama and Mizuguchi, 1993).

The purpose of this study is to investigate the influence of the incident wave angle on wave overtopping rate and reflection coefficient, by extending the model for normal incidence to oblique incidence. Validity of the extended model is checked experimentally.

2. Theoretical Approach

Wave field in front of vertical wall for oblique incidence

Figure 1 shows the coordinate system. When oblique waves incident a vertical wall, wave field in front of the vertical wall fully apart from the wall end is free from scattering waves forms bi-directional wave field. We supposed that wave field is uniform along the wall.

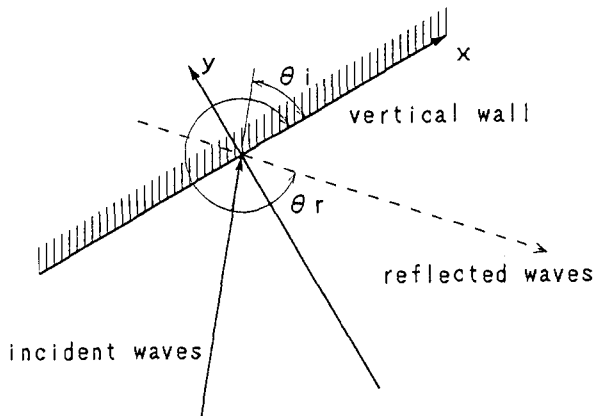

Figure 1 Coordinate system.

A finite amplitude wave theory is needed in evaluating the overtopping rate for waves with large height, especially in estimating the threshold wave height for overtopping. Since coastal structure are normally built in shallow water areas, the wave theory to be employed is the linear superposition of the first order cnoidal waves. The interaction between the incident waves and the reflected waves may be negligible as the interaction time is short. Surface elevation η in front of the vertical wall may be given by following formula:

$$\eta = \eta_i + \eta_r \quad (1)$$

$$= \frac{H_i}{2} [cn^2(\varphi_i; \kappa) - \overline{cn}] + \frac{H_r}{2} [cn^2(\varphi_r; \kappa) - \overline{cn}] \quad (2)$$

in which φ is the phase:

$$\varphi_j = \frac{K(\kappa)}{\pi} \{kx \cos \theta_j + ky \sin \theta_j - \sigma t\} \quad j=i, r \quad (3)$$

where, H is the wave height, k is the wave number, σ is the angular frequency, θ is the wave angle, $K(\kappa)$ is the complete elliptic integral of the first kind of modulus κ . The symbols cn denotes Jacobian elliptic function with modulus κ , and an overbar represents the average value over one period. The subscript i and r denote the quantity of the incident waves and the reflected waves, respectively.

Horizontal velocities of x and y direction, u and v , in front of the wall may be given by following formula:

$$u = \sqrt{\frac{g}{h}} (\eta_i \cos \theta_i + \eta_r \cos \theta_r) \quad (4)$$

$$v = \sqrt{\frac{g}{h}} (\eta_i \sin \theta_i + \eta_r \sin \theta_r) \quad (5)$$

where, g is the gravitational acceleration and h is the water depth.

Wave overtopping

Figure 2 shows schematic illustration of the wave overtopping over a vertical wall. For normal incidence, wave overtopping discharge is evaluated using an ideal fluid flow model over a sharp-edge weir by Kikkawa et al. (1967). When oblique waves are incident on a vertical wall, surface rise of the wave crest progresses along the wall. Wave overtopping for oblique incidence is supposed to be a kind of overflow of the surface rises over the wall. Then wave overtopping discharge, q_e , for oblique incidence averaged over one wave period may be given by following formula:

$$q_e = \frac{2\sqrt{2g}}{3T} \int_{\eta_t > H_c} \left\{ \left(\frac{v_w^2}{2g} + \eta_e - H_c \right)^{\frac{3}{2}} - \left(\frac{v_w^2}{2g} \right)^{\frac{3}{2}} \right\} dt \quad (6)$$

Figure 2 Schematic illustration of wave overtopping over a vertical wall.

where, T is the wave period, H_c is the crown height of the vertical wall above the still water level, η_e is the overtopping waves at the wall (η at $y = 0$) and v_w is the approaching velocity perpendicular to the wall.

Energy flux conservation

Figure 3 Schematic illustration of the energy flux conservation.

We consider the balance of the energy flux among the incident waves, the reflected waves and the wave overtopping flow. Figure 3 shows schematic illustration of wave energy

flux conservation. Here, F_x and F_y are the energy flux of x and y direction and F_e is the energy loss due to overtopping. We assume that the phenomenon of x direction (along the wall) is uniform, so the balance of energy flux yields following formula:

$$E_i c_g \sin \theta_i + E_r c_g \sin \theta_r = F_e \quad (7)$$

or

$$f_{2i} H_i^2 \sin \theta_i - f_{2r} H_i^2 K_r^2 \sin \theta_i = \frac{2\sqrt{2g}}{3T\sqrt{h}} \int_{\eta_e > H_c} \left\{ \left(\frac{v_w^2}{2g} + \eta_e - H_c \right)^{\frac{3}{2}} - \left(\frac{v_w^2}{2g} \right)^{\frac{3}{2}} \right\} \left(\eta_e + \frac{1}{2g} |u_w^2 + w_w^2|_{z=0} \right) dt \quad (8)$$

where, K_r is the reflection coefficient defined as the wave height ratio and u_w is the velocity along the wall. f_2 is the ratio between the energy and the wave height square on the first order cnoidal wave theory (Isobe, 1985), and is 1/8 for the small amplitude wave theory.

Equation (8) gives the reflection coefficient, when incident wave height, period and angle are prescribed together with geometry or the freeboard of the vertical wall. The wave overtopping discharge can be estimated from eq. (6) by using the reflection coefficient.

Numerical calculation

We performed numerical calculation of this model. We examine the influence of the incident wave angle and the incident wave height while water depth 20.0 cm and wave period 1.2 s are kept constant.

Figure 4 shows examples of the calculated non-dimensional overtopping rate q_e/q_0 and reflection coefficient K_r with respect to incident wave angle. Wave overtopping discharge, q_e , is non-dimensionalized with q_0 defined as

$$q_0 = \frac{H_i \sqrt{gh}}{2} \quad (9)$$

We performed the calculation using not only the first order cnoidal wave theory but also the small amplitude wave theory. It is clear that the wave overtopping rate and the reflection coefficient slightly decrease with the decrease of the incident wave angle. Significant decreases of more than 10%

Figure 4 Examples of the calculated non-dimensional overtopping rate q_e/q_0 and reflection coefficient K_r with respect to incident wave angle. (calculation condition $h=20\text{cm}$, $T=1.2\text{s}$, $H_i=6\text{cm}$, $H_c=3\text{cm}$)

Figure 5 Examples of the calculated non-dimensional overtopping rate q_e/q_0 and reflection coefficient K_r with respect to incident wave height. (calculation condition $h=20\text{cm}$, $T=1.2\text{s}$, $\theta_i = \pi/3$, $H_c=3\text{cm}$)

are expected only for the incident wave angle less than $\pi/4$. Nonlinear effect yields the increase of the overtopping rate and the decrease of the reflection coefficient.

Figure 5 shows examples of the calculated non-dimensional overtopping rate q_e/q_0 and reflection coefficient K_r with respect to incident wave height. The difference between for the small amplitude waves and for the cnoidal waves in the overtopping rate and the reflection coefficient becomes larger as the incident wave height gets larger.

3. Experimental Confirmation

Experimental facilities

Figure 6 Experimental facilities and the coordinate system.

Experimental confirmation of this model is undertaken by using a multi-directional wave basin. Figure 6 shows the experimental facilities and the coordinate system. The basin is 10.5 m wide, 6.8 m long and 0.6 m depth. The distance from wave paddles to opposite end-wall is 5.2 m. The concrete floor of the basin is almost flat. The multi-directional wave maker consists of 28 piston-type wave paddles continuously linked or 29 sets of actuator rod. Each paddle is 30 cm wide and 50 cm high.

A vertical wall with 12.0 cm high and 540 cm long is installed in the basin. The influence of the scattering waves from the wall ends may be suppressed by placing wave absorbers around the wall ends.

In a multi-directional wave basin, generating a uniform wave field with the target value of wave height and angle is important. However, it is well known that both wave height and angle of generated regular waves show considerable spatial variation. The main cause is the finite length of the wave maker. The effect of the discontinuity at both ends of the wave maker may be suppressed by employing linear decrease of wave paddle amplitude (Mizuguchi, 1994). We applied this ends control method.

Water depth $h = 10.0$ cm, the crown height of the wall $H_c = 2.0$ cm, and a wave period of $T = 1.0$ s are kept constant. Incident wave height and incident wave angle are varied.

Wave field in front of the wall

Non-overtopping experiments (incident wave height $H_i = 1.0$ cm) were carried out in order to check the uniformity of the wave field in front of the vertical wall. Wave gauges are installed 1.0 cm distant perpendicularly to the wall. An array of wave gauge and electro-magnetic current meter measures the surface elevation and the horizontal velocity at the same point $1/12$ of wave length perpendicularly apart from the wall.

Figure 7 shows the wave height and the total amplitude of the horizontal velocity distribution in front of the vertical wall for non-overtopping cases. Wave field in front of the wall can be assumed to be uniform at the center of the wall. Where we measure wave overtopping discharge for all the cases.

Separation method between incident and reflected waves

A separation method is developed to evaluate the reflection coefficient and the reflected wave angle from the measured data. The method assumes the linear superposition of the incident waves and the reflected waves, both of them being long waves.

Mathematically, we have eq. (10), eliminating η_i and η_r from eqs. (1), (4) and (5),

$$\frac{\sqrt{h/gu} - \eta \cos \theta_i}{\sqrt{h/gv} - \eta \sin \theta_i} = \frac{\cos \theta_r - \cos \theta_i}{\sin \theta_r - \sin \theta_i} = \alpha \quad (10)$$

where, α is theoretically a constant, although α vary for a measured data. Symmetrical reflection ($\theta_r = 2\pi - \theta_i$) gives $\alpha = 0$. Incident waves and reflected waves are calculated by following formula,

(a) $\theta_i = \pi/2$

(b) $\theta_i = 5\pi/12$

(c) $\theta_i = \pi/3$

(d) $\theta_i = \pi/4$

(e) $\theta_i = \pi/6$

(f) $\theta_i = \pi/12$

Figure 7 Wave height and total amplitude of horizontal velocity distribution in front of the wall.

$$\eta_i = \frac{\sqrt{h/gv} - \eta \sin \theta_r}{\sin \theta_i - \sin \theta_r} \left(= \frac{\sqrt{h/gu} - \eta \cos \theta_r}{\cos \theta_i - \cos \theta_r} \right) \quad (11)$$

and

$$\eta_r = \eta - \eta_i. \quad (12)$$

Reflection coefficient is the ratio between the incident wave height and the reflected wave height.

Wave overtopping rate and reflection coefficient

Incident wave heights are $H_i = 2.0, 2.5, 3.0$ and 3.5 cm in wave overtopping experiments. The wave overtopping discharge are measured by using a wave gauge in the box installed just behind the wall.

Figure 8 shows examples of measured data of surface elevation η and horizontal velocities u and v . Figure 9 shows separated incident waves and reflected waves calculated from equation (10) and (11) together with the time series of α , as using data shown in Fig. 8. Reflected wave angle is calculated by using mean value of α passed from -1 to 1.

Figure 10 shows reflected wave angle obtained from experimental data. When incident wave angle is large, the reflected wave angle shows almost symmetry. However, when incident wave angle is small, the reflected wave angle shows large discrepancy from symmetrical reflected angle. We may consider the reason why the separation method for incident and reflected waves suffers strongly influence from experimental noise. Figure 11 shows incident wave height obtained from experimental data. Incident wave height is almost the same as the target value. When incident wave angle is large, the validity of the separation method was confirmed.

Figure 12 shows measured and calculated wave overtopping rates and reflection coefficients with respect to the incident wave angle. Wave overtopping was not observed, for incident wave height $H_i = 2$ cm of all incident wave angles and $H_i = 2.5$ cm of incident wave angle $\theta_i = \pi/4, \pi/6$ and $\pi/12$. When wave overtopping occurs, good agreement between the model and the experiment results is found for the wave overtopping rate. The reflection coefficients for large incidence ($\theta_i = \pi/2, 5\pi/12$ and $\pi/3$) show reasonable values. For small incident wave angle, the reflection coefficient obtained from experimental data did not plot.

4. Conclusion

Wave overtopping over a vertical wall for the oblique incidence were treated analytically by extending normal incidence (Mizuguchi's) model. Wave overtopping rate and reflection coefficient can be estimated from the extended model which does not include any experimental constants. The results of numerical calculation show the slightly decrease of the wave overtopping rate with the decrease of the incident wave angle.

Experimental confirmation of this model was undertaken by using a multi-directional wave basin. Satisfactory agreement between the model and the experimental results is found for the wave overtopping rate. The reflection coefficient for large incidence ($\theta_i = \pi/2, 5\pi/12$ and $\pi/3$) shows reasonable agreements. The validity of the model was confirmed at least for large incident wave angle.

CHAPTER 202

Sediment transport and wave reflection near a seawall.

Jonathon R. Miles¹, Paul E. Russell¹, David A. Huntley¹.

Abstract

This paper describes results of a field experiment to examine the effect of wave reflection on suspended sediment transport in front of a seawall. High frequency measurements of wave elevation, velocity and suspended sediment concentrations were made simultaneously on a natural beach and in front of a seawall at Teignmouth in South Devon (U.K.) in June 1995. Wave reflection at the natural beach was found to be dependent on frequency; low frequency waves being preferentially reflected while incident waves were dissipated. At the seawall the incident wave reflection coefficient was 0.9 indicating only a small amount of dissipation. The doubling of energy over the sea bed was found to greatly increase the suspended sediment concentrations in the water column, although the amount of this increase depended on the water depth. A data analysis technique was developed which allowed the incoming and outgoing wave contributions to the sediment transport to be analysed. In these accretionary conditions incoming waves transported sediment onshore in both wall and beach cases, while in the wall case sediment transported offshore by the outgoing waves balanced the onshore transport. Sediment build up which was observed at the top of the natural beach was not observed in front of the wall. Sediment maintained in suspension in front of the wall was available for longshore transport, and this was enhanced by the presence of the wall.

Introduction

Seawalls have been used for many years as a method of coastal protection on eroding shorelines. It has been suggested that the reflection of wave energy over the beach fronting the wall actually helps to erode the beach (Silvester 1977), but the processes controlling this erosion remain poorly understood. There has been considerable debate over the effect of the seawall on the beach in recent years

¹ Institute of Marine Studies, University of Plymouth, Drake Circus, Plymouth, U.K., PL4 8AA.

(Kraus, 1988; Kraus and McDougal, 1996), with experimenters carrying out laboratory experiments with moveable beds (e.g. McDougal et al., 1996) or carrying out surveys of defended and undefended coastlines (e.g. Griggs and Tait, 1988). Researchers into beach processes have identified driving forces behind beach morphology change using high frequency point measurements of suspended sediment concentrations and water velocities (e.g. Jaffe et al., 1984). This approach has been applied to the reflective seawall environment for the first time and the method and initial results are presented in this paper.

Method

To compare similar wave conditions in a surf zone with a reflective wall environment a location was required with a wall adjacent to a natural beach. The site chosen was Sprey point at Teignmouth in South Devon, UK which has a 7m high seawall fronted by a beach of slope 1/15. The sand in front of the wall is medium quartz sand with $D_{50}=0.24\text{mm}$. The beach is macro-tidal and morphodynamically intermediate. A rig designed to minimise interference with the hydro and sediment dynamic conditions whilst providing a stable base for instrumentation was built and bolted to the wall. An extendable rod was positioned on the front of the rig, extending close to the bed, to which the instruments were attached. Two EMCMs, (Electro Magnetic Current Meters) two OBSs (Optical Backscatter Sensors) and a PT (Pressure Transducer) were attached to this rod, 1.5m from the wall in a vertical array. A rig of instruments was also dug in to the adjacent beach on a similar depth contour so that comparisons could be made. This beach site had one EMCM, one OBS and one PT.

All of the *in-situ* monitoring devices were logged at a frequency of 8Hz and were pre-filtered between 3-4Hz. EMCM and PT offsets were determined in the field at the beginning and end of each tide. Surveys were carried out daily to establish beach morphology. Sediment samples were taken for size distribution analysis. During the period of observation and recording, in June 1995, the wind was generally light and the waves were, on average, 30cm in height at the breakpoint with an average period of 4 seconds. The robust design of the rig should enable measurements to be made in waves of up to 2m. The layout of the site is shown in figure 1:

figure 1. Experiment site at Teignmouth.

Instruments were calibrated both before and after the experiment, and the calibrations were applied to the raw data. EMCs were calibrated in a tow tank at the Royal Naval Engineering College (RNEC) at Manadon, Plymouth (U.K.). Pressure transducers were calibrated for water depth in a 3m deep tank at the RNEC. OBSs were calibrated in the laboratory using sediment samples taken from the experiment site. To calibrate the OBSs a paint stirrer was used to suspend sediment in a tank while samples of the beach sediment were filtered from next to the OBS head. This calibration of the OBSs provided an excellent linear correlation between suspended sediment concentrations and voltage output.

Time series

Time series of surface elevation and suspended sediment concentration are shown in figure 2. Time series have been selected so that water depths are similar in the wall and beach examples, in this case the water depth is approximately 0.8m. Instruments suspended from the wall are 1.2m away from it. This puts them closer to the antinode at the wall than the node 2.7m away from the wall (for a wave period of 4 seconds). The maximum surface elevation deviation from the mean is therefore clearly larger than that observed at the beach rig. Suspended sediment data which is

compared in these examples is taken from OBSs at similar heights, both being approximately 18cm from the bed. The scale of the axis of the wall OBS is reduced so that the data fits the plot. In similar incident wave conditions levels of suspended sediment are clearly much larger at the wall, reaching 4 kg/m^3 at this height above the bed, while at the beach OBS sediment concentrations only reach 0.6 kg/m^3 .

figure 2. Time series of surface elevation and suspended sediment concentrations at the wall and beach rigs. N.B. The sediment concentrations in the wall time series have been scaled down by a factor of 10.

Theory

Incoming and outgoing elevation time series were obtained from elevation and velocity time series using the method of Guza, Thornton and Holman (1984). The separation of incoming and outgoing waves forms the basis for most reflection analysis techniques which involve co-located elevation and velocity sensors. The analysis can also be extended to obtain the incoming and outgoing velocity time series. This allows the frequency dependent oscillatory sediment transport associated with the incident reflected waves to be found.

The derivation of Guza et al.'s (1984) time domain technique arises from linear shallow water theory:

The velocity potential for progressive water waves is as follows:

$$\phi = \frac{-a \cdot g}{\sigma} \cdot \frac{\cosh k(z+h)}{\cosh kh} \sin(kx - \sigma t)$$

The surface elevation can be obtained from this by differentiating with respect to time, and the attenuation term tends to 1 in shallow water.

$$\eta = \frac{1}{g} \left[\frac{\partial \phi}{\partial t} \right]_z = 0 \quad \text{giving} \quad \eta = a \cos(kx - \sigma t)$$

A similar equation for velocity is obtained by differentiating with respect to x

$$u = - \frac{\partial \phi}{\partial x} \quad \text{gives} \quad u = \frac{g a k}{\sigma} \cos(kx - \sigma t)$$

By dividing the elevation and velocity equations the following time domain transformation can be obtained relating velocity and surface elevation (provided the water is shallow).

$$\eta(t) = \frac{c}{g} u(t)$$

It is necessary to transform to the frequency domain and use full linear theory if this relationship is to be applied in intermediate or deep water.

Progressive wave surface elevation traces for waves incoming to a beach and outgoing from it can be obtained from the time series of elevation and velocity as follows:

$$\eta_{in}(t) = \left(\eta(t) + \frac{c}{g} u(t) \right) / 2$$

$$\eta_{out}(t) = \left(\eta(t) - \frac{c}{g} u(t) \right) / 2$$

In this case, a positive velocity implies an onshore flow, while a negative velocity an offshore flow. In order to obtain a frequency dependent reflection function (FDRF) it is necessary to carry out a spectral analysis of the incoming and outgoing elevation traces separately. After obtaining the power spectra of the incoming and outgoing elevation time series, $S_{ii}(f)$ and $S_{oo}(f)$ respectively, the frequency dependent reflection coefficient is simply:

$$R(f) = \sqrt{\frac{S_{ii}(f)}{S_{oo}(f)}}$$

This technique was examined for signal noise related bias by Huntley et al. (1995) who found that when the coherence between elevation and velocity was high, the bias in the FDRF was low. Two other techniques were discussed by Huntley et al. (1995). These were a frequency domain method by Tatavarti (1989) and a Principal Component Analysis method (Tatavarti et al., 1988). All three techniques were applied to the data in order that the frequency dependent reflection coefficient for the beach and wall cases could be identified. The three different methods were

found to offer similar results. This gives confidence in the time domain method which is the most simple to program and extend for incoming and outgoing sediment analysis.

In order to understand the effect of the reflected wave field on the suspended sediment transport, it is possible to carry out a cross-spectral analysis of the incoming and outgoing waves with the sediment.

It is first necessary to apply the transformation from elevation to velocity to obtain incoming and outgoing velocity time series. The appropriate transformations are:

$$u_{in} = \frac{g}{c} \eta_{in}$$

$$u_{out} = -\frac{g}{c} \eta_{out}$$

A wave crest (elevation maximum) correlated with onshore flow therefore represents a wave crest travelling onshore, while a wave peak correlated with an offshore velocity represents a wave crest travelling offshore. The equations for incoming and outgoing velocity are therefore:

$$u_{in} = \frac{1}{2} \left(u + \frac{g}{c} \eta \right)$$

$$u_{out} = \frac{1}{2} \left(u - \frac{g}{c} \eta \right)$$

It is next necessary to assume that the oscillatory sediment flux can be split into incoming and outgoing components. Jaffe et al. (1984) assumes a similar principle when considering the breakdown of the mean and oscillatory fluxes. They assume that the total velocity can be split into a mean and oscillatory component:

$$U = \bar{u} + u'$$

and that the sediment concentration is also separable into mean and oscillatory parts:

$$C_s = \bar{c}_s + c'_s$$

The time average of the flux therefore reduces to the mean flux and the flux coupling:

$$\overline{UC_s} = \bar{u} \bar{c}_s + \overline{u' c'_s}$$

Signals are routinely de-meant, and the remaining step is to split the oscillatory velocity into incoming and outgoing components before crossing with the suspended sediment to obtain the flux:

$$u' = u'_{in} + u'_{out}$$

The time average of the incoming and outgoing oscillatory flux is therefore:

$$\overline{u' c'_s} = \overline{u'_{in} c'_s} + \overline{u'_{out} c'_s}$$

Huntley and Hanes (1987) identified that the frequency dependent sediment transport could be found by taking the co-spectrum of the oscillatory cross shore velocity with the sediment concentration time series. The frequency dependent

sediment transport associated with the incoming and outgoing waves is therefore obtained from the co-spectrum of the incoming or outgoing velocity time series with the sediment time series. The contributions of the incoming and outgoing waves to the sediment transport can therefore be identified.

Frequency dependent wave reflection

Three methods were used to determine levels of energy incoming and outgoing from the natural beach and the wall. Incoming and outgoing wave spectra were obtained from the incident and reflected time series obtained using Guza et al.'s (1984) method. The frequency dependent reflection coefficient was then determined using this method and two frequency domain methods. All three methods require that the current meter and pressure transducers are co-located and log data simultaneously. The analysis was first applied to data from the beach rig (figure 3).

figure 3. Frequency dependent wave reflection at the beach. a: Incoming and outgoing wave spectra calculated using the time domain method. b: Coherence between calculated incoming and outgoing time series. c: Frequency dependent reflection coefficient calculated using time domain (solid), frequency domain (dashed) and principle component analysis (dotted) methods. d: Coherence between elevation and velocity. Water depth is 1.28m.

The energy spectra show clearly that the incident waves (frequency 0.25 Hz) are dissipated by the natural beach, while at a lower frequency (0.1Hz) wave reflection is taking place. By dividing the square root of the spectral estimates, the FDRF for this time domain method was obtained, and this shows a reflection coefficient of 0.1 for the incident waves on the natural beach while for the low frequency waves the reflection coefficient is 0.8. Of the three lines on the reflection coefficient figure above (top right), the lines show the methods of the time domain method (top), the frequency domain method (middle) and the Principal Component Analysis (bottom). The three methods give good agreement where there is good coherence between elevation and velocity.

A similar analysis was carried out to data from the wall rig. The results are shown in figure 4.

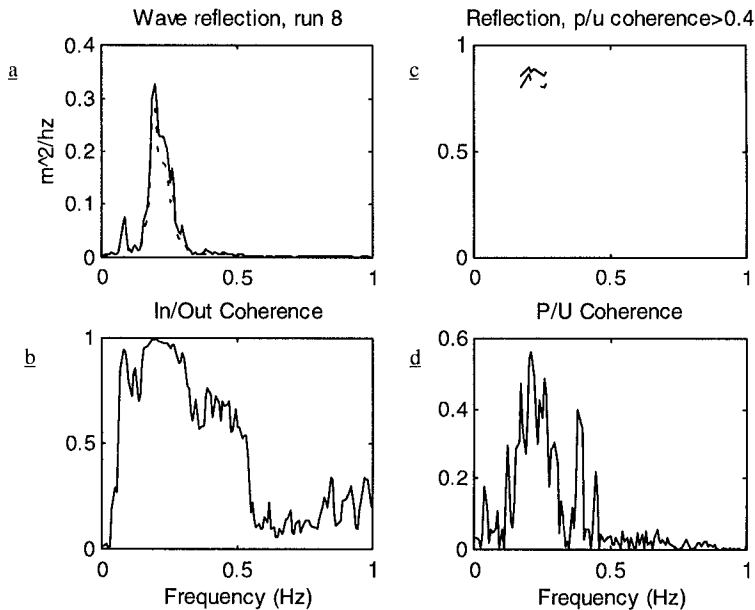

figure 4. Frequency dependent wave reflection at the wall. a: Incoming and outgoing wave spectra calculated using the time domain method. b: Coherence between calculated incoming and outgoing time series. c: Frequency dependent reflection coefficient calculated using time domain (solid), frequency domain (dashed) and principle component analysis (dotted) methods. Reflection estimates are plotted for values of P/U coherence > 0.4 so that there is 95% confidence in the coherence between P and U. This is necessary as cross spectral analysis is carried out in the determination of the FDRF using the frequency domain methods. d: Coherence between elevation and velocity. Water depth is 1.30m.

Similar amounts of energy were found in the spectra of both incoming and outgoing wave time series, indicating that reflection of the incident waves was occurring at the wall. At incident wave frequency all three methods of determining the frequency dependent reflection coefficient gave a value of 0.9 at the wall. The wall is in fact slightly sloping at the position of the rig and this may account for the reflection coefficient being less than unity.

Mean suspended sediment concentrations

The next part of the investigation was to examine the effect of the increase in reflection coefficient at the shoreline on concentrations of suspended sediment. To do this, data from OBSs on the beach and wall rig were compared. During the experiment OBSs were carefully positioned on each rig so that they were at the same height above the bed and are therefore comparable. Mean concentrations were calculated for each run. Mean water depths were also calculated and sediment concentrations in each case were then plotted against depth. The results are shown in figure 5.

figure 5. Mean suspended sediment concentrations - comparison of data from wall and beach OBSs. Both instruments were mounted approximately 18cm from the bed. Incident waves were approximately 30cm high at the breakpoint.

The results show a greater concentration of sediment was in suspension in front of the wall than was in suspension on the natural beach when water depths were the same. Incoming wave conditions did not vary significantly during this tide, and the results therefore imply that it is the increase in wave reflection at the shoreline which must be responsible for increasing the concentrations of suspended sediment in front of the wall. The distinct linear trend in the data, especially in the wall rig data suggests that it may be possible to parameterise the mean suspended sediment concentrations in this region in terms of the reflection coefficient, water depth, height above bed and incident wave height. Further experimentation with a larger array of instruments would be necessary for this however.

Frequency dependent sediment transport

The incoming and outgoing frequency dependent sediment transport was obtained for both wall and beach rigs for each run of data logged. A clear picture emerged in all runs as to the nature of this transport and this is shown in figure 6.

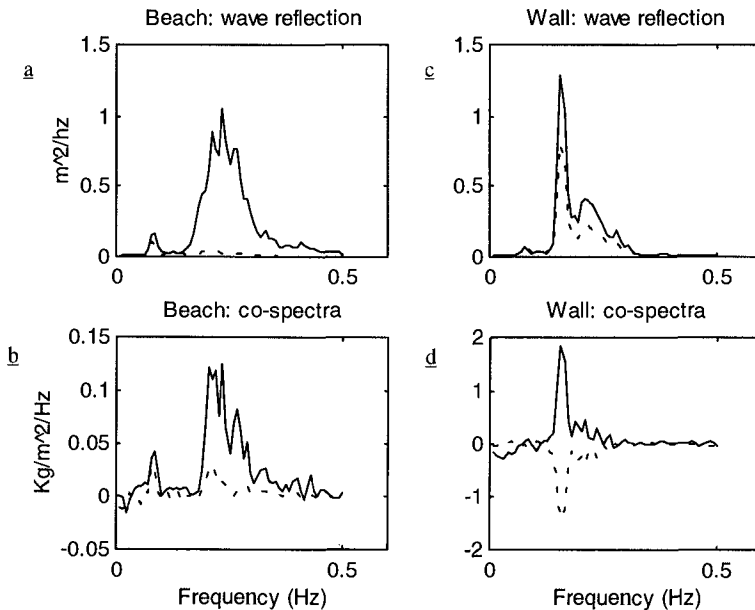

figure 6. Incoming and outgoing spectra and co-spectra in beach (a,b) and wall (c,d) cases. In the energy spectra plotted above, the solid lines represent incoming energy, the dashed lines represent outgoing energy. In the co-spectra, positive is onshore, solid lines are the cospectra between incoming waves and the sediment, dashed lines are cospectra between outgoing waves and sediment. Water depth is 1.3m

In the beach case (figure 6b), incoming waves are found to transport sediment onshore. This result is similar to that observed by Huntley and Hanes (1987). Suspension events occur at the same time as onshore directed flows, and the resultant transport is onshore. There is little energy outgoing from the beach however, and there is therefore little transport associated with the offshore directed waves.

At the wall, the situation is rather different (figure 6d). The incident waves are still responsible for onshore sediment transport, while the outgoing waves give rise to offshore transport. The onshore transport by the incoming waves is effectively halted by the outgoing waves. The net cross-shore oscillatory transport is therefore reduced. The fact that there is more sediment in suspension in front of the wall is also evident in this analysis as the magnitudes of the co-spectra are considerably larger in the wall case than in the beach case.

Longshore transport comparison

Mean longshore transport rates were calculated for both wall and beach rigs. The results are shown in figure 7.

figure 7. Longshore transport rates measured at the beach and wall.

Longshore transport rates in front of the wall were found to be greater than at the beach rig at all times, and this was attributed to both the increase in suspended sediment concentrations and also an increase in the longshore current which passed

in front of the wall. The south-westward direction of longshore transport in the wall case is a result of the oblique wave approach from the east (see figure 1).

During the period of observation, morphology changes were monitored using surveying techniques. Increased levels of longshore transport along the Sprey point wall resulted in the development of a small bar to the south west of the wall. (extending SW from point 294990,73740; see figure 1). Shoreward of the beach rig, a net accretion was observed. This is likely to have resulted from the onshore transport by the incident waves. At the wall rig however there was no net accretion or erosion. The balance in transport between the incoming and outgoing waves prevented accretion taking place in this region, while increased levels of sediment in suspension led to an enhanced longshore transport of sediment in front of the wall.

Conclusions

This paper has described initial results of a field experiment to examine the effect of wave reflection on suspended sediment transport in front of a seawall. High frequency measurements of wave elevation, velocity and suspended sediment concentrations were made simultaneously on a natural beach and in front of a seawall. The doubling of energy over the sea bed was found to greatly increase the suspended sediment concentrations in the water column, although the amount of this increase depended on the water depth. A data analysis technique was developed which allowed the incoming and outgoing wave contributions to the sediment transport to be analysed. Incoming waves transported sediment onshore in both wall and beach cases, while in the wall case outgoing waves balanced the onshore transport. Sediment which was maintained in suspension in front of the wall was available for longshore transport, and this was enhanced by the presence of the wall.

Symbols

a	wave amplitude
c	wave celerity
c_s	sediment concentration
f	wave frequency
g	gravitational acceleration
h	water depth
k	wave number ($2\pi/\lambda$)
t	time
u	horizontal cross shore velocity
x	horizontal co-ordinate
z	vertical position. $z = 0$ at the surface, $z = -h$ at the bed
R(f)	frequency dependent reflection coefficient
S_{ii}	power spectrum of incoming wave time series
S_{oo}	power spectrum of outgoing wave time series
T	wave period

σ	angular frequency ($2\pi/T$)
η	surface elevation
λ	wavelength
ϕ	velocity potential
in	denotes incoming wave
out	denotes outgoing wave

CHAPTER 203

WAVE ENERGY DISSIPATION IN KELP VEGETATION

Alfonse Dubi¹ and Alf Tørum²

ABSTRACT

A laboratory experiment was carried out to investigate wave energy dissipation in a coastal kelp field of *Laminaria hyperborea* with a purpose of finding the damping rate. Parameters measured were wave heights at 8 locations along the direction of wave propagation, forces on artificial kelp plants, and velocities in between the plants in 4 different water depths. It was found that in 4, 6, 8 and 10 meter water depths, the damping coefficient was 0.0094, 0.0032, 0.0014 and 0.0005m⁻¹ respectively. Results show that the damping rate varies with population density, size of plant, water depth and wave period.

1. INTRODUCTION

Through a variety of processes, waves lose energy. Among the commonly known processes are wave breaking, bottom friction, reflection and interaction with porous beds and soft muds. Waves propagating through vegetation also lose energy due the work done on the vegetation.

Following Ippen (1966), the wave amplitude attenuation can be evaluated through the steady-state conservation of wave energy flux equation:

$$\nabla \cdot (E \vec{C}_g) = -E_D \dots\dots\dots(1.1)$$

where $E = \frac{1}{2} \rho g a^2$ is the wave energy density, ρ is the density of water, C_g is the group velocity and E_D is the energy dissipation rate. The local wave amplitude a is found to decay exponentially (see for example, Asano et al., 1992) as

$$a(x) = a_o e^{-k_i x} \dots\dots\dots(1.2)$$

where k_i is the damping rate (also known as the damping coefficient) of the wave height with distance and $a = a_o$ at $x = 0$.

In a study on the interaction between ocean waves and a kelp farm, Dalrymple et al. (1982) arrived at a wave height attenuation formula of the form:

¹ Research Fellow, Institute of Marine Sciences, University of Dar Es Salaam, P.O. Box 668 Zanzibar, Tanzania.

² Professor/Head of Research, Dept. of Structural Eng., NTNU/SINTEF-NHL, N-7034 Trondheim, Norway.

$$\frac{a(x)}{a_0} = \left(\frac{1}{1 + \alpha_d x} \right) \dots\dots\dots(1.3)$$

where

$$\alpha_d = \frac{2C_D}{3\pi} \left(\frac{d_k}{b} \right) \left(\frac{a_0}{b} \right) \left[\sinh^3 kd + 3 \sinh kd \right] \left[\frac{4k}{3 \sinh kD (\sinh 2kD + 2kD)} \right] \dots\dots\dots(1.4)$$

in which only the real part of the wave number k is used. C_D is the drag coefficient assumed constant over depth, d is the height of plant above the bottom, d_k is the plant diameter, and b is the spacing between plants. This approximation, however, takes plants as rigid cylinders; an assumption which results in assigning different values to the drag coefficient to cover the ignorance of the plant motion. Dalrymple et al. (1982) applied Eq.(1.4) for waves propagating through *Macrocystis pyrifera* kelp forest using known values of $C_D = 1.0$, $d_k = 0.3$ meters, $b = 1.5$ meters and $D = 15$ meters. They found that incident wave heights of 6.1 meters with 10-20 seconds periods could be reduced by 50% over a distance of 800 meters. This is equivalent to $\alpha_d = 0.0013m^{-1}$ and applying the exponential law of attenuation, $k_i = 0.0009 m^{-1}$.

Recently, Kobayashi et al. (1991) developed an analytical model, hereafter known as the Kobayashi model, to describe a 2D problem of small amplitude waves propagating over submerged or subaerial vegetation. They assumed the effect of the vegetation to be expressible in terms of the drag resistance against the fluid motion. The vertical component of the drag resistance and the proximity effects of the surrounding strips on C_D were neglected. Although an analytical solution was obtained, the calibrated drag coefficient C_D varied widely due to the fact that the swaying motion of an individual vegetation stand had been neglected.

Later, Asano et al. (1992) improved the Kobayashi model by including the interaction between the wave and the vegetation motion. Whereas the Kobayashi gave the calibrated values of C_D to the order of 0.1, the model of Asano et al. produced C_D of the order unity and the vertical force was neglected while the horizontal drag force was assumed to be dominant and linearized as

$$F_x = \rho D_k u_2 \dots\dots\dots(1.5)$$

where D_k is a linear force coefficient determined by the least squares method, u_2 is the horizontal particle velocity in the vegetation zone. Solution of the linear model gives the dispersion equation as

$$\omega^2 = gk \frac{k \tanh kh + \alpha_k \tanh \alpha_k d}{k + \alpha_k \tanh \alpha_k d \tanh kh} \dots\dots\dots(1.6)$$

in which ω is the angular frequency, d is the vegetation height, h is the water depth above vegetation and

$$\alpha_k^2 = \frac{\omega k^2}{\omega + iD_k} \dots\dots\dots(1.7)$$

In the case of weak damping, $\omega \gg D_k$, separation of the real and imaginary parts of the dispersion equation yields the following

$$\omega^2 = gk_r \tanh k_r (h + d) \dots\dots\dots(1.8)$$

which implies that the presence of vegetation does not change the real wave number k_r as long as $\varepsilon_k \ll 1$. The damping rate is then approximated by

$$k_i = \varepsilon_k k_r \frac{2k_r d + \sinh 2k_r d}{2k_r (h + d) + \sinh 2k_r (h + d)} \dots\dots\dots(1.9)$$

where $\varepsilon_k = \frac{D_k}{2\omega} \dots\dots\dots(1.10)$

On the other hand, applying the energy conservation equation, Eq.(1.1), and invoking Eq.(1.2), the Kobayashi model gives the damping rate as

$$k_i = \frac{D_k}{C_g} \left(\frac{2k_r d + \sinh 2k_r d}{2 \sinh 2k_r (h + d)} \right) \dots\dots\dots(1.11)$$

A more recent theoretical model based on limited experimental data is that of Wang and Tørum (1994) in which the dispersion equation is given by

$$\omega^2 = \frac{\tanh kh - \frac{i}{\alpha f_x} \tanh k_s h_s}{1 - \frac{i}{\alpha f_x} \tanh k_s h_s \tan kh} \dots\dots\dots(1.12)$$

where $\alpha = \sqrt{\left| \frac{f_z}{f_x} \right|}$ is the force ratio $\dots\dots\dots(1.13)$

and $k_s = \alpha k$, f_x and f_z are linearized horizontal and vertical force coefficients respectively, h_s = height of plant. The complex wave number is solved by iteration for known parameters and an assumed value of $\alpha = 0.8$.

Results from this model show that the damping coefficient increases with increasing wave period until it reaches an asymptotic values of just below $0.0015m^{-1}$, $0.0020m^{-1}$ and $0.0025 m^{-1}$, for densities of 8, 12 and 16 plants/ m^2 .

In this paper three different ways of finding the damping rate are used and compared. The first way is to get an analytical expression of the energy dissipation rate E_D using the linearized dissipative force and then apply Eq. (1.1). The second way, is to get a numerical value of the dissipation rate from time series of the horizontal velocities measured in between the plants and the corresponding horizontal force on the plants and apply Eq.(1.1) again. The third way, is to solve the complex dispersion equation for the complex wave number k by iteration as proposed by Wang and Tørum, (1994).

2. THE DAMPING RATE

2.1 Energy dissipation and the damping rate

Energy dissipation considered to be real and positive takes place mainly in the vegetation zone and partly in the boundary layer at the interface and near the solid

bottom. For a given volume of the vegetation zone, energy dissipation during a time period T is given by (e.g Madsen, 1974)

$$E_D = \frac{1}{T} \int_t^{t+T} \int_V \vec{F} \cdot \vec{U} dV \dots\dots\dots(2.1)$$

where $\vec{F} = \vec{F}(x,y,z,t) = (F_x, 0, F_z)$ is the dissipative force vector in the vegetation zone and $\vec{U} = (u_2, 0, w_2)$ is the complex velocity vector for the 2D case. Defining the force and velocity vectors as $(\mathbf{i}, \mathbf{j}, \mathbf{k})$ in the (x, y, z) directions as

$$\left. \begin{aligned} \mathbf{F} &= F_x \mathbf{i} + F_z \mathbf{k} \\ \mathbf{U} &= u \mathbf{i} + w \mathbf{k} \end{aligned} \right\} \dots\dots\dots(2.2)$$

and substituting into Eq.(2.1) we get

$$\left. \begin{aligned} E_D &= \frac{1}{T} \int_t^{t+T} dt \int_{-(h+d)}^{-(h+l_k)} (F_x \cdot u_2 + F_z \cdot w_2) dz \\ &= \frac{1}{T} \int_t^{t+T} dt \int_{-(h+d)}^{-(h+l_k)} F_x \cdot u_2 \left(1 + \alpha^2 \left(\frac{w_2}{u_2}\right)\right) dz \end{aligned} \right\} \dots\dots\dots(2.3)$$

The second term under the integral in Eq.(2.3) is found to be at least of the order α^2 and if we assume that $w_2/u_2 = O(\alpha^2) \ll 1$, which is generally true in coastal waters (Mei, 1982), the time averaged energy dissipation then becomes

$$E_D = \frac{1}{T} \int_t^{t+T} dt \int_{-(h+d)}^{-(h+l_k)} F_x \cdot u_2 dz + O(\alpha^4) \dots\dots\dots(2.4)$$

The dissipative force is linearized and expressed as

$$F_x = \rho f_{dx} u_2 \dots\dots\dots(2.5)$$

where f_{dx} is a linear drag force coefficient (Dubi, 1995) given as

$$f_{dx} = \frac{4n_k \alpha_r F_\lambda k_s |1 - A_m| \cosh^2 k_s h_f}{\rho(2k_s d + \sinh(2k_s d))} \dots\dots\dots(2.6)$$

where n_k is the number of plants per unit horizontal area, α_r is a force reduction factor accounting for group shielding and is found experimentally as a fitting coefficient equal to 0.08. F_λ is an empirical force coefficient evaluated at the canopy level, i.e. at

$z = -(h + l_k)$ and $h_f = (d - l_k)$ where l_k is half length of the kelp frond. A_m is the velocity amplification factor obtained from the solution for the vegetation motion. The complex horizontal velocity in the vegetation zone is given in Dubi and Tørum (1994) as

$$u_2 = \frac{iCk}{\omega f_x} \cosh(k_s(h + d + z)) \exp[i(kx - \omega t)] \dots\dots\dots(2.7)$$

where

$$C = \frac{ga}{\cosh(k_s d) \cosh(kh) \left[1 - \frac{i}{\alpha f_x} \tanh(k_s d) \tanh(kh) \right]} \dots\dots\dots(2.8)$$

Substituting Eq.(2.7) into Eq.(2.4) we get the linearized form of energy dissipation, after time averaging, as

$$E_D = \frac{\rho f_{\dot{a}x}}{2} \int_{-(h+d)}^{-(h+l_k)} |u_2|^2 dz = \frac{\rho f_{\dot{a}x} |C|^2 |k|^2 \sinh(2k_s h_f) + 2k_s h_f}{2\omega^2 |f_x|^2 4k_s} \dots\dots\dots(2.9)$$

in which only the real part is considered. Substituting Eq.(2.9) into Eq.(1.1) for the 2D case we have

$$\frac{\partial}{\partial x} (EC_g) = \frac{1}{2} \rho g C_g \frac{\partial a^2}{\partial x} = -Ba^2 \dots\dots\dots(2.10)$$

in which C_g is assumed to be constant due to constant water depth and

$$B = \frac{\rho g^2 |\alpha k|^2 f_{\dot{a}x}}{2\omega^2 F^2 |\alpha f_x - iG|^2} \left(\frac{\sinh(2k_s h_f + 2k_s h_f)}{4k_s} \right) \dots\dots\dots(2.11)$$

where $F = \cosh k_s d \cosh kh$ and $G = \tanh k_s d \tanh kh$. The solution of Eq.(2.10) is

$$\frac{a}{a_0} = e^{-\frac{B'}{2}x} \dots\dots\dots(2.12)$$

where $B' = B/1/2\rho g C_g$. Equating Eq.(2.12) and Eq.(1.2) we find the damping rate to be

$$k_i = \frac{g|\alpha k|^2 f_{\dot{a}x}}{2\omega^2 F^2 |\alpha f_x - iG|^2 C_g} \left(\frac{\sinh(2k_s h_f + 2k_s h_f)}{4k_s} \right) \dots\dots\dots(2.13)$$

in which we shall adopt $|k| \cong k_r$ derived from the solution of the dispersion equation.

2.2 Solution of the complex dispersion equation and the damping rate.

The dispersion equation contains complex unknown variables k and f_x . The angular frequency ω is real and assumed to be known. The solution for the complex dispersion equation is found by iteration when Eq.(1.12) is rewritten as:

$$F(k, f_x) = \omega^2 \left(1 - \frac{i}{\alpha f_x} \tanh(k_s d) \tanh(kh)\right) - gk(\tanh(kh) - \frac{i}{\alpha f_x} \tanh(k_s d)) = 0 \dots (2.14)$$

The iteration scheme is carried out as follows:

(i) As a starting approximation we apply Eq.(2.14) for very small damping force coefficient, that is, for $f_x \rightarrow -i$, leading to an approximate solution for the wave number k_o for given α, ω, h and d . Then $k_1^{(o)} = \text{real}(k_o)$

(ii) With an initial guess $k_2^{(o)}$ for the imaginary part of k , we solve Eq.(2.14) with $k^{(o)} = k_1^{(o)} + ik_2^{(o)}$ as initial value input. The solution gives $k_r = \text{Re}(k)$ and $k_i = \text{Im}(k)$. The convergence criterion for the case is

$$\left| \frac{k^{(n)} - k^{(n-1)}}{k^{(n)}} \right| \leq e(k) \dots (2.15)$$

with $e(k)$ being an arbitrary small number which in our case is set equal to 10^{-5} . Results of the damping coefficient computed from the dispersion equation shall be compared with those obtained from the energy dissipation equation.

2.3 The damping rate from measured force and horizontal particle velocity

The damping rate can also be evaluated by making use of the measured force and horizontal velocity time series. Integrating the product of these two quantities and time averaging gives the energy dissipated per unit time as

$$E_D = \frac{1}{AT} \int_0^T F_m U_m \cos^2 \omega t \, dt = \frac{1}{2} \frac{F_m U_m}{A} \dots (2.16)$$

where F_m is the total measured force amplitude and U_m is the measured horizontal velocity amplitude. To get energy dissipation per unit horizontal surface area we have divided by $A = 8 \text{ m}^2$, which is the horizontal surface area of the shear plate used in the experiment. Inserting Eq.(2.16) into Eq. (1.1) we find that

$$k_i = \frac{1}{A} \frac{F_m U_m}{\rho g C_g \alpha_o^2} \dots (2.17)$$

in which ρ, g, C_g and maintain the same definition as in previous formulae, converted to full scale. For irregular waves we shall take significant force and significant velocity.

3. LABORATORY EXPERIMENT

The experiment was carried out in a 33 m long, 1 m wide and 1.6 m high wave tank as shown in Figure 1. The width of the channel was partitioned to give a width of 0.5 m. Five thousand models (scale 1:10) of *Laminaria hyperborea* plants were fixed on the bottom over a span of 9.3 meters. This represented a density of about 0.12 plants per horizontal square centimeter in the laboratory or 12 plants/square meter in the field. The setup consisted of eight capacitance wave gauges to measure surface elevations, one shear plate which was fixed flush with the bottom, to measure the horizontal force and a mini-current meter which was inserted in between the plants 4 centimeters above the shear plate to measure horizontal particle velocities. One of the wave gauges was placed above the shear plate. The first wave gauge, taken to be located at $x = 0$ and the last taken to be located at $x = 7$ m, were fixed about 1.2 meters inward from the inner and outer boundaries respectively.

We started with 6 m water depth and tested with regular waves with periods ranging from 4-14 seconds, full scale. With the same water depth, irregular waves with peak periods ranging from 4-14 seconds were tested. For each wave period, several wave heights were tested.

Figure 1 Laboratory experiment layout

4. RESULTS

(1) The exponential decay model given by Eq.(1.2) was fitted to measured data by regression analysis based on the least squares method. Figure 1 shows an overview of the exponential decay of the wave heights with respect to distance from the origin. Figure 3 shows theoretical variation of the damping rate with wave period T obtained from Eq.(2.14) and Eq.(2.13) for total water depth $D = 6$ m using the following kelp

plant properties: total kelp height $d = 2\text{m}$, frond half length $l_k = 0.5\text{m}$, density of kelp $\rho = 1120\text{ kg/m}^3$, mass of frond and stipe = 0.75 kg/m , linearized spring constant $k_o = 20\text{N/m}$, linearized (empirical) force coefficient $F_\lambda = 30\text{N}/(\text{m/s})$, added mass for both frond and stipe $C_a = 1$, number of plants per horizontal square meter $n_k = 12\text{plants/m}^2$. For the given parameters the damping rate using Eq.(2.13) increases with the wave period for small values of T to a maximum and then decreases gently for larger values of T to an almost asymptotic value. On the other hand, the damping rate from the dispersion equation decreases rapidly for larger values of T . In the same figure, we also compare the damping rates derived from Eq.(1.11) given by Asano et al. (1992) and the solution of the dispersion equation given by Wang and Tørum (1994).

(2) Figure 4 shows a comparison of theoretical values obtained from Eq.(2.13) with those obtained experimentally for irregular waves in a water depth of 4m. Theoretical models by Asano et al. (1992) and Wang and Tørum (1994) are also compared to the measured data points.

(3) Figures 5 through 8 show a comparison of theoretical values of the energy dissipation equation with measured values from regular and irregular waves in water depths of 6, 8 and 10 meters. From these figures we observe several things:

First, the experimental damping coefficient varies more widely for shorter peak periods and almost converges (narrower scatter) for longer peak periods.

Second, for longer peak periods the theoretical damping coefficient is almost independent of the peak period despite a gradual decrease.

Third, when we compare the damping rates in 4 and 6 meters water depths, we find larger values for the shallower water. We may conclude that the shallower the water, the higher the damping coefficient. This observation is also in agreement with field results by Mork (1995).

Fourth, The theoretical model by Asano et al. (1992) is good only for the prediction of the damping rate for small damping. For large damping, the model grossly overestimates the damping rate. The model by Wang and Tørum (1994) underestimates the damping rate for small waves and overestimates it for large damping. For the whole range and especially for practical wave periods (6-14 seconds), the present model is very good.

Fifth, the damping rate obtained from the experiment for regular waves shows a very wide scatter. However, the theoretically predicted values appear to fit within the range of scatter as shown in Figure 6.

Sixth, as the water depth increases, the energy dissipation equation (Eq.(2.13.)) tends to over-estimate the damping coefficient, while the dispersion equation (Eq.(2.14)) comes closer and closer to the measured values. The reason for this discrepancy is not clear. However, since the empirical force coefficient F_λ was evaluated at 6m water depth, in the absence of force data for other water depths, it may be that this coefficient is variable with water depth.

(4) Figures 9 and 10 show the general functional relationship between the damping coefficient and total water depth and the number of plants per square meter respectively. For all wave periods $k_t = 0.0658\exp(-0.5*D)$.

Figure 2 Comparison of exponential decay for different total water depths.

CONCLUSION

(1) As waves propagate in kelp fields, their wave heights are reduced significantly and wave lengths are shortened. Both theoretical and experimental studies indicate that the damping coefficient is governed by the wave period. It increases with wave period for shorter periods, reaches a maximum and then decreases gradually with the wave period for longer periods (Figures 5 through 8)

(2) The damping coefficient is also governed by the water depth and population density of plants. Figure 9 shows that the damping coefficient decreases with increasing water depth. Figure 10 shows that it increases with increasing population density until it reaches a maximum, after which it decreases sharply with increasing density.

(3) Basing on the theoretical and experimental results, wave height attenuation is more substantial in shallow water than in deep water. In fact it is almost negligible in water depths greater than 10 meters. For a population density of 12 plants/m^2 , significant heights of irregular waves will be reduced by say 50% over a distance of 74, 216, 495 and 1390 meters in 4, 6, 8 and 10 meters mean water depth respectively.

(4) The linear assumption of the wave force in relation to the particle velocities leads to an exponential decay (damping) coefficient of the wave height with respect to distance.

CHAPTER 204

EXPERIMENTAL STUDY ON THE EFFECT OF GRAVITY DRAINAGE SYSTEM ON BEACH STABILIZATION

Hiroshi KANAZAWA ¹⁾, Fumihiko MATSUKAWA ¹⁾
Kazumasa KATO ²⁾ and Iwao HASEGAWA ³⁾

Abstract

In order to develop a new beach preservation technique which has two functions of protecting the beach in a storm and enabling utilization of beach during calm sea, we consider the system of controlling a groundwater level by burying a permeable layer under the foreshore. Since most of the components are buried underground, people on the beach do not notice the presence of the system, enabling preservation of the beach in its most natural state. The greatest challenge of the system is, however, whether installation of the permeable layer alone will fully prevent erosion. Authors therefore conducted an experiment to evaluate beach stabilization effect of the present system. The result indicates that the permeable layer buried in the sand can prevent rise in the groundwater level and the wave set-up. The critical wave height for the foreshore erosion is 1.66 times higher than that on the beach without the permeable layer.

1. Introduction

Against severe natural conditions in Japan, we have constructed seawalls with wave breaking blocks, jetties, detached breakwaters, and so on. These protection measures have stopped further erosion, and also protected the hinterland and people from large waves in a storm. However, in a calm sea condition, the structures keep the people away from the waterfront. Therefore, we are developing a new beach stabilization technique, which has functions of disaster prevention in a storm and beach utilization in a calm. In order to develop such a new beach stabilization technique, first of all a beach erosion mechanism

during stormy weather was investigated in the field (Katoh and Yanagishima: 1992, 1993). These investigations elucidated the relation between rise in the watertable due to wave run-up and the beach erosion. That is, when waves run-up beyond the berm crest in a storm, the sea water stays for a good while on the horizontal area of berm, which accelerates the infiltration of water into the beach. As a result, the watertable becomes higher, and the water exfiltrates through the surface of foreshore. The seepage level of water corresponds to the critical level of berm erosion. Taking this result into consideration, there are two countermeasures for reducing the beach erosion in a storm. One is a construction of a structure offshore to decrease the wave energy and to suppress the wave run-up on the beach. Another is to lower the watertable by some method.

As a latter measure, we consider a permeable layer setting up under the beach. In a storm, waves run-up to the high level and the water infiltrate into the beach. However, the groundwater may be gravitationally drained to the offshore through the layer. Concerning to the effect of permeable layers, two- and three-dimensional experiments were conducted with regular waves to compare the groundwater levels and the profiles on the beach with and without the permeable layer.

2. Details of Experiments

2.1 Aims of Experiments

Aims of two- and three-dimensional experiments are as follows:

- (1) Two-dimensional experiments : A purpose is to know the possibility of controlling watertable and reducing the beach erosion for three different kinds of permeable layers.
- (2) Three-dimensional experiments : There are two purposes in the three-dimensional experiments. One is to confirm the effect of the convergence type drainage system, in which the water gathered by the permeable layer is drained offshore through one pipe. Another is to evaluate the effect of permeable layer on beach stabilization quantitatively.

2.2 Conditions and Methods in Two-dimensional Experiments

The experiments were carried out in a experimental flume of 38.0 m long, 0.5 m wide and 1.5 m high. The movable profiles were made with sand of 0.135 mm in a median grain size. The permeability coefficient of sand is 6.28×10^{-3} cm/s, which is the result of permeability test.

As the permeable layer, three types shown in Figure 1 were tested. Features of these types are as follows, respectively.

- (1) Gravel Permeable Layer (GPL) : Gravels of 13 - 20 mm in size were laid with the thickness of 10 cm from the backshore to the breaker zone (Figure 1, top). Plankton nets were interposed between the sand layers and the gravel layer to prevent sand from intruding into the gravel layer. The sand layer above the permeable layer was 10 cm thick. A still water level was situated inside the permeable layer of horizontal part.

(2) Gravel Permeable Layer with Drainage Pipe (GPL-DP) : The thickness of the permeable layer and the sand layer were decreased to half that of GPL, respectively (Figure 1, middle). The permeable layer in the backshore was therefore situated above the still water level. A drainage pipe (44 mm in inner diameter) extended from the permeable layer near the shoreline toward offshore. The pipe was buried along the wall of experimental flume, with its outlet vent located at the wave breaking point.

(3) Permeable Pipe with Drainage Pipe (PP-DP) : Three permeable pipes were used in place of the permeable layer (Figure 1, bottom, Figure 2). The permeable pipe was a spring coil of 15 mm diameter wrapped up with a plankton net as shown in Figure 3. Groundwater percolates into the pipe through the plankton net. Three permeable pipes were buried under the beach with a 15 cm interval in the traverse direction. To protect the permeable pipes, a gravel layer was placed above the pipes. This gravel layer did not act as a permeable layer because sand was filled in the voids of gravel layer. The drainage pipe extending toward the offshore direction from near the shoreline was the same as that used in the GPL-DP.

Figure 1: Types of Permeable Layer in Two Dimensional Experiment.

Figure 2 : Plane view of PP-DP.

Figure 3 : Structure of Permeable Pipe.

Table 1 : Waves in Two Dimensional Experiments.

10.0	1.79	0.03	○	○	○	○
15.0	1.79	0.03	○			○

The wave conditions in the two dimensional experiments are listed in Table 1, in which the cases with a circle were conducted. In the experiment, the level of groundwater in the section from the backshore to the shoreline, wave set-up in the surf zone, and the profile changes were measured. To measure the groundwater level and the wave set-up, a manometer using a vinyl tube 6 mm in inner diameter was used. Measurements were carried out with an interval of 25 cm along the wall of the flume in the cross-shore direction. Using a sand level meter, the profile changes were measured along three measurement lines in the traverse direction with an interval of 10 cm. The mean value of the profiles along the three measurement lines is calculated and used for further analysis of the profile changes. These result are compared with those obtained in the profile without permeable layer. In the profile without a permeable layer and the profile with GPL, a dye (methylene blue) was injected close to the glass wall of the flume. The seepage velocity inside the permeable layer and the sand layer above the permeable layer respectively were estimated from the travelling distance of the gravitational center of the dye patch and its elapsed time.

2.3 Conditions and Method in Three-Dimensional Experiments

Test conditions were primarily the same as those in the two dimensional experiments except the following.

Figure 4 : Layout of Permeable Layer in Three-Dimensional Experiments.

A wave basin (35.0 m L × 1.1 m H × 15.0 m W) was divided into two sections (7.5 m W) to enable simultaneous experiments on the two beaches with PP-DP and without the permeable layer. Figure 4 shows the layout of PP-DP: 100 permeable pipes measuring 2.9 m in length and 15 mm in inner diameter were buried with a 7.5 cm longshore interval and eight drainage pipes measuring 44 mm in inner diameter with a 94 cm longshore interval. The outlet vent of the drainage pipe was positioned at the wave breaking line. The median grain size of the sand used in the experiments was $d_{50} = 0.16$ mm and the permeability coefficient was $k = 1.14 \times 10^{-2}$ cm/s.

Table 2 : Waves and Profile Changes in Three-dimensional Experiments.

T (s)	H _o (cm)	Value of C	Classification of Profile Changes	
			Without a Permeable Layer	PP-DP

	5.4	5.5	I	II
	7.2	7.4	I	I
	9.0	9.2	I	I
	☆ 12.5	12.8	I	I

The wave conditions used in the experiments are listed in the first two columns of Table 2. The waves were acted for one hour in each case. The three columns on the right in the table give information on the shoreline changes; the details are given later.

The groundwater level was measured with a 1.25 m interval in the longshore direction along the two measurement lines, the initial shoreline (shoreline at the time of still water) and the line near the tip of the wave run-up. Profiles were measured with a 0.125 m interval in the cross-shore direction along the three measurement lines set with a 2.25 m interval in the longshore direction. For the cases with the wave height values marked with asterisks in Table 1, additional measurements of profile were done along the measurement lines set with 0.25 m interval in the longshore direction.

3. Results of Experiments

3.1 Comparison of Groundwater Levels

Figure 5 shows the groundwater level in the two-dimensional experiment in which waves of 8.4 cm in height and 1.34 s in period were acted on the beach without the permeable layer. The reference level for elevation on the ordinate is the initial still water

level. The groundwater level begins to rise immediately after waves are acted, and substantially levels off after 11 minutes. The peak of the watertable near the location of 2.0 m substantially coincides with the tip end of the run-up, and the water level exceeds the still water level by 2 cm. The wave set-up at the shoreline located at 2.5 m is 1 cm above the still water level.

Figure 5 : Changes of Groundwater Level with Time in the Beach without the Permeable Layer (two-dimensional experiment).

Figure 6 : Comparison of Groundwater Levels between Beaches with and without the Permeable Layer (two-dimensional experiment).

Figure 6 shows the distributions of groundwater level and the wave set-up measured ten minutes after the waves of 10.0 cm in height and 1.79 s in period were acted on the beaches without the permeable layer and with three types of permeable layer. Because of

the severe wave conditions, rise in the groundwater level and the wave set-up on the beach without a permeable layer are greater than those shown in Figure 5. In the beaches with the permeable layers, both the rise in the groundwater level and the wave set-up are quite insignificant. In particular, the groundwater level in the beach with PP-DP is lower than the initial still water level. This is considered to be the effect of wave set-down because the terminal end of the drainage pipe on the offshore side is located at the wave breaking point.

3.2 Wave set-up

It is confirmed that the permeable layer has a function to suppress rise in the groundwater level. The experiment results, however, suggest that it can also prevent the wave set-up. Figure 7 shows the relation between the wave set-up at the initial shoreline and the wave steepness in the two-dimensional experiment. For all cases, the values of wave set-up measured 10 minutes after the start of wave action are plotted. The broken line in the figure is a theoretical value of wave set-up according to Goda's theory (1975) when the bottom gradient is 1/10. The wave set-up on the beach without a permeable layer substantially agrees with Goda's theoretical value. On the beach with the permeable layer, particularly with PP-DP, no wave set-up is observed.

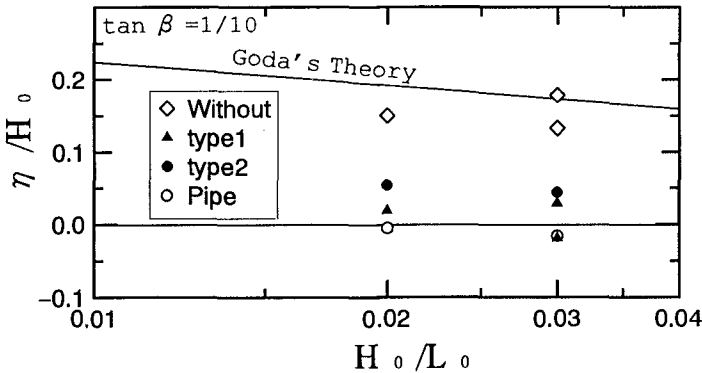

Figure 7 : Relation between Wave set-up and Wave Steepness
(two-dimensional experiment).

Figure 8 shows the longshore distributions of wave set-up at the shoreline on the beaches with and without the permeable layer in the three-dimensional experiments. The wave height was 12.5 cm and the period was 2.01 s, and the measurements were taken 30 minutes after the waves were acted. On the beach without the permeable layer, the wave set-up agrees with the theoretical value of Goda (1975) which is shown by a horizontal line in the figure. On the beach with the permeable layer, on the other hand, the average wave set-up is about 0.5 cm. The relative position between the measurement point of groundwater level and the position of the drainage pipe, which is shown by \uparrow in the Figure 8, changes from a location to a location. The wave set, however, is considered to

be constant in the longshore direction, although a slight fluctuation is observed. This result indicates that groundwater within the range of 0.94 m along the longshore direction could be discharged by one drainage pipe, suggesting that convergence type drainage system is feasible.

Figure 8 : Comparison of Groundwater Levels between on the Beaches with and without the Permeable Layer (three-dimensional experiment).

3.3 Seepage velocity in the Sand Layer and the Permeable Layer

Figure 9 shows the seepage velocity in the sand layer and the permeable layer. The top portion shows the values for the beach without the permeable layer, the bottom portion those for the GPL. The velocity in the profile without the permeable layer is smaller than 0.15 mm/min. The velocity in the sand layer located above the still water level is directed onshoreward, whereas the flow in the sand layer below the still water level is directed toward the offshore along the sea bottom. In the beach with the permeable layer, the seepage velocity is two to three times that in the beach without the permeable layer, with a offshoreward velocity of about 30 cm/min (about 1000 times the velocity in the sand layer; note that velocity vectors are in logarithmic expression in the figure). It must be noted that the flow in the permeable layer fluctuated with the same period as wave motions, but the time average velocity is shown in Figure 9.

A reason of the fast velocity in the permeable layer is studied. Firstly, a numerical simulation of two dimensional unsteady flow was conducted to evaluate the amount of water infiltration into the beach due to the wave run-up. The simulation was carried out for the entire model beach. The water infiltration into the beach in the portion from the shoreline to the run-up level was given, so that the calculated groundwater level agreed with the measured value. The rate of infiltration into the beach without the permeable layer was estimated to be $1.1 \text{ cm}^3/\text{min}/\text{cm}$. As for the beach with the permeable layer, if the same amount of water is assumed to infiltrate into the beach due to the wave swashing,

the seepage velocity in the permeable layer (10 cm thick) would be 0.37 cm/min, given the void ratio of 0.3. Thus, the fast velocity in the permeable layer cannot be explained solely by this infiltration. In the following consideration, therefore, the experimental fact that no wave set-up is observed on the beach with the permeable layer is taken into account.

Figure 9 : Seepage Velocity in the Sand Layer and the Permeable Layer (two-dimensional experiment).

Assuming two-dimensional steady-state condition and ignoring the term of horizontal diffusion, the equation of motion in the breaker zone is

$$\frac{d}{dx} (\rho U^2 (h + \eta) + Sxx) = - \rho g (h + \eta) \frac{d \eta}{dx} - \tau_b \dots\dots\dots (1)$$

with the offshore direction taken along the positive x-axis, where U is the mean velocity, h water depth, η wave set-up, Sxx radiation stress and τ_b bottom shear stress. Since there is no wave set-up, $\eta = 0$. Then, by assuming $\tau_b = 0$, the equation (2) can be easily integrated.

From the radiation stress given by the equation below,

$$Sxx = - \frac{3}{16} \rho g \gamma^2 \tan^2 \beta \dots\dots\dots (2)$$

which is approximated by the linear shallow-water theory by assuming a uniform slope ($h = x \tan \beta$) and a constant proportionality between the wave height and depth ($\gamma = H / h$), then it holds:

$$U = -\frac{\gamma}{4} \sqrt{3 g x \tan^3 \beta} \dots\dots\dots (3)$$

If it is assumed that a flow which compensates the onshoreward discharge ($U \times h$) is generated in the permeable layer, then the velocity V_i in the permeable layer is

$$V_i = \frac{\gamma}{4 \lambda D} \sqrt{3 g x^3 \tan^3 \beta} \dots\dots\dots (4)$$

where λ is the porosity (=0.3) and D is the thickness of the permeable layer (=10 cm). By assuming $\gamma = 0.78$, V_i at a distance of 5 cm offshore ($h=0.5$ cm) from the shoreline is calculated to be 75 cm/min, which is almost 2.5 times larger than the value actually measured in the permeable layer. This is probably because the velocity is overestimated in equation (3). The calculated value would be much closer to the actual measurement if considerations are given to the factors that the onshore velocity in the surf zone is subject to the bottom shear stress, that any small rate of wave set-up would act to decelerate the velocity, and that there is the effect of the permeability coefficient in the sand layer above the permeable layer. It can be said that the fast velocity in the permeable layer is subject to the strong influence of the gradient of the radiation stress.

3.4 Profile changes

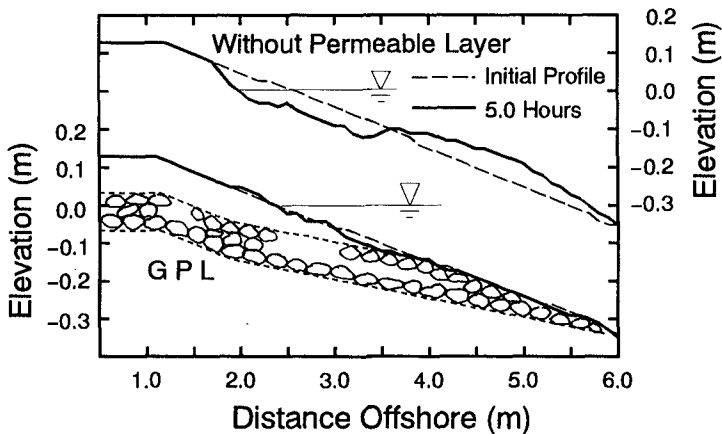

Figure 10 : Comparison of Profile Changes
(two-dimensional experiment : $H=8.4$ cm, $T=1.34$ s).

Figure 10 shows the profile changes on the beach without the permeable layer and with GPL, respectively acted with waves of 1.34 s in period and 8.4 cm in height for five hours. The profile without the permeable layer eroded in the range including the initial shoreline, and the sand deposited on the offshore forming a bar. The shoreline receded for about 0.5 m. On the beach with GPL, on the other hand, hardly any profile change is observed except for a small berm slightly on the onshore side of the shoreline. No change

in the shoreline position is observed. In this case, the permeable layer is effective in preventing erosion near the shoreline.

Figure 11 shows the profile changes acted with waves of 1.79 s in period and 15.0 cm in height for five hours. Because of severe wave conditions, the beach without the permeable layer eroded in the range from 1.3 m to 4.3 m. At a point about 4.1 m, there is formed a trough, of which on the offshore side a bar is formed. Although similar erosion is observed on the beach with GPL, no trough is formed since the erosion do not extend deeper than the permeable layer. Sand from the layer above the permeable layer is transported toward offshore direction and deposits on the outlet vent of the permeable layer. This phenomenon was observed from an early stage of wave action. The drainage capacity of the permeable layer was reduced by the clogging of the outlet vent. The erosion occurring at the initial stage of wave action was attributable to the insufficient drainage capacity of the permeable layer, but the eventual erosion similar to that occurring on the beach without the permeable layer was probably because the outlet vent was clogged.

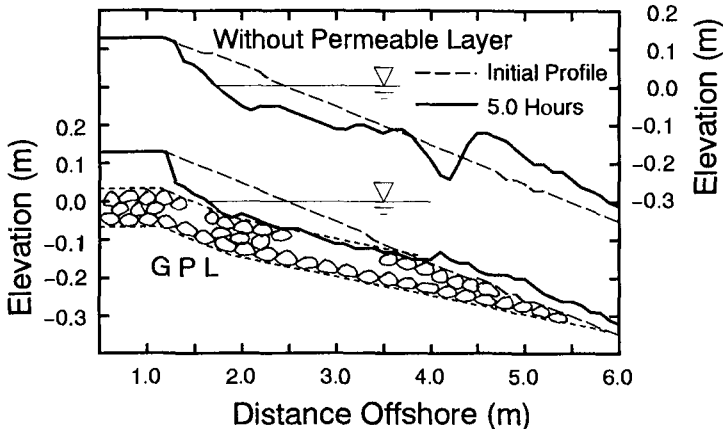

Figure 11 : Comparison of Profile Changes
(two-dimensional experiment : $H=15.0$ cm, $T=1.79$ s).

The top part of Figure 12 shows the topographical change on the beach with the permeable layer, PP-DP. Waves of 8.4 cm in height and 1.34 s in period were acted for one hour. The locations of drainage pipes are clearly shown in the figure, but as they were actually buried underground, only the outlet vents were visible. Because of the wave incident angle of 90° to the shoreline, the profile change is two dimensional and there is no three dimensional effect of draining the water offshore through the eight drainage pipes.

As for the changes in the cross-shore direction, the foreshore is eroded and a bar is formed offshore at about 4 m. The outlet vents of the drainage pipes was located on the immediately onshore side of the bar. However, the vents were not clogged by the sand because the terminal end of the drainage pipe was set slightly above the sea bottom (see Figure 1). Then, the groundwater controlling effect of the permeable pipes is included

even in this foreshore erosion. To demonstrate this point, we conducted a similar experiment using a beach without the permeable layer. The result is shown in the bottom part of Figure 12. On the beach without the permeable layer, erosion on the foreshore is extensive, with a substantial amount of deposition on the offshore bar.

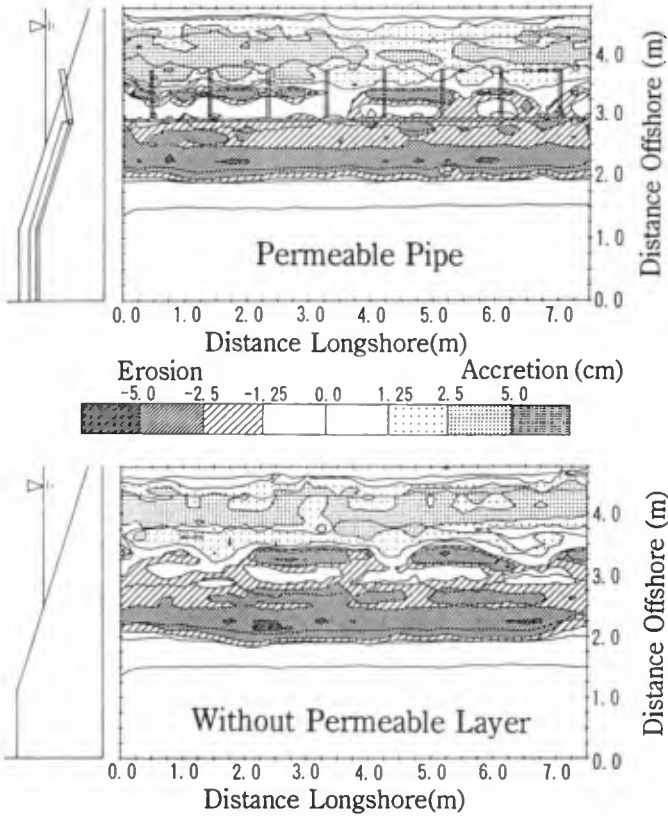

Figure 12 : Comparison of Topographical Changes
(three-dimensional experiments : $H=8.4$ cm, $T=1.34$ s).

As discussed above, in some cases erosion do occur on the beach with the permeable layer, although its extent is slightly less. To have quantitative understanding on the effect of permeable layer, we conduct an analysis using the constant C of the beach profile type classification (Sunamura and Horikawa, 1974) which is evaluated by the equation (5), in which an averaged profile is considered in each case.

$$C = (\tan \beta)^{0.27} \left(\frac{d}{L_0} \right)^{-0.67} \left(\frac{H_0}{L_0} \right) \dots\dots\dots (5)$$

According to Sunamura et al, profile changes can be classified into three types depending on the value C . Characteristic features of each type with regard to the change of the shoreline position can be described as follows:

- $C > 8$ Type I : Recession
 $8 > C > 4$ Type II : Stable
 $4 > C$ Type III : Advancement

The value C calculated by the equation (5) for each case is listed in the third column of Table 2. The value C is the same so long as the wave conditions are identical, without regarding to whether or not the permeable layer is employed. However, different types of shoreline changes are observed on the beaches with and without the permeable layer even if the value C is identical. The types of shoreline changes were investigated for all cases in the three-dimensional experiment. The results are listed in Table 2 and shown in Figure 13. Referring to Figure 13, it is noted that the value C in the case of experiment without the permeable layer is smaller than that of Sunamura et al. This is probably because of the following differences in the experimental conditions: the present experiment is the three-dimensional one (two-dimensional in Sunamura et al); the foreshore slope was 1/10 (many cases gentler than 1/10 are contained in Sunamura et al); and, waves were acted for one hour (more than 40 hours in Sunamura et al). Because of these differences, we evaluate the effect of permeable layer by comparing the results obtained for the beaches with and without the permeable layer instead of comparing with the results obtained by Sunamura et al. Referring to Figure 13, it is seen that the value C is larger on the beach with the permeable layer. In the case without a permeable layer, the mean value of C in the category of shoreline stable is 3.2, while in the case with the permeable layer it is 5.3. In short, the value of C is larger in the case with the permeable layer by a factor of 1.66.

Figure 13 : Classification of Types of Shoreline Changes
in Three-Dimensional Experiment.

When the changes in the value C are viewed from a different angle, the following can be said. When a beach with the permeable layer is subjected to waves having a value C_a , shoreline changes of the beach will be the same as those observed in the natural

beach (without the permeable layer) subjected to waves of $C_a / 1.66$. In other words, the permeable layer is effective in reducing the value C_a to about 60 %. This effect can be achieved also by a wave controlling structure. Generally, a wave controlling structure can control the wave height and not the wave period. Thus, given a constant bottom gradient, grain size and wave length (period) in equation (5), the value C will be in direct proportion only to the wave height. This in turn means that reduction of the value C to about 60 % attained by the permeable layer is comparable to the effect of a structure which is capable of decreasing the wave height to about 60 %. This wave decreasing effect is achieved by a submerged breakwater with a slightly larger crown depth with slightly narrower crown width. It should be noted, however, that a permeable layer has additional effect in that hardly any wave set-up near the shoreline occurs, which is a function not obtained by a submerged breakwater.

4. Conclusion

Effects of the permeable layer are as follows:

- ① Substantially no wave set-up occurs at the shoreline.
- ② Rise in the groundwater level can be suppressed to a greater extent.
- ③ Erosion near the shoreline can be mitigated.
- ④ According to our experiment, combination of permeable pipe and drainage pipe is most effective.
- ⑤ Effect of permeable layer in respect of shoreline changes is comparable to that obtained by reducing the wave height by about 40 % .

It can be concluded that the effect of permeable layer is demonstrated by our laboratory model experiments. Presently, we are conducting filed experiments at a beach in order to complete the present technique. (Katoh and Yanagishima, 1996).

CHAPTER 205

Field Experiment on the Effect of Gravity Drainage System on Beach Stabilization

Kazumasa KATOH ¹ and Shin-ichi YANAGISHIMA ²

Abstract

To have a coastal protection work of high quality, we are developing a new beach protection system, that is a beach drainage system, in which the groundwater is naturally drained to the offshore through a permeable layer setting up under the beach. To examine the drainage function of the permeable layer and its effect on the beach stabilization, a field experiments have been conducted during storms. As a result, it is confirmed that the permeable layer drain the groundwater gravitationally into the surf zone and has a function of decreasing a speed of erosion in a storm, and the eroded foreshore is recovered quickly in a calm.

Introduction

As Japan has a long coastline and exposed to severe natural conditions, strong efforts on the coastal protection works such as detached breakwaters, jetties, seawalls are necessary to prevent the coastal disasters. However, these concrete hard structures keep the people away from the waterfront. The view of coastal regions are worse than they were. Over against this the demand for a better quality of protection gets greater, and multipurpose use of valuable coastal zone comes to be required.

In order to make the coasts what people currently desire to be, we started from the basic research on the changes of sandy beach in a storm because a sandy beach is fundamentally essential to create the desired coast. The series of researches have been reported in the ICCE (Katoh and Yanagishima, 1988,

Chief ¹ and member ² of Littoral Drift Laboratory, Port and Harbour Research Institute, Nagase 3-1-1, Yokosuka, 239, JAPAN

1990, 1992; Katoh, 1994). According to the results of basic researches, a shoreline rapidly recesses and a berm on the foreshore erodes in one or two days during a storm, which is due to the development of infragravity waves. When infragravity waves run up beyond the berm crest in the storm, the sea water stays for a good while on the horizontal area of berm, which accelerates infiltration of water into the beach. As a result, the water table becomes higher, and the water exfiltrate through the surface of foreshore. The seepage level of water corresponds to the critical level of berm erosion.

Taking these results into consideration, there are two kinds of measures for maintaining the sandy beach against the severe natural conditions. One is a construction of structure in the offshore such as detached breakwaters to diminish the wave energy and to suppress the wave run-up on the beach. Another is to lower the water table by some method. The system of lowering the level of water table by pumping, which is called the sub-sand filter system, has been tested in the laboratories and in a small scale field experiment in a calm (Chapell et al., 1979; Vestebey, 1991). There is a problem in this method, that is to say, a continuous pumping of the groundwater is required for lowering the water level. Then, an alternative drainage system is considered, in which the ground water is naturally drained to the offshore through a permeable layer setting up under the beach. We carried out an experiment on the function of permeable layer under the beach in a flume (Katayama et al., 1992), of which the final result is reported by Kanazawa et al. (1996). Davis et al. (1992) developed the prototype beach drainage system which incorporated an array of shore normal strip drains made of geotextile fabric enclosing a plastic core in an "egg-carton" configuration, and examined its function for lowering the water table and stabilizing the beach in the field. The results of these researches strongly suggest a possibility of gravity drainage system which enhances the stabilization of beach. If so it will be possible to maintain the beach of beautiful view without any artificial obstacles, because the whole system may be built under the ground.

To examine the drainage function of permeable layer under the foreshore and its effect on the beach stabilization, especially during a storm, a field experiment has been conducted.

Field experiment

1. Site of field experiment

The site of field experiment is an entirely natural sandy beach, being exposed to the full wave energy of the Pacific Ocean (see Figure 1). The foreshore slope is about 1/50, and the median diameter of sand on the beach is 0.18 mm which is nearly constant during the calm and storm conditions (Katoh and Yanagishima, 1995) . The tide range is about 1.5 m. According to the

analysis of shoreline locations which were read from eleven aerial photographs taken during a period from 1947 to 1984, the shoreline advanced about 50 m during a period from 1975 to 1979, which was due to the construction of Kashima in 1974. However, it has been stable since 1979. On this beach, Port and Harbour Research Institute, Ministry of Transport, has constructed the Hazaki

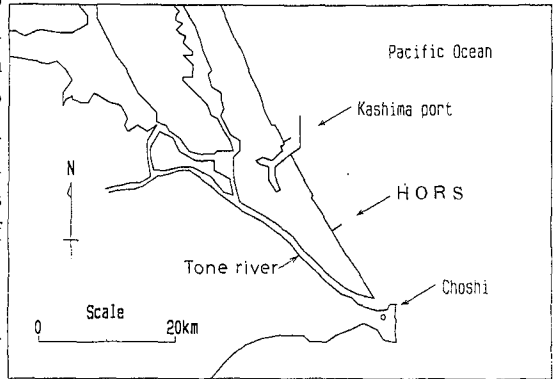

Figure 1 Site of Field Experiment.

Oceanographical Research Station (HORS) in 1986 for carrying out field observation in the surf zone even under the sever sea conditions. The research pier is a 427 meters long concrete structure supported by 0.8 meter diameter concrete-filled steel piles in a single line, at 15 meters interval. Although the beach is stable, the field experiment is being carried out on this beach because the basic data obtained in HORS have been accumulated since 1986.

2. Permeable layer and its execution

As the permeable material, the unit such as shown in Figure 2 is produced with the two sheets of corrosion-proof expanded metal in a factory, being wrapped with a geotextile fabric. A dimension of the unit is 1 meter wide, 2 meters long, and 20 centimeters thick. There is nothing inside the unit. The units can be connected by using couplers in the longitudinal direction. In August 1994 the permeable layer was set up under the beach in six columns from the foreshore to the backshore, being 30 meters apart in the longshore direction from the pier, as shown in Photo. 1. The elevation of permeable layer is about 3 meters below the beach surface, which is just below an envelope of the beach profiles overlapping for the last decade. The area is 88 meters in the cross-shore direction and 7.8 meters in width, which was enclosed by sheet piles when the permeable layer was being set. The pipe of 0.4 meter in

Figure 2 Permeable Layer.

Photo. 1 Execution of Permeable Layer.

diameter has been connected to the sea-side end of permeable layer to drain the ground water into the middle surf zone, 144 meters offshore from the shoreline. The pipe has been buried in the sea bottom with keeping the outlet in the sea. After setting, sand was put on the permeable layer so that we had the same profile as before. The sheet piles at the sea and land sides have been removed. The sheet piles along the longitudinal sides, however, were left without removing in order to make two-dimensional situation in the first experiment. In the second experiment, all the sheet piles were removed.

3.Items of measurements

In the first two-dimensional experiment, two representative measuring lines were taken into account in the cross-shore direction; one was coincided with the center line of the area where the permeable layer was buried, another was the line on the natural beach which was parallel to the first and 29 meters apart in the longshore direction. Along these lines, profiles of groundwater table and beach were surveyed once a day during a calm or every several hours in a storm, respectively. In the second three-dimensional experiment, a topography and plane distribution of water table were measured once a day in an area of 110 meters in the cross-shore direction and 75 meters in the longshore direction, including the area of permeable layer. The drained discharge through the pipe was continuously measured by a supersonic type discharge meter. Waves were measured near the shore line and the offshore.

Result of the first two-dimensional experiment

After about one month of setting up, on 18th September, 1994, a typhoon

Figure 3 Waves in Typhoon No.9424.

attacked the experimental site. Waves at the offshore and infragravity waves near the shoreline are shown in Figure 3. The extreme value of significant wave height was 5.8 meters. The infragravity waves developed well, being about 1.5 meters in height near the shoreline, which run up to the backshore. The berm on the beach eroded during the days from 18 to 20, which is denoted in the Figure 3.

Photo. 2 was taken from the rooftop of laboratory at HORS on 19th September, on the second day of the storm, when an infragravity wave was running up on the drained beach. Small poles dug into the beach at the cross-shore intervals of 5 meters were arranged along a center line of the area where

Photo. 2 Infragravity Waves Running on the Drained Beach.

Photo. 3 Dried up Area on the Drained Beach.

the permeable layer was set up. Under this situation, sea-water infiltration into the beach was considered to be enhanced in the drained area, because on the drained beach we recognized a very interesting phenomenon that air bubbles came out actively from the ground through the surface of beach, which had never been seen in the laboratory. It is not difficult to infer the situation that the water was infiltrating into the beach because the effusion of air bubbles was a result of being replaced with the infiltrated water into the ground. Photo. 3 is a picture taken about one minute after the situation of Photo. 2, when the infragravity wave was running down to the sea. The beach surface of drained area, of which both sides were cut off by the sheet piles, was already dried up, while the surface of natural beach was still wetted.

Figure 4 is a comparison of profiles of water table between the natural beach and the drained beach, measured on the day of 18th September when the beach began to erode. Infragravity waves had already developed well, and run up to the high elevation denoted by an arrow which was higher than the usual H.W.L. of 1.4 meters. The elevation of groundwater table in the natural beach, which is denoted by triangles, rose up

Figure 4 Comparison of Water Tables.

Figure 5 Changes of Tide Level, Water Table, and Drained Discharge.

to the beach surface. In other words, the ground was completely saturated with the water. On the other hand, that in the drained beach which is denoted by circles was 0.6 meter lower in maximum than the beach surface. The area between the beach surface and the water table in the drained beach was unsaturated, which means that the groundwater was gathered to the permeable layer and drained offshore through the drainage pipe.

Figure 5 shows the changes of a tide level at the outlet of drainage pipe, the water table at the point of -25m in the drained area, and a mean discharge in the drainage pipe for 20 minutes. On the day of 17th September, before the storm, the discharge was small. From the day of 18th September on, during the storm, The discharge was large, being about 30 lit/s. The groundwater level changed with a lag of about one hour behind the tidal change. As a result, the level difference between the groundwater table and the tide level became large during the ebb tide, which produced larger discharge.

Figure 6 shows the actual fluctuations of ground water level in the drained

Figure 6 Fluctuations of Groundwater level, Water Surface, and Discharge.

beach and the drained discharge in the surf zone during the segment of twenty minutes in the storm. The level of water surface at the point of outlet in the surf zone, which is the result of running average with 10 seconds, is also presented in the same figure. These elevations were measured on the day of 18th September, the first day of storm. The fluctuation of groundwater level was smooth and small, while that of surface elevation was large, being 70 cm in amplitude and 1 to 2 minutes in period, which was due to the infragravity waves in the surf zone. As the surface level at the outlet was lower than the groundwater level in the better part of time, the water in the pipe usually flowed offshoreward with the discharge of 100 lit/s in maximum, which was equivalent to the mean velocity of 80 cm/s in the pipe. However, the surface level at the outlet was sometimes higher than the groundwater level when the crest of infragravity waves is passing over the point of outlet. When the surface level at the outlet was higher than the groundwater level, the water flows backward, or in the onshore direction.

In Figure 7, the mean discharges are plotted against the level difference between the ground water level and the surface level at the outlet. These values are the averaged ones for every 20 minutes before and during the storm. The averaged discharge was in roughly proportional to the difference of water level, which means that the water was gravitationally drained into the surf zone.

Figure 8 shows the successive comparisons of beach profiles on the natural beach and the drained beach. On the two day before the storm, the day of 16th September, berms were formed on the foreshores of both the natural and the drained beaches (Figure 8, top) due to the relatively calm wave conditions during the three weeks before the storm. The berm on the drained beach was developed better, which is considered to be the effect of drainage. On the first day of storm, the berm on the natural beach eroded to the constant slope as seen in the middle figure, while the berm existed on the drained beach. In the bottom figure, one hour after, the berm still existed on the drained beach, which gradually eroded with time. Around 16 h of 18th, September, which was 13 hours after the time of profiles shown in the bottom figure, the tide level became highest and the height of infragravity waves also became the largest. Under this severe condition, the berm on the drained beach eroded completely to be the same constant slope as that of natural beach. In short, the effect of

Figure 7 Relation between the Level Difference and the Drained Discharge.

Figure 8 Comparisons of Profiles on the Natural and the Drained Beaches.

permeable layer is to decrease the speed of beach erosion in the storm.

Result of the second three-dimensional experiment

In the second field experiment, the sheet piles along the both sides of drained area had been removed. About one year after, on the day of 17 September 1995, a large typhoon No.9512 passed near the experimental site. Figure 9 shows the changes of the offshore significant waves and the height of infragravity waves near the shoreline. The extreme height of significant wave occurred at 14h on the day of 17th September, being 6.0 m. The height of infragravity waves near the shoreline increased from about 1.0m at 7th on the same day to 1.8m in maximum at 15h, which is the largest in the last 9 years

Figure 9 Waves in Typhoon 9512.

since the observation of infragravity waves have started at HORS in 1987.

Figure 10 shows a plane distribution of water table on the day of 16th, September. The water table above the permeable layer was lower than that of the circumference. Waves run up to the location of $y=0\text{m}$, where the water table was higher than 2.0 m in the areas apart from the permeable layer and lower than 1.5 m above the permeable layer.

Figure 11 shows the topography around the drained area, which was surveyed at 7h on the day of 17th, just before the storm. The slope is gentle in the area from $y=-50\text{m}$ to 0m , while it is steep in the area offshoreward from $y=0\text{m}$, because a berm is formed on the foreshore. At this time, waves run up to the location of $y=-55\text{m}$, which was observed visually during surveying.

In order to survey the wide area in a short time, nine researchers took part in surveying. During the time from 7h to 14h, on the day of 17th September, however, we could not succeed in obtaining the data of topography because it was very dangerous for us to survey due to the large run-up of infragravity waves and a strong wind velocity of 29 m/s in average.

Figure 12 shows the topography around the drained area which was surveyed after the extreme condition, at 14h on the day of 17th. The foreshore has almost completely eroded to be a plane beach of the two dimensional state of 1/40 in slope. A contour line of 2m has recessed by 30

Figure 10 Water Table before the Storm (16th Sep., 1995).

Figure 11 Foreshore Topography, just before the storm

Figure 12 Foreshore Topography, after Erosion.

Figure 13 Foreshore Topography, One Week after the Storm.

meters from $y=0m$ (in Figure 11) to $y=-30m$. No effect of permeable layer is observed in this topography. It is considered to be due to the narrow width of drained area, 7.8 meters, and the attack of extreme large waves. As the interruption of surveying was 7 hours, the effect of permeable layer on decreasing the speed of beach erosion was not confirmed.

After the storm, it was continued to survey the topography in the same area once a day. Figure 13 shows the topography on the day of one week after the storm, 25th September. The contour lines of 1.4m to 2.2m advanced offshoreward, being convex in the area above the permeable layer. As a result, in the area above the permeable layer a slope was gentle in the area higher than 2m in elevation, while it

Figure 14 Change of Topography during one week.

was steep in the area lower than 2m. In short, a new berm was formed on the foreshore above the permeable layer.

The rate of sand accumulation during this one week has been calculated, of which result is shown in Figure 14. The area of sand accumulation more than 10 cm is hatched. In the middle of this area, on the drained beach, the thickness of accumulation is more than 40 cm. Then, it can be said that there was a quick recovery on the drained beach. The effect of permeable layer extended to the both lateral areas for about 20 meters, which suggests a possibility of beach protection by setting up the belts of permeable layers in stripes. On the lateral beaches where there was no permeable layer below, sand accumulated gradually and the berms were formed finally, being as the same topography as that before the storm (see Figure 11).

Conclusions

The effects of permeable layer set up under the beach are as follows:

- (1)The permeable layer can drain the groundwater gravitationally through the drainage pipe into the surf zone even in a storm.
- (2)It has a function of decreasing the speed of foreshore erosion in a storm.
- (3)On the drained beach, the eroded foreshore is recovered quickly after a storm.

CHAPTER 206

On the change of velocity field in nearshore zone due to coastal drain and the consequent beach transformation

Michio Sato¹, Tadahiro Fukushima², Ryuichiro Nishi³
and Masahiko Fukunaga⁴

ABSTRACT

It is essential to understand the details of the mechanisms by which a coastal drain works in order to build up the method which enables us to estimate discharge requirement for effective operation in field conditions. Some measurements on the changes of quantities which may be relevant to the function of coastal drain are discussed. Then, an attempt to implicate the current components produced by drainage in a numerical model of beach profile evolution is discussed.

INTRODUCTION

The coastal drain has been considered to be an effective soft approach to coastal erosion control and beach erosion. From the practical point of view, it is indispensable to know how to estimate discharge requirement for effective operation in field conditions. Small scale physical experiments give us qualitative information on some physical aspects related with the coastal drain. There seems, however, to be a difficulty in estimating discharge needed for a coastal drain system based on experimental results due to scale effects. Hence, when we consider the remarkable recent progress of numerical models on beach profile evolution, it will be a practical way to construct a numerical model which enables us to estimate beach profile change under the operation of a coastal drain system. To do this, it is essential to understand the details of the mechanisms by which the coastal drain works.

Authors have shown the following results on forced coastal drain experimentally(1994),

- 1) seaward area of a shoreline is most appropriate for the installation of a drain pipe
- 2) as the discharge increases, the drain system becomes effective even for storm wave conditions.

Figure 1 is an example of beach profiles under erosive wave condition. In this case, sediments on the initial shoreline moved mainly toward the upper beachface and the bottom level lowered. But, the erosion in the shoreward part of the drain pipe was

Figure 2 Beach profile change (2)

Figure 3 Beach profile change (3)

restrained on the whole. This example made us have expectation the landward area of a drain pipe to be protected at the worst, when the drain pipe was installed in seaward area of a shoreline.

Figure 2 shows an example of the case in which drain was done under the shoreline. Erosion due to erosive waves attained almost to the initial shoreline for the same drainage as the case mentioned above.

Figure 3 is the case which attracted our attention specially in that it showed remarkable accretion in the inshore area after wave action of two hours. The wave condition was less steeper compared with the cases in Figures 1 and 2, but it was not accretive one at all for the cases of without or smaller drainage. This result suggests that, when a storm passes by a shore, similar situation may occur in some stages of the storm passage according to wave condition and drainage. And the process which brought the accumulation of sediments is expected to retard erosion and accelerate restoration of an eroded beach. So, our main interest has been directed to determine under what conditions the accretion takes place.

Generally, the reason a coastal drain system works has been explained by relating effects of drainage to the net sediments carried due to runup-down wash processes of waves on a beachface. Our observation, however, showed that the changes of the hydraulic conditions in the nearshore zone were important. Especially, shoreward flow component induced by drainage in and out of a surf zone, which carried suspended sediments and migrated a bar toward the beachface, seemed to play the dominant role for the accretion when the drain pipe was installed in the seaward area of a shoreline.

In this paper, some measurements on the changes of quantities which may be relevant to the function of coastal drain are discussed. Then, an attempt to implicate the current components produced by drainage in a numerical model of beach profile evolution is discussed.

EXPERIMENTS

The changes of wave runup, wave setup and mean velocity fields due to coastal drain were investigated experimentally by using a wave flume of 13m long, 0.4m wide and 0.4m deep (Figure 4). Water elevation was measured by capacitance type wave gages and velocity fields were measured with an electromagnetic current meter. The measurements were limited in the range between the level about 1cm lower from wave trough and the level 2cm above the bottom.

RESULTS AND DISCUSSIONS

Wave set-up : In their experiments on the gravity drainage system which utilize permeable layer artificially placed under a beach, Kanazawa et.al.(1996) observed no wave set-up, the gradient of which in on-offshore direction provides one of the driving force of undertow. We also anticipated similar result for our cases in early stage. Our measurements of mean water level, however, did not show any definite change in the mean water level as shown in Figure 5. The difference may be considered to reflect the difference of mechanisms which make each system effective.

Figure 4 Experimental setup

Figure 5 Wave setup

Wave runup : Wave runup was measured visually. The change of wave runup was small. This was supported by the numerical model of wave runup including the effects of coastal drain (Figure 6). These results reveals the change of runup-down wash process due to coastal drain is not necessarily the dominant mechanism when a drain pipe is buried in the seaward part of a shoreline.

Numerical computation was done based on the equations of continuity and motion for nonlinear shallow water waves implicating infiltrating flow from the bottom surface due to drain. The non-dimensional form of the equations are as follows.

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(hu) = -v^* \quad (1)$$

$$\frac{\partial}{\partial t}(hu) + \frac{\partial}{\partial x}\left(hu^2 + \frac{h^2}{2}\right) + \theta h + f_w |u|u + uv^* = 0 \quad (2)$$

$$x = \frac{x'}{\sqrt{gh'T'}}, \quad t = \frac{t'}{T'}, \quad h = \frac{h'}{H'}, \quad u = \frac{u'}{\sqrt{gh'}} \quad , \quad v^* = \frac{v'}{H'/T'}$$

$$\theta = \frac{\tan \theta'}{H'/(\sqrt{gH'T'})}, \quad \tau_b = \frac{\tau'_b}{\rho g H'^2 / (\sqrt{gH'T'})}$$

where h is water depth, t is time, u is fluid velocity in x -direction, v^* is infiltration velocity, H is wave height, T is wave period, τ_b is shearing stress on the bottom, g is the gravitational acceleration and f_w is friction factor. Prime denotes the dimensional variables.

The infiltration velocity v^* was given as the velocity $-(a'q')/\{\pi(x'^2 + a'^2)\}$ of the flow induced along x' -axis by a source at $z' = i a'$ with the intensity of $-q'/2\pi$ and a sink at $z' = -i a'$ with the intensity of $q'/2\pi$ in z' -plane (Figure 7). The non-dimensional form of the velocity for the coordinate system in Figure 8 is given by the following equation.

$$v^* = -\frac{aq}{\pi\{(x-x_0)^2 + a^2\}} \quad (3)$$

In conducting the numerical computation, Kobayashi et al.(1987) was referred to.

Mean velocity : Measurements of the mean flow field over the beach in the wave channel were carried out. The beach was plane uniform one of 1/10 slope initially. Wave action of several minutes, however, changed the beach profile to the extent we could ignore. Then, the bed was flattened in every several minutes. Nevertheless, the measurements seems to contain the influence due to the bottom change in the course of measurement.

Figure 9-A shows the mean velocity distribution induced by waves without drain. Figure 9-B and C are the velocity field induced by drain without wave action. And Figure 9-D and E are the velocity field due to waves and drain.

Figure 6 An example of measured and calculated runup

Figure 7 Infiltration velocity model used in the calculation of wave runup

Figure 8 Definition sketch

From these measurements we can see that the flow in the direction of offshore decreases the intensity near the drain pipe. And the reverse of the flow direction was observed in close proximity to the pipe.

BEACH PROFILE EVOLUTION AND COASTAL DRAIN

In an attempt to know what changes in beach profile evolution will result when the following two effects are taken into consideration, numerical simulations of beach profile evolution based on a modified existing model (Dally and Dean(1984)) were done.

1. the horizontal velocity component of the flow produced by drainage reduces the wave induced offshore-directed mean current,
2. the vertical velocity component of the flow adds to the settling velocity of sediment particles and modify the vertical distribution of suspended sediments.

The flow components due to drain were simply modeled by the flow in a wedge shaped region produced by a point sink on a side of the wedge(Figure 10). The velocity components (u , v) are given by

$$u - iv = \frac{m\pi}{\theta} \cdot \frac{(z/a)^{\pi/\theta}}{z\{(z/a)^{\pi/\theta} - a\}} \quad (4)$$

where $z = x + iy$ and $i^2 = -1$. The calculated flow distributions are shown in Figure 11.

Sediment transport rate Q_{SS} was given by

$$\begin{aligned} Q_{SS} &= \int_{-h}^0 \bar{u}(z) \cdot C(z) dz \\ &= \int_{D_r-h}^0 \{u_1(z) + u_{Dx}(z)\} \cdot C(z) dz + \int_{-h}^{D_r-h} \{u_2(z) + u_3(z) + u_{Dx}(z)\} \cdot C(z) dz \end{aligned} \quad (5)$$

where \bar{u} is mean velocity, $C(z)$ is concentration of suspended sediments, u_{Dx} is x -component of the velocity induced by drain (Figure 12).

The concentration of suspended sediments was given by

$$C(z) = C_A \exp\left\{-1.5(w + u_{Dz}) \cdot (z - z_A) / (h\sqrt{\tau/\rho})\right\} \quad (6)$$

where C_A is reference concentration, w is the settling velocity of sediments, u_{Dz} is z -component of the velocity induced by drain.

Beach profile evolution was calculated by

$$\frac{dh}{dt} = \lambda \frac{dQ_{SS}}{dx} \quad (7)$$

Figure 13 shows the calculated results. For the case of without drain, specious results were obtained. Addition of the flow due to drain makes the sediment transport rates several times larger in magnitude and the sediment transport direction onshore over the whole beach area. And accretion of the shore-side area of the pipe was obtained.

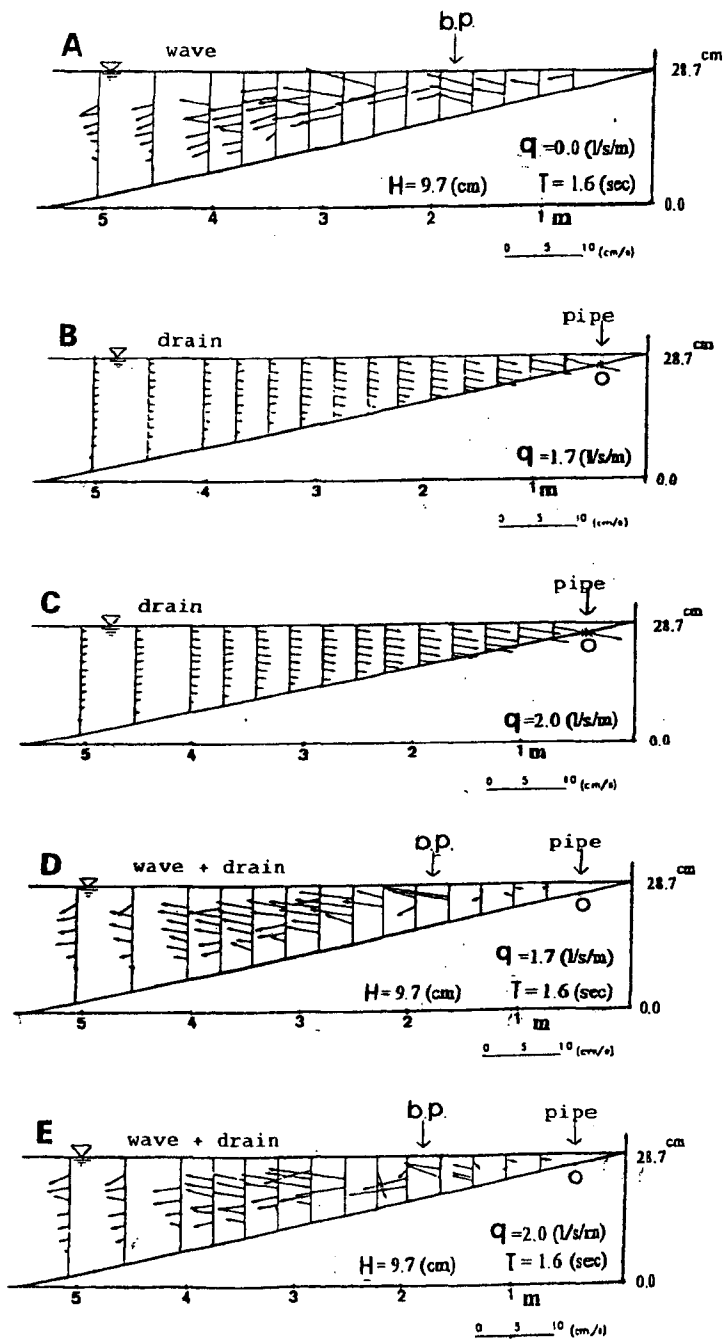

Figure 9 Measured mean velocity

Figure 10 Model of the drain induced flow

Figure 11 Examples of calculated velocity distribution

Figure 12 Definition of variables in Eq.(5)

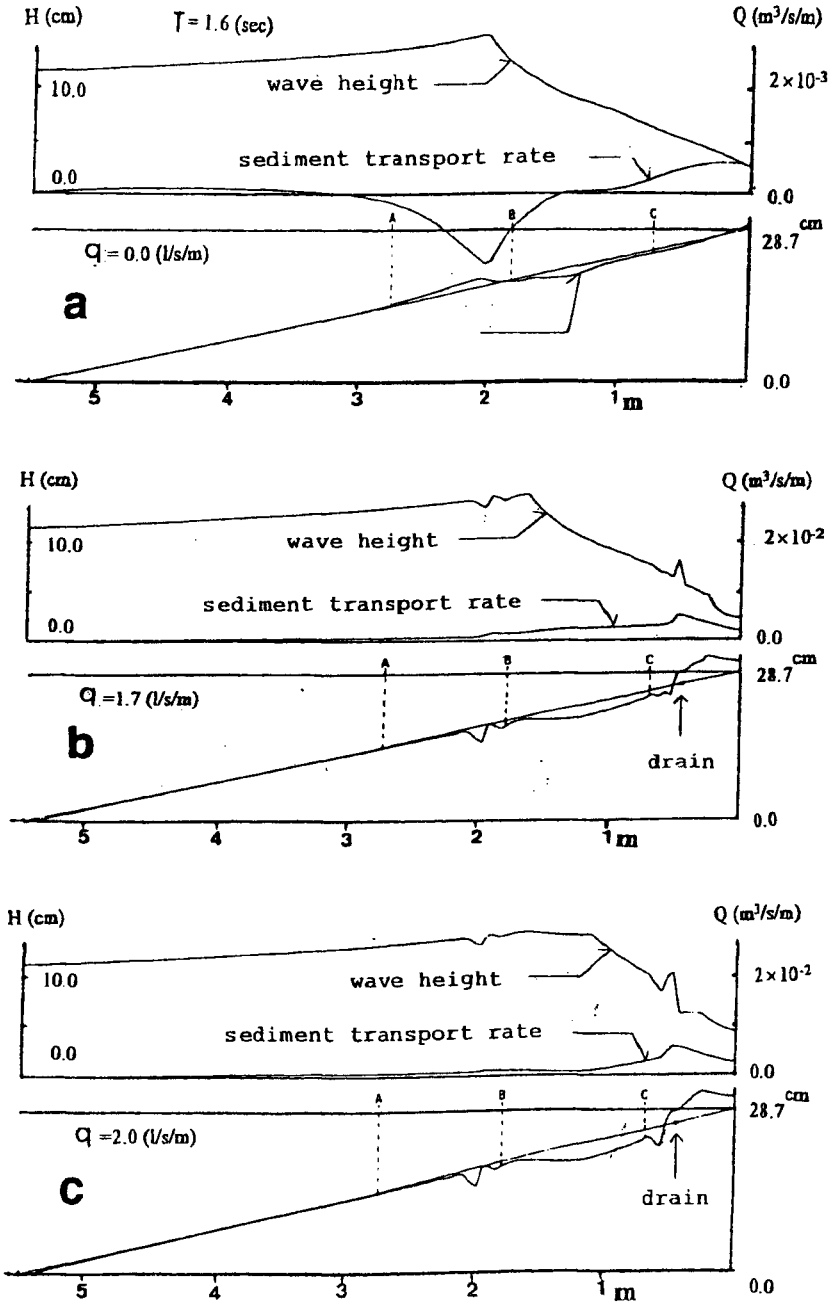

Figure 13 Calculated beach profile evolutions

Therefore, the calculated results show some features of beach profile evolution and they are considered to account for one of possible mechanisms how a coastal drain works though in a qualitative sense, when the pipe is installed under the bottom of the seaward area of a shoreline. The results, however, show fairly bumpy transformation of wave height and bottom topography. Some trials to improve the situation have been done. But, they are not successful so far. Besides, this model does not include bed load sediment transport.

To complete the numerical model for the coastal drain, it will be essential to take the bed load into consideration. However, there are some problems remained to be investigated on the bed load sediment transport under the operation of a coastal drain system like the change in flow within a wave bottom boundary layer over a drain pipe due to suction by forced drain and its effect on bed load sediment transport.

CONCLUSIONS

The following conclusions were drawn from the study:

When a drain pipe is installed in the seaward area of a shoreline,

1. the mean flow in the offshore direction over the whole beach area is reduced by the onshore current induced by drainage. This will result in the reduction of offshore suspended sediments transport in stormy conditions.
2. In this case, the changes in wave runup and wave setup, which are connected with the processes on a uprush zone, were small.

Then, an attempt to implicate the current components produced by drainage in a numerical model of beach profile evolution is discussed. To complete the numerical model, however, there are some problems remained to be investigated, especially on the effects of forced drain on bed load sediment transport.

CHAPTER 207

EVALUATION OF A BEACH DEWATERING SYSTEM: NANTUCKET, USA

William R. Curtis¹, Jack E. Davis², Ian L. Turner³

Abstract

A commercial multi-segmented beach dewatering system became operational December 1994 on the eastern shoreline of Nantucket Island, Massachusetts, USA. The objective of the installation was to cost-effectively stabilize a critically eroding reach of shoreline with minimal environmental impact. To assess the potential for wider use of beach dewatering in coastal erosion management, a comprehensive and independent monitoring program was developed and implemented to objectively evaluate the beach dewatering project. Observational methods and analyses are discussed relative to the ability to differentiate between the influence of the dewatering segments on beach response, in contrast to 'natural' shoreline response to coastal processes. Economics, measurement needs, measurement accuracy, and temporal and spatial resolution of data acquisition are discussed and evaluated.

Introduction

Nantucket Island is the eastern most member of the Elizabethan Island chain located 48 km southeast of the New England coast, USA (Figure 1). The eastern shoreline of the island is exposed to direct attack from the high-energy wave environment of the North Atlantic. Mean offshore significant wave heights are on the order of 2 m. However, offshore significant wave heights in excess of 5 m are frequently measured, particularly during winter storms. The maximum wave height offshore measured between 1984 and 1993 was 11.6 m (Hubertz, 1995). Historical charts and aerial photography indicate that, for at least the past 150 years, the beach face, dune line and bluff face have experienced episodic accretion and recession (Tiffney et al., 1991). Present estimated erosion rates along the eastern shoreline range from 0.8

¹Research Oceanographer, ²Research Hydraulic Engineer, USAE Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Rd., Vicksburg, MS 39180, USA.

³Assistant Research Scientist, University of Maryland, Laboratory for Coastal Research, College Park, MD 20742, USA.

m/yr to 4.6 m/yr, depending on location. An analysis of wave refraction patterns suggested that episodic erosion events are due primarily to the focusing of storm wave energy by an offshore shoal complex along the south eastern shoreline of Nantucket (Weishar et al., 1991).

Bluff and dune recession are presently encroaching on private and public facilities of several Nantucket coastal communities. On the eastern shore of the island, where coastal storm damage has been catastrophic, increased coastal development has led to serious consideration of beach management and land use practices.

In 1990, the Siasconset Beach Preservation Fund (SBPF), a private organization of Nantucket homeowners, sponsored an evaluation of shoreline stabilization options. Results of the evaluation revealed that structural shoreline protection alternatives such as large stone revetments and cement seawalls are not economically feasible to construct at Nantucket. In addition, state and local regulatory agencies firmly restrict use of permanent shoreline structures. Beach nourishment was also evaluated, with a projected cost of \$20 million (US) with an annual maintenance cost of \$1 million (US) to protect approximately 4.27 km of shoreline. In light of these costs, the SBPF opted to privately fund the installation of three commercial beach dewatering-system segments. The dewatering-system segments cost \$1 million (US) to construct. Projected annual maintenance costs are approximately \$100,000 (US) for the three segments.

Installation

The three beach dewatering segments were developed and installed by Coastal Stabilization, Inc., under license to the Danish Geotechnical Institute (DGI) and became fully operational in December 1994. The project at Nantucket Island is the third commercial installation of beach dewatering technology in the United States, and one of several prototype or full scale facilities installed on North Atlantic coastlines by DGI or under license to DGI (Ovensen and Schuldt, 1992; Lenz, 1994).

Each STABEACH segment consists of buried, perforated drain pipes installed in a shore-parallel orientation below the beach face swash zone. The pipes slope toward wet wells located in the back shore region of the beach. Two dewatering segments drain by gravity, while drainage at the third segment is aided by a vacuum pump. Water collected in the wells is pumped offshore through a 35.5 cm discharge pipe by a 25 hp pump. The stated operational concept of the system is to induce continuous draw down of the watertable at the beach face, enhancing the depositional effect of wave uprush and reducing the erosive effect of wave backrush during natural accretionary periods.

In total, the project spans 9.8 km of shoreline (Figure 2). The northern most segment is referred to as Lighthouse North (*LHN*). The segment immediately to the south of *LHN* is referred to as Lighthouse South (*LHS*). The southern most segment is referred to as Codfish Park (*CFP*). The three systems are separated by stretches of beach outside the influence of groundwater draw down. Figure 3 illustrates the plan-view design of the *LHN* system. Constructed STABEACH segments at *LHS* and *CFP* are similar in concept. STABEACH system parameters are presented in Table 1. Each drain pipe connects to a 1.2 m diameter wet well.

Figure 1. Location of Nantucket Island relative to New England mainland (after Oldale, 1987).

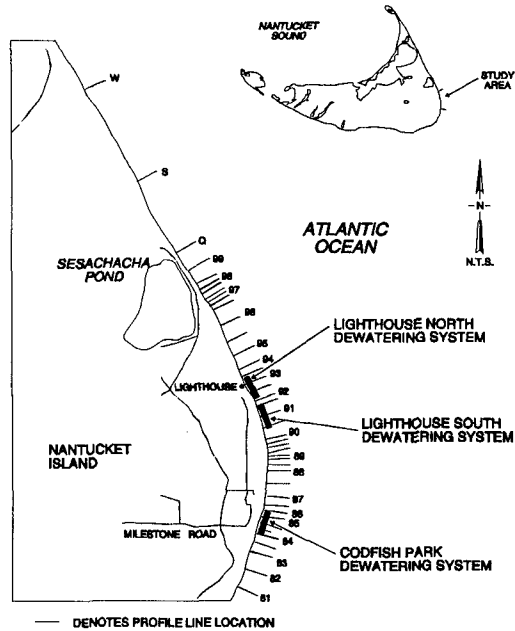

Figure 2. STABEACH segment and profile transect locations (after Coastal Planning and Engineering, Inc., 1996).

Figure 3. Plan-view schematic of Lighthouse North STABEACH segment.

Table 1. STABEACH Installation Parameters						
Segment	Drain Length	Drain Diameter	Drain Elev. (-MSL)	Drain Method	Pump Capacity	Initial Flow Rate
<i>LHN</i>	405 m	30.5 cm	2.4-3.6 m	gravity wet well	22716 lpm 6000 gpm	52 lpm/m 4.2 gpm/ft
<i>LHS</i>	309 m	30.5 cm	2.4-3.6 m	gravity wet well	22716 lpm 6000 gpm	30 lpm/m 2.45 gpm/ft
<i>CFP</i>	357 m	30.5 cm	2.4-3.0 m	low vac. wet well	11350 lpm 3000 gpm	28 lpm/m 2.25 gpm/ft

Note: gpm = gallons (US)/minute, lpm = liters/minute.

Prior to installation of the STABEACH segments, a series of tests were performed by Coastal Stabilization, Inc., to characterize hydrogeological properties of the project site. Subsurface borings identified vertical and horizontal variation of grain-size distributions. Hydraulic conductivity tests were used to optimize vertical and horizontal placement of drain lines and optimize discharge pump design. Table 2 presents average subsurface soil properties for each STABEACH location.

Location	Soil Type	Hydraulic Conductivity (calculated)
<i>CFP</i>	med-coarse sand, no fines clean, uniform	0.233 cm/s
<i>LHS</i>	fine-coarse sand, clean	0.089 cm/s
<i>LHN</i>	fine-med sand, silt/clay	0.2 cm/s

Monitoring Program

Laboratory and prototype field demonstration studies suggest that beach dewatering technology has the potential to stabilize a shoreline. However, the practical application of the technology as a viable means of coastal protection has yet to be adequately documented (Turner and Leatherman, 1996).

To assess the potential for the wider use of beach dewatering in coastal erosion management, a comprehensive and independent monitoring program was developed and implemented by the US Army Engineer Waterways Experiment Station (WES) to objectively evaluate the STABEACH project underway on Nantucket Island. The primary emphasis of the monitoring program is to evaluate whether observed beach changes can be attributed to the dewatering segments. If successful, data from the monitoring program will be used to address quantitative guidelines for the design, construction and operation of future beach dewatering-systems.

Elements of the monitoring program include measurements of beach profiles, bathymetry, hydrogeology, sediment characteristics, coastal processes and system parameters. System parameters such as discharge, operational period, and power requirements have been measured at each dewatering segment for the duration of the monitoring program. The elements of the monitoring program are described in more detail below.

Quarterly Beach Profiles

Beginning in November 1994 (pre-construction), forty-two transects have been established and surveyed on a quarterly basis (Figure 2). The project extends 9.8 km with survey transect 81 at the south end and transect W at the north end. Profile transects are regularly spaced at 305 m intervals, with the exception of 122 m intervals in the vicinity of system drain pipes. For reference, *CFP* system extends from 67 m south of transect 81 to 44 m north of transect 84; *LHS* system extends from 131 m south

of transect 91 to 83 m north of transect 91; *LHN* system extends from 46 m north of transect 92 to 122 m north of transect 93.

Each transect extends from the crest of the dune or base of the coastal bank to wading depth (-1.5 m MLW) and was surveyed with a total station and prism rod system. Elevations were surveyed at inflection points in the profile slope and at 6 m intervals from the baseline to wading depth.

To date, quarterly beach profile data have been analyzed for volume and shoreline change. Quarterly measurements document seasonal variability, and comparisons to the pre-construction surveys document the longer-term trends. Figures 4a and 4b present the variation in shoreline position (as defined by the 0.0 m MLW contour) for June 1996 data compared to pre-construction (November 1994) data. When considering profile transects 81-96.5, dewatered beaches have experienced an average shoreline recession of -5.2 m and non-dewatered beaches an average recession of -8.2 m between November 1994 and June 1996. North of transect 96.5, the averaged shoreline has accreted since project installation (0.1 m).

Figures 4a and 4b suggest that rates of recession generally decrease from south to north along the project area. Figure 5 confirms the inference as volumetric changes of the beach profiles between November 1994 and June 1996 range from -115 m³/m at profile 81 to +12.5 m³/m at profile W. The trends are consistent with longshore currents which are generally from south to north and dominated by tidal currents (Gutman et al., 1979).

Bi-Monthly Beach Profiles

Spatially and temporally dense data were acquired and are being analyzed to understand small scale variations in beach morphological dynamics as influenced by the system segments. Beach profiles were obtained at 15 day intervals for a six month period (June-November 1996) at eleven transect locations in the vicinity of and outside the influence of the *CFP* segment. Transect locations (82.6, 83.0, 83.5, 84.0, 84.3, 84.6, 85.0, 86.0, 86.4, 87.0, 87.4) were spaced at 122 m intervals in the longshore direction and had a cross-shore spatial resolution of 1.5 m from the dune to -0.9 m MLW. The objective of the high resolution profiling initiative is to correlate beach profile response with concurrent dewatered and non-dewatered groundwater elevation measurements. Through a statistical correlation of profile data with groundwater measurements, an assessment of the system-induced manipulation of beach groundwater on morphological response will be quantified.

Bathymetry

The forty-two transects established for beach profiles were extended offshore using a ship-mounted digital fathometer interfaced to the Coastal Oceanographic HYPAC program. Hydrographic surveys were conducted November 1994, December 1995 and September 1996 using standard fathometer techniques. In September 1995 and June 1996 Scanning Hydrographic Operational Airborne Lidar System (SHOALS) surveys were conducted (Lillycrop et al., 1996). Complete SHOALS surveys of the *LHN* and *LHS* offshore regions were obtained on both occasions, while surveys offshore

CFP were unobtainable due to water clarity and weather limitations. Data obtained using standard fathometer and SHOALS methods will be used in combination with the beach profiles by comparative analysis to assess the response of morphological processes to the STABEACH segments.

Groundwater Elevation

Two cross-shore transects of buried pressure sensors were installed in December 1995 and re-installed in May 1996 following storm damage at the project site to monitor the variations of watertable elevation below a dewatered and non-dewatered beach (Figure 6). Groundwater monitoring transects are located at *CFP* and at the non-dewatered beach between *CFP* and *LHS*. Sensors are either directly buried or encased in screened wells and connected to recording instruments. Data loggers sample watertable fluctuations every 30 seconds and average them over 5 minutes at 15 minute intervals. A barometer and internal thermometers are used to correct absolute pressure measurements for low-frequency barometric and temperature fluctuations. The objective of the measurements is to determine the influence of a STABEACH segment on beach groundwater dynamics and address key issues such as the effect of dewatering on bed saturation characteristics at the beach face, the influence of dewatering during storms and during post-storm recovery of the beach profile, and the effect of dewatering on the local fresh groundwater supply. The second transect of pressure sensors outside the influence of the *CFP* system will be used as a control for comparative analysis.

Other Morphological Monitoring Elements

Additional WES-sponsored monitoring include quarterly controlled aerial photographic surveys and use of a video imaging system. Aerial photographic surveys will be used to compliment analyses of shoreline and coastal dune position for the project.

A digital imaging system was installed on a lighthouse located on the bluff above the *LHN* segment. The cameras were located approximately 55 m above the beach. Three cameras were needed to photograph the full extent of the beach within view of the lighthouse. The imaging system is capable of quantifying beach changes and patterns of incident wave breaking within the camera's field of view (Lippman and Holman, 1989). The system obtains instantaneous images of the beach (Figure 7) on the hour during daylight. In addition, the system produces a 10 minute time-averaged image (Figure 8). The time averaged image is produced by sampling at a rate of 3 Hz for 10 minutes and applying an averaging routine to produce a statistically stable image. Images will be used to analyze variations in foreshore morphology at a dewatered and adjacent non-dewatered beach.

Wind and Wave Parameters

Deep water wave parameters are measured on the continental shelf at approximately 500 km east and at 223 km southeast of Nantucket Island. The moored discus buoys are maintained by the National Data Buoy Center and provide directional wind spectra, non-directional wave spectra and climatic data. Unfortunately, no shallow

Figure 7. Instantaneous digital image of Lighthouse North dewatered swash zone.

Figure 8. Time-averaged digital image of Lighthouse North dewatered swash zone and adjacent non-dewatered shoreline to the north.

or intermediate depth wave parameters are measured in the nearshore region. However, given the NDBC buoy data, shallow or intermediate water depth equivalents can be estimated. In addition, the SBPF sponsors data collection of local climate variables (e.g., wind speed, direction and barometric pressure).

Monitoring Elements of Public Concern

The SBPF sponsors environmental impact monitoring of the STABEACH segments. Parameters of public concern are measured quarterly and include the impact of beach groundwater draw down on the public fresh water supply, on dune vegetation communities, on beach meiofauna, and on system discharge quality.

Discharge Quality

Salt water is discharged offshore from all three dewatering segments. Salinity of the discharged water ranges from 21-33 ppm and is comparable to nearshore ocean water (30-33 ppm). Bacteria levels of water discharged offshore are an order of magnitude below the standard acceptable for safe swimming. Measured nitrate levels are slightly higher at the *CFP* discharge (0.21-0.54 mg/l) than the *LHS* and *LHN* discharges (0.07-0.29 mg/l). The close proximity of residential septic systems to the dewatering segment is responsible for the higher nitrate measurements at *CFP*. Variations in the elevation of the public fresh water supply aquifer are monitored at 0 m, 70 m, 104 m, 453 m and 640 m landward of the *CFP* wet wells. Monitoring results follow the fluctuation trends in the elevation of the regional aquifer landward of the wet wells, as measured by the United States Geological Survey (USGS) (Figure 9).

Maritime Vegetation and Meiofauna

Monitoring transects were established at *CFP* and *LHS* for evaluation of the impact of groundwater elevation draw down on dune vegetation communities. Variations in the vegetative communities are not influenced by dewatering-system operation. Since project construction, variations in the vegetative communities are primarily due to vegetation lost during wave erosion events. Attempts to quantify dewatering effects on beach meiofauna are not definitive. Spatial and temporal variability in taxonomic richness, diversity, evenness and total number of organisms per sample was significant at dewatered and non-dewatered sample stations (Figure 10). The influence of the STABEACH system on local meiofauna communities is not detectable from the available monitoring data.

Summary

The objective of this paper is not to present definitive conclusions as to the effectiveness of the STABEACH installations at Nantucket Island. Rather, the emphasis has been to convey elements of an independent monitoring program which was established to evaluate beach dewatering technology as a means to stabilize sand on a receding shoreline in a high wave energy environment. Shoreline position of Nantucket Island is highly variable when considering temporal scales ranging from several hours to decades. Monitoring efforts were established to identify trends in shoreline

Figure 9. Vertical changes in groundwater elevation landward of Codfish Park STABEACH segment (after Fugro East, Inc., 1996).

Figure 10. Meiofauna count for dewatered and non-dewatered beaches: 1994 and 1995 (after Fugro East, Inc., 1995).

morphodynamics on varying temporal scales as influenced by operational STABEACH segments.

WES-sponsored monitoring was initiated in June 1995 and is scheduled to terminate in May 1997. After the data collection is terminated, a comprehensive evaluation of use of the STABEACH system as a shoreline stabilization method at Nantucket Island will be presented in the literature.

Three STABEACH segments have been in operation at Nantucket Island for two years. Operation of the *LHN* segment has been nearly continuous since installation. Discharge pumps located at *LHS* were damaged during a storm in January 1996 and returned to operation at 70% capacity in July 1996 and 100% capacity in September 1996. The pump which draws water through the drains at the *CFP* segment was rendered inoperable February 1996. It is speculated that the *CFP* segment operated at 50% capacity under gravity drainage, until the pump returned to operation in August 1996.

Following 18 months of quarterly monitoring, visual and statistical analyses confirm that both dewatered and non-dewatered beaches have highly variable seasonal profile fluctuations. Quantification of the influence of drainage of the beach face on sand stabilization at the project site is presently under investigation.

SBPF-sponsored monitoring reveals that the quality of discharged water has negligible impact on water quality offshore of the dewatering-system segments. Groundwater draw down attributed to the STABEACH segments has had no discernable impact on local vegetative and meiofaunal communities. In addition, the drainage of the beach face has no adverse impact on the local public freshwater aquifer.

Acknowledgments

The Authors would like to acknowledge Coastal Planning and Engineering, Inc., Boca Raton, Florida, USA for providing shoreline analysis and beach profile volume change calculations and Fugro East, Inc., Sandwich, Massachusetts, USA for providing environmental analysis information. Results and information presented herein, unless otherwise noted, were obtained from research conducted under the Construction Productivity Research Program of the US Army Corps of Engineers by the US Army Engineer Waterways Experiment Station. Permission to publish this paper was granted by the Chief of Engineers.

CHAPTER 208

SEDIMENT TRANSPORT PROCESSES AT OCEAN BEACH, SAN FRANCISCO, CALIFORNIA

Robert T. Battalio, P.E.¹ & Dilip Trivedi, Dr. Eng., P.E.¹

The San Francisco estuary inlet and tidal bar is a highly complex system that strongly influences littoral processes on adjacent beaches. Ocean Beach is about 4 miles long, located near the entrance to the estuary (Figures 1 and 2). The purpose of the study was to investigate the extent and causes of shoreline variability at Ocean Beach, and identify possible sand transport processes and directions based on available information (Moffatt & Nichol Engineers, 1994; 1995).

Geographic Description of Vicinity

Ocean Beach is a sandy beach on the west side of San Francisco, California, USA (Figures 1,2 and 3). A linear dune behind the beach forms an embankment covering the West Side Sewer Transport Box, supporting the Upper Great Highway, and protecting the urban residential area from the Pacific Ocean. Seawalls have been constructed where the embankment eroded frequently. These structures are the most obvious indications of impacts by man dating back to the late 1800's (O'Shaughnessy, 1924; Olmsted and Olmsted, 1979; Berrigan, 1985a; O'Doherty, 1994). Perpendicular to the Great Highway are a series of streets named alphabetically from north to south (eg. Noriega, Ortega, Pacheco, Quintara, etc.) which are often used as location references.

The offshore bathymetry and shoreline to the north and south are very irregular, affecting wave propagation and littoral sand transport (Figure 1). The Golden Gate is located to the north of Ocean Beach. This channel connects San Francisco Bay with the Pacific Ocean. The large tidal prism (2.3×10^9 cubic meters, m^3 for a typical tide range of 1.5 meters) and rocky shoreline results in a relatively constricted channel (0.084 square kilometer) and strong currents (typical peaks about 10 kilometers per hour) (USACE, 1990).

1) Civil/Coastal Engineer, Moffatt & Nichol Engineers, 131

Steuart Street, Suite 300, San Francisco, California, 94105

The San Francisco Bar is a horseshoe-shaped, sandy shoal with a radius of about 5 kilometers (3 miles). The Bar crest depths are as shallow as 7.3 meters (24 feet) at low tide. Every winter, larger storm seas and swells induce wave breaking along the crest of the Bar. There are several sand shoals just east of the Golden Gate in San Francisco Bay. Sand beaches exist along the south boundary of the Golden Gate.

Figure 1: Site Location Figure 2: Aerial Photo of Site

Sediment Characteristics

Median grain sizes of sand samples from the vicinity were reported by Trask(1958), Moore(1965), Johnson(1971), USACE(1974;1993), Galvin(1979a), Woodward-Clyde Consultants (1979), Ecker(1980), and Noble(1985). At Ocean Beach, the median grain sizes were typically 0.2 to 0.6 millimeters (mm), but occasionally between 0.6 and 1.6 mm. Grain sizes vary significantly along the beach and seasonally, with larger grain sizes in the spring (Trask, 1958; Galvin,1979), especially near the base of the San Francisco Bar. Median grain sizes on the crest of the San Francisco bar are the smallest (0.1 to 0.2 mm), with coarser sizes inside the crest (0.2 to 0.7 mm). Median grain sizes inside the Golden Gate are similar.

Johnson (1971) summarizes mineralogy studies in the area.

NOTES:

1. DEPTH CONTOURS (FT) SHOWN BASED ON MEAN LOWER LOW WATER, FROM 1954 - 1956 HYDROGRAPHIC SURVEY.
2. PLANIMETRIC MAP OBTAINED FROM HAMMON, JENSEN & WALLEN, NOVEMBER 1992.

SCALE IN FEET

Figure 3: Study Area

Similar heavy mineral content in the sands were found at Ocean Beach and nearby areas (San Francisco Bar, Golden Gate, and beaches south to Pedro Point), but not for offshore areas or beaches to the north or farther south. Johnson(1971;1977) concluded that there was probably very little net sand transport at the boundary of the area defined by the San Francisco Bar and Entrance, and the beaches south to Pedro Point.

Currents

Detailed data regarding tidal currents and sediment grain sizes can be found in Enclosure 1 of USACE (1974). Tidal current charts show directions that "fan-out" to cross the San Francisco Bar roughly perpendicular to the crest. At Ocean Beach, ebb tide currents are roughly parallel to shore and southward. Flood tide currents are roughly northward. Due to the diurnal inequality, the strongest currents are associated with the larger ebb tides. Peak annual tide ranges are about 2.5 to 2.8 meters, with peak ebb currents between 2 and 4 kilometers per hour. During these strong flows, large eddies form near headlands, causing nearshore currents to flow in the opposite direction. Currents in the surf zone are strong, complex and variable. Detailed measurements are not available.

Waves

Ocean Beach is exposed to storm seas and swell generated in the Northern Pacific, and swell generated in the Southern Pacific. Large wave power is incident, with the greatest in the winter (Johnson,1977; Woodward-Clyde Consultants,1978; Cross,1980; Berrigan,1985b, Wiegel,1992). Wave refraction causes focusing of incident waves at Ocean Beach for most directions and especially for longer wave periods (Street, Mogel and Perry,1970; Woodward-Clyde Consultants,1978; USACE,1993). Long period waves begin to refract around the 200-fathom (360 meters) line noted on Figure 1. The complex bathymetry results in multiple wave travel paths incident to Ocean Beach, and exposure to waves incident from north of the geometric shadow formed by Point Reyes. Refraction over the San Francisco Bar contours causes a focusing of wave energy near the base of the Bar, even for relatively short wave periods (Figure 4). Figure 2 is a high-altitude photograph which shows wave crossings due to refraction (see also, Vincent et. al., 1994). The result is an amplified breaking wave height at the location of wave crossing, resulting in a very peaked wave form (Figure 5, Battalio, 1994).

Prior estimates of wave-induced alongshore sand transport do not agree in direction nor magnitude. Estimated rates are typically around 5×10^5 to 1.5×10^6 m³/yr (7×10^5 to 2×10^6 cubic yards/yr, yd³/yr) for the gross, and zero to 6×10^5

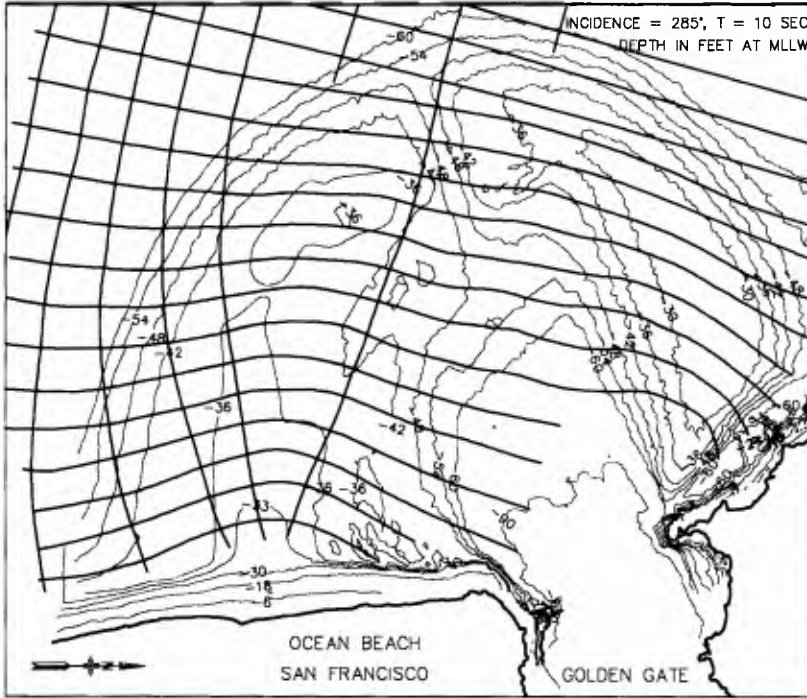

Figure 4: Wave Refraction Over San Francisco Bar
 (Source Woodward Clyde Consultants, 1978)

Figure 5: Grant Washburn Observes Breaking Wave Heights near Taraval Street, Ocean Beach, San Francisco, (Winter 1992).
 For scale, the surf board is 9 feet long. Photo: Tim Britton

m^3/yr ($8 \times 10^5 \text{ yd}^3/\text{yr}$) for the net (Street et. al., 1970; Kamel, 1962; Johnson, 1979; USACE, 1979; Galvin, 1979; Domurat, Pirie, and Sustar, 1979).

A five-year data set of daily visual observations of breaking wave heights was reviewed (Washburn, 1996). Table 1 summarizes the cumulative distribution of breaking wave heights from these data, which were observed near the base of the San Francisco Bar (Taraval Street). These observations were compared to deep water significant wave heights recorded by the San Francisco Buoy and the Monterey Bay Buoy (see Figure 1 for locations): A time series correlation analysis produced coefficients of 0.79 and 0.76, respectively, indicating a strong correlation (maximum coefficient is 1.0).

Table 1: Cumulative Distribution of Breaking Wave Heights, Taraval Street, Ocean Beach (1991-1996)

Breaking Wave Height		Frequency of Occurrence
Meters	(Feet)	Larger Waves (% of Daily observations)
1.8	(6)	50%
3.0	(10)	25%
4.6	(15)	10%
7.3	(24)	1%

The method of Hands & Allison (1991) was used to gage the potential for onshore sand transport from the Bar to Ocean Beach. An average wave period of 12 seconds, a depth of 9 meters, and the cumulative distribution given in Table 1 were used. Calculations show a strong potential for onshore sand transport, as concluded by others (Kamel, 1962; Galvin, 1979).

Wind

Strong onshore (mostly northwest) winds occur at Ocean Beach. Prior to major development in the 1900's, the area behind Ocean Beach was an extensive dune field (Olmsted and Olmsted, 1979). Sand losses due to inland transport by wind are estimated to be zero to $23 \times 10^3 \text{ m}^3/\text{yr}$ ($30 \times 10^3 \text{ yd}^3/\text{yr}$) prior to 1975, and zero to $7.6 \times 10^3 \text{ m}^3/\text{yr}$ ($10 \times 10^3 \text{ yd}^3/\text{yr}$) since then. The reduction is based on the City's practice of returning sand to the beach since 1975.

Man's Activities

Significant beach and dune fill occurred during the period 1882 to 1929, when the natural dunes were re-graded to form a straight embankment for the shore-parallel Great Highway (Olmsted and Olmsted, 1979). This resulted in a seaward shift of the shoreline of about 60 to 90 meters (200 to 300 feet) (Figures 3 and 6). The estimated net

volume changes to the beach and dunes by man since 1929 were summarized for the sediment budget (Table 3). Comparison of the shoreline data with the timing and location of sand placement indicates a northward littoral drift from the base of the Bar, which agrees with Johnson (1979).

The need for safe navigation to and from San Francisco Bay requires a dredged channel through the San Francisco Bar. The Bar Channel is authorized to a depth of 17 meters (55 feet) below mean lower low water. Since the Bar Channel was last deepened in 1975, annual dredging has totaled about $4.6 \times 10^5 \text{ m}^3$ ($6 \times 10^5 \text{ cy}$) of sand. The sand is dumped on the south part of the Bar (see Figure 10). Prior to 1971, the dredged sand was reportedly dumped about one mile southwest of the Bar Channel entrance in about 24 meters (80 feet) of water. The dump location was changed so that the sand would stay in the littoral zone (USACE, 1974).

Prior to 1971, at least 20 million m^3 (26 million yd^3) of sand was dredged. Since 1971, about 11 million m^3 (14 million yd^3) were dredged from the channel area and reportedly placed near the crest of the south side of the Bar. Of this total, about 4.6 million m^3 (6 million cy) was attributed to deepening of the channel.

Shoreline, Dunelines, and Related Volume Changes

Shorelines and toe-of-dune lines from historic maps and aerial photographs were used to investigate changes and as input to the sediment budget analysis. Five shorelines digitized from smooth sheets for the period 1850 to 1944, and eleven shorelines and toe of dune positions from aerial photographs for the period 1938 to 1993 were mapped (Moffatt & Nichol, 1994). The mean high water shoreline was used from the maps. The wetted bound visible in the aerial photos was used to estimate the shoreline position, which was found to approximate the Mean Higher High Water elevation of about +1.8 meters (6 feet) Mean Lower Low Water datum.

Time histories of the shoreline positions and beach widths for Ocean Beach and South Ocean Beach are shown in Figures 6 and 7. The Ocean Beach data show a large seaward offset between 1900 and 1929, while South Ocean Beach data do not. This is attributed to the construction of the embankment supporting the Great Highway, and related beach nourishment. The Ocean Beach data show large fluctuations about an accretion trend, while South Ocean Beach data show smaller fluctuations about a slow erosion trend. Both areas show erosion to the early 1970's, and a recovery in recent years.

Beach and shoreface volume changes were estimated by applying a conversion factor of volume change per beach area change. A range of 8 to 14 m³/m², (1.0 to 1.7 yd³/ft²)

Figure 7: Shoreline Change Data So. Ocean Beach

due to erosion of sand placed by man on the upper beach and dune, per Galvin(1979) and Ecker (1980). Volume changes for the dune face were calculated using a conversion factor that ranged between zero and 6 m³/m² (0.74 yd³/ft²) of dune line change.

San Francisco Bar Depth Changes

Prior studies of historic changes to the San Francisco Bar have been identified by Gilbert(1917), Homan and Schultz(1963), and Johnson(1965). Figure 8 shows the depths surveyed in 1900. Figure 9 shows the depths surveyed in 1956, and major depth changes since 1900.

Prior to 1900, the Bar had a relatively consistent "cusplate" shape. By 1956, outer portions eroded and inner portions accreted. Significant changes include the dredged channel, which is deeper, the area closer to Ocean Beach, which is shallower, and the Bar crest, which

of beach change was used to calculate the values for Beach and Shoreface in Table 3. The higher value was developed based on a review of profile "closure" elevations and the assumption that the shoreface geometry remains essentially constant as the shoreline migrates. The minimum conversion factor was based on the assumption that shoreline changes were

Figure 8: Bathymetry of San Francisco Bar, Circa 1900

generally shows a radial "shrinking."

Volume changes calculated for the San Francisco Bar by a comparison of the 1900 and 1956 survey maps are provided in Table 2. The Table includes volume changes adjusted for two arbitrary systematic elevation corrections.

Since no recent survey is available, and due to the sensitivity to vertical control, the Bar changes were not directly incorporated into the sediment budget.

TABLE 2: San Francisco Bar Volume Changes and Sensitivity to Systematic Elevation Corrections

LOCATION	VOLUME CHANGES FOR 1900-1956 TIME PERIOD		
	Million Cubic Meters		
	Calculated	0.09 m correction	0.12 m correction
Four Fathom Bank	4.5	0.0	-1.5
Channel	-10.2	-12.4	-13.2
South Bar	19.2	14.6	13.1
Net Change	13.5	2.2	-1.5
Average Rate (m3/year)	241,000	39,000	-28,000

Sediment Budget Analysis

The sediment budget was developed to best use the available data, as summarized in Table 3. A range of values were used to reflect the uncertainty of the available data, and to facilitate a sensitivity analysis. The sediment budget analysis was applied to the Ocean Beach shoreface, beach, and dune face.

Based primarily on the historic shoreline positions, the sediment budget analysis was applied to the time period of 1929 to 1971 and 1971 to 1992. By 1929, the shoreline and embankment had been established roughly in its present location. An erosion trend dominated to 1971, becoming an accretion trend to the present. Starting in 1971, sand dredged from the Bar Channel was disposed on the Bar offshore of Ocean Beach, and the Channel was deepened significantly. Starting in 1975, wind blown sand was returned to the beach by the City.

For 1929-1971, a net deficit of 1.3×10^4 to 1×10^3 m³/yr (1.7×10^4 to 1.4×10^3 yd³/yr) is calculated (**Subtotal (I-II)** in Table 3). This range is small, and within the possible range of wind-induced losses inland, so that it is possible to balance the budget for this time frame by assuming zero net sand transport at the area boundaries, or that net input at one boundary (onshore from the Bar), is balanced by losses past other boundaries (north past Point Lobos, and/or south past South Ocean Beach). Local

knowledge indicates erosion is occurring in the area south of Ocean Beach, while sand accumulation is a problem in several areas along the north waterfront of San Francisco. It is therefore considered more likely that losses from Ocean Beach are passing Point Lobos and migrating into San Francisco Bay.

TABLE 3: Sediment Budget for Ocean Beach, San Francisco (Annualized for Listed Time Periods)

No.	ITEM	RANGE OF SAND VOLUME CHANGES (Thousands of Cubic Meters per Year)					
		1929-1971		1971-1992		1929-1992	
		Low	High	Low	High	Low	High
I	VOLUME CHANGES						
1	Beach & Shoreface	(7.3)	(12.6)	103.4	175.9	29.6	50.2
2	Dune Face (data from 1938)	0.0	(3.1)	0.0	(10.9)	0.0	(5.7)
	Net Volume Changes	(7.3)	(15.7)	103.4	164.9	29.6	44.5
II	SAND INPUT (LOSSES)						
3	Net Beach/Dune Nourishment (+) Mining (-)	5.5	9.1	36.4	36.4	15.8	18.2
4	Wind Blown Loss to Inland	0.0	(23.7)	0.0	(7.3)	0.0	(18.2)
	Net Input (Losses)	5.5	(14.6)	36.4	29.1	15.8	0.0
	Subtotal (I - II)	(12.7)	(1.1)	67.0	135.8	13.8	44.5
III	Estimated to Balance Budget						
6	Minimum Northward Transport Past Point Lobos	(12.7)	(77.6)	(12.7)	(77.6)	(12.7)	(77.6)
7	Minimum Onshore Transport From San Francisco	0.0	76.5	79.7	213.4	26.6	122.1
	Subtotal	(12.7)	(1.1)	67.0	135.8	13.8	44.5
III	Total (I - II - III)	0	0	0	0	0	0

For 1971-1992, a net surplus of 6.7×10^4 to 1.4×10^5 m³/yr (8×10^4 to 1.8×10^5 yd³/yr) is calculated, which is a significant change from the previous period. This rate of input can only be explained by alongshore transport from the area south of Ocean beach, or onshore transport from the Bar. However, only the onshore transport potential from the Bar changed markedly around 1971, due to the change in dredging practices.

Postulated Rates to Balance Sediment Budget

The third part (III) of Table 3 shows one possible solution to the sediment budget. Assuming a range for onshore transport from the Bar during 1929-71 to be zero to 7.6×10^4 m³/yr (1×10^5 yd³/yr), the loss due to alongshore transport past Point Lobos is calculated to be about the same as the input from the Bar. For the period 1971-92, the rate of alongshore transport past Point Lobos is assumed to be the same as for 1929-71. The required onshore sand transport rate from the bar is then calculated to be 8×10^4 to 2.1×10^5 m³/yr (1×10^5 to 2.8×10^5 yd³/yr).

Figure 10 presents the 1971-92 rates and postulated sand transport for the Ocean Beach, Golden Gate cell. The net alongshore transport rate at Ocean Beach is estimated to

be northward. The rate decreases with distance north, with sand accumulating in the beach and dunes. South of the base of the Bar, the net alongshore transport rate is unknown, but expected to be near zero.

The sand that passes Point Lobos is believed to mostly continue alongshore through the Golden Gate. Some is lost to maintenance dredging and dunes. The remainder is speculated to return to Ocean Beach by ebb tide currents, probably diverting from shore at several locations. Some or most of the sand is believed to migrate back to the San Francisco Bar prior to returning to Ocean Beach.

These rates are presented as long-term, average annual rates that could be substantially different in any particular year. Further study is needed, including

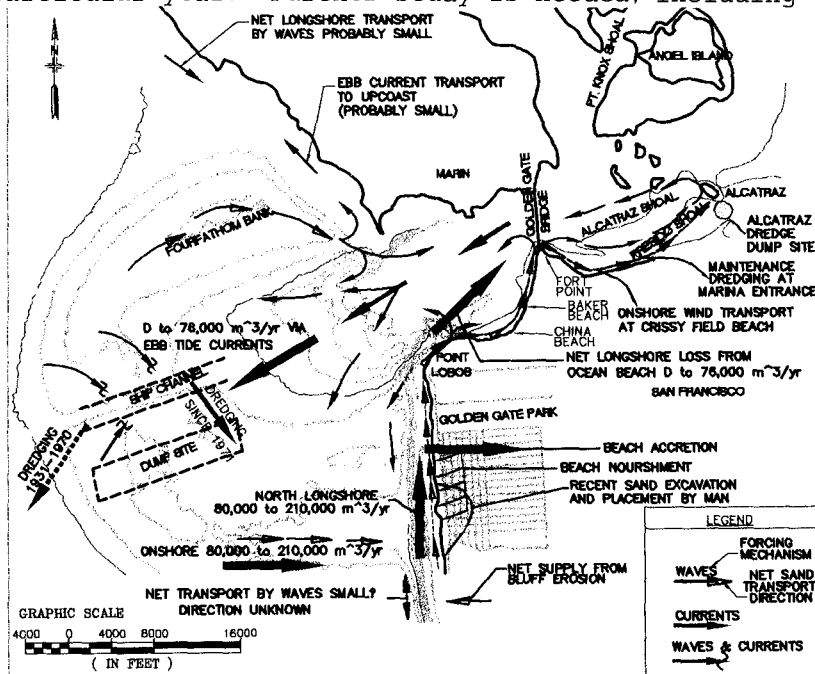

Figure 10: Residual Sediment Transport at Ocean Beach

recent Bar changes, sand transport and sediment budget in the Golden Gate area, and sand transport and sediment budget south of Ocean Beach to Pedro Point, Pacifica.

Acknowledgements

A Technical Review Panel reviewed the methodology and results, and provided guidance. Members included USACE (George Domurat, Tom Kendall and Len Madalon), City and County of San Francisco (Dave Jones), U.S. Geological Survey (John Dingler), Professors Robert Wiegel, Paul Komar and Ray Krone,

CHAPTER 209

TWO TREATMENTS OF SHORE EROSION IN EXTREME FLOODS ON U.S. GREAT LAKES

Robert J. Hallermeier¹

Abstract

This investigation addresses empirical evidence on wave action and shore erosion during extreme floods on Great Lakes coasts. Historical information shows that record coastal floods on the Great Lakes usually involve moderately extreme storms during relatively brief intervals with overall lake level much above the long-term average. The 100-year flood on U.S. lakeshores appears most likely to be accompanied by coastal wave heights with recurrence interval of about: three years on the four upper Great Lakes; or one-half year on Lake Ontario. Shore changes during the 100-year flood seem susceptible only to a coarse statistical estimate because available studies reveal Great Lakes erosion to be extremely variable in onset and amount. Two simplified erosion treatments are outlined here, one applying average annual recession rate for a locality, and the second, an empirical relationship originally developed for seacoast storm effects. The latter treatment appears verified by evidence from a Lake Michigan study, and such estimates of episodic erosion cross section are much lower than for extreme events on U.S. seacoasts.

INTRODUCTION

Conclusions developed in the following material are intended for application in the U.S. National Flood Insurance Program (NFIP). The NFIP includes the generation of maps quantifying expected hazards for the local base flood, an event having average annual probability of one percent (or mean recurrence interval of 100 years). Suitable coastal assessments must take into account distinctive characteristics of extreme events along Great Lakes shores, reflecting the particular basin configurations along with the marked variations of mean water levels over long terms.

To demonstrate the distinctive circumstances on the Great Lakes, Figure 1 displays annual mean water levels since 1860 for Lake Huron, with very large oscillations apparent but no clear trend during this century. That behavior strongly differs from the historical sea levels on the Atlantic ocean, where a rising trend is the most notable feature and other variations appear relatively minor. These signals indicate a

¹ Senior Coastal Scientist, METS Division, Dewberry & Davis, 8401 Arlington Boulevard, Fairfax, Virginia 22031-4666, U.S.A.

Figure 1. Annual mean water elevations on Lake Huron and Atlantic seacoast

markedly different context exists for coastal processes and extreme floods on the Great Lakes, in comparison to seacoasts.

Until recently, only stillwater inundation was considered in mapping coastal flood hazards for the Great Lakes, but documented flooding during the 1985-1987 highs clearly established the importance of additional wave effects. For NFIP treatments of U.S. Great Lakes shores, a full suite of methodologies for hazard assessment now addresses local stillwater flood elevations, shore erosion expected during the base flood, wave dimensions including growth or decay in coastal areas, and wave runup elevations at barriers to flooding. The U.S. Army Corps of Engineers (USACE) has documented conclusions on extreme local stillwater elevations from long-term records (USACE, 1988) and has provided a simplified treatment for wave runup at the most common types of shore barrier (USACE, 1989). This paper outlines the development of guidance on two other aspects of flood hazards: incident wave action

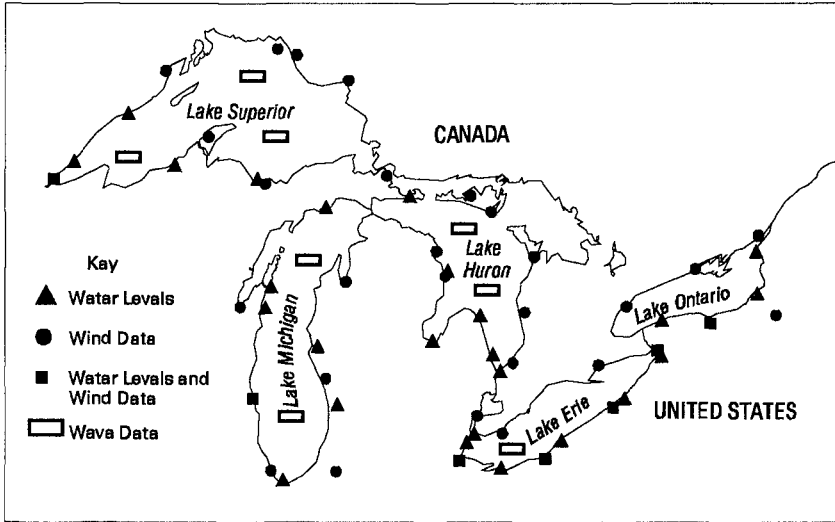

Figure 2. Pertinent data locations for Great Lakes investigations

and resultant shore erosion expected to accompany a base flood on the Great Lakes. These topics are interrelated, since shore erosion from wave action with flood waters alters the crucial boundary condition for storm impacts, thus controlling magnitude and penetration of wave effects over flooded land.

The following considerations are entirely empirical in basis, using best available information on recent extreme events. Quantitative analyses (Dewberry & Davis, 1995) have examined storm wave heights, flood elevations, and erosion magnitudes documented at about 100 varied sites on the U.S. Great Lakes. The necessary order of treatment begins with wave conditions during floods and proceeds to erosion considerations.

WAVE ACTION DURING FLOODS

Wave conditions during record Great Lakes floods have been computed in the recent USACE hindcast covering 1956 to 1987 (e.g., Hubertz and others, 1991). That interval includes 20th-century highs in mean lake levels during 1973-1975 and 1985-1987, along with record instantaneous elevations at many water-level gauges. Before combining this disparate information on waves and water levels for extreme events at particular sites, it is appropriate to examine the reliability of wave hindcast results. Figure 2 provides a map locating important data sites.

The USACE hindcast procedure applies measured winds at scattered land stations (Figure 2) to define wind fields over each lake, and then computes resultant wave action at many deep-water sites. Validation possibilities for hindcast computations are restricted to limited nearshore measurements and to several long-term buoy sites near the lake centers (Figure 2). The reported verifications of hindcast waves tend to

Figure 3. Hindcast versus measured extreme wave heights on four upper Great Lakes; separate lakes identified by initials used in plot.

focus on overall distributions of parameters, consistent with a comprehensive long-term hindcast. However, the present application utilizes brief intervals of storm winds, surges and waves, so the hindcast reliability for such extreme conditions merits evaluation. This is in line with the caveat stated by Hubertz and others (1991): "It is recommended that separate studies be done for specific storms at specific sites for more detailed information."

A convenient evaluation of the hindcast may be based on 35 extreme wave heights tabulated in a published summary of buoy data (Gilhousen and others, 1991). Those 1979-1987 measurements pertain to eight buoy sites on the four upper Great Lakes, and include all tabulated wave heights among the extreme 1% at each site. Hindcast wave height for each case is taken as the highest value during the same wind episode at a nearby computation point. This present selection yields a fairly balanced sample of extreme conditions, with separate lakes identified by the initial used in plotting results on Figure 3. Measured wave heights in this sample are typically on the order of 4.5 m (or 15 feet). Comparison of hindcast and measured wave heights yields a correlation coefficient sufficient to confirm a linear relationship with certainty. However, the hindcast does not accurately reproduce these measured conditions, being 20% low typically and having an error band of $\pm 20\%$. Part of the hindcast bias may be explained by a lower peak value with the three-hour hindcast interval versus hourly measurements, but the error band remains notable. That sizable random scatter of hindcast wave heights appears related to errors in interpolated winds at buoy sites, as shown in Figure 4 using measured windspeeds also tabulated for a typical 7 of the 35 cases (Gilhousen and others, 1991).

Figure 4. Relation of wave height and windspeed errors in Great Lakes hindcast.

According to this modest but objective selection of storm events, there are considerable errors in the USACE hindcast of extreme wave conditions on the Great Lakes. The data buoy sites may present a notable challenge for wave hindcasts, given relatively large separations from wind data locations. Hindcast results may generally be more reliable at nearshore sites, but appreciable variations in accuracy still seem likely in view of the scattered stations providing wind data. To apply USACE hindcast information in assessing wave action accompanying extreme floods, it seems advisable to maximize the variety of sites and events considered together, aiming at a simplified conclusion with generic pertinence to Great Lakes shores.

That program is carried out by considering in one group the record flood during 1956-1987 at each of 32 water-level gauges (Figure 2), along with wave hindcast results at a nearby computation point for the same episode. To use evident measures of extremity, both peak measured water elevation and largest computed wave height for each event are converted into recurrence intervals from the type of results shown in semi-logarithmic form on Figure 5. There, purely exponential recurrence relations as straight lines are fully defined by the medians of monthly and yearly highs, plotted at recurrence intervals of two months and two years, respectively. Such simplified analysis provides the advantages of a direct basis in annual probability along with a recurrence estimate for any value; note that results for relatively common flood elevations relate smoothly on Figure 5 to reported USACE conclusions on extremes. This example of recurrence relations is remarkable because each line has nearly

Figure 5. Summaries of extreme effects on Lake Erie at Toledo, Ohio

identical inclination. The inclination is representative of flood elevations on any of the Great Lakes except Lake Superior, where the line would tilt much less; for wave heights, the line has about the minimum inclination to be found on the Great Lakes, while water rises typically define a line with less inclination.

Figure 6 presents a logarithmic cross-plot of recurrence measures for the 32 extreme events, again distinguishing the separate Great Lakes by initial. Measured flood elevations for these cases typically have recurrence intervals on the order of 50 to 100 years. Immense scatter is evident among these results, in part reflecting the notable errors possible in hindcast wave heights and those recurrence intervals. The $\pm 20\%$ estimate based on Figure 3 converts to various sizable ranges in recurrence intervals for wave heights here, depending strongly on the hindcast result and the local recurrence relation; a usual error bar for representative results extends over a factor of ten. However, a very wide range in wave extremity certainly can be associated with a given flood elevation on the Great Lakes, considering that significant variables include mean lake level and lake seiches, in addition to storm winds.

From close inspection of available evidence, floods on Lake Ontario differ from effects on the four upper lakes in always being associated with very common hindcast wave conditions; in contrast, notably extreme waves occasionally occur during many floods on the other Great Lakes. Deleting the Lake Ontario floods in Figure 6, remaining results yield a sizable positive correlation between recurrence intervals for wave height and flood elevation. The regression result shown in Figure 6 has statistical significance at the 5% level (but not the 1% level; Sachs, 1984), and indicates wave height recurrence of about 1 year for the 100-year or base flood. Since the correlation has limited significance, this evidence may also be examined

Figure 6. Parameters describing 32 recent extreme floods on Great Lakes; displayed regression result omits events on Lake Ontario (O).

without regard to trend: the most common condition with these record floods is about a 2-year wave height, according to the band of results in that vicinity. Such wave conditions occur during events from mid-November through mid-April, when storm winds can overwhelm the seasonal water levels least conducive to flooding. Taking into account the hindcast bias, these considerations indicate a prudent conclusion to be that a 3-year wave condition (as defined here by an exponential recurrence relation) accompanies the base flood at typical U.S. shore sites on Lake Erie, Huron, Michigan, or Superior.

Hourly water-level measurements demonstrate that lake seiches rather than storm surges are dominant in extreme flood elevations on the U.S. shore of Lake Ontario. There, the large seasonal excursion of mean lake level enhances flooding during the usual May-July high, when onshore storm winds rarely occur. An appropriate conclusion is found to be that wave height with a ½-year recurrence interval accompanies the base flood on U.S. shores of Lake Ontario.

Present conclusions must be recognized as highly generic regarding the likely wave action during extreme floods on the Great Lakes, and as somewhat tailored for routine NFIP application. Additional analysis or historical evidence may provide more appropriate estimates for specific shore sites.

EROSION EFFECTS AND TREATMENTS

Detailed measurements of shore changes pinpoint the apparent complexity of Great Lakes effects over space and time. A striking attribute is erosion variability over all but the longest terms, so that coastal changes during extreme conditions seem coherent only in a statistical sense over appreciable shore reaches. Many factors can be important in Great Lakes erosion processes, but the characteristic result appears to be quite intermittent progress in the fall and removal of dune or bluff sediments, yielding a markedly slowed or interrupted replica of typical seacoast storm effects. This discussion will address just a few erosion studies on sandy coasts of Lake Michigan, considered representative for various erodible lakeshores.

Two intensive studies, Hands (1979) and Birkemeier (1981), documented erosion along the eastern shore of Lake Michigan during the 1964-1973 interval when the increase in mean lake level was about 1.5 meters. Hands (1979) reported shoreline positions at irregular time intervals of a year or more, for a total of 30 transects spanning about 50 km near Pentwater, Michigan. Alongshore variability of retreat rate was extreme as lake level generally rose over 8 years, but the average or median rates over available transects were rather steady in time, regardless of mean lake level or storm climate variations. Those findings do not appear sensitive to the spatial or temporal frequency of measurements, or a later study area extension. As lake level declined over the last study year, shore accretion typically reversed about two years of retreat. The basic results might be summarized as indicating a lagging response to the increasing erosive stress with rising water, but only in an overall sense; changes on individual transects appear too variable in time for simple interpretation.

In the other study, Birkemeier (1981) summarized survey results at four-week intervals during 1970-1974, for 17 profiles roughly 20 km apart. Shore erosion appeared somewhat random in time and location: various numbers of profiles showed bluff or terrace retreat in greatly varying amounts over separate intervals. However, erosion was also clearly seasonal, in phase with the annual storm cycle but not with

Figure 7. Bluff recessions during 1970-1974 on 17 Lake Michigan profiles.

the lake level cycle. Through the complete study term, changes accruing through sporadic episodes disclose some orderly variation over the entire data set: total recessions on individual profiles conform to a normal probability distribution with sizable dispersion, as shown in Figure 7. With no clear geographical trends, nor much correlation between adjacent profiles, the effectively random scatter of recorded erosion seems to result from the interplay of many independent factors, with insufficient time to develop an equilibrium response.

Even long-term changes on the Great Lakes can require careful interpretation due to the dependence of shore erosion on mean lake level, as revealed by results from two recent studies of Lake County, Illinois. Jibson and others (1994) addressed rates and processes of bluff erosion based on measurements for 1872-1937 and 1937-1987. Average retreat rate over the region showed no significant difference for the two periods, during which mean lake level or precipitation was nearly identical. However, Chrzastowski and others (1993) studied the same shore reach and timespan, but with three intervals isolating sizable elevation differences for Lake Michigan. Documented results reveal significant correlations between the mean lake level and representative movements of sandy shoreline or coastal bluff top, as demonstrated in Figure 8. Since differences from the long-term mean can be larger over briefer intervals, mean lake levels apparently contribute to sizable departures from an average erosion rate.

With this brief outline of factors and variabilities in Great Lakes erosion, it seems clear that statistical viewpoints can most conveniently provide useful summaries or projections. In turn, projections for short-term or storm erosion may be expected to

Figure 8. Representative erosion rates versus mean Lake Michigan levels.

attain only order-of-magnitude agreement with actual effects, but suitable procedures for erosion estimates might be rather simplified or generalized in basic character. Two treatments outlined here apply either average local recession rate, or storm erosion quantities from a generic database, the two evident alternatives. The independent treatments take into account distinctive attributes of the Great Lakes.

The first alternative applies the local value of A , average annual rate of shore recession over a long term. This development presumes available topography to be defined during usual lake levels, and addresses cumulative erosion until the base flood is likely to be encountered. As mean lake level rises to highs conducive for the base flood, shore recession is more rapid than the long-term average, and described as a rate of $(2.5 A)$. If that rate occurs over about one-third of a long term, it implies that $(0.25 A)$ is characteristic otherwise, and such a range of values appears appropriate according to available Great Lakes studies. Projected erosion before the base flood equals the accelerated rate times an expected waiting time of 4.8 years with high lake levels. That waiting time is supported by the normal probability distribution defined by data in Figure 9: actual intervals of high lake level before the record flood during 1972-1987, at 31 gauges on the four upper lakes. Given the notable storm waves likely to accompany an extreme flood on the four upper lakes, the additional allowance of $(3A)$ for storm erosion in the base flood appears appropriate. These considerations yield $(15A)$ as projected site erosion on Lake Erie, Huron, Michigan,

Figure 9. Waiting times for record floods at 31 sites on four upper Great Lakes, after onset of monthly mean levels higher than long-term mean.

or Superior; and (12A) on Lake Ontario. These recession distances describe a parallel retreat of the shore profile from the reference feature to which A pertains.

Such treatment seems relatively straightforward, but the result does not appear validated by measured Lake Michigan erosion reported by Birkemeier (1981). On 17 profiles in nine separate Michigan counties, total recessions over 4.3 years of high lake level show essentially no correlation with average long-term recession rates documented for the individual counties. Although no extreme flood occurred within the study area over this term, cumulative recessions make the present estimation method seem of dubious usefulness. This might be caused by the multiplication of two very uncertain quantities, in regard to short-term applicability at specific sites.

The second alternative considers only the storm effects likely to be associated with the base flood, using an empirical relationship for expected erosion in duneface retreat on U.S. Atlantic and Gulf coasts (Hallermeier and Rhodes, 1988). The relationship

expresses eroded cross section above flood elevation in terms of recurrence interval for the flood, amounting to 50 m² erosion in a 100-year event:

$$\text{Erosion [m}^2\text{]} = 8 (\text{Recurrence Interval [yr]})^{0.4} \quad (1)$$

This erosion treatment has proved to be suitable for NFIP applications in defining coastal flood hazards, and has been validated by effects recorded in more recent extreme events (e.g., Wolf and others, 1993).

Along U.S. seacoasts, wave condition and flood elevation generally may be expected to have comparable recurrence intervals for most episodes in a sizable sample of extreme events, but that is not the case for the base flood on the Great Lakes, as established by Figure 6. This application therefore employs a blend of individual erosion estimates for the wave and flood recurrences, using the geometric mean of cross sections defined by the basic relationship in Equation (1). Resultant erosion for the base flood, with a 1/2-year wave condition on Lake Ontario and a 3-year wave condition on the four upper lakes, is estimated as: 17 m² for Lake Ontario sites; and 25 m² on Lake Erie, Huron, Michigan, or Superior. These quantities are taken to be eroded amounts above local 100-year stillwater elevation.

Results from this erosion treatment appear consistent with storm erosion quantities documented in the Lake Michigan study by Birkemeier (1981). Erosion was recorded on a majority of the 17 profiles only during two intervals, covering notable storms in mid-December 1971 and in mid-March 1973. As defined by USACE hindcast wave heights and measured water elevations: the 1971 storm had 1/2-year waves and a 1-year flood, giving an erosion estimate of 7 m²; and the 1973 storm combined 4-year waves and a 1 1/2-year flood, for an erosion estimate of 11 m². Average bluff cross sections removed on the eroding profiles in those events were 8 m² during December 1971 (for 10 profiles) and 10 1/2 m² during March 1973 (11 profiles). The quantitative agreement of estimates with representative erosion magnitudes in these cases provides appreciable validation of the present viewpoint, since base flood estimates for the Great Lakes lie between these amounts and many documented seacoast episodes. However, serious uncertainties in predicting the onset and amount of short-term erosion at Great Lakes sites remain worth emphasizing.

CONCLUSIONS

Empirical evidence provides an extensive basis for simplified summaries of the wave action and erosion expected to accompany the base flood on U.S. shores. Lake Ontario sites may be expected to experience wave heights having recurrence interval of 1/2 year and eroded cross section of 17 m² above flood elevation. Wave heights having recurrence interval of 3 years and erosion of 25 m² are projected for sites on Lake Erie, Huron, Michigan, or Superior. These results pertain only to storm-induced flood episodes, and are intended for routine application in flood hazard assessments within the National Flood Insurance Program.

CHAPTER 210

LONG-TERM BEACH RESPONSE TO SHORE STABILIZATION STRUCTURES ON THE OREGON COAST

G.E. Hearon¹
W.G. McDougal²
P.D. Komar³

ABSTRACT

Increased development along the Oregon coast has led to heightened concern over beach erosion. As a result, more shore stabilization structures have been erected in recent years. A long-term field monitoring program, involving seven typical structures located on the central Oregon coast, was initiated in the spring of 1986 to quantify the effects of shore stabilization structures on the surrounding beach and adjacent properties. All structures are rip-rap revetments or seawalls. Volumetric changes of the subaerial beach at each site were examined at scales ranging from the entire beach surrounding the structure to the beach in the immediate vicinity of the structure. When the data coverage and site geometry permitted, a far field control section was utilized to compare the volumetric response of a portion of beach relatively uninfluenced by the presence of the structure with that of the beach on the two structure flanks. Measurements are presented for the seven structures over the observation period of ten years to document the long-term effects the structures are having on the fronting beach and adjacent unprotected properties. Ten years of monitoring has revealed that the structures at these seven sites are having no adverse impacts on the surrounding beach or adjacent properties. This can be attributed to the limited amount of wave attack that the structures have experienced. The structures are built high on the profile, and experience wave attack only during the most severe storms.

INTRODUCTION

The structures selected for the monitoring program are located between Neskowin and Florence; spanning a distance of nearly 100 miles of the central Oregon coast. Structures were selected in locations such that the number of factors that could affect the long-term beach change were reduced primarily to the structure itself. As a result, the majority of the structures were chosen such that there were no headlands, jetties, or river mouths in the immediate vicinity, and the adjacent properties were unprotected for at least three structure lengths on either side of the structure. The structures are backed by dunes, sea cliffs, or bluffs; all common coastal environments in Oregon. Table 1 shows the characteristics and site codes

Table 1 Site and Structure Characteristics

Site	Site Code	Structure Type	D ₅₀ (mm)	Length (m)
Pacific Sands Motel	PSM	Timber Seawall	0.30	70
Gleneden	GE	Rip-Rap Revetment	0.53	40
Pacific Palisades	PP	Rip-Rap Revetment	0.31	300
Pacific Shores	PS	Rip-Rap Revetment	0.20	20
C&L Ranch	CL	Rip-Rap Revetment	0.20	25
San Marine	SM	Rip-Rap Revetment	0.22	150
Driftwood Shores	DS	Rip-Rap Revetment	0.21	30

(abbreviations) of the seven sites selected for the field monitoring program. The study was initiated to aid the Oregon State Parks Division and DLCD, which regulates the construction of coastal structures in their permit review process.

DATA COLLECTION

Field data, in the form of multiple beach profiles, were collected intermittently from the fall of 1986 to 1990, and resumed in the winter of 1995. On average, the database contains fifteen surveys per site. An effort was made to obtain at least a winter and summer survey for each year. Numerous transects were measured with an EDM in order to monitor the topography of the beach surrounding each structure. Weather permitting, the surveys provided coverage at least five structure lengths on either side of the structure, and seaward to the swash zone. Transects were spaced on the order of 20 m to 30 m on planar beaches with little three-dimensionality in the longshore direction. For more three-dimensional beaches displaying cusps, transects were spaced accordingly to achieve an accurate representation of the beach.

ANALYSIS METHODS

The beach profile data were analyzed using contour plots, surface plots, contour of difference plots, and results from sand volume calculations. The profile data were interpolated to a uniformly spaced rectangular grid using MatLab codes, from which the plots and sand volume calculations were generated. To obtain the maximum use from the gridded data and explore all aspects of the structures effect on the surrounding beach, several scales were examined. A large scale (Scale I) was examined by considering the largest common area of beach covered in the field monitoring program. To reduce seasonal contamination and noise in the analysis, an intermediate scale (Scale II) was employed, defined as two structure lengths to either side of the structure and one structure length seaward. Finally, to concentrate on effects in the immediate vicinity of the structure, a scale consisting of the two structure flanks and beach immediately fronting the structure (Scale III) was examined. Each scale was divided into three sections; north, center, and south. When possible, the north and south survey sections were defined with the same sizes, thereby allowing a direct comparison between the two sections.

This approach was used primarily for analyzing the changes in sand volume. The volume of sand on the beach was calculated in reference to the 1929 NGVD mean sea level. Volumetric response, or the magnitude to which the sand volume is changing due to erosion and accretion events, was examined with the results of the volumetric calculations. The flanks on either side of the structure are typically considered the most susceptible to erosion; therefore, the sand volume of the north and south flanks, and the volumetric changes of the sand at these flanks over the observation period were of particular interest. Comparison of the sand volumes at these flanks with a far field control section, relatively uninfluenced by the presence of the structure, was an important analysis tool. The far field section provides a baseline to which volumetric responses close to the structure can be compared. The location of the far field section was always taken at the same distance from the bluff and defined with the same plan area as the flank section.

Contour and surface plots provide a means to observe seasonal changes at the sites, such as profile slope or formation of a berm or rip current embayment, as well as an indication of how the beach changes or adjusts in the vicinity of the structure. Figure 1 shows a contour and surface plot from Gleneden, obtained in June 1989. Contour of difference plots were used to show the specific areas of erosion and accretion between two sequential sets of beach profile data. They are useful in determining the degree to which the beach in the vicinity of the structure was responding to erosion and accretion events. Used in conjunction, this array of tools, contour and surface plots, contour of difference plots, and sand volume calculations, provide a detailed account of the long-term changes at the sites.

Figure 1 Contour and Surface Plot for Gleneden, June 1989

RESULTS

Analyses were undertaken by examining the contour and surface plots and the sand volume calculations for each site at of the aforementioned scales. One site will be analyzed in greater detail to illustrate the methodology and techniques used throughout the study to derive conclusions for all seven sites. A complete analysis of all sites is given in Heaton (1995) and Sturtevant (1987). Data for the remaining six sites will be presented in two forms, the volume of sand at Scale I over the observation period, and the results of the far field baseline comparison. Research has shown that the structure flanks are susceptible to erosion, therefore the results of the far field comparison are an effective indicator of structure induced impacts. The far field comparison data will be displayed in a normalized form, the volume of sand at the structure flank divided by the volume of sand in the far field control section ($V_{\text{flank}}/V_{\text{far field}}$). It is stressed that conclusions for each of the sites were derived by utilizing all analysis tools discussed in the previous section, and not solely from the data presented herein.

C&L Ranch (CL)

C&L Ranch provides an excellent open coast site. The structure is a 25-m long rubble mound revetment that protects and stabilizes the backing bluff. There are no headlands, jetties or river mouths in the vicinity. The bluff is shore parallel and unprotected for several structure lengths to either side. The land slide potential of

the bluff is high. Evidence of several recent localized slides was observed during the 1995 data collection. Aerial photographs indicate that the beach and bluff line at C&L Ranch has changed little from 1965 to 1983.

The complete series of contour and surface plots indicates that the beach at C&L Ranch is very flat and planar throughout the year, exhibiting very little three-dimensionality. A summer berm was not observed in any of the surveys. The flat, dissipative beach at C&L Ranch is common on the central Oregon coast. A slight increase in sand elevation in the vicinity of the structure was observed in the majority of the contour and surface plots. The increased sand elevation was generally at the beach face junction of the flanks or at the seaward corners of the structure. The increased sand elevation at the seaward corners would generally extend several meters seaward of the structure. However, it cannot be concluded from this slight increase in sand elevation that the structure was retaining sand in its vicinity.

Figure 2 shows the volumetric responses of the north, south, and center sections for Scale I. The north and south sides of the structure are of equal area, but the center section is not of comparable size. The three sections all responded similarly to each other and to the total volumetric of Scale I shown in Figure 3. It appears as though the beach on the north side of the structure responded less sensitively to major erosion and accretion events than the beach on the south side of the structure. Similar to the total volumetric response of Scale I, all three sections of beach shown in Figure 2 displayed a balanced volumetric response fluctuating seasonally about a nearly constant mean and experienced a negligible net change in sand volume over the observation period. The volumetric response at Scale II was nearly identical to that of Scale I, showing seasonal fluctuation about a nearly constant mean.

Figure 2 C&L Ranch Section Sand Volumes, Scale I

Figure 3 Total Sand Volumes at Each Site, Scale I

Far field sections were used both to the north and south of the structure. Figure 4 shows the comparison of the north far field and the north flank of the structure. The volumetric responses of the two areas were remarkably similar. The sensitivity to erosion and accretion events was approximately the same for both the north flank and the north far field. The north flank experienced a slight net gain in sand volume over the observation period, whereas the north far field section experienced a slight net loss. As Figure 5 indicates, the volumetric response of the south far field and the south flank of the structure were reasonably similar. The south far field section appeared to be slightly more sensitive to erosion and accretion events than the south flank. Both far field and the flank experienced a moderate net loss in sand volume over the observation period. Each of the structure flanks and corresponding far field volumes displayed a balanced volumetric response and negligible net change in sand volume over the ten year period.

The beach at C&L Ranch was very stable. The volumetric response of the beach followed a pattern of fluctuation between summer accretion and winter erosion. Erosion events were followed by periods of comparable recovery. The volumetric response of the beach was very similar for Scale I and Scale II, indicating the absence of seasonal features such as berms. The far field baseline comparison indicated that the structure flanks are responding similarly to the beach uninfluenced by the structures presence. The south flank appeared to be more stable than the south far field, and the north flank experienced a net gain in sand volume over the observation period, whereas both far field sections experienced a slight net loss.

Figure 4 C&L Ranch North Far Field Comparison

Figure 5 C&L Ranch South Far Field Comparison

Pacific Sands Motel (PSM)

Pacific Sands Motel, located in Neskowin, is the northern most site considered in this study. The structure is a timber seawall fronting the Pacific Sands Motel. The seawall is constructed of railroad ties with limited steel lateral supports and a 4 cm x 25 cm timber cap. The upper portion of the beach is characterized by low dunes with non-continuous low bluffs to the south of the structure. Proposal Rock, located to the south of the structure, is the predominate morphological feature

in the area. Evidence suggests that Proposal Rock has a considerable influence on the beach processes at the site, mainly in the formation of a rip current embayment. Concentrated foot traffic at the north end of the seawall results in lower a local dune elevation and sparse vegetation at the foot path, making it difficult to separate structure induced flank erosion from foot traffic induced erosion. Aerial photographs for Pacific Sands Motel show that the coastline has not changed much since the mid-1960's.

Examination of the contour and surface plots reveal that during the summer, generally May through September, when the beaches are subjected to low wave energy, the beach at PSM is characterized by a well defined berm and cusps. The berm is often altered by a rip current embayment formed by the presence of Proposal Rock. During periods of high wave energy, typically November through April, the beach becomes very flat in order to dissipate the increased wave energy. The seawall and dunes are most susceptible to wave attack during these periods.

Figure 3 gives the results of the sand volume calculations for Scale I. Profile data for January 1989 and February 1988 were not used in the Scale I calculations due to insufficient range of coverage. The volume of sand fluctuates between winter lows and summer highs about a slightly increasing mean. The beach experiences a sizable net gain in sand volume over the observation period. The volumetric response of Scale II was very similar to that of Scale I.

Comparison of the volume of sand at the structure flanks with far field control sections, in plots similar to Figures 4 and 5, indicates that the flanks responded less sensitively to seasonal erosion and accretion. This data is presented in a normalized form in Figures 6 and 7. The north flank contained a greater volume of sand than the far field section throughout the observation period. A portion of the north far field control section is located landward of the mean dune line. The dune line tends to migrate seasonally, and at the time of the April 1988 survey the dune line had receded several meters. This results in the +2.40 spike in the V_n/V_{aff} data indicating a much larger volume at the north flank in comparison to the north far field. As shown in Figure 7, the volume of sand at the south flank deviates only slightly from that of the south far field. Sand volumes at the south flank are greater than those of the south far field section over the vast majority of the observation period. The results of the far field baseline comparison indicate that the structure flanks appear to be more stable than far field control sections partially because the seawall tends to stabilize the position of the dune line at its flanks. Overall, the south side of the structure was very stable, and although the north side occasionally underwent large volumetric changes, it was fairly stable over the long-term.

Gleneden (GE)

The Gleneden site is located in the town of Gleneden. The structure is a rubble mound revetment approximately 40 m long. The beach is backed by bluffs approximately 10 m in height. The revetment has two well defined flanks as the structure extends several meters from the bluff. This site provides a good open coast

scenario, as the beach extends several miles in either direction without any significant obstructions. A beach access is located approximately 90 m to the south of the structure. A cut, several meters in width, was excavated through a low section of the bluff and partially paved to create this access. The access is significant to the site because a great deal of the storm water runoff from the neighborhood is discharged onto the beach at this point. Depending on the time of year, high flows associated with this runoff scour a creek through the beach face. A considerable volume of sand can be removed through this hydrologic process. Aerial photographs of Gleneden indicate that the coastline has changed little from 1963 to 1983.

The beach at Gleneden is characterized by a well defined berm and cusps in the low wave energy summer months (Komar and McDougal, 1988). A berm of some magnitude usually formed in the early spring and remained until October, however, a slight berm was often present through most of the year. A dominant reflective profile at Gleneden can be partially attributed to the presence of coarser sands on the beach (Shih and Komar, 1994).

The results of the sand volume calculations for Scale I are given in Figure 3. Profile data from January 1989 were not incorporated into the Scale I analysis due to lack of data range in the cross-shore direction. The volumetric response of the beach in Scale I shows the typical pattern of winter erosion followed by summer accretion or recovery. A sizable net loss in sand volume over the observation period had occurred primarily as a result of the severe erosion in May 1996. Recovery from this erosion event indicated from the July 1996 volume was significant, however, this data point probably does not represent full recovery. Oregon experienced a late summer in 1996, and beaches commonly experience accretion well into October.

Due to the drainage area located to the south of the structure, only a north far field control section was utilized for the baseline comparison. Normalized far field comparison data shown in Figures 6 and 7 indicate that the sand volume at the flanks was similar to that of the north far field section throughout the observation period. On average, both the north and south flanks of the structure contained greater volumes than the far field section. During the most severe erosion event recorded over the ten year monitoring period, May 1996, both flanks retained over 10% more sand than the north far field section. This is an indication that the flanks are more stable than the far field control section, and appear to be less sensitive to seasonal fluctuations. Although the beach at Scale I and the far field control section experienced significant net losses in sand volume, the north and south flanks of the structure were not impacted as severely by comparison. The north flank actually recorded a slight net gain in sand volume.

Pacific Palisades (PP)

Pacific Palisades is located just south of Lincoln Beach. The site is on the north side of Fishing Rock, a rocky point of land jutting out approximately 150 m into the ocean. Fishing Rock is not considered a littoral cell boundary, but it does inhibit longshore sediment transport and has a substantial effect on the beach

processes at the site. The bluff line north of Fishing Rock forms a crescent shape, indicative of a hooked beach. A rubble mound revetment follows the curve in the bluff for approximately 300 m. The rubble blends into the bluff face and there are no discernible flanks on either end of the structure. The south end of the structure essentially extends to the base of Fishing Rock. The analysis of Pacific Palisades was limited to investigations of Scale I and Scale II. A far field investigation was not feasible considering the crescent shaped backing bluff and the lack of identifiable flanks. Aerial photographs indicate relatively little change in the coastline from 1962 to 1983.

Figure 6 Normalized North Far Field Comparison

Figure 7 Normalized South Far Field Comparison

When the beach at Pacific Palisades was subjected to low energy waves, usually May through October, the beach was typified by a well defined berm, cusps,

and a rip current embayment. The rip current embayment, present throughout most of the year, was most likely caused by Fishing Rock. The sand volume of the beach at Scale I, shown in Figure 3, fluctuates seasonally about a nearly constant mean. The beach experienced a slight net gain in sand volume over the observation period.

Pacific Shores (PS)

Pacific Shores is a sea cliff backed site located approximately three miles south of Newport. The dominant morphological feature at the site is a section of the sea cliff that protrudes further seaward than the adjacent cliffs on either side. This protruding section of cliff, which is probably subjected to wave attack on a regular basis, is composed of an erosion resistant material. The cliff line south of the protrusion, where the structure is located, forms a crescent shape similar to that of Pacific Palisades. The original structure selected for the field monitoring program was a rubble mound revetment measuring approximately 20 m in length. However, since the initiation of the study in 1986, a new 140 m long rubble mound revetment has been constructed immediately north of the original structure. The newer structure was probably built in response to localized land slides which occur at the site. The two structures were not joined together, thus leaving a 15 m gap of unprotected sea cliff between them. The addition of this enormous new structure during the observation period and in such close proximity to the original, smaller, structure made for a complicated analysis. Aerial photographs show that parts of the southern portion of the protruding cliff have been eroded since 1965. It is also possible that parts of the cliff were removed as part of the construction of the newer structure.

The complete chronology of contour and surface plots suggests the beach at Pacific Shores was very flat and planar throughout the year. A summer berm was not present, and there was no evidence of a rip current in any of the surveys. The contour plots did not indicate a trend of sand accumulating in front of any part of the structure. The volumetric response of the beach at Scale I, shown in Figure 3, followed a typical pattern of summer accretion and winter erosion, with the exception of 1989 when the beach experienced a prolonged period of accretion. Ten years of monitoring yielded a negligible net change in sand volume. A far field comparison was not feasible due to the addition of the new structure and the geometric nature of the backing bluff.

San Marine (SM)

San Marine is located between Walport and Yachats. The beach is backed by a low bluff, which is very irregular, containing several indentations and moderately protruding areas along a lengthy front. These are rather small scale features on the bluff, which is essentially shore parallel. The structure is a rubble mound revetment that measures approximately 150 m in length. The bluff line position is several meters further seaward at the structure. The bluff appears to be fairly stable with

respect to slides. Aerial photographs for San Marine indicate that the coastline and the bluff were remarkably stable from 1962 to 1983. Several of the unique and irregular features in the bluff, which is composed of an erodable material, are present in both the 1965 and 1983 photos. This suggests that waves seldom reach the bluff line.

The beach at San Marine was very flat and dissipative throughout the year. The majority of the Scale I contour and surface plots indicate a slight rise in elevation near the structure flanks. This slight rise may be attributed to the fact that the bluff is recessed several meters on either side of the structure.

Seasonal fluctuations about a slightly increasing mean are apparent in the volumetric response of the beach at Scale I, Figure 3. The beach at San Marine experienced a considerable net gain in total sand volume over the observation period. This can be attributed to significant recovery following the winter erosion events.

Far field control sections were defined both to the north and south of the structure. Normalized results of the far field comparison, shown in Figures 6 and 7, indicate that the volume of sand at the north flank deviates little from the volume of sand at the far field control section. A trend of increasing volume in the south flank in comparison to the south far field is apparent in Figure 7. This trend can be attributed to a volumetric response about an increasing mean for the south flank, and a volumetric response about a nearly constant mean for the south far field section. Volumes for both the north flank and the north far field section fluctuated about an increasing mean. A gain in net volume over the observation period and the stability of the bluff indicated in the aerial photos suggest that the structure is having no adverse affect on the surrounding beach or adjacent properties.

Driftwood Shores (DS)

Driftwood Shores, the southern most site included in this study, is located at Heceta Beach just north of Florence. The structure is a low rubble mound revetment measuring approximately 30 m in length. There are large dunes to the south of the structure and the area north of the structure is more similar to low hills with heavy vegetation than dunes. The structure is located at a low point in the dune. The backshore area behind the dune is actually lower than the structure and many parts of the upper profile. A house is situated several meters behind the structure. The house is not built in the backshore depression, but is very low relative to the other houses in the vicinity.

The beach exhibits a great deal of local three-dimensionality. The small scale three-dimensionality of the upper portions of the beach appears to be aeolian dominated. The complete chronology of contour and surface plots indicates that the beach was reasonably flat and dissipative during much of the year. The dunes to the south were evident in several of the surveys, but absent in the majority. It was likely that the dunes migrated back and forth in the cross-shore direction during the observation period. There were no typical summer profile features evident in the

contour and surface plots, although it was generally in the summer months when the south dunes were present in the contour and surface plots.

The volumetric response of the beach at Scale I, contained in Figure 3, shows seasonal fluctuation about an increasing mean, and a dramatic net increase in sand volume over the observation period. Driftwood shores was the only site which experienced accretion during the May 1996 period. The beach appeared to be gaining sand volume during the active portion of the study, 1986 through 1990, but the most substantial net gain in sand volume occurred between 1990 and 1996. Results from plots similar to Figures 4 and 5 show that the flanks responded nearly identical to the far field section over the ten year period. As indicated in Figures 6 and 7, the flank volumes deviated little from the respective far field volumes throughout the study. Similar to the volumetric response at Scale I, both flanks experienced a considerable net gain in sand volume.

CONCLUSIONS

All seven sites on the Oregon coast behaved in a similar manner. The volumetric response of the beach at each of the sites fluctuated seasonally between low sand volumes in the winter and higher sand volumes in the summer. Considerable recovery following periods of erosion resulted in net gains in sand volume over the observation period at Scale I for three sites (PSM, PP, DS), negligible changes at three sites (PS, CL, SM), and a significant net loss in sand volume at only one site (GE).

The structure flanks at each site, including Gleneden, were stable over the observation period. Sand volumes at the structure flanks deviated little from those of the far field control sections used in the baseline comparison. The average $V_{\text{flank}}/V_{\text{far field}}$ value for all seven sites, regardless of north or south flank, was 1.094 with a coefficient of variance of 0.102. This indicates that the structure flanks were retaining greater volumes of sand over the observation period than the far field control sections. In general, the structure flanks experienced negligible net changes in sand volumes, and often slight net gains in sand volume over the observation period.

There were no significant negative effects caused by the structures at any of the seven sites. This can be attributed to the lack of wave attack that these structures experience (Ruggiero et. al., 1997) The structures were built high on the profile against the base of the bluff or dune. Each site has a wide buffer beach fronting the structure which dissipates the high wave energy found on the Oregon coast and prevents waves from reaching the structure or bluff except during the most severe storms. The structures tend to serve as bluff retention and stabilization structures as much as shore protection structures. Structures built against bluffs appear to be doing an excellent job supporting the bluff and preventing landslides, which can be brought about by undercutting of the bluff or cliff by wave action, but many other non-beach process related factors are also recognized (Komar and Shih, 1994).

When examining the long-term effects of seawalls on beaches, the analysis must be site specific. Susceptibility to wave attack should be considered when permitting or building a shore stabilization structure on the central Oregon coast.

CHAPTER 211

Profile Volumes as a Measure of Erosion Vulnerability

Timothy W. Kana, Ph.D.,¹ and Ram Krishna Mohan, Ph.D., P.E.²

ABSTRACT

Profile volumes provide an indication of the condition of barrier islands and beaches. While site specific, they can be used along any littoral shoreline as a measure of the relative "health" of one section compared with another. Assuming shorelines develop an equilibrium profile around which the beach cycle and cross shore changes occur, profile volumes integrate small scale perturbations and provide a target sediment volume for the site between reference contours. Profile volumes may be considered for various parts of the profile as follows:

- *Dune volume above storm surge levels* (after FEMA) as a measure of the reservoir of sand required to prevent over topping.
- *Mean sea level (MSL) barrier cross-section* — the section that must be fully scoured to produce a full breach channel.
- *Inner beach profile* — the section that represents the condition of the recreational beach.
- *Inshore profile* — the section that represents the core "base" of the barrier island.

By comparing versions of these sections from site to site, especially where there have been known breaches and variations in beach erosion rates it is possible to develop systematic criteria for the health of the shoreline in question. Profile volumes provide a straight-forward technique for diagnosing barrier erosion problems. A case study from Westhampton Beach and Fire Island (New York) illustrate the application.

INTRODUCTION

Profile volumes, that is, the unit quantity of sediment contained between defined contour limits in the littoral zone, can be used as predictors of erosion vulnerability, breach vulnerability, and nourishment requirements. They are especially useful for analyzing sites with few data or sites where surveys are spaced widely in time. The profile volume for a site, ideally, should incorporate the foredune (or the entire backshore seaward of buildings where development is a concern), berm, intertidal beach, and lower foreshore to closure depth.

Multiple transects surveyed between common boundaries along shorelines having similar orientations and exposures provide a set of profile volumes that can be normalized and compared statistically by simple means (Fig. 1) (Kana et al., 1984; Kana, 1993). The unit volume of any one profile to closure integrates all small-scale perturbations in slope and bar formation, and becomes a reasonably pure measure of the littoral condition. Seasonal or beach-cycle-related variations are accounted for in the volume. Therefore, the phasing of surveys with storms or seasons is less critical. Where the setting is a narrow barrier beach, the profile volume method also provides a measure of vulnerability to breaches.

FIGURE 1.

The reference profile illustrates how average unit-width profile volumes can be developed on a site-specific basis for analyses of the condition of the beach from one section to another, as well as from one survey to the next (after Kana et al., 1984).

Barrier Sediment Volumes

There are no universally accepted criteria defining the condition of a barrier beach to withstand erosion and storm surges without breaching. In the United States, FEMA (Dewberry & Davis, 1989) has developed rough guidelines relating to dune preservation during storms. FEMA considers a particular volume of sand above the still-water flood level and seaward of the dune crest as being the minimum necessary to prevent overtopping and washovers for a particular return-period storm. Dutch coastal engineers (TAW, 1985; Van de Graaff, 1986) further consider the amount of freeboard above the still-water surge level needed to absorb wave runup without overtopping and breaching. These criteria are based on probabilities and are poorly documented because there are so few sites where all necessary data are available to quantify the relationship. In most cases, dunes either remain standing with considerable excess sediment landward of poststorm scarps, or they are washed out. Thus, establishing threshold minimum quantities to sustain surges without (dune) breaching is difficult.

The present criteria of FEMA are given in a rating curve (Fig. 2). The minimum cross-sectional areas recommended above the still-water surge elevation (for a particular return period) equate to unit volumes of sand (cubic yards per foot) as given on the graph. In simple terms, the 100-year storm would require about 20 cy/ft (50 m³/m) above its still-water surge level, whereas a 5-year storm would require about 6 cy/ft (15 m³/m) for protection. FEMA representatives emphasize these criteria are for guidance only and may not apply for certain dune configurations (R. Hallermeier, Dewberry & Davis, pers. comm., March 1994). In other words, the absolute quantity of sand above the surge level must be configured to absorb wave runup effectively; otherwise, breaching may still occur.

FIGURE 2.

FEMA minimum criteria for dune unit volumes above flood still-water level as a function of storm-return period (based on guidelines in Dewberry & Davis, 1989). Standard deviation for the 100-year storm is ± 10 cy/ft, confirming a wide range of "safe" values based on experience.

In the following example application, the authors have computed reference sand volumes above particular datums to relate the condition of a barrier to FEMA criteria. Unit-volume analysis is also useful for comparing the overall condition of the barrier island, including the underwater portion of the profile. By comparing barrier sections that have experienced breaches with unbreached sections, it is possible to develop site-specific criteria relating to the potential vulnerability of future breaches along nearby sites.

EXAMPLE APPLICATION

Winter storms (northeasters) on 11 December 1992 and 13 March 1993 caused widespread damage along the south shore of Long Island, New York (Fig. 3). In terms of beach erosion, structural damage, and mainland flooding, these two storms were the worst for this part of the coast since the well-known 4-6 March 1962 northeaster (USACE, 1963). Over 100 houses were lost along Pikes Beach (Westhampton, immediately downdrift of the groin field) as a result of continued erosion and a breach through the barrier in December. The 1992 breach was left open for over ten months and contributed to locally higher tides in Moriches Bay (J. Tanski, unpubl. data,

SUNY, Stony Brook, March, 1993) before it was closed by the U.S. Army Corps of Engineers by hydraulic dredge (contractor: Great Lakes Dredge & Dock Co.).

The breach at Westhampton demonstrated the problem of unstable inlets near development and the potential for increased flooding around the lagoon shoreline. Concerns over the possibility of a similar breach through Fire Island, the next barrier island downdrift of Westhampton Beach, and a possible increase in the tide range within Great South Bay led to a study funded by the New York Coastal Partnership (Kana and Krishnamohan, 1994). The purpose of the study was to assess the vulnerability of Fire Island to storm breaches and determine the likely physical impacts along Great South Bay (Fig. 3). The study was multidisciplinary and drew on historical shoreline data, developed an updated sediment budget for Westhampton and Fire Island, and used available predictive models of storm surges to evaluate flooding potential. One analysis (the subject of the present paper) evaluated profile volumes in an attempt to develop site-specific criteria for barrier sections that had breached in the past and to identify other potential sites for breaches.

FIGURE 3. General location map of representative barrier-island cross-sections developed for the 1994 study (after Kana and Krishnamohan, 1994).

Methodology

Representative cross-sections through Westhampton Beach and Fire Island were developed from USACE profiles (RPI, 1985), unpublished surveys, and planimetric maps (see Fig. 3). These were selected to represent the range of conditions including physical dimensions of the barriers and historical erosion trends. The profiles extend

from the bay shoreline across the barrier and out to approximately -30 ft below MSL. Table 1 describes some of the cross-sections, localities, and significant features [see Kana and Krishnamohan (1994) for details].

TABLE 1. Representative barrier island cross-sections, relevant physical dimensions, and key distinguishing features. [* (1) Width at mean sea level. (2) Highest dune elevation. (3) Distance from MSL to -20 ft contour.]

USACE Transect ID	Locality	1979 Dimensions (ft)			Key Features
		(1)*	(2)*	(3)*	
WESTHAMPTON BEACH					
468+00	Between groins 1 and 2, east end of groin field	825	21	1,400	Rapid accretion and growth of a new foredune to 15 ft MSL between 1962 and 1979; continued accretion through 1993.
670+00	2,700 ft west of groin 15, compartment 143B	700	10	1,600	Rapid erosion between 1962 and 1979, loss of an 18-ft-high foredune within 1,000 ft of 1962 and 1992 breaches.
790+00	2,000 ft east of east jetty, Moriches Inlet	450	15	1,950	Situated btwn 1980 breach and east jetty; breach widening and easterly migration eroded the section btwn January and July 1980.
FIRE ISLAND					
34	6,700 ft east of Smith Point Park Pavilion, eastern Fire Island	1,225	18	1,350	Zone of washovers west of Moriches Inlet; high erosion rates; artificial dune (spoil area from bay dredging) constructed 400 ft landward of the shoreline.
~26	West walk at Saltaire, western Fire Island	2,050	15	1,375	Wide barrier section; highly erosional; first row of houses lost between 1967 and 1979; area of concentrated damage in 1992-93.

Westhampton Profiles

In 1962, Westhampton had sustained its worst storm since the 1938 hurricane (storm of record). The March northeaster breached the barrier along Pikes Beach and caused extensive structural damage. Prior to the storm, erosion had reduced the width of the barrier and chronic problems of overwash forced periodic sand scraping to clear Dune Road. The USACE (1958) had been developing a shore protection plan which proposed construction of 21 groins and concomitant nourishment. By December 1962, emergency repairs had closed the storm breach and had added almost one million cubic yards of additional sand to Westhampton Beach (USACE, 1963). Construction of a

portion of the groin field was initiated in 1964 and the final four of 15 groins were completed around 1969.

Two transacts illustrate dramatically different results along Westhampton Beach between 1962 and 1979--USACE station 468+00 (Fig. 4a) situated at the updrift end of the groin field between groins 1 and 2, and USACE station 670+00 (Fig. 4b) situated 2,700 ft downdrift of groin 15. In 1962, both transacts represented narrow sections of the barrier island. In fact, the updrift station (468+00) was barely 600 ft wide from the ocean to the bay shoreline and contained a single, well-developed foredune to 20 ft above sea level. The downdrift station (670+00) was slightly wider at about 725 ft with a smaller foredune reaching about 17 ft.

FIGURE 4. Representative, barrier-island cross-sections from the east end of the Westhampton groin field (a) and Pikes Beach (b), illustrating opposite trends in shoreline change between 1962 and 1979. Unit volumes refer to the profile areas between the indicated contours.

By 1979, station 468+00 had gained a second foredune and the shoreline built seaward, increasing the barrier width to about 825 ft (Fig. 4a). Associated with the dune and upper beach building was a large increase in sand volume below MSL. This trend of large-scale accretion has continued through 1993 as shown in nearby profile 461+25 at groin 1 (Fig. 5). By January 1994, groins 1 and 2 (500-ft-long structures when built) were completely buried.

In contrast, transect 670+00 lost dune elevation and width between 1962 and 1979. The trends shown in Figure 4b actually incorporate several beach fills during the period. By July 1975, the barrier had narrowed to about 600 ft and the maximum elevation at the transect was only 7 ft above sea level. Nourishment is believed to have restored part of the beach between 1975 and 1979, but the dune elevation remained no higher than 10 ft MSL. An aerial photo from August 1981 (Fig. 6) in the vicinity of station 670+00 shows the recession of the shoreline downdrift of the groin field and a number of houses left standing on the active beach.

The 1992 northeaster caused at least two breaches between transect 670+00 and groin 15. The easternmost breach immediately downdrift of groin 15 became the dominant and only channel and expanded from several hundred feet wide after the storm to over 2,000 ft wide by the summer of 1993 (Westhampton Fire Marshall's Office, unpubl. reports). Field observations by the authors in March 1993 and January 1994 confirmed deposition of a flood delta in Moriches Bay in connection with the breach channel. Around November 1993, the breach was closed by hydraulic dredge using a USACE-approved offshore borrow source ~1.5 miles south of the breach.

A third Westhampton Beach transect considered here is from USACE 790+00, ~2,000 ft east of the east jetty of Moriches Inlet. This undeveloped section of Cupsogue spit consists of a narrow barrier segment flanked on the landward side by the navigation channel to Moriches Inlet. During the 1960s, the bay channel meandered closer to Cupsogue spit and contributed to scour along the bay shoreline.

By 1979, portions of the spit about 0.5 mile north of the jetties had been reduced in width to 300 ft from ocean to bay. In January 1980, continued narrowing of the spit combined with higher-than-normal wave action breached the barrier (Kana et al., 1981). Between January and July, the breach channel widened and migrated west until it removed the last part of the spit and coalesced with the navigation channel between the jetties.

Transect 790+00 is situated between the January breach point and east jetty. At the time of the breach, section 790+00 had a width of about 450 ft and a dune elevation of 15 ft (Fig. 7). Much of this section was artificial, having been filled several times in connection with dredging projects in the bay. As the breach widened, it migrated through section 790+00, washing out the beach and depositing a large volume in the bay channel.

FIGURE 5. Comparative profiles at groin 1 (easternmost) for December 1979 and September 1993. Data courtesy of U.S. Army Corps of Engineers.

FIGURE 6. Pike's Beach and Westhampton Beach in August 1981, looking east. Groin field is at top of photo.

As Figure 7 shows, by July 1980, the elevation across 790+00 was about 4 ft below sea level. The breach was closed in January 1981 by hydraulic dredge, using barrier and littoral sediments that had accumulated in the bay channel, and by trucks using sand from an inland source.

Unit volumes were computed through each barrier cross-section by 10 ft contour intervals (example values given on Fig. 4a). Conveniently, the predicted 100-year still-water surge elevation along this microtidal coast nearly equals +10.0 ft MSL (FEMA, 1987).

Unit volumes above the +10 ft contour generally reflect the condition of the dunes. At Westhampton, the volumes above 10 ft are much greater at section 468+00 (groin field) than the sections near recent breaches. If 468+00 is typical of the groin field, dune unit volumes approached 50 cy/ft by 1979 and are higher today (see Fig. 5). In contrast, stations 670+00 and 790+00 yield an average volume of about 10 cy/ft with zero volume occurring in three of the six surveys used in the analysis.

FIGURE 7. USACE station 790+00 situated ~2,000 ft east of Moriches Inlet. Erosion in 1980 occurred after the January 1980 breach to the east migrated through this section.

Between +10 ft and mean sea level, the barrier cross-section volume is largely a function of barrier width. Of the few surveys used for Westhampton, a typical section volume is about 160 cy/ft.

Relative to the total section volumes above MSL, the net changes for the three Westhampton stations generally represent a high percentage of the maximum section volume. For example, station 468+00 gained 108 cy/ft between 1962 and 1979, a volume which is 35 percent of the 1979 section volume (i.e., a gain of over 50 percent of the original unit volume). Station 790+00 lost 100 percent of its 1974 section volume due to the January 1980 breach; station 670+00 lost more than reflected (see Fig. 4) because of remedial nourishment between surveys.

Underwater sand volumes for Westhampton Beach stations similarly reflect the trends above sea level. Typical unit volumes from MSL to -10 ft seaward of the fore-dune are about 125 cy/ft and from -10 ft to -20 ft are about 425 cy/ft. The net change for 468+00 (groins) between MSL and -20 ft was 235 cy/ft, nearly 50 percent more sand than the 1962 volume. Assuming 461+25 (see Fig. 5) is similar, 468+00 has probably gained an additional 240 cy/ft in these lenses between 1979 and 1993.

Station 670+00 actually contained almost 20 percent more sand than 468+00 between MSL and -20 ft in 1962 before the groins were built. By 1979, this section contained about 75 percent of the unit volume at 468+00 (between MSL and -20 ft); a greater loss occurred between MSL and -10 ft; unit volumes between -10 ft and -20 ft increased by about 5 percent. Most likely, the change would have been much greater if there had been no beach fills.

Station 790 + 00 had a healthy underwater profile prior to the 1980 breach. As the breach widened and eroded the section, unit-volume losses between MSL and -20 ft were 260 cy/ft, an exceedingly rapid loss over the five-year survey interval. The upper lens from MSL to -10 ft was reduced to a section of about 50 cy/ft by July 1980, a volume representing the underwater sill through the breach. The lower shore-face (-10 ft to -20 ft) eroded severely, reducing the section volume to 330 cy/ft (about 80 percent of the same lens at station 670 + 00).

Based on the sand volume results in Table 2, typical Westhampton Beach values (rounded) are as follows:

Dune Volume	Mean (cy/ft)	Std. Dev. (cy/ft)	(No. of Surveys)
Above + 10 ft MSL	20	±20	(8)
+ 10 ft to MSL	150	±77	(8)
MSL to -10 ft*	125	±45	(7)
-10 ft to -20 ft*	425	±75	(7)

[*Seaward of dune crest of earliest survey]

The results show high standard deviation because one station built up rapidly and one incorporated breach conditions. Thus, the "healthy" profiles reflect volumes incorporating the additional volume indicated by the plus standard deviation. Unhealthy profiles vulnerable to breaching reflect mean volumes minus the standard deviation. These results provide benchmarks for comparison with Fire Island profiles.

TABLE 2. Barrier-island unit-profile volumes (cy/ft) from the bay to -30 ft NGVD (above MSL encompasses entire barrier width; below MSL extends from foredune seaward). [Numbers in parentheses represent number of surveys.]

	Above 10 ft	10 ft to MSL	MSL to -10 ft	-10 ft to -20 ft	-20 ft to -30 ft
WESTHAMPTON					
468 + 00 (avg)	43.8 (2)	212.2 (2)	154.4 (2)	450.6 (2)	754.2 (2)
Breach sections (avg)	12.6 (6)	139.6 (6)	115.6 (5)	420.6 (5)	811.2 (4)
FIRE ISLAND					
Minimum	3.1	210.0	90.7	310.9	665.5
Maximum	90.0	475.1	176.3	459.2	786.8
Mean	32.3 (11)	343.3 (11)	134.3 (10)	407.7 (10)	739.6 (9)

Fire Island Profiles

Six transects across Fire Island (two of which are shown in Figure 8) illustrate the typical range of conditions (see Table 1). Unit volumes have been computed for the same contour intervals and boundaries as Westhampton (Table 2). Some differences are immediately apparent. Above mean sea level, Fire Island profiles typically contain more sediment. The average unit volume above +10 ft is 32 cy/ft (± 27.7 cy/ft standard deviation) for 11 surveys. Point O' Woods (USACE-28) and Saltaire (near USACE-26) had the lowest dune volumes, ranging from 3.1 cy/ft for the 1993 Saltaire profile to 7.1 cy/ft for the 1967 Point O' Woods profile. Three Sisters dunes off Bellport represented the maximum with 90 cy/ft above +10 ft (1979). Between +10 ft and MSL, Fire Island sections averaged about 345 cy/ft (± 98.6 cy/ft standard deviation), much of which is due to the wider backshore. In fact, volumes in this lens

FIGURE 8. Representative, barrier-island cross-sections from (a) Pattersquash Island area east of Smith Point Park (locality for numerous washovers) and (b) west end of Saltaire, where major erosion of the underwater profile has accelerated erosion of the foredune.

are roughly double those of Westhampton (Table 2). Below mean sea level, unit volumes were very similar to Westhampton's, averaging -135 cy/ft between MSL and -10 ft, and ~400 cy/ft between -10 and -20 ft. This is expected because the landward computation boundary in each case is the dune crest.

Highest erosion rates were at the Pattersquash section (near USACE-34) and at Saltaire (near USACE-26) (see Fig. 8). The net change for these stations, respectively, ranged from about 10 cy/ft to 50 cy/ft above MSL and from 200 cy/ft to 150 cy/ft below MSL. In 1979, station USACE-34 was reduced to a volume of 415 cy/ft below MSL (to -20 ft) compared to an average of -550 cy/ft for other stations.

Aerial overflights by the authors and reports from officials of Suffolk County Department of Public Works (SCDPW) indicate the area around the Pattersquash Island transect continued to overwash through January 1994. But at this station, the setback of the artificial dune appears to have prevented a more landward shift of sediment. The artificial dune ends less than 1,000 ft to the east of transect 34, suggesting that more easterly areas are likely to experience deeper penetration of overwash along the back barrier. The authors observed a number of large washovers in that area during a January 1994 overflight. Officials at SCDPW confirmed these trends along eastern Fire Island over the past ten years. The results of the profile volume analysis suggest washovers will be more likely along Fire Island when the profile volumes between MSL and -20 ft go below 500 cy/ft relative to the foredune and when the foredune has negligible volume above +10 ft MSL.

The Saltaire section (near USACE-26) bears some similarities to USACE-34 because of its rapid erosion since 1967. While the barrier is much wider at Saltaire, its backshore elevations are low, averaging less than 5 ft above sea level (Fig. 8b). A single foredune has existed along the oceanfront. In 1967, the dune contained about 24 cy/ft above the +10 ft contour, about 75 percent of the average for the selected Fire Island transects. By June 1993, dune volume above +10 ft was reduced to only 3 cy/ft. This low volume is offset by over 450 cy/ft between +10 ft and MSL (a total approximately three times that of Westhampton sections). Below mean sea level, station 26 lost about 155 cy/ft between 1967 and 1993, reducing its volume seaward of the 1967 dune crest to 450 cy/ft. As discussed in a regional sediment budget analysis (Kana, 1995), rapid erosion in the western Fire Island area is believed the result of depletion of offshore shoals associated with an earlier position of Fire Island Inlet. This has left the foredune much more vulnerable to erosion. An ~80 ft recession of the foredune since 1967 has destroyed (or caused to be removed) the oceanfront structures at this site, leaving the second row buildings on the oceanfront in 1993.

On the basis of backshore volumes above mean sea level, the Saltaire section is less likely to breach than Pattersquash because it contains almost twice the volume. But the Saltaire foredune is more likely to recede than Pattersquash's artificial dune because of the low unit volumes seaward of it and the lesser setback. Pattersquash's artificial dune profile could be created at Saltaire, but to be stable under present offshore conditions, it would have to be set back at least 150 ft from the 1993 dune

crest. Planimetric maps indicate there are at least three rows of houses within 150 ft of the present dune crest at that locality.

SUMMARY — CASE STUDY

The remaining four sections along Fire Island represent intermediate conditions and are not discussed in this paper (see Kana and Krishnamohan, 1994, for details). By the measure of profile volumes through 1979, Fire Island cross-sections generally contain much more sand above MSL than Westhampton Beach sections. The difference in dune volumes between the two islands represents only a fraction of the total lens of sand comprising the barrier. The bulk of the subareal barrier is contained between MSL and +10 ft. Westhampton profiles contain roughly half the volume of Fire Island profiles above mean sea level. Transects that are breached along Westhampton typically contained less than 150 cy/ft above MSL before breaching.

While absolute volumes above mean sea level are not the only parameters to rank the condition of the barrier and establish vulnerability to breaching, they provide one quantitative measure to compare with historical breach areas.

CHAPTER 212

BREACH GROWTH: EXPERIMENTS AND MODELLING

by

Harry de Looff ¹⁾, Henk J. Steetzel ²⁾, Arie W. Kraak ³⁾

ABSTRACT

Since 1989 research has been conducted in the Netherlands on the issue of breach growth. This contribution describes the set-up and results of wave basin experiments which had the aim to obtain insight into the process of growth of the width of a breach. From analysis of the recorded data (flow characteristics in the breach and the development of the breach) an empirical relation for breach width growth has been derived. This relation has been implemented into a (conceptual) numerical model which is briefly described in this document also.

1. INTRODUCTION

The Dutch Technical Advisory Committee on Water Defences (TAW) is aiming for a design method for water defences in which the optimal safety level of these defences is related to the risk of flooding. Risk is defined as the product of the probability of failure and the expected damage costs in case of failure. One of the key factors in the damage costs assessment is the speed and rate of inundation

of a polder. The latter is predominantly determined by the discharge rate through the breach [Kraak et al., 1994].

Research regarding breach growth in a sandy dike-like structure started in 1989 with an exploratory field experiment. Further, flume experiments have been carried out for the initial phases of the breach erosion process (lowering of the dike crest) [Steezel & Visser, 1992]. More recently wave basin experiments were done to investigate the breach widening process. Finally a large scale field experiment has been carried out in order to investigate the three-dimensional aspects of breach growth i.e. widening of the breach in combination with the development of a scour hole [Visser et al., 1995].

One of the main instruments to predict inundation and damage costs assessment is a theoretical model for breach growth and inundation. Recently, as a first step towards that model, a conceptual numerical model for breach growth prediction in a sanddike has been developed.

The present contribution is focused on the wave basin experiments regarding the widening of the breach and the conceptual numerical model of the breach growth process.

2. WAVE BASIN EXPERIMENTS

2.1 Set-up of the experiments

The set-up of the experiments is similar to the experiments which have been carried out to investigate the initial phases of breach growth (lowering of the crest) as is described in [Steezel & Visser, 1992]. The cross-sections of the dike-structure are identical in both experiments. The only difference is the use of a wave basin instead of a wave flume, with the purpose of investigating the widening of the breach.

All model tests have been carried out at DELFT HYDRAULICS and started with a sandy dike-like structure situated transversely across the wave basin. Because a breach develops symmetrically to the centre of the breach, it was sufficient to investigate only one side of the breach. The breach development, originated from minor initial overflow through a small pilot channel in the crown of the dike, was recorded using three simultaneously operating video camera's and a large number of precise instruments to obtain time series of both the water levels and the velocities in the area next to the breach. By using a recirculating system with an optional pump capacity up to 1.0 m³/s, the upstream water level was kept as constant as possible. In this way the widening of the breach could be studied in detail until the major part of the dam was eroded.

In order to complete this description of the experiment set-up, in figure 1 a planview of the wave basin lay-out is shown.

Figure 1: Planview of the wave basin lay-out

2.2. Description of the tests

The influence of several parameters on the breach erosion process has been investigated, viz. the width and height of the dike, the level of the foundation, the seaward bottom slope and the additional effect of (perpendicular) wave attack.

A total of 8 experiments have been performed in which the above mentioned parameters have been varied. Figure 2 gives an overview of the typical cross-sections used for the experiments. The focus lies here on the widening of the breach; in order to avoid effects of depth-growth, a treshold construction has been used for the experiments T1 .. T7 (as can be seen in figure 2). In the test T8 the treshold construction was absent; the only depth limitation is the floor of the basin. In this latter situation, a full three-dimensional experiment was conducted also.

In short the description of the experiments:

T4 = reference case

T1 = as T4, level of treshold is 0.1 m higher;

T2 = as T4, smaller crest width (0.7 m vs. 1.3 m);

T3 = as T4, lower (0.19 m) crest level

T5 = as T4, higher (0.2m) crest level

T6 = as T5, with wave attack (all other tests were without wave attack);

T7 = as T4, with a milder outer slope

T8 = as T7, treshold equals basin floor.

Figure 2: Overview of the cross-sections used for the tests T1 .. T8

2.3 Results of the experiments

The observed breach width development in time (B(t)) is presented in figure 3. It shows that the erosion of a dam having a narrow (T2) or low (T3) crest is more rapid than in case of a wider (T4) or a higher (T4, T5) crown. Relative to the case T5, additional wave attack (T6) yielded a larger breach width, whereas the opposite effect was present in the case of a less steep foreshore (T7, relative to reference case T4). The case without a threshold (T8) shows the slowest development of the breach width of all the tests due to the fact that a lot more sand has to be eroded in order to create the same breach width as for the other tests.

Figure 3: Overview of observed breach growth for all tests performed.

For modelling reasons a new parameter, the breach growth velocity, has been defined as:

$$\beta(t) = dB(t)/dt \quad [m/min] \tag{1}$$

To get an impression of this parameter, figure 4 gives its development as a function of time. It shows that a milder outer slope (case T7) yields a smaller breach growth velocity in respect to the reference case (T4).

figure 4: development of the breach growth velocity as a function of time; shown is the effect of a mild foreshore slope

To get additional physical insight into the background of the breach growth velocity, this parameter is linked to the recorded flow characteristics in the breach.

Firstly, the relation with a characteristic water velocity in the breach ($v_{breach}(t)$), has been investigated. Figure 5 shows for the reference case (T4) and for the case T7 (milder outer slope) the breach growth velocity as a function of the water velocity in the breach. It can be seen that in order to obtain the same breach erosion velocity ($\frac{dB}{dt}$) as for the reference case, a higher water velocity in the breach (v_b) is required for case T7 (milder outer slope).

One of the conclusions is that breach width growth stops (and starts) when a certain critical water velocity in the breach is reached. From the experiments (laboratory and field) a critical value of 1.0 m/s can be derived

Secondly, the erodable volume is important. Therefore the volumetric breach growth velocity has been defined as:

$$\frac{dV}{dt} = \beta(t) \cdot A_d \quad [m^3/min] \tag{2}$$

in which A_d = eroded cross-section of the dam as is illustrated in figure 6.

Figure 7 shows the volumetric breach growth velocity as a function of the water discharge through the breach. In this figure all the tests performed are present, except for T6 (waves) and T8 (3D). A more or less linear relation can be derived.

figure 5: development of the breach growth velocity as a function of the water velocity in the breach, shown is the effect of a mild foreshore slope

figure 6: definition of the eroded cross-section A_d

figure 7: volumetric breach erosion velocity as a function of the water discharge in the breach

3. NUMERICAL MODEL FOR BREACH GROWTH

The breach erosion process is characterized by a complex three dimensional behaviour in which low as well as very high velocities and thus erosion rates occur. The Froude number varies typically in the range of 0.03 to 3 and the Shields parameter varies from 0.03 - 50 [Visser et al., 1995]. In order to describe this complex process in a numerical model, five different phases in the breach erosion process have been distinguished [Visser, 1994]:

- Phase 1: steepening of the inner slope;
- Phase 2: narrowing of the dike crest;
- Phase 3: erosion of the dike crest;
- Phase 4: breach widening under super-critical flow and development of a scour hole;
- Phase 5: breach widening under sub-critical flow until velocities are under a critical value.

In every phase a characteristic set of discharge and transport formulae is used to calculate the development of the breach during each time step. In the first three phases the rate of erosion is described by a Visser-Bagnold equation in which the erosion rate is proportional to the kinetic energy of the flow. The modelling of the first three phases has been described in [Visser, 1994]. For the modelling of the phases 4 and 5, the results of the wave basin experiments have been used. With the parameters and relations mentioned in chapter 3 the following empirical relation for the breach width growth velocity has been derived.

$$\beta = C_b \cdot (d_b \cdot q_b) / A_d \quad [\text{m/s}] \quad (3)$$

where: q_b is the water discharge rate per unit breach width [$\text{m}^3/\text{m/s}$]; q_b is described by a weir formula.
 A_d is the eroded cross-section of the dam as defined in figure 6
 d_b is the water depth in the breach
 C_b is a coefficient, related to the sediment concentration near the edges of the breach

$$C_b = \bar{c} \cdot b_r / d_b \quad [-] \quad (4)$$

where: \bar{c} = depth averaged sediment concentration near the edges of the breach

b_r = width of the zone near the edges for which \bar{c} is defined

At present there is a test-version of the numerical model available. This model covers all the above mentioned phases of the breach growth process. The main input parameters of the model are:

- * cross-section of the sand-dike (array of (x,z) values):
 - erodable cross-section
 - cross-section with initial breach
 - ir-erodable cross-section (sill)
 - breach and material characteristics:
 - initial breach width
 - mean grain size diameter D_{50}
 - sediment fall velocity w

- porosity n
- bottom roughness r
- * outside boundary:
 - waterlevel as function of time (array of (z,t) values)
 - optional: in case of e.g. a lake: areas/volume of the outer basin
 - optional: in case of river: external input discharge
- * inside boundary (in the polder):
 - initial waterlevel
 - area of the polder that will be inundated

During 1996 and the first half of 1997 this model will be completed. The results of the large-scale field experiments (1989 and 1994) and findings of the 1953 and earlier flood disasters will be used to calibrate and verify the model.

CHAPTER 213

THE IMPACT OF AN EXTREME EVENT ON THE SEDIMENT BUDGET: HURRICANE ANDREW IN THE LOUISIANA BARRIER ISLANDS

Jeffrey H. List¹, Mark E. Hansen², Asbury H. Sallenger, Jr.², and Bruce E. Jaffe³

Abstract

This paper examines the influence of Hurricane Andrew on the sediment budget of an 80-kilometer section of the Louisiana barrier islands west of the modern Mississippi delta. Because long-term bathymetric change has been extensively studied in this area, excellent baseline data are available for evaluating the impact of Hurricane Andrew. Results show that despite the high intensity of the storm and a storm track optimally positioned to impact the study area, the storm did not have an overwhelming influence on the sediment budget when compared to the changes occurring over the previous 50 years. For the Louisiana barrier islands, a 50-year record appears to be adequate for averaging the long-term contributions of both major and minor storm events to the sediment budget.

Introduction

The coastal sediment budget, i.e., the identification of sediment sources, sinks, and transport pathways, is essential information for predicting rates of shoreline erosion and for planning beach nourishment projects (e.g., Kana, 1995). Unfortunately, most investigators have had to assume that the sediment budget, derived from past measurements, is an adequate representation of future trends as well. This assumption is weakened by the commonly unknown influence of changing and difficult to predict processes, such as the impact of infrequent but high-energy storm events. Few studies have been able to assess their potentially important impact. In one exception, Morton et al. (1995) monitored changes in beach volume associated with a major hurricane along the Texas coast, concluding that large storms can

significantly alter the long-term sediment budget and hence, shoreline evolution. They demonstrate that short term sediment budget data (< 10 yr) are inadequate for modeling and predicting future changes because of the variable influence of great storms. It remains unclear whether longer term data, which would potentially include the effects of many major storm events, would be more representative of future conditions.

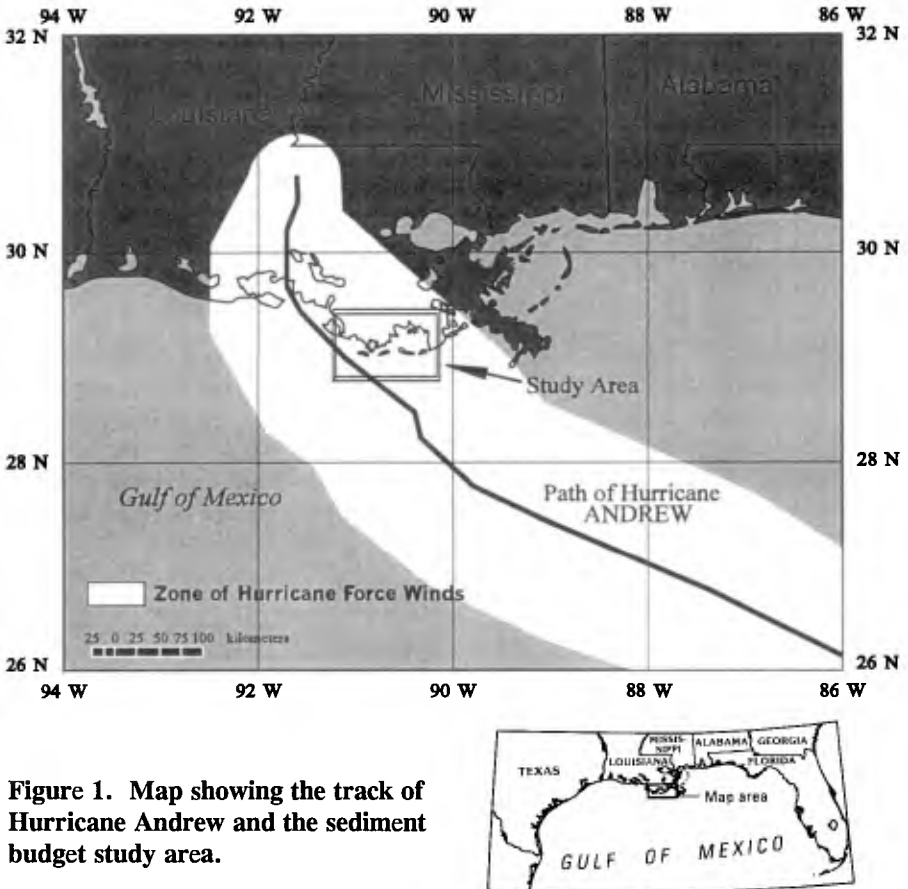

Figure 1. Map showing the track of Hurricane Andrew and the sediment budget study area.

A unique opportunity to address this issue was presented to us in 1992 when Hurricane Andrew impacted the Louisiana coast with wind speeds of more than 50 m/s (Grymes and Stone, 1995), offshore significant wave heights of more than 10 m (DiMarco et al., 1995; Stone et al., 1995), and a maximum storm surge of more than 2.5 m (Halford, 1995). This Class 3 storm on the Saffir-Simpson scale passed just west of a series of barrier islands (Figure 1) which had been the focus of an intensive study on the physical and geological processes responsible for the rapid erosion and disintegration of these islands (the Louisiana Barrier Island Erosion Study, Sallenger et al., 1987, 1991). In response to Hurricane Andrew, several components of the

original study were repeated, including measurements of shoreline position, nearshore profiles (Dingler, 1995), and near-island bathymetry. In this paper we compare the bathymetric changes in a six-year period including Hurricane Andrew with the bathymetric changes observed for the 50 years prior to the storm, and evaluate the impact of Hurricane Andrew on the sediment budget.

Data Sources and Processing Techniques

Bathymetric surveys from three time periods were used as the basic source of sediment budget information considered here. Two surveys, from the 1930's and 1980's, were processed or collected as part of the U.S. Geological Survey's Louisiana Barrier Island Erosion Study (1986-1991). The third bathymetric survey was conducted in 1993/1994 following Hurricane Andrew.

The data sources, processing techniques, and error assessment for the 1930's and 1980's surveys are described in detail by List et al. (1991, 1994), and will only be briefly summarized here. The 1930's survey consists of soundings obtained in digital form from the National Geophysical Data Center in Boulder, CO. Data were digitized by the National Ocean Service of the National Oceanic and Atmospheric Administration (NOAA) from U.S. Coast and Geodetic Survey (USCGS) hydrographic smooth sheets for the years 1933, 1934, 1935, and 1936. The 1980's bathymetry was constructed from soundings obtained in digital form from hydrographic surveys conducted in 1986, 1988, and 1989 by companies under contract to the USGS. In addition to bathymetric data, shoreline data were obtained for each of these time periods to provide a mean high water (MHW) line to constrain the bathymetry surrounding the study area's many small islands. Shorelines for the 1930's were digitized from USCGS topographic smooth sheets, while for the 1980's, shorelines were photo-interpreted and digitized from National Aeronautics and Space Administration (NASA) high-altitude photography. A detailed description and analysis of shoreline data for the Louisiana barrier islands are found in McBride et al. (1992).

The post-Andrew bathymetric data were collected by the U.S. Geological Survey in 1993 and 1994, using an Innerspace 448 echosounding fathometer and a Global Positioning System (GPS) for navigation. Although we originally intended to correct soundings for tide effects using post-processed differential GPS vertical measurements, processing difficulties resulted in unreliable depth values. Thus the data were corrected using the same methods as were used in the 1980's survey, i.e., by applying corrections based on local tide observations. Shoreline data assumed to represent the MHW line were also incorporated into the 1993/1994 data set; post-Andrew shorelines were digitized by the Louisiana State University in 1993 (Penland, pers. comm.). The 1993/1994 bathymetric survey was processed exactly as were the 1930's and 1980's surveys, as described by List et al. (1994). Figure 2 shows the 1993/1994 bathymetric coverage area; for comparative purposes, analysis of the 1930's and 1980's data is restricted to the same area.

1993/1994 Bathymetry (Post-Andrew)

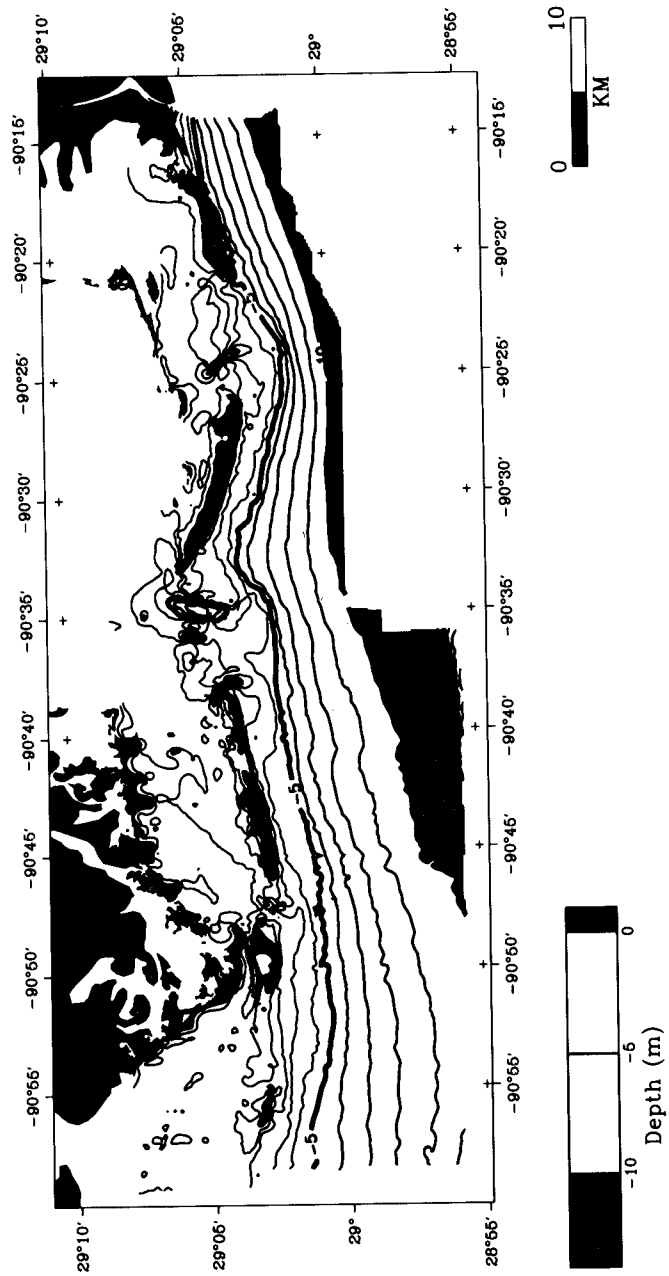

Figure 2. Post-Hurricane Andrew bathymetry collected in 1993 and 1994, showing the coverage area for this study. Depths are relative to Mean Low Water. For comparison purposes, data from the 1930's and 1980's data sets are analyzed within this same region.

After constructing surface models of each survey period's bathymetry using a minimum-tension gridding technique (Briggs, 1974; Dynamic Graphics, Inc.), we calculated bathymetric change grids for the 1930's to 1980's and 1980's to 1993/1994 periods. These change grids, with a spacing of 135 m (see List et al., 1994), form the basis for this study's comparison between long-term changes and changes occurring during a six-year period which included a major storm. Because of the approximate 1 cm/yr relative sea-level rise in the study region (Penland and Ramsey, 1990), a sea-level correction was necessary to prevent a strong bias toward erosion and to permit calculations of erosional and accretionary volumes. As continuous tide records were not available for the entire study period, we employed an alternate means of correcting for relative sea level using an area of sea floor which was judged to have minimal accretion or erosion (Jaffe et al., 1991). The error associated with this datum correction constitutes a large part of the overall data uncertainty.

The total error associated with sea-floor change calculations is a complex combination of many potential sources of error, including sounding measurement error, tidal correction problems, vertical and horizontal datum inconsistencies, computer gridding errors, and non-synoptic sources of data for each survey period. Although some errors can be quantitatively evaluated, others, such as the tidal datum correction problem mentioned above, could only be evaluated qualitatively. Therefore, a combination of quantitative and qualitative approaches were employed to assess the error in bathymetric comparisons (List et al., 1994). As a conservative estimate, a ± 0.5 m range of sea-floor change was designated as a zone of no significant change.

Results

Regional

Figures 3 and 4 show the patterns of erosion and accretion associated with the 1930's to 1980's and 1980's to 1993/1994 change periods respectively. Overall, the strikingly coherent and large-scale patterns of erosion and deposition observed in the 1930's to 1980's change period are lacking in the 1980's to 1993/1994 change period. (For a description and analysis of the changes occurring in the 1930's to 1980's change period, see List et al., 1991, 1994, 1997a, 1997b; Sallenger et al., 1992; Jaffe et al. 1989, 1997).

Figure 5 quantifies the total volumes of erosion and accretion within the area enclosed by the data limit polygon in Figure 4, excluding areas of no significant change. In Figure 5A, both erosional and depositional volumes are significantly smaller for the change period encompassing Hurricane Andrew, indicating that the storm did not have an overwhelming influence on the sediment budget of the study area.

However, as the 1980's to 1993/1994 change period represents only about six years compared to the 50 years in the 1930's to 1980's change period, a better comparison between these two periods may be the rates of volume change, as shown

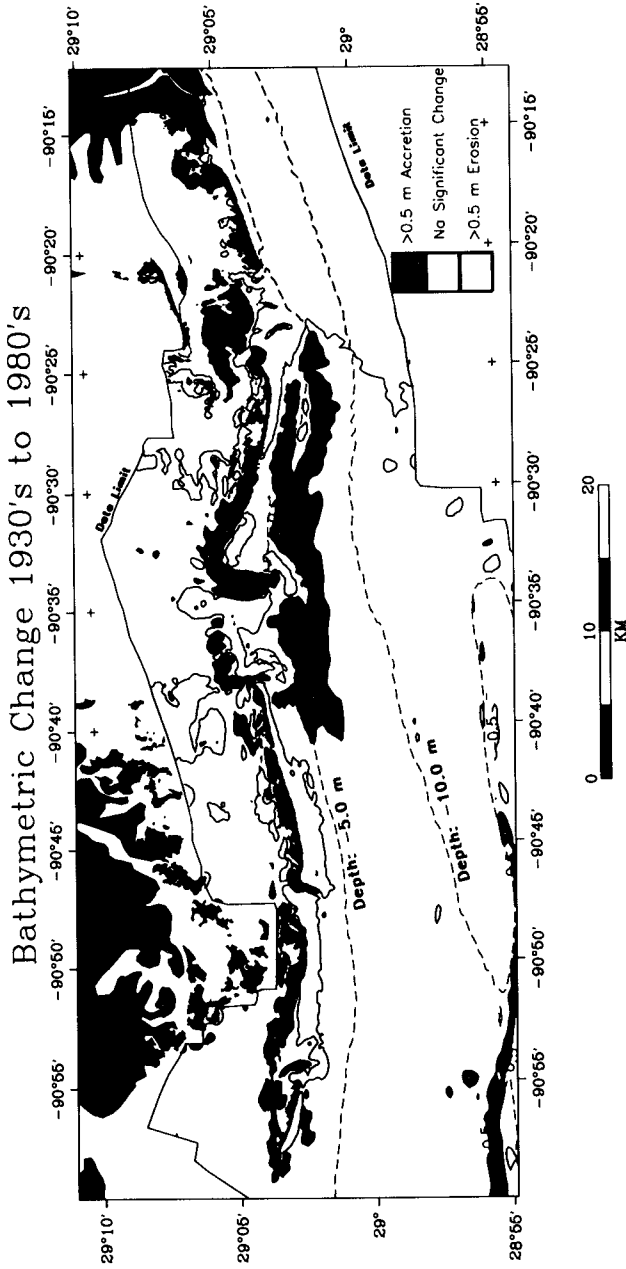

Figure 3. 1930's to 1980's bathymetric change within the complete study region. The -5.0 and -10.0 depth contours are from the 1980's bathymetry. The region encompassed by the line marked "data limit" is the area of overlap between the 1930's and 1980's bathymetries.

Figure 4. 1980's to 1993/1994 bathymetric change within the complete study region. The -5.0 and -10.0 m depth contours are from the 1993/1994 bathymetry. The region encompassed by the line marked "data limit" is the area of overlap between the 1980's and 1993/1994 bathymetries.

in Figure 5B. This figure shows that two change periods' erosional and deposition rates do not differ significantly, within the error bars resulting from the assumption of a ± 0.5 m zone of no-significant change (after List et al., 1994).

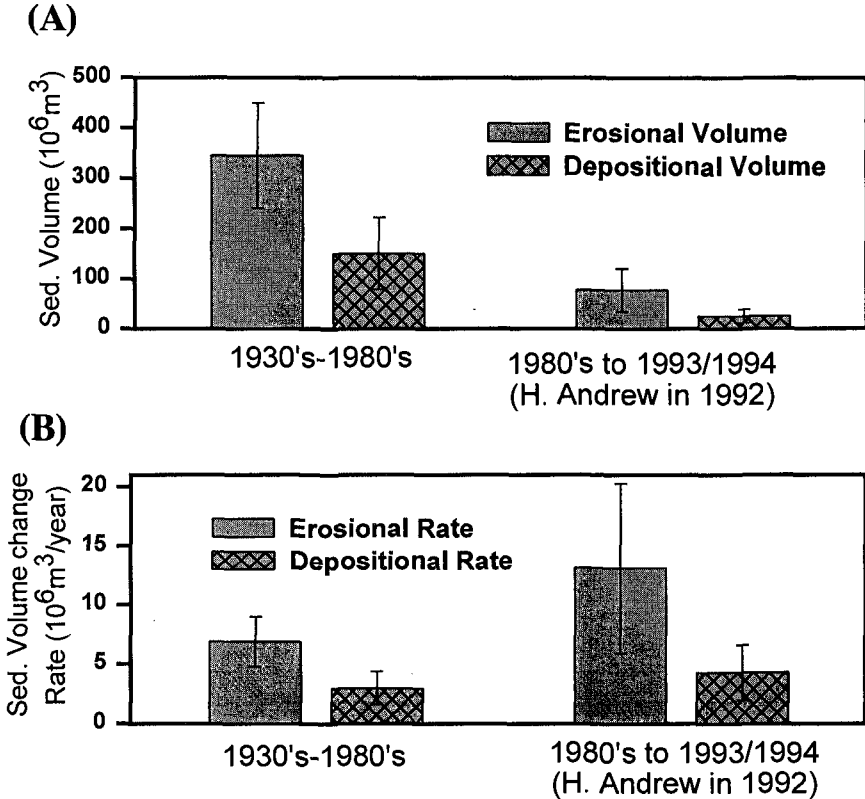

Figure 5. Volumes of sediment change within the area enclosed by the data limit region shown in Figure 4, excluding areas of no significant change. Error bars are based on the assumed ± 0.5 m range of no significant change following List (1994). For comparison purposes, the same data limit region is applied for calculating volumes within the 1930's to 1980's change period. (A) Total erosional and depositional volumes for the 1930's to 1980's and 1980's to 1993/1994 change periods. (B) Corresponding yearly rates of erosion and deposition, using intervals of 50 and 6 years for the 1930's-1980's and 1980's-1993/1994 change periods respectively.

Eastern Portion of the Study Area

Figures 6 and 7 focus on changes in the eastern portion of the study area. Again, the 1980's to 1993/1994 change period exhibits few of the large and coherent patterns of erosion and deposition observed in the 1930's to 1980's change period. Still, it is noteworthy that there are *any* coherent patterns of erosion and deposition in the 1980's to 1993/1994 period, given the short six year period of change and the ± 0.5 m range designated as no-significant change. While the extensive area of offshore erosion present in the 1930's to 1980's comparison is lacking in the 1980's to 1993/1994 period, many of the smaller patterns, especially in depositional areas, appear to duplicate the later change period, albeit at reduced magnitudes.

Four of these depositional areas in the 1930's to 1980's change period are labeled A through D in Figure 6, with 1980's to 1993/1994 deposits interpreted to be of the same origin similarly labeled in Figure 7. Area A represents a shoreface deposit that appears to extend from erosional areas to the east. In the 1930's to 1980's change period, this depositional area extends from the extensive area of shoreface erosion it adjoins to the east to the next chain of barrier islands to the west, suggesting a mode of sediment bypassing of a wide inlet complex (Figure 3 here, see also Jaffe et al., 1991, 1997). In the 1980's to 1993/1994 change period, deposit A is much less coherent, but still occupies approximately the same location along the 5 m depth contour. Erosion of an ebb-tidal delta to the east suggests a source for the deposit in this change period (compare the bathymetry in Figure 2 with the bathymetric change in Figure 4). Area B represents a bay-side deposit that seems to be associated with landward migration of small barrier islands within a large inlet complex (similarly, they may be, in part, migrating flood-tidal delta deposits). In the 1980's to 1993/1994 period, depositional area B comprises several small areas that are clearly associated with the landward migration (and submergence) of small barrier islands (the depositional area between the two parts of B is associated with inlet migration). Area C represents another bay-side region of accretion, similar in both change periods. This deposit takes the form of a flood-tidal delta, but arguably could also be related to strong landward-directed flows associated with storm surges. Finally, area D in both change periods is a result of inlet infilling at the terminus of a westward migrating barrier island.

Similar to Figure 5, Figure 8 gives the total volume and yearly rates of deposition within areas A-D for the 1930's to 1980's and 1980's to 1993/1994 change periods. Again, while the total volumes associated with the 1980's to 1993/1994 period are much less than in the 1930's to 1980's period (Figure 8A), the *rates* of accretion are not significantly different (Figure 8B).

Discussion

Because the average rates of change in the period bracketing Hurricane Andrew were not significantly different from the average rates of change in the previous 50 years, we cannot conclude with certainty that *any* of the bathymetric changes are

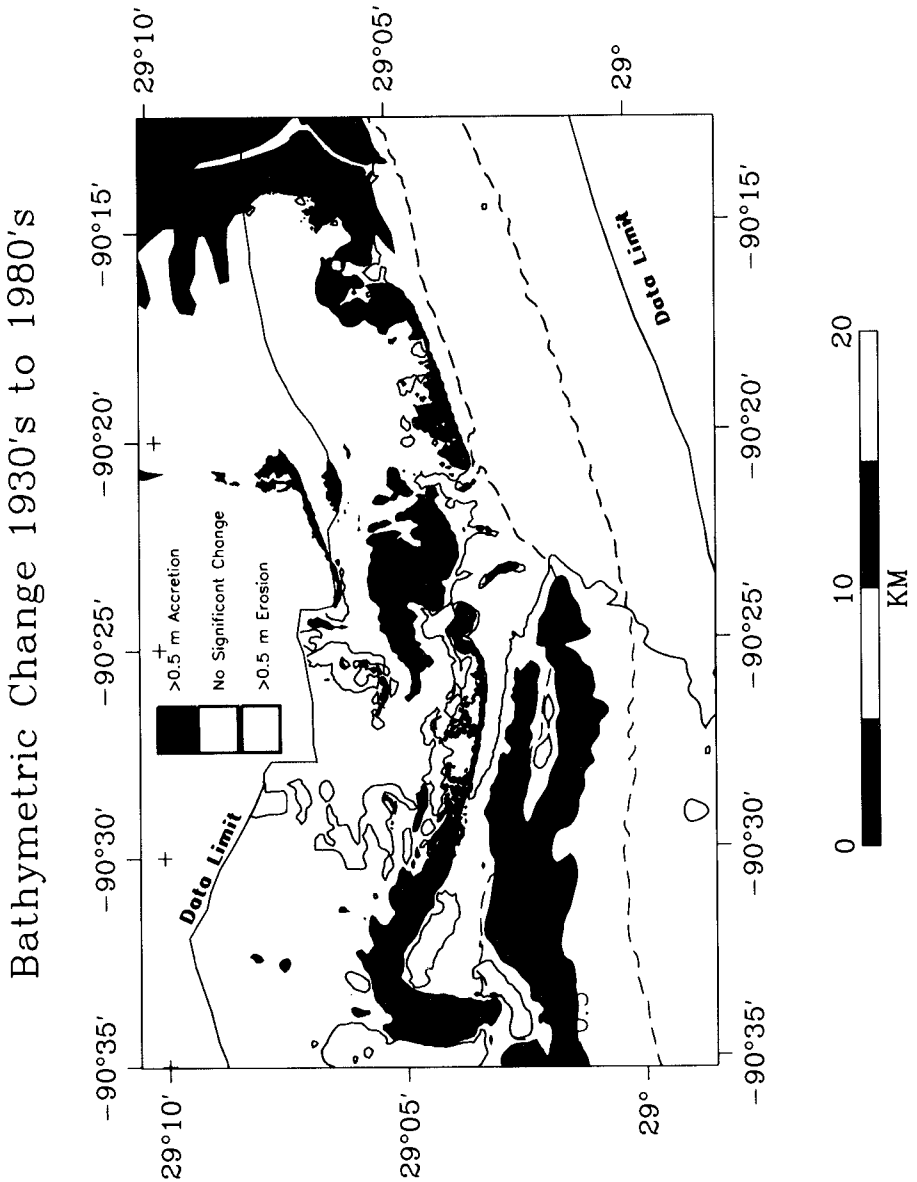

Figure 6. 1930's to 1980's bathymetric change within the eastern portion of the study region. The depth contours (unlabeled) and data limit boundary are the same as in Figure 3. Letters A through D represent areas of accretion for which volumes are shown in Figure 8. In the volume calculations shown in Figure 8, area A is limited to the area east of longitude $-90^{\circ}34'$, and Area D is limited to the area west of the adjoining barrier island.

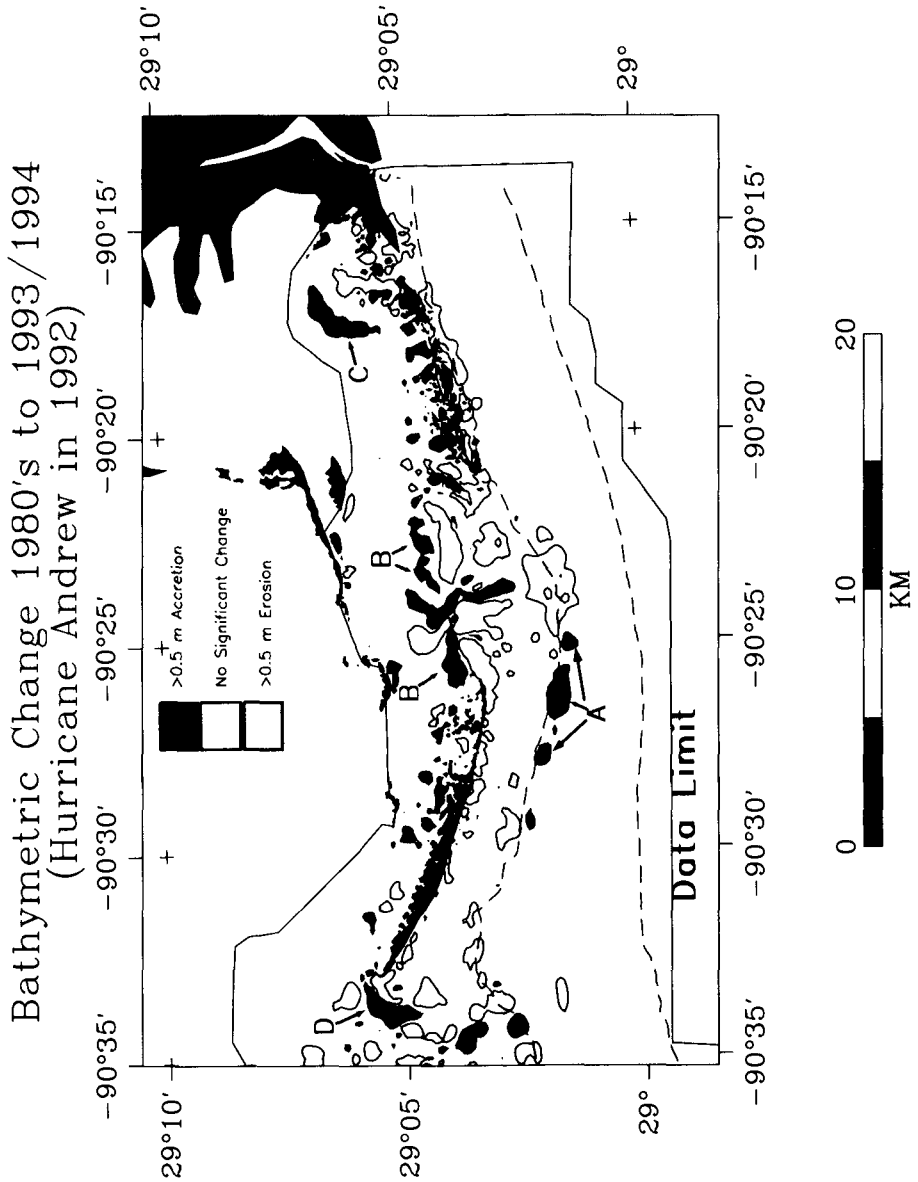

Figure 7. 1980's to 1993/1994 bathymetric change within the eastern portion of the study region. The depth contours (unlabeled) and data limit boundary are the same as in Figure 4. Letters A through D represent areas of accretion for which volumes are shown in Figure 8.

attributable to Hurricane Andrew, rather than typical storm conditions that occur much more frequently. However, as Hurricane Andrew was without doubt the largest storm in the 1980's to 1993/1994 change period, it is reasonable to assume that many of the changes are, in fact, due to this storm. With this assumption, we surmise that Hurricane Andrew had a moderate, through not overwhelming, contribution to the area's sediment budget.

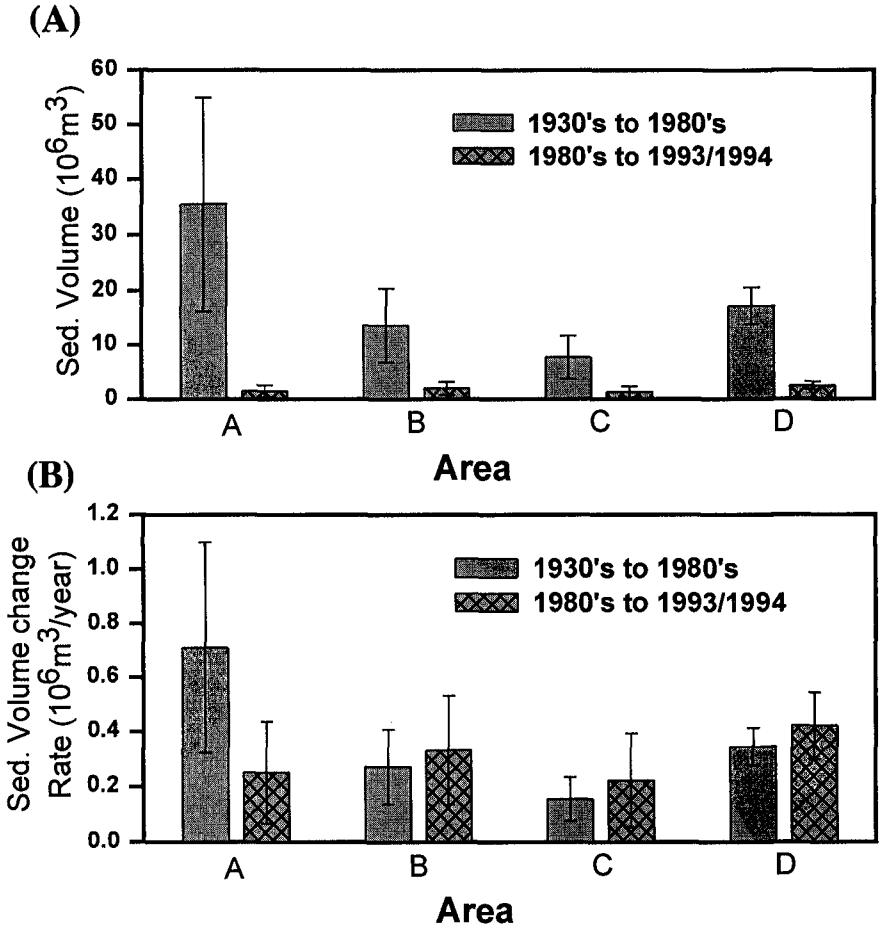

Figure 8. (A) Depositional volumes and (B) rates of deposition within the labeled deposits shown in Figures 6 and 7. Rates are found by dividing the depositional volumes for each region by the 50 and 6 year intervals for the 1930's to 1980's and 1980's to 1993/1994 change periods respectively. Error bars are found as in Figure 5.

Because the rates and patterns of change were similar in both change periods examined here, it seems likely that the processes were similar as well. An examination of the historical database of hurricane tracks (Jarvinen et al., 1984) shows that while Hurricane Andrew might have been the *most* intense storm experienced by the study area in the last 50 years (in terms of both magnitude and track), there were many other hurricanes that could have had a comparable impact. In terms of average rates of change, the 6-year period encompassing Hurricane Andrew (and many minor storms) appears to be representative of the long-term average of processes occurring in the previous 50 years.

Conclusions

Despite Hurricane Andrew's high intensity and a track that was near optimal for impacting the study area, the storm did not have an overwhelming influence on the sediment budget of an 80-km section of the Louisiana barrier islands when compared to the changes occurring over the previous 50 years. However, with the assumption that most of the bathymetric changes observed in the pre/post-Andrew survey were due to the storm, we conclude that the storm had a moderate impact on the sediment budget; however, other storms in the 50-year period prior to Andrew likely had a similar impact. For this study area, 50 years appears to be adequate for averaging the cumulative contributions of both major and minor storm events.

Acknowledgments

This work was conducted as part of the Hurricane Andrew in Louisiana Project and the Louisiana Barrier Island Study, cooperative studies between the U.S. Geological Survey, Coastal and Marine Program, and the Louisiana State University. We thank Shea Penland, Randy McBride and others at the Louisiana State University for providing shoreline-position data. The bathymetric data were collected and processed through the efforts of numerous people, including Greg Gabel, Thang Phi, Graig McKendrie, Rob Wertz, Todd Holland, Carolyn Degnan, Clint Steel, Tracy Logue, Dorothy Hopkins, Keith Dalziel, Lance Thornton, and Jennifer Bexley. Karen Morgan is thanked for contributions to the figures. Any use of trade names in this publication is for descriptive purposes only and does not imply endorsement by the USGS.

CHAPTER 214

BEACH MAINTENANCE STRATEGIES, A COMPARISON FOR A RECREATIONAL BEACH

M. Pluijm¹, G. Kant¹, R. Nolten², A.P. de Looff³

ABSTRACT

This paper describes the morphological and economical evaluation of the beach nourishment maintenance strategy of an eroding recreational beach at the Dutch coast. In addition to the results of this evaluation two alternative strategies were analysed. In order to assess the economical feasibility of the alternatives appeared to be essential to estimate the morphological effectiveness of the alternative strategies. Therefore, an extensive numerical modelling scheme was set up. The numerical modelling played a key role in the understanding of the existing morphological system and subsequently in the assessment of the effectiveness of the alternatives on a long term basis. The morphological effectiveness of the alternatives, being offshore breakwaters and a 450 m long groin, was calculated in terms of reduction of required beach nourishments. The objective of the study was not only to find an optimal coastal morphology strategy but also to find the best strategy which combines a sound beach protection with effects valuable for the specific recreational function of the beach, including an effective way to deal with eventual lee-side erosion. Possibilities were studied to shift the erosion to the dune area in the north which would allow a more flexible and dynamic way of maintenance.

SITE DESCRIPTION

Scheveningen Beach (Figure 1) is located on the west coast of The Netherlands. Scheveningen Port is located just south of the beach with its breakwaters reaching 550 and 725 m into the sea. During the entire year but especially in summertime, the sandy beach attracts thousands of locals and holiday making tourists.

The beach consists of sand with a characteristic grainsize (D50) of about 200 µm. The slope of the beach is approximately 1:40. The -10 m MSL contour lies about 1300 m offshore. Scheveningen is also protected by a seawall with a length of 2.5 km. The beach level at the toe of the seawall is about +3 m MSL. North of Scheveningen the land is protected by a massive dune area.

Scheveningen Beach is eroding continuously. In the beginning of the century a system of 150 m long groins (spacing 500 m) was built but the erosion was not stopped. Up to now five beach nourishments were carried out starting in 1969 (see Table 1).

The Dutch west coast is known as a morphological dynamic system. The wave and current climate result in massive longshore sediment transports in northern as well as in southern direction. The average yearly sand transport is directed to the north and is estimated, for this part of the coastline, at 500,000 m³/year.

Figure 1 *Scheveningen Beach*

year	1969	1975	1985	1991	1996
volume [m ³]	45,000	700,000	330,000	1,000,000	850,000

Table 1 *Beach Nourishment Volumes at Scheveningen Beach*

HYDRAULIC BOUNDARY CONDITIONS

The average wave climate on the southern North Sea is presented as a wave rose diagram in Figure 2. The most persistent conditions develop from south-western directions whereas the highest extreme conditions are to be expected from north-western directions.

The average amplitude of the diurnal tide for this part of the Dutch Coast is 1.7 m. The tidal variation induces a significant tidal flow along the coast. Typical flood currents are in the order of 0.6 m/s, typical ebb currents are 0.4 m/s. Peak flood currents may reach up to 0.9 m/s and ebb currents to 0.75 m/s. However, during extreme south west storms (directed parallel along the shore) the wind-driven current can give a significant contribution to the flow especially in shallow areas (surf zone). Consequently, the longshore sediment transport along this part of the Dutch coast is dominated by the interaction between the waves (disturbance, wave-driven current) and the tidal current. The wind-driven current effect pays a minor but nevertheless a not to be neglected contribution.

Figure 2 *Directional Average Wave Height Distribution*

EVALUATION PRESENT BEACH NOURISHMENT STRATEGY

The evaluation of the present beach nourishment strategy concentrated on the behaviour of the executed nourishments and the sand transports along the coast. Regular measurements of the Ministry of Transport, Water Management and Public Works were analysed giving insight in the behaviour of the beach nourishments. Based on the measurements and sediment transport calculations it was concluded that (i) especially the first nourishments were used as restoration of the steepened cross sectional profile, that (ii) the aims of the nourishments were initially met but (iii) that the lifetime of the nourishments was almost completely determined by extreme wave conditions, which resulted in a rather random nourishment behaviour. The characteristics of the morphological system do not allow a complete natural restoration of the beach after an erosion causing storm. The unpredictability of the wave conditions results in a capricious development of the beach. This has already led to an unexpected narrow beach in the summer having negative effects on the tourist industry.

NUMERICAL MODELLING ANALYSIS

Based on the conclusions of the beach development evaluation one- and two-dimensional wave, flow, and sediment transport models were applied (DHI, 1995 and DH, 1992). The well calibrated models of the wave- and flow climate were combined in sediment transport simulations using the Bijker sand transport formulae. The model results were used to understand the importance of the various sediment transport mechanisms and to finally formulate a well based hypothesis of the morphological system. After the formulation of the hypothesis simulations were made of alternative coastal protection structures. These were, among others, offshore breakwaters and a 450 m long groin perpendicular to the coastline. The effects of the structures were brought in relation with the hypothesis of the existing system in order to quantify the predicted impacts on the coastal development.

existing situation

The key questions after the evaluation of the nourishment strategy were (i) what are the physical reasons for the erosion and (ii) where is the sediment going to. It was clear that the position of the beach, the breakwaters of the port, the seawall and the geometry of the beach were essential elements in the morphological system. With the use of the mentioned numerical simulations the following conclusions (schematically presented in Figure 3) could be drawn:

- (1) The net north going longshore sediment transport is not blocked by the breakwaters of the port but is passing these obstacles. It was shown that under

Figure 3 *Sediment Transport Capacities, Existing Situation*

south-western wave conditions the contracted current (tide-, wave- and wind-driven current) in combination with the orbital wave motion result in a substantial sediment transport in front of the breakwaters. This transport is developing in front of the breakwater tips in a water depth of -8 m MSL. Evidence that this process exists is the absence of a sedimentation zone south of the breakwaters. The passing of the net northern transport around the breakwaters is very important for the development of Scheveningen Beach. This transport is the main feeding mechanism of the beach.

- (2) It was found the sediment transport north of the port is about 10% higher than south of the port. The reason for this was found in the bathymetry of both areas. The beaches north of the port appear to be more gentle sloping. This results in a wider surf zone north of the port which in this case (transport driven by the combination of waves and tidal current) generates a higher sediment transport. This effect can be observed while standing on the breakwaters.
- (3) Because of the forced orientation of Scheveningen Beach by the seawall a strong local longshore transport gradient develops at the northern side of the beach.
- (4) The natural beach restoration after a north-western storm is distorted due to the presence of the breakwaters. The timescale of storm events is in the order of hours whereas the timescale of the restoration is weeks to months. In this part of the Netherlands the time averaged flow along the shore is directed to the

north. Sediment deposited on the foreshore during a storm event will therefore contribute to the beach restoration of a beach section somewhat to the north. The presence of the breakwaters of the port distorts this mechanism which results in an incomplete natural restoration of the beach or, in other words, erosion of the beach.

These four main conclusions are the basis of the hypothesis of the morphological system of Scheveningen Beach. The hypothesis is schematically presented in Figure 3. In the figure the annual yearly north going and south going transports are shown as well as the total average yearly transport.

offshore breakwaters

One of the alternative measures which was defined was offshore breakwaters. The impacts were studied on the basis of the developed hypothesis of the existing morphological system. The simulations were repeated for the schematized offshore breakwaters. The main result of the computational effort was that offshore breakwaters do not fit in the morphological system of Scheveningen Beach. Indeed the structure reduces the wave action and thus the sediment transport on the beach. But the structure also redirects the sediment which is transported past the port's breakwaters along the seaward side of the structure. This transport was found to be the most important feeding mechanism of the beach. It is therefore expected that the construction of offshore breakwaters as defined for this study will result in an even stronger erosion on the beach. The predicted sediment transport patterns after the construction of the offshore breakwaters are presented in Figure 4.

Figure 4 *Sediment Transport Capacities, Offshore Breakwaters*

450 m long groin

Another alternative was the construction of a 450 m long groin at the northern side of Scheveningen Beach. This would prevent the build up of the transport gradient due to the shoreline orientation. The simulations show (Figure 5) that indeed positive results for the beach development are to be expected. The redistribution of sediment due to the local gradient will be prevented and part of the erosion of Scheveningen Beach will be shifted towards the north. This was one of the objectives of the study. A relatively wide dune area is located north of the Beach. Here, the opportunity exists to handle the erosion in a more flexible dynamic way. The construction of a long groin would result in a less frequent nourishment need. This predicted effectiveness of the structure was used to compute the cash flow over a long term period. In this way an economical comparison could be made to the present nourishment strategy including maintenance and re-nourishment needs.

COST COMPARISON

The long term costs of investment of the various beach maintenance schemes were evaluated by means of a Nett Present Value (NPV) computation (Pluijm et al., 1994). In this calculation all the costs of an alternative are capitalized over a period of 50 years. Construction costs, interest, inflation, maintenance but also the nourishment need (the results of the morphological studies) are taken into account in this analysis. The results of the NPV cost comparison are presented in Figure 6. It can be seen that with the present rates for sand it is economically more attractive to proceed with the present nourishment strategy. However, when the prices of sand would increase the construction of a long groin would then become an attractive alternative.

Figure 5 Flow model result
450 m long groin

For this cost comparison the extra benefits for the local tourism industry have not been taken into account. The construction of a groin would result into two advantages over the beach nourishment strategy being (i) a more predictable development of the beach

(coastline stability) and (ii) a wider beach. In view of the recreational function of the beach this is an important factor.

Figure 6 Cost Comparison Beach Maintenance Strategies Scheveningen Beach

CONCLUSIONS

Numerical models are of significant importance to develop insight and understanding of the role of each of the morphological processes. The models help to understand the development of a particular beach section, to define the governing processes and to indicate the beach developing sediment transport patterns. Based on this understanding of the morphological system a well-based assessment can be made of impacts of a structure on each of the processes. In many cases this comprehension will allow a reliable prediction of coastline development.

In this paper the methodology has been presented which was adopted to compare alternative beach maintenance strategies. A key element in this evaluation is the nourishment need which will be required when one of the strategies is implemented and which is an important factor in the long term costs. It has been described how numerical simulations models were adopted to assess the morphological effectiveness of the alternatives. These results were then used as input for the cost evaluation resulting in a well based comparison of various beach maintenance strategies.

ACKNOWLEDGEMENT

This study was executed with the full support of the Ministry of Transport, Water Management and Public Works, Directorate Zuid-Holland which is gratefully acknowledged..

CHAPTER 215

Littoral Impact of Ocean City Inlet, Maryland, USA

Julie Dean Rosati¹, M. ASCE, and Bruce A. Ebersole², M. ASCE

ABSTRACT

Ocean City Inlet, Maryland presents a data-rich site for evaluating the total littoral impact of an inlet system with a significant adjacent beach response. Analysis of adjacent beach and bay shoreline data, adjacent beach profiles, ebb and flood shoal evolution, and dredge/fill history provided a database with which the inlet's littoral impact to adjacent beaches was quantified. The even/odd method, which decomposes shoreline changes into their symmetric (even) and antisymmetric (odd) components about a point of significance, was applied to the volume change dataset. This analysis indicated a present-day (1996) alongshore impact distance of 8 to 13 km from the centerline of the inlet. A second method, which relates the total "inlet sink" volume to adjacent island (ocean and bay) volume change, was also applied. The total inlet sink volume ranged from 10.8 to 15.6 million m³, and reflects the volume of material captured by the inlet which is assumed to have been derived from adjacent beaches. The inlet sink method indicated that, at most, 10.8 million m³ can be realized within ± 14.2 km (data limit). The paper concludes that the alongshore impact of Ocean City Inlet most likely extends beyond ± 14.2 km.

1.0 EVOLUTION OF OCEAN CITY INLET

Ocean City Inlet is located on the Atlantic coast of the United States (Figure 1), and was created by a hurricane on 25 August 1933 which breached the outer barrier island. In 1922, groins were constructed on Fenwick Island (to the north) to stabilize this increasingly-popular beach resort. Assateague Island (to the south) remained in a natural state, and, in February 1920, Sinepuxent Inlet breached the island approximately 4.8 km south of the existing inlet, and had migrated southward about 0.8 km until it was closed by another storm in May 1928. After the hurricane of August 1933, jetty construction commenced in September and the inlet quickly scoured to 3 m depth and 76 m width (Underwood and Hiland 1995).

A study by Dean and Perlin (1977) and Dean, Perlin, and Dally (1978) documented sediment transport moving north along northern Assateague Island, which deposited in the inlet channel. As a result of the study, in 1985 the south jetty was raised and

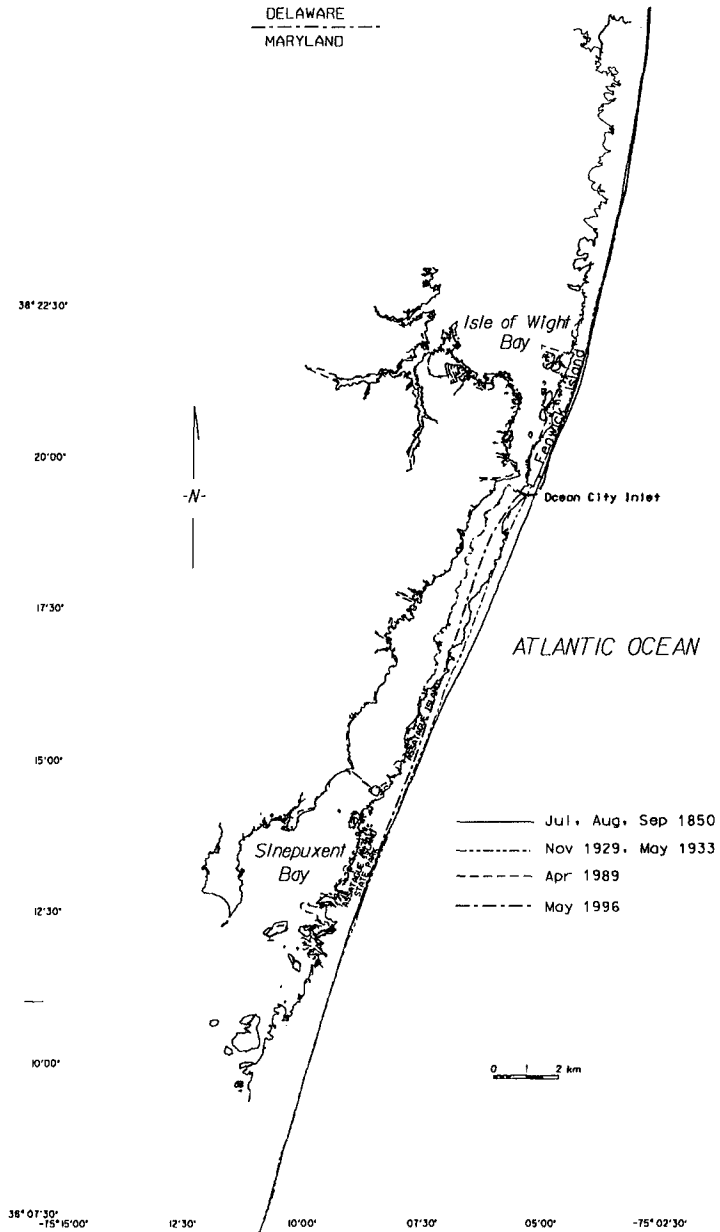

Figure 1. Historical shorelines, Ocean City Inlet, Maryland, USA

tightened, and the northern Assateague Island channel bank was stabilized with three detached breakwaters. The most recent significant engineering event affecting the littoral system has been the placement of approximately 7.4 million m³ of beach fill on Fenwick Island from June 1988 through April 1995, which extended from the just north of the inlet to the Maryland-Delaware state line.

2.0 DATA ANALYSIS

Shoreline position, adjacent beach profile, ebb shoal bathymetry, and flood shoal data sets as well as dredging events were analyzed and used to create a volume change database. A range of parameters which were applied in sensitivity evaluations were also defined, and are discussed below.

2.1 Variation of Shoreline Position with Time

Both ocean and bay shoreline position were recorded with respect to an alongshore coordinate, x , which was set to zero at the centerline of the inlet and used a right-handed coordinate convention (i.e., negative x indicates north; positive x indicates south). The shoreline position represents the high water line, and was calculated for each time period at a 50-m alongshore cell spacing. Results of the shoreline change analysis are presented in Table 1.

Time Period	Alongshore Extent: Ocean (km)	Alongshore Extent: Bay (km)	Fenwick Island		Assateague Island	
			Ocean	Bay	Ocean	Bay
1850-1929/33	-15.1 to 14.2 ¹	-13.7 to 3.3	-0.37 ± 0.98	~0 ²	-1.5 ± 1.7	2.8 ± 1.8
1929/33-1995/96	-15.1 to 14.2	Varies; range -13.5 to 16.6	0.44 ± 0.80 ³ -0.21 ± 0.91 ⁴	0.75 ⁵	-2.9 ± 2.2 ³ -2.9 ± 2.7 ⁴	2.5 ⁶

¹ Full extent was -19.4 to 23.5 km; the analysis was limited here to equal the alongshore extent for the post-inlet period.

² Calculated value was a small negative number. Because it is not likely that pre-inlet bay processes would erode the bay shoreline, a near-zero bayshore change rate was assumed for the pre-inlet time period.

³ Shoreline change rate reflects advancement due to beach fill.

⁴ Adjusted shoreline change rate to remove advancement due to beach fill.

⁵ Calculated by prorating 1929-1965 and 1965-1980 bay shoreline change rates. Standard deviation values are unavailable.

⁶ Calculated by prorating 1933-1965, 1965-1980, 1980-1989, and 1989-1995 bay shoreline change rates. Standard deviation values are unavailable.

Ocean shoreline change rates for Assateague Island extending 14.2 km south of the inlet nearly doubled from a pre-inlet (1850-1929/33) erosion rate averaging -1.5 ± 1.7 m/yr to an average post-inlet (1929/33-1996) erosion rate averaging -2.9 ± 2.7 m/yr (latter rate excludes shoreline advancement due to documented beach fill of 0.9 million m³). For both the pre- and post-inlet time periods, overwash processes were significant along Assateague Island, with bay shoreline change indicating accretion. For the Fenwick shoreline extending approximately 15.1 km north of the inlet, the ocean shoreline

responded to construction of the jetties by decreasing the pre-inlet erosion trend (-0.37 ± 0.98 m/yr for the pre-inlet time period to -0.21 ± 0.91 m/yr in the post-inlet time period (latter rate excludes shoreline advancement due to documented beach fill of 8.1 million m^3). For the pre-inlet time period, the bay portion of Fenwick Island was comparably stable. The post-inlet time period reflects some bay shoreline accretion, which occurred prior to 1980 (a majority of the Fenwick bay shoreline in the vicinity of the inlet has been developed since 1980).

2.2 Profile Data

Beach profile data were analyzed to provide a relationship to convert shoreline change rates into volumetric change rates. Shoreline change within a given alongshore cell is estimated to represent a horizontal translation of the profile over its active depth. The absolute sum of the berm elevation and the depth at which profile changes are insignificant, the closure depth, is one method of estimating the active profile depth. A second method relates the profile volume change to shoreline movement for a given time period. Sensitivity testing of values from both methods indicated that the difference was not significant (less than 2-percent difference in total volumes). Thus, the first method was applied herein. For Fenwick and Assateague Islands, ocean beach profile data were analyzed to estimate active depth. Fenwick Island pre- and post-fill profile data were also analyzed to estimate the percentage of Fenwick Island beach fill remaining in 1996, which was required to correctly account for alongshore movement of this material from Fenwick Island into other regions of the project.

In evaluating the initial performance of the Fenwick Island beach fill, Stauble et al (1993) estimated the depth of closure for Fenwick Island using profile data measured from the spring of 1988 through the winter of 1992, and concluded that 6.1 m relative to National Geodetic Vertical Datum (NGVD) was a representative value. Because coastal processes at this depth are most likely similar offshore of Fenwick and Assateague Islands, this depth was also assumed to be representative of Assateague Island. However, this active depth was not used for southern regions of Fenwick Island and northern region of Assateague Island which were sheltered by the ebb tidal shoal. For these regions, the depth at the shoreward edge of the ebb shoal was used in active depth calculations. Volume change within the ebb shoal was accounted for separately.

Stauble et al (1993) estimated the active berm elevation for Fenwick Island as 3.0 m NGVD, resulting in an estimate of active depth for regions of Fenwick Island outside the shelter of the ebb shoal equal to 9.1 m. For Assateague Island, the sensitivity of applying pre- versus post- rehabilitation jetty berm crest elevations was insignificant; therefore, post-rehabilitation jetty berm crest elevations were applied herein. The estimate of active depth for the regions of Assateague Island unaffected by the ebb tidal shoal (from 2 to 14 km south of the inlet) ranged from 8.3 to 8.5 m.

Seven profiles from June 1988 (immediately pre-fill) and May 1996 (present-day condition) were analyzed to determine the rate of beach fill "loss" from the profile.

Volume change for each profile was multiplied by an alongshore distance represented by that profile to properly “weight” results at each profile location. Results from this analysis indicated that approximately 17 percent of the placed material was lost over the active depth. An additional 10 percent of material was originally placed in a dune feature (above 3.0 m NGVD), and this entire volume was assumed to remain on the profile. Because the fill material was similar to or coarser than the native sediments, it was assumed that any fill loss moved alongshore rather than offshore. The portion of the 1988-1995 Fenwick Island beach fill that was assumed to move alongshore, totaling approximately 1.7 million m³, was assumed to deposit and remain within the inlet sink. Shoreline change calculations assumed a beach fill “loss” rate of approximately 2-percent per year.

Profile data for the bay shoreline were only available for the northwest corner of Assateague Island (Dean, Perlin, and Dally 1978), and represented conditions prior to sand-tightening and raising of the south jetty and construction of the detached breakwaters. These data extended into the channel, and reflect stronger current conditions than the rest of the bayshore. Based on estimates of bay active depth of approximately 4 m for this small, higher energy, region of the bayshore, the sensitivity of results to a range of slightly smaller bay shoreline active depths, thought to be more representative of conditions along the majority of the bay (1 m, 2 m, and 3 m) was evaluated. The sensitivity of volume calculations to the choice of bay active depth was found to be significant for certain cases (see Section 3.4).

2.3 Ebb Shoal Evolution

Bathymetric data from 1933, 1976, and 1995 were utilized to define the ebb shoal planform “footprint,” depth at the landward edge of the footprint (used in estimating active depth), and volume. Visual inspection of a bathymetric data set or a bathymetric contour plot to delineate an ebb shoal is rather subjective. For this study, the availability of a pre-inlet (1933) bathymetry enabled application of a more objective procedure, as modified from that discussed by Hicks and Hume (1996). First, an idealized “non-inlet” bathymetry was created by using the 1933 bathymetric data set, but replacing the 1933 shoreline and nearshore beach profile data along the northern region of Assateague Island with present-day shoreline and bathymetry which were typical of that found outside the influence of the ebb tidal shoal. Using this idealized non-inlet bathymetry, “residual” topographies were created by subtracting it from the subsequent time periods. Next, the ebb tidal shoal footprint for each residual topography was estimated by four different individuals, and residual ebb shoal volumes were calculated. Four independent estimates of the ebb shoal footprint gave an indication of the error associated with personal subjectivity.

Estimates 1, 2, and 4 applied similar methods of using the 1-m residual contour to delineate the ebb shoal footprint. This contour appeared to provide a planform shape of the ebb tidal shoal that reflected onshore and alongshore evolutionary trends of the shoal as evidenced from bathymetric data. Estimate 3 used the 0-m residual contour to

delineate the shoal, and therefore these volume and area estimates are higher. Estimate 3 chose the 0-m residual contour to fully capture bathymetric regions which may have accreted. These regions resulted in a footprint which included more of the areas reflecting growth and lengthening of finger shoals, and deposition in troughs, which are probably only partly represented by Estimates 1, 2, and 4. All residual volumes were calculated by using the selected footprint and determining the volume above a 0-m residual contour within this polygon. Bathymetric data from 1995 did not fully cover the ebb tidal shoal. Therefore, 1933-1976 residual ebb shoal data were used to complete coverage on the outer edges of the ebb tidal shoal for the 1933-1995 residual bathymetry. Results are presented in Table 2.

Estimate Number	Volume (million m³)	Area (million m²)	Volume Change Rate (m³/yr)

For estimates of total ebb shoal volume from 1933 to 1996, two ebb shoal volumes were used: a minimum value was obtained by extrapolating the average of Estimates 1, 2, and 4 to 1996 (approximately 10 million m³); and a maximum value was obtained by extrapolating Estimate 3 to 1996 (approximately 13 million m³). For each estimate, depths at the landward edge of the ebb tidal shoal footprint were applied in calculating active depth for regions of Fenwick and Assateague Islands sheltered by each ebb shoal. In sensitivity testing, the differences between active depths for the 10 and 13 million m³ ebb tidal shoal footprints were found to have an insignificant impact on final calculations. Therefore, results are presented herein for active depths as indicated by the 10 million m³ ebb shoal footprint.

2.4 Flood Shoal Evolution

Information about deposition in the bay is necessary to account for losses to the littoral system. Unfortunately, detailed bathymetric data provide only partial coverage for Isle of Wight and Sinepuxent Bays. For this study, the flood shoal/bay accretion rate calculated by Dean and Perlin (1977) and Dean, Perlin, and Dally (1978) using 1931 to 1972 bathymetry was used, 19,600 m³/yr. It is likely that the 1972 through 1996 flood shoal accretion rate has decreased somewhat, perhaps half this value, for a present-day estimate of total flood shoal/bay volume equal to 1 million m³. This estimate is based on the belief that flood shoal accretion would probably be greatest during the initial years after inlet formation, and would decrease with time. The sensitivity of calculations presented herein was evaluated with two other flood shoal/bay accretion estimates. A maximum estimate assumed that the original rate continued through the present, for a total flood shoal/bay volume of 1.2 million m³. A minimum volume of 0.76 million m³ was estimated by assuming that no additional bay/flood shoal accretion has occurred since 1972.

2.5 Dredging History

Various sources were culled to determine the dredging and placement history for Ocean City Inlet. A total of 24 dredging events between 1947 and 1995 indicated a channel shoaling rate of approximately 56,000 m³/yr, with many dredge placements on northern Assateague Island. For this study, a minimum channel shoaling volume between 1933 and 1996 was calculated by assuming that only the documented dredging events occurred (2.7 million m³). A maximum channel shoaling volume assumed that the 56,000 m³/yr rate continued from 1933 through 1996 (3.5 million m³). Adjacent beach placement of the dredged material was accounted for in the shoreline change database.

3.0 LITTORAL IMPACT OF OCEAN CITY INLET

3.1 Volume

The "inlet sink volume" captured by Ocean City Inlet is defined as the volume of material within the inlet which is assumed to have been derived from adjacent ocean and bay beaches. A range of volumes representing the Ocean City Inlet sink was calculated by summing the minimum and maximum estimates for ebb shoal volume, flood shoal volume, and channel shoaling volume, subtracting maximum and minimum estimates for the original 1933 Ocean City Inlet breach, and subtracting the volume of Fenwick Island beach fill which was assumed to move alongshore and deposit in the inlet. The initial loss of material due to the island breach in 1933 was estimated using typical ocean and bay profile shapes (best estimate: 0.53 million m³, with a range between 0.43 and 0.97 million m³).

The minimum inlet sink volume was estimated as 10.8 million m³ (ebb shoal: 10 million m³ + flood shoal: 0.76 million m³ + shoaling volume: 2.7 million m³ - initial breach: 0.97 million m³ - alongshore movement of Fenwick Island beach fill: 1.7 million m³). The maximum inlet sink volume totaled 15.6 million m³ (ebb shoal: 13 million m³ + flood shoal: 1.2 million m³ + shoaling volume: 3.5 million m³ - initial breach: 0.43 million m³ - alongshore movement of Fenwick Island beach fill: 1.7 million m³). Thus, **the total volume of material captured by Ocean City Inlet which can be attributed to adjacent beaches is estimated to be between 10.8 and 15.6 million m³.**

3.2 Alongshore Impact: Overview. Two methods were used to estimate the distance alongshore for which the inlet has affected adjacent beaches: the even/odd procedure (Section 3.3), and an examination of the inlet's net sink effect and adjacent island response (Section 3.4). Both methods accounted for a background erosion rate, and assumed that pre-inlet volume change trends would have continued through the present if the inlet had not been created. Thus, pre-inlet (1850-1929/33) volume change rates were subtracted from post-inlet (1929/33-1996) volume change rates. The effect of beach fill (which is reflected in the shoreline position) was removed from the signal by subtracting an estimate of the beach fill volume remaining from the volume in each 50-m shoreline calculation cell. An estimate of beach fill reflected in the shoreline position was

estimated by assuming a beach fill "loss" (or alongshore movement) rate of approximately 2-percent per year (discussed in Section 2.2).

The assumption of a background erosion rate is reasonable, as evidenced from the Fenwick Island shoreline change rates from 1929/33-1996 (Table 1 with beach fill advancement removed), and the trend for relative sea level rise in this region of the U.S. (1.1 mm/yr for Lewes, Delaware, north of Ocean City Inlet, Marine Board 1987). In addition, the 1850 to 1929/33 reorientation of the Fenwick-Assateague Island barrier island from a convex to a more "linear" shoreline orientation (see Figures 1 and 3a) most likely is a long-term, large-scale response which is continuing through the present.

3.3 Alongshore Impact: Even/Odd Method. The even/odd method is a simple analytical procedure discussed and applied by Dean and Work (1993) and Bodge (in preparation) among others, and can be solved from the linearized treatment of shoreline evolution (Pelnard-Considere 1956). The method decomposes shoreline change (or, as applied in this case, volume change) data into their symmetric (even) and anti-symmetric (odd) components about a point of significance. For application at Ocean City Inlet, the center of the inlet was chosen as the point about which data were decomposed into even and odd components. Volumetric change data were used so that the effects of beach fill could be removed, and so that the alongshore variation in active depth could be incorporated. Due to space limitations herein, the reader is directed to Dean and Work (1993) or Bodge (in preparation) for a description of even/odd calculation procedures.

The even and odd functions are indicators of those shoreline or volumetric changes which have been symmetric or anti-symmetric, respectively, about the point of significance. For an inlet with the centerline chosen as the point of significance, the even function reflects changes in shoreline position (or volume change rate) which have occurred symmetrically about the inlet, such as shoreline retreat or advance due to cross-shore transport (due to storms and relative sea level change), and symmetric shoreline retreat due to sediment feeding the ebb and flood tidal shoals. An example of an anti-symmetric change common to stabilized inlets, which is reflected by the odd function, is impoundment on the updrift beach at the expense of the downdrift beach. The alongshore point at which the odd function returns to a zero value is an indicator of the alongshore distance influenced by the anti-symmetric effects, such as impoundment, which is a project-induced impact. The alongshore point at which the even function approaches a constant value is an indication of the alongshore distance influenced by symmetric inlet-induced effects such as shoreline retreat due to feeding the ebb and flood tidal shoals.

Figure 2a shows the post-inlet (1929/33-1996) even/odd analysis, and Figure 2b shows results for the post-inlet rate adjusted by the background erosion rate as defined by the pre-inlet (1850-1929/33) data set. Negative distances indicate shoreline to the north along Fenwick Island. For both Figures 2a and b, the "total" curve shows the updrift

(a)

(b)

Figure 2. Total volumetric change, even, and odd functions for (a) post-inlet volume change rates (1929/33-1996); and post-inlet minus pre-inlet (1850-1929/33) volume change rates

accretion that has occurred as a result of inlet stabilization and the groin field along Fenwick Island. It is interesting to note the erosional peak in the post-inlet volume change rate ("total" curve in Figure 2a) at approximately 8 km updrift of the inlet, which agrees in concept with a longshore sediment transport nodal point in the vicinity of York Beach, Delaware (approximately 18 km north of the inlet), with a variation of 10 km (Mann and Dalrymple 1986). For Assateague Island, except for a peak in the total adjusted volume change curve at approximately 1 km (Figure 2b), the entire shoreline response has been erosional. The peak at approximately 1 km in Figures 2a and b agrees well with the presently-observed bridging of the ebb tidal shoal to the downdrift beach. The "odd" function indicated in Figures 2a and b illustrates the strong alongshore impact that the inlet and Fenwick Island groin field have incurred on the adjacent beaches. This function returns to a zero value approximately 10 km from the inlet in Figure 2a, and at approximately 8 km in Figure 2b. The "even" function in Figure 2a returns to a near-constant value at approximately 13 km from the inlet, and approaches a constant value in this region for Figure 2b. If Figure 2a were taken to represent the inlet's impact (i.e., no background erosion existed from 1933 to 1996), then the alongshore impact distance would be interpreted as between 10 and 13 km. However, we have evidence that background erosion has occurred during the post-inlet time period. Thus, considering both the even and odd functions, **the alongshore impact distance of the inlet (and Fenwick Island groin field) is estimated to be between 8 and 13 km from the centerline of the inlet.**

3.3 Alongshore Impact: Net Sink Effect

Overview. A second method of determining alongshore impact distance is discussed by Bodge (in preparation). This method calculates the alongshore variation in total volume change, and determines the alongshore distance for which the total inlet sink volume can be accounted. Alongshore impact distance as determined through application of this method is very sensitive to the total sink volume estimate, due to the fact that the alongshore volume changes due to the inlet will decrease with distance from the inlet.

Pre- and Post-Inlet Volumetric Change. Shoreline change from August/September 1850 to November 1929/May 1933 indicated that the pre-inlet Fenwick-Assateague barrier island in the region ± 7 km from the centerline of the existing inlet was in an erosive state (Figure 3a). The island (ocean and bay) cumulative volume change rate for what would become Fenwick Island (extending 14.2 km north of the inlet location) was $-42,500 \text{ m}^3/\text{yr}$ during this time period (independent of bay active depth; the bay shoreline change rate was approximately zero during this period, see Table 1). The cumulative island pre-inlet volume change for 14.2 km of Assateague Island ranged between $-137,700$ and $-59,300 \text{ m}^3/\text{yr}$, depending on bay active depth.

In the post-inlet (November 1929/May 1933 through March 1995/May 1996) time period, Fenwick Island stabilized with cumulative island volumetric change rates ranging from $-16,500$ to $+4,400 \text{ m}^3/\text{yr}$, depending on bay active depth. However, cumulative

(a)

(b)

Figure 3. (a) Pre-inlet (1850-1929/33) and (b) post-inlet (1929/33-1996) island (bay and ocean) volumetric change rates as a function of bay active depth (1, 2, or 3 m)

volumetric erosion rates along Assateague Island increased, ranging from -293,000 to -224,000 m³/yr depending on bay active depth (Figure 3b). The first four columns of Table 3 summarize these results.

Island	Bay Active Depth (m)	Net Island ¹ Volume Change Rate (m ³ /yr)		Present-Day Normalized ² Cumulative Volume (million m ³)
		Pre-Inlet (1850-1933)	Post-Inlet (1933-1996)	
Fenwick	1	-42,500	-16,500	+1.6
	2	-42,500	-6,000	+2.3
	3	-42,500	+4,400	+3.0
Assateague	1	-137,700	-293,000	-9.8
	2	-98,500	-259,000	-10.1
	3	-59,300	-224,000	-10.4

¹ Net ocean and bay volume change.
² Post-inlet minus pre-inlet rate multiplied by the number of years since inlet creation (1996-1933=63 years).

Present-Day Impact Accounting for Background Erosion. The fifth column of Table 3 presents the cumulative volume change, accounting for "background erosion" which was defined by the pre-inlet condition, at ± 14.2 km of the inlet. The degree to which the bay active depth assumption influences magnitudes of cumulative impact can be evaluated from these data. For Fenwick Island, the bay active depth assumption can alter the normalized cumulative volume by nearly a factor of two. For Assateague Island, ocean volumetric change dominates the volumetric impact and the influence of bay active depth is less significant.

Summing the Fenwick and Assateague Islands cumulative volumes for a given bay active depth gives *total adjacent beach impact volumes* which vary at most by 10-percent as a function of bay active depth (-8.2, -7.8, and -7.4 million m³ for 1, 2, and 3 m bay active depth, respectively). Note that only 0.9 million m³ of dredged material is documented as being placed on Assateague Island, whereas between 2.7 and 3.5 million m³ were dredged. If it is assumed that this entire dredged volume was placed on Assateague Island (as has been standard practice), and (to be conservative) that this entire volume moved alongshore or was lost to the profile and is not reflected in the shoreline data, then an additional loss of 1.8 to 2.6 million m³ can be assigned to the adjacent island losses. Using the upper value of 2.6 million m³, it can be

concluded that the volumetric impact of Ocean City Inlet realized on adjacent ocean and bay shores within 14.2 km from the inlet, is *at most* 10.8 million m³. This estimate approaches the minimum total inlet sink volume, which was estimated to range from 10.8 to 15.6 million m³. (However, note that the 10.8 million m³ adjacent island loss was developed with the *upper* dredge volume estimate, whereas the 10.8 million m³ sink volume was developed with the *lower* dredge volume estimate.) Thus, with a pre-existing background erosion rate which is defined by the pre-inlet condition, it is likely that the inlet's influence exceeds the available data limit (14.2 km).

4.0 SUMMARY AND CONCLUSIONS

A database representing 146 years of beach response in the vicinity of Ocean City Inlet, Maryland, was created to reflect adjacent beach, bay, and inlet volume change. Analyses were conducted to evaluate the total sink volume of the inlet, and the alongshore distance associated with this volumetric impact. The total inlet sink, defined as the volume captured by the inlet which can be attributed to the adjacent ocean and bay shorelines, was estimated to range between 10.8 and 15.6 million m³. The even/odd method was applied to ocean shoreline change (adjusted by a background erosion rate) since inlet formation, and indicated an alongshore impact distance (which includes the effects of the Fenwick Island groin field) of approximately 8 km from the centerline of the inlet. The inlet sink analysis, assuming that pre-inlet trends continued through the present, indicated, *at most*, that 10.8 million m³ can be realized along 14.2-km of up- and downdrift ocean and bay shorelines. This analysis indicated that the alongshore impact distance most likely exceeds the available data limit (± 14.2 km from the centerline of the inlet).

CHAPTER 216

EXTREME WATER LEVELS, WAVE RUNUP AND COASTAL EROSION

P. Ruggiero¹ , P.D. Komar² , W.G. McDougal¹ and R.A. Beach²

ABSTRACT

A probabilistic model has been developed to analyze the susceptibilities of coastal properties to wave attack. Using an empirical model for wave runup, long term data of measured tides and waves are combined with beach morphology characteristics to determine the frequency of occurrence of sea cliff and dune erosion along the Oregon coast. Extreme runup statistics have been characterized for the high energy dissipative conditions common in Oregon, and have been found to depend simply on the deep-water significant wave height. Utilizing this relationship, an extreme-value probability distribution has been constructed for a 15 year total water elevation time series, and recurrence intervals of potential erosion events are calculated. The model has been applied to several sites along the Oregon coast, and the results compare well with observations of erosional impacts.

INTRODUCTION

Much of the Oregon coast is characterized by wide, dissipative, sandy beaches, which are backed by either large sea cliffs or sand dunes. This dynamic coast typically experiences a very intense winter wave climate, and there have been many documented cases of dramatic, yet episodic, sea cliff and dune erosion (Komar and Shih, 1993). A typical response of property owners following such erosion events is to build large coastal protection structures. Often these structures are built after a single erosion event, which is followed by a long period with no significant wave attack. From a coastal management perspective, it is of interest to be able to predict the expected frequency and intensity of such erosion events to determine if a coastal structure is an appropriate response. Predicting the frequency and magnitude of the most extreme erosion conditions is also important for the establishment of setback lines for coastal developments.

Field studies have been undertaken along the Oregon coast to better understand the processes involved in wave-induced sea cliff and dune erosion. The

¹ Ocean Engineering Program, Civil Engineering Dept., Oregon State Univ., Corvallis, OR 97331

² College of Oceanic and Atmos. Sciences, Oregon State Univ., Corvallis, OR 97331

goal is to develop simple methods for estimating the susceptibilities of coastal properties to wave attack. Wave-induced property erosion generally occurs when wave runup reaches the junction between the beach face and the sea cliff or dune. However, depending on a number of wave, water level and morphological parameters, both the elevation attained by wave runup and the elevation of the beach-face junction are highly variable. This paper presents a simple probabilistic method for predicting the frequency of occurrence of cliff or dune erosion. The predicted frequencies are then compared with the observed shoreline stability for several beaches along the Oregon coast.

Other researchers have attempted to determine the risk of coastal properties to flooding using probabilistic techniques. For example, Gares (1990) demonstrates a method for using runup to determine flooding risk on the New Jersey shoreline. Runup is calculated using the composite slope technique presented in the *Shore Protection Manual* and probability curves are produced assuming that maximum runup occurs at times of maximum storm surge. In the current work, an attempt is made to characterize extreme runup statistics on the high energy, yet dissipative beaches common in Oregon where the storm surge is small. Extreme total water levels, hence erosion risks, are then predicted utilizing a long term data base consisting of both measured tides and measured wave characteristics.

MODEL DEVELOPMENT

There are two main components, in Figure 1, which combine to generate total water levels (Shih *et al.*, 1994). The first is the tide elevation, ζ ; all tidal and land elevations presented in this paper will be referenced to the U.S. National Geodetic Vertical Datum (NGVD) of 1929. Superimposed on the measured tide level is the vertical component of wave runup, R , which consists of both wave setup, $\bar{\eta}$ and the swash fluctuations, S , about the setup. Wave induced erosion of a sea cliff or dune will occur only when the total elevation of the water at times of maximum runup exceeds the elevation of the beach-face junction ($\zeta + R > E_j$). Once again, the objective of this study is to predict the frequency with which the total water level, E , reaches or exceeds the elevation E_j of the junction between sea cliff, dune or coastal protection structure and the beach face. To achieve this goal, we construct extreme-value probability distributions (e-v pdf) for water levels measured by tide gauges, water levels due to wave runup, and finally for the combined total water levels.

Extreme Water Levels

Measured tides are often greater than predicted due to the occurrence of a storm surge, or the effects of water temperatures, currents and atmospheric disturbances such as an El Niño. A 24 year time series of hourly measured tides taken from a tide gage in Yaquina Bay, Oregon, has been analyzed to investigate some of these processes. The yearly maxima have been fitted to a Fisher-Tippet Type I extreme-value probability distribution, commonly known as the Gumbel extreme value distribution, and return intervals have been computed for extreme tides. A

Figure 1: The basic model for the quantitative assessment of the susceptibilities of sea cliffs and dunes to wave-induced erosion.

predicted tide time series has been generated for the same 24 year period, and the predicted yearly maxima have also been fit to a Gumbel distribution. Shih *et al.* (1994) noted that for long return periods there are significant differences, on the order of 0.5 m, between predicted and observed extreme tides.

The difference between measured and predicted tides has been computed for the entire 24 year data set. The auto-correlation of this raw residual time series shows a roll off in correlation at a lag of approximately 48 hours. This lag corresponds well with the typical storm duration on the Oregon coast. The raw residuals were then filtered using a 48 hr low pass filter, eliminating measurement noise from the signal. The standard deviation of the low pass filtered residual time series is approximately 13 cm, giving a typical elevation for storm surge on the Oregon coast. Figure 2 shows the 24 year residual time series after applying a 1 month low pass filter in which single storms as well as spring and neap tides have been averaged out. Surprisingly, there is no distinct seasonal pattern in the figure. The extreme residuals evident in the smoothed time series, those in 1973, 1977, 1982-83, 1992 and 1993, all correspond to times of well-documented El Niño events. Although these events are usually associated with increased wave energy, both the residual and the measured tide are not significantly correlated with wave height throughout the period of overlap between the tide and wave data, a period of approximately 15 years. This observation, along with the relatively low contribution of storm surge to extreme total water levels on the Oregon coast, suggests that models such as that proposed by Gares (1990) may not be applicable to the Oregon coast. Models in which extreme measured water levels and extreme runup occur at the same time, although well suited for coastlines which experience hurricanes and Nor'Easters which generate significant storm surge, are not generally suitable to conditions typical of the Oregon coast.

Wave Runup

The second water-level component in the sea cliff and dune erosion model, superimposed on the measured tide, is wave runup. It is necessary to have the

Figure 2: Thirty day low-pass filtered residual time series of measured minus predicted tides in Yaquina Bay, Oregon.

capability to predict extreme runup statistics utilizing measured wave parameters and beach morphology characteristics. Data bases containing a decade or more of measurements of wave heights and periods are now becoming readily available for use by engineers, scientists and planners, and much effort has been spent in finding simple relationships between deep-water wave parameters and runup on beaches. A well known data set of extreme runup statistics is that of Holman and Sallenger (1984) and Holman (1986), who measured wave runup using video techniques on the relatively steep beach of the Field Research Facility, Duck, North Carolina. Among other runup statistics, Holman (1986) examined the 2% exceedence elevation for runup maxima, non-dimensionalized by wave height, and found a dependence on the dimensionless surf similarity parameter, ξ_0 , commonly referred to as the Iribarren number, the ratio of the beach slope to the deep-water wave steepness. The resulting relationship is

$$R_{2\%}/H_S = C \xi_0 = C \beta / (H_S/L_0)^{(1/2)} \quad (1)$$

where C is an empirical constant determined by the measurements, β is the beach slope, H_S is the deep-water significant wave height, and L_0 is the deep water wave length given by $L_0 = (g/2\pi)T^2$ where g is the acceleration of gravity and T is the wave period. This result has been proposed by many researchers, including Battjes

(1971) and van der Meer and Stam (1992). In an attempt at further simplification, Holman's data were re-analyzed by Douglas (1992), who found that removing the beach slope term from Eq. (1) does not cause any reduction in the ability to predict runup on beaches. By analyzing a wide variety of Australian beaches, Neilson and Hanslow (1991) found that the relationship proposed by Holman explained results from field experiments on relatively steep beaches, $\beta > 1:10$, while for flatter more dissipative beaches with $\beta < 1:10$, runup depended only on the wave steepness. Many Oregon beaches are extremely dissipative with beach slopes much less than 1:10. The resulting Iribarren numbers are usually less than for beaches studied by other researchers, including the most dissipative in the Neilson and Hanslow (1991) study.

To test the dependence of extreme runup statistics on measured wave and beach morphology characteristics, video techniques were used to measure wave runup on several Oregon beaches over a broad range of dynamic conditions. Deep-water significant wave heights ranged from 1.9 to 4.6 m, periods from 7 to 17 seconds, and foreshore slopes from 1:100 to 1:20. This field program culminated in February 1996 at Agate Beach on the central Oregon coast, with a major investigation into the dynamics of high energy dissipative beaches. During this experiment, three video cameras were used to measure wave runup, and the overlap between the cameras allowed for continuous coverage of runup measurements over approximately 2 km of beach. Detailed analysis of the longshore variability of runup on dissipative beaches is underway. Runup elevation time series were extracted from all video data using image-processing techniques developed at the Coastal Imaging Lab of Oregon State University (Holman and Guza, 1984; Holland *et al.*, in press). For each data record, the tide has been removed and extreme runup statistics have been computed after identifying the local maxima of the shoreline elevation time series. Although there is a distinction in the processes which force wave setup and swash fluctuations, for most engineering applications the measure of interest is the extreme statistics associated with the total runup. Therefore, all runup statistics presented include both setup and swash.

The Oregon measurements of $R2\%$ are non-dimensionalized in the form of Eq. (1), and compared with the data of Holman (1986) in Figure 3. The Iribarren number distinguishes between the dynamically different nearshore systems from which the data were taken. The Oregon data falls in the extremely dissipative range of Iribarren numbers, while the FRF data range from dissipative to reflective. Although the Oregon data are of the expected order of magnitude, any linear predictive model such as Eq. (1), derived from Holman's data, would tend to under predict $R2\%$ on the flatter Oregon beaches, an observation noted earlier by Shih *et al.* (1994). The data from Oregon have been re-plotted in Figure 4a, which suggests that extreme runup statistics do not depend on the Iribarren number over this dissipative range. Figure 4b shows that the Oregon runup data has virtually no dependence on the beach slope, and Figure 4c shows a lack of dependence of $R2\%/H_s$ on the wave steepness. Although not shown, the extreme runup also does not depend on the wave period. This is surprising, as runup has a first order dependence on the wave

Figure 3: Comparison between non-dimensional extreme runup statistics obtained by Holman from the FRF and from Oregon beaches.

Figure 4: Relationships between non-dimensional extreme runup statistics and a) the Iribarren number, b) beach slope, and c) wave steepness.

period in the dimensional form of Eq. (1). The best parameterization of $R_{2\%}$ for the Oregon data is a simple dependence on the deep-water significant wave height as shown in Figure 5. The best-fit straight line matched to the Oregon data is

$$R_{2\%} = 0.5 H_s - 0.22 \text{ (m)} \quad (r^2 = 0.72) \quad (2)$$

A linear relationship between runup elevation and wave height on relatively low energy dissipative beaches was also found by Guza and Thornton (1982) in Southern California, and by Aagaard (1990) in Denmark and Australia. Guza and Thornton (1982) found that the significant vertical swash excursion, defined as 4σ , where σ^2 is the total variance of the runup elevation time series, was approximately 70% of the significant wave height, a slightly stronger dependence on wave height than found for the Oregon data and the results presented by Aagaard (1990). The FRF data of Holman (1986) are shown again in Figure 5 to emphasize the fact that the data are derived from dynamically very different systems as the Holman data clearly falls above the Oregon data. More research is needed to identify regimes where different models for extreme runup statistics are applicable.

Figure 5: Dependence of extreme runup statistics on the deep-water significant wave height.

The extreme runup statistics presented here, as in the work done by other researchers, are monochromatic representations of spectral phenomena. In fact, all of the Oregon runup data, particularly that on the very low sloping Agate Beach, were dominated by infragravity energy ($f < 0.05$). Spectral peaks typically occurred at

periods ranging from approximately 100 seconds to 200 seconds, and usually more than 90% of the runup elevation variance fell in the infragravity band. This infragravity dominance helps explain why runup statistics are independent of the incident band wave period. The incident band energy was saturated for most data runs, and the dependence on wave height shown in Figure 5 can almost entirely be explained by the infragravity band energy and its dependence on the wave height. Again, this is a similar result to that found by Guza and Thornton (1982).

Waves and Total Water Levels

In the previous section we showed that the best predictor of extreme runup on dissipative Oregon beaches is simply the deep-water wave height. A 15-year wave data set from the Coastal Data Information Program buoy offshore from Bandon, Oregon, has been used to estimate the extreme wave climate of the Oregon coast. This irregularly spaced data set has been interpolated to hourly measurements to match the measurement interval of the Yaquina Bay tide measurements. A Gumbel extreme-value distribution has been fitted to this data, and the resulting recurrence intervals for extreme waves are shown in Figure 6. This extreme value pdf has been produced by using all of the wave data above 6.5 meters, rather than just the yearly maxima (Muir and El-Shaarawi, 1986).

Figure 6: Extreme-value probability distribution and recurrence intervals constructed from 15 years of wave height data obtained by the CDIP buoy offshore from Bandon, Oregon.

Figure 6, as well as results presented by Tillotsen and Komar (in press), clearly demonstrate the intense nature of the wave climate experienced along the Oregon coast. The linear relationship between wave height and extreme runup statistics given in Eq. (2) can now serve as a transfer function to construct an extreme value distribution for $R_{2\%}$ from the distribution of wave heights, and is shown in Figure 7.

Figure 7: Extreme-value probability distribution and recurrence intervals for wave runup calculated from the wave height distribution in Figure 6.

Analytic probability density functions have been determined for both extreme measured tides and extreme wave runup, the two components of the sea cliff and dune erosion model. Assuming that runup and tides are statistically independent, the joint probability of tides and runup is easily calculated. This exercise has been completed, and contours of equal probability of occurrence have been generated. However, a more useful and direct method for determining the statistics of extreme total water levels is to apply the above model for wave runup to the wave component of the joint time series of waves and water levels. This joint time series is constructed from the time periods in which the wave data and tide data overlap. In doing this, we generate a runup time series which can be added to the measured tide to give a simulated total water level time series. An extreme value distribution is determined from this time series directly, using all total water levels above 2.8 m, and

is shown in Figure 8. The recurrence intervals of the total water level reaching or exceeding any elevation can now be determined.

Figure 8: Extreme-value probability distribution and recurrence intervals for total water levels, measured tides plus wave runup.

MODEL APPLICATION

The Oregon coast is divided into a series of littoral cells, with beaches confined between large headlands. The elevation of the beach-face junction varies considerably between cells due to differences in sediment grain sizes, and the quantities of sand in a particular cell. This elevation can also vary within a cell due to local effects such as the lowering of the beach by rip current embayments (Shih and Komar, 1994). A number of beaches with varying morphologies are being monitored in Oregon to determine these elevations relative to NGVD, as well as to quantify typical summer and winter profiles and long term morphology changes. The model has been applied to 13 sites along the central Oregon coast, accounting for 9 of the 13 littoral cells. The beaches are backed by sea cliffs, dunes and shore protection structures and all have beach slopes within the range of applicability of the runup model. The model allows for the determination of the frequency with which the total water level exceeds the elevation of the beach-face junction, thus being a good indicator of potential erosion.

Table 1: Impacts per year as compared to beach stability observations.

Site	Backing Feature	β	E_j (m)	Impacts per year (hrs)	Observations
Jump off Joe	Sea Cliff	.034	2.90	173	severe erosion
Nye Beach	Sea Cliff	.034	3.70	13	stable
Beverly Beach	Sea Cliff	.043	4.02	4	erosion
Oceanside	Dune	.023	3.60	18	stable/erosion
South Beach	Dune	.026	4.12	3	accretion
Manzanita North	Dune	.025	4.20	2	stable/accretion
Manzanita South	Dune	.038	6.30	---	heavy accretion
Nestucca Spit	Dune	.046	6.50	---	heavy accretion
C&L Ranch	Sea Wall	.030	3.15	77	severe erosion
Pacific Shores	Sea Wall	.039	3.65	15	erosion
San Marine	Sea Wall	.030	3.75	11	erosion
Pacific Palisades	Sea Wall	.052	5.30	---	accretion
Driftwood Shores	Sea Wall	.033	7.50	---	heavy accretion

Table 1 summarizes the results as applied to the sites on the Oregon coast. The table lists the average winter beach slopes and the average elevations of the junction between the beach and the respective backing feature. The return interval, the fraction of time when the 2% exceedence elevation of runup maxima superimposed on the tide reaches or exceeds E_j has been calculated. However, since we have used all of the data above a threshold value from our simulated total water elevation time series to construct the extreme pdf shown in Figure 8, we can convert return intervals to the more convenient unit of hours of wave runup impact per year. This column in Table 1 gives an estimate of the number of hours per year in which $R_{2\%}$ exceeds E_j for a particular beach, thus being a reasonable proxy for potential erosion at the site. The final column in the table lists basic field observations concerning the morphologic stability of the particular site. The first site, Jump Off Joe, is backed by the remains of a massive landslide which protrudes out onto the active beach profile, hence the very low E_j . The toe of the landslide is actively eroding and is reached by swash during most higher high tides in the winter. Nye Beach, immediately to the south of Jump off Joe, is relatively stable and backed by a vegetated sea cliff. The model predicts that the sea cliff at Jump off Joe will be hit by wave runup much more often than any other site including the cliff at Nye Beach, agreeing well with observations.

SUMMARY AND DISCUSSION

With an appropriate model relating runup elevations to deep-water wave conditions, the frequency of occurrence of sea cliff or dune erosion can be predicted using historical wave and tide records. Coastal regulators, the anticipated users of the model, will have a quantitative method to determine the susceptibilities of properties to erosion and thus a rationale to establish setback distances for coastal developments. The model can also aid in the development of dune-management plans which balance the role of dunes in reducing future property losses versus the development pressure currently being experienced on the Oregon coast. For

example, from this data set it appears that shorelines subjected to less than 1 hour of attack per year tend to be stable, while those with more than 10 hours per year tend to experience erosion. In its present form the model may be used to evaluate the need for shore protection structures and may potentially assist in their design. Future model development will attempt to include impact forces in order to predict erosion rates of both sea cliff and dune backed shorelines. The major weakness of the model is the simple relationship between extreme runup statistics and wave height. The model takes no account of the possibility that the functional relationship between runup and wave height may change under more extreme conditions than those measured. The model also ignores large-scale morphology, including offshore bars and bathymetry, as well as large-scale alongshore variability. More runup data are needed on beaches between the dissipative extremes presented here, and the more intermediate to reflective systems to help identify appropriate runup models for a particular beach state.

ACKNOWLEDGMENTS

We would like to thank Rob Holman for the use of his extensive data set. This work is a result of research supported by the NOAA Office of Sea Grant, Department of Commerce. The Agate Beach field experiment and data analysis was supported by ONR Grant # N000-14-94-11196.

CHAPTER 217

A morphological “mixed-type” model for the Ebro delta coast

Agustín Sánchez-Arcilla and José A. Jiménez¹

Abstract

A conceptual model to explain and simulate the long-term (decadal) Ebro delta coast evolution is presented as well as the approach to be followed to convert this conceptual model into a numerical one able to quantitatively predict the deltaic coast behaviour. Moreover, a first running sub-model which simulates most of the changes suffered by the outer coast is described in details. This sub-model is a long-term scale version of a one-line coastal model in curvilinear coordinates. The developed model has been verified and predictions of coastline evolution under different scenarios are also presented.

Introduction

The impact assessment of management policies and/or climate change on coastal zones requires comparing the coastal evolution under the present management/climate scenario with respect to the evolution under a different (targetted) scenario. To do this, it is necessary to develop proper tools to predict coastal evolution at adequate temporal and spatial scales.

According to the analysis of scales in coastal morphology done by Sánchez-Arcilla and Jiménez, (1994a, 1996), the representative scale for this kind of tools must be the large spatial scale and the long-term temporal one. In this case, long-term refers to a temporal scale of decades and large scale refers to a length of tens of kilometres up to the entire littoral cell. This implies building models able to adequately reproduce/simulate coastal processes and the corresponding behaviour at this scale, *i.e.* long-term/large scale morphological models.

One of the main questions to solve in large scale coastal modelling is the level of accuracy in the description of the driving terms to be considered. This will determine the

¹ Laboratori d'Enginyeria Marítima (LIM), Catalonia University of Technology (UPC), c/Gran Capitá s/n, 08034 Barcelona, Spain (arcilla@etseccpb.upc.es, jimenez@etseccpb.upc.es).

aggregation level of the processes included in the model. According to deVriend *et al.* (1993) three main approaches exist in large scale modelling:

- (i) *input data reduction*, in which it is assumed that large scale processes can be modelled by using process-oriented-models (usually employed to characterise short-term morphological processes) fed by aggregated input data representative of the process to be modelled;
- (ii) *model reduction*, in which the model is re-formulated according to the scale of interest (and avoiding shorter scale processes or retaining its integrated effect) and;
- (iii) *behaviour-oriented models*, which describe coastal changes without considering the underlying physical processes.

The model here presented is a kind of combination of approaches (i) and (iii) and it is thus called “mixed-type” model. The concept *mixed-type* model refers to a morphological set of equations derived by combining two approaches: (i) the underlying physical processes, particularly at large time scales -*i.e.* subject to an averaging from which only the “residual” effect of small scale processes is retained- and (ii) the actually “observed” morphological evolution, which integrates all “driving” agents into an a priori assumed “predictable” behaviour -from which governing equations could also be derived in an heuristic manner-.

Thus, the aim of this work is to introduce a morphological *mixed-type* model developed for the Ebro delta coast to predict the large scale deltaic evolution. The model is based on the analysis of (i) the existing information on “driving” agents (basically river regime, wind-wave and meteorological climates and mean sea-level fluctuations) and associated physical processes (see *e.g.* Jiménez *et al.* 1996) and (ii) the observed Ebro delta coast evolution at different scales (Jiménez and Sánchez-Arcilla, 1993; Sánchez-Arcilla and Jiménez, 1994; Jiménez, 1996).

After introducing this model, a first sub-model is developed quantitatively. This sub-model deals with one of the main processes involved -the longshore sediment transport- and is used to predict the deltaic coastline behaviour for different scenarios.

Conceptual model

The term conceptual applied in this context refers to a model explaining all the processes governing the Ebro delta coastal behaviour at different temporal and spatial scales as well as their dependence with the acting driving terms and for a defined set of boundary conditions.

This means to develop a model for the Ebro delta coast evolution using all the available relevant information where the coastal response at the different scales is isolated and quantified and, moreover, integrated into a general framework able to explain the coastal evolution as a whole.

This model has been developed for the Ebro delta coast after a detailed analysis of forcing agents, induced processes and associated coastal responses at three main scales: medium-term (Jiménez and Sánchez-Arcilla, 1993), episodic events (Sánchez-Arcilla and Jiménez, 1994) and long-term (Jiménez *et al.* 1993). These components have been

integrated into a generic model in which the processes are linked through sediment fluxes (across- and alongshore) and the coastal response is aggregated (Jiménez, 1996).

Figure 1 shows a cross-shore section of the model in which the main considered processes are presented. The coast is thus divided alongshore into a series of cells, each one composed by different units linked by sediment fluxes.

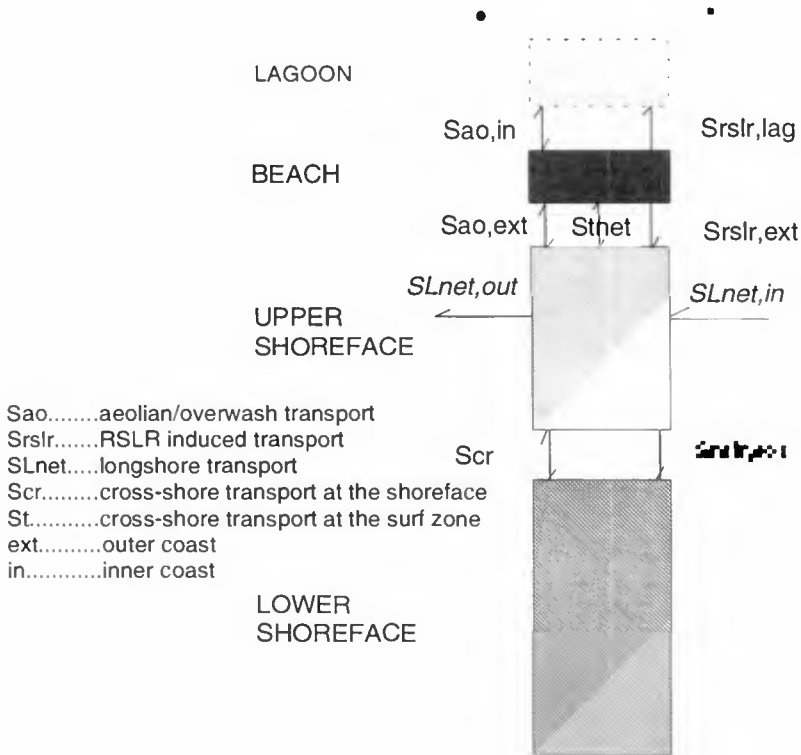

Figure 1. Cross-section of the conceptual model and considered sediment fluxes.

Full details on the conceptual model as well as on the way of quantifying the different sediment fluxes are given in Jiménez (1996).

As a sample description, the most apparent conclusions arising from the developed conceptual model is that, at present times, the Ebro delta coast is subject to a reshaping process in which the net longshore wave-induced sediment transport pattern is the main driving term. This longshore sediment transport pattern (fig. 2), although with a peak frequency located at the medium-term scale (*i.e.* over several years) has a very important residual effect at a longer time scale, since it can be shown that it is also one of the main agents responsible for the sediment redistribution along the coastline on the “long-term” scale (*i.e.* over decades). At this long-term scale, longshore transport will redistribute the sediment along the coast, whereas river sand supplies (severely limited at present), cross-

shore sediment exchanges at the shoreface, RSLR induced changes and aeolian and overwash transports (over the dune rows and subaerial coast) will determine the global sediment budget.

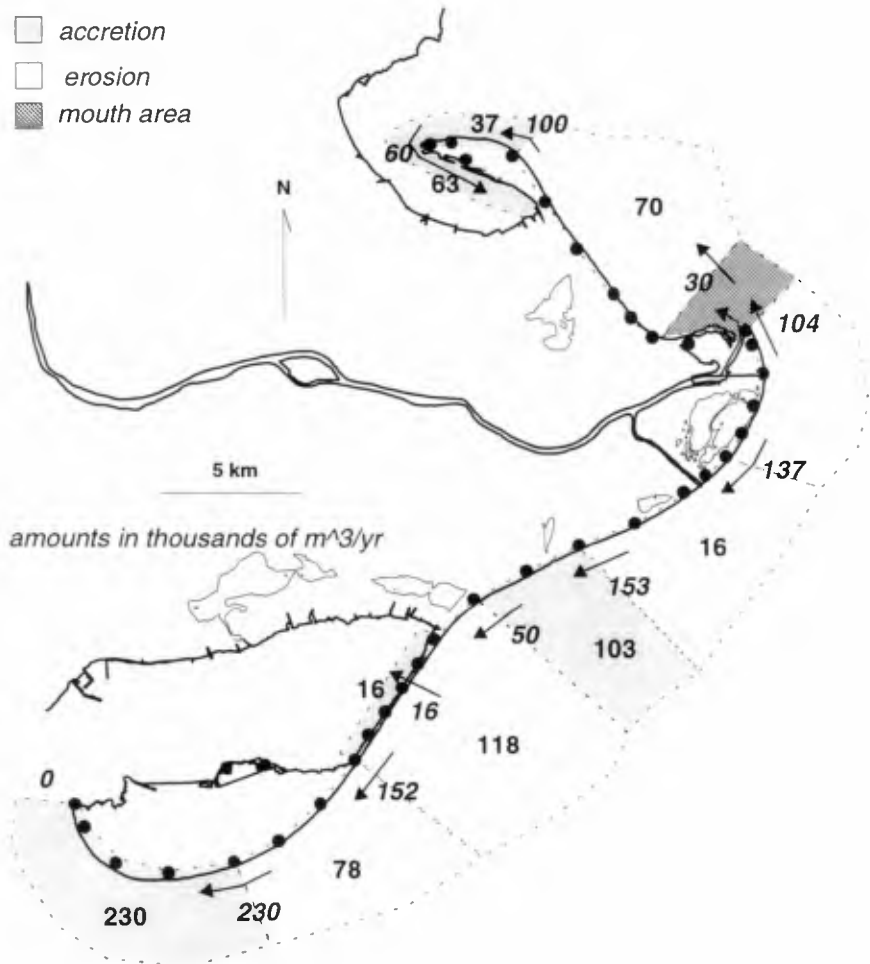

Figure 2. Net longshore sediment transport pattern and associated sediment budget at the medium-term scale (adapted from Jiménez and Sánchez-Arcilla, 1993).

The resulting morphological model has been developed using all the identified “transport mechanisms” relevant for the decadal scale. To estimate the “predictable” coastal evolution, a numerical “box-type model” (*i.e.* based on sediment budget considerations) is being built. This general model is composed by a series of sub-models considering the different processes to be afterwards coupled.

In what follows, the sub-model to predict the coastal "reshaping" due to the existence of a longshore sediment transport gradient (as the only driving term) along the coast is presented and used to simulate/predict the Ebro delta coastline evolution.

Longshore sediment transport parameterization

The net longshore sediment transport rate along any coast, $Sl_{net,i}$, can be expressed as the summatory of contributing transport rates induced by wave conditions acting on that coast,

$$Sl_{net,i} = \sum_{w=1}^{w=n} Sl_{w,ii} f_w \quad (1)$$

where $Sl_{w,i}$ is the local longshore transport rate induced by the w waves and f_w is the occurrence frequency of those waves, subscript i indicates the position along the coast.

Due to the selected approach - the model to be developed is a combination of *input data reduction* and behaviour oriented models which represent a kind of *result reduction*, equation (1) will be solved at the maximum aggregation level here considered. This approach implies to consider the net longshore sediment transport as the result of a *representative morphological wave*, i.e. integrating the effects of the existing wave climate on the Ebro delta coast from a longshore transport standpoint (see e.g. DeVriend *et al.*, 1993 for review of wave data reduction approaches).

The way of parametering sediment transport must be done considering the functional relationship between the type of transport to be modelled and the wave parameters controlling such transport. Since the net longshore sediment transport is the "object" to be parameterized and considering that, in previous studies, the CERC formula has proven to be simple while reasonably reproducing the obtained net longshore transport pattern (Jiménez and Sánchez-Arcilla, 1993; Jiménez, 1996), it has been selected to parameterize this transport.

Transport parameterization

Due to the above mentioned assumptions (maximum aggregation and functional relationship given by the CERC formula), the local net longshore sediment transport in each control point i can be represented by

$$Sl_{net,i} = C K_i H_{b,i}^{2.5} \sin[2(\alpha_{b,i} - \alpha_{s,i})] \quad (2)$$

where C groups all the constant terms of the CERC formula, K_i is the CERC calibration factor, $H_{b,i}$ is the "morphological wave height" at breaking in each point along the coast, $\alpha_{b,i}$ is the local wave angle at breaking and $\alpha_{s,i}$ is the local shoreline orientation.

In this approach, the CERC calibration factor, K_i , is permitted to vary alongshore to account for local factors which may influence the transport capacity such as differences in the sediment grain size, sediment availability, beach slope, etc.

Equation (2) is expressed in terms of breaking wave characteristics so that, offshore waves must be propagated towards the coast to evaluate wave parameters at breaking.

This would be equivalent to employing a short term evolution model coupled with a wave propagation model.

In order to obtain a simpler (parametric) formula to be included in a long term evolution model, it will be expressed as a function of deep water wave characteristics as

$$Sl_{net,i} = CK_i Kw_i H_o^{2.5} \sin[2(\alpha_o - \alpha_{s,i})] \quad (3)$$

where Kw_i is a local constant including wave propagation effects. For a "steady" incident wave climate and for coastal changes small enough not to affect wave propagation, the local values will be "steady" as the coast evolves.

Thus, the parameterized net longshore sediment transport rate will be composed by four components: (i) a global constant ($KI = CH_o^{2.5}$) including all the common terms such as "universal" constants and offshore morphological wave height; (ii) a local constant (K_i) -the calibration factor of the CERC formula- accounting for local effects such as sediment availability, grain size variations, beach slope, etc.; (iii) a local constant (Kw_i) representing the modifications of wave characteristics due to wave propagation and (iv) a sinusoidal function in which the argument varies as the coastline orientation does. In a compressed manner, the net longshore sediment transport rate is given by

$$Sl_{net,i} = Ksl_i \sin[2(\alpha_o - \alpha_{s,i})] \quad (4)$$

where $Ksl_i = KI K_i Kw_i$.

Transport constants

The application of equation (4) requires to know the net longshore sediment transport rates along the coast of study, Sl_{net} , the actual coastal orientation for which transport rates are estimated, α_s , and, a deep water "representative wave" angle, α_o .

Assuming that the first two variables, transport and orientation are known as it has been already pointed up in the previous section, it remains the problem of the selecting wave angle.

Fig. 3a shows the directional wave climate off the Ebro delta coast in which three main directional components can be seen. From these, the NW component is not relevant for morphological processes due to the coastline orientation since it will represent calm conditions for coastal dynamics (NW waves are generated by local winds blowing offshore). The other two components, E and S, have similar occurrence percentages being Eastern waves slightly more frequent.

In order to see the relative importance of each one of the two components, their energetic content was estimated through their respective offshore wave energy flux. This flux was calculated as the yearly-integrated value of $H_s^2 T_p$ -being H_s the significant wave height and T_p the peak period- (see Fig. 3b). The obtained pattern of wave energy flux indicates the effectiveness of waves acting on the Ebro delta coast. It is clear that, the "representative" morphological wave, must be close to the East component. This is clearly reflected in the Ebro delta coastal morphology, where the presence of the two spits

indicates a net longshore transport directed towards the north northwards of the river mouth, and towards the south southwards of the river mouth.

Figure 3. (a) Offshore directional wave distribution. (b) Offshore directional distribution of the yearly-integrated wave energy flux (calculated as $H_s^2 T_p f$) (Jiménez, 1996).

To select the *representative* long-term morphological wave angle the various wave energy fluxes associated with all effective wave directions (from N to S) were vectorially added, resulting in a "net" wave direction of 100° .

Once this *representative* wave angle was selected, the long-term transport coefficient, Ksl , was calculated using equation (4) fed by the estimated net longshore transport rates for the Ebro delta coast from measurements during the period 1988-1992 (Jiménez and Sánchez-Arcilla, 1993) and the coastal configuration for which these transport rates verify. The so obtained Ksl values along the Ebro delta coast will reflect all the terms affecting local net longshore sediment transport rates (such as the longshore variation in wave height and wave power along the coast, sediment grain size, etc). Fig. 4 shows the estimated long-term transport constants along the southern part of the Ebro delta coast and their variability as a function of the selected *representative* wave angle. As it can be seen, there are some stretches where the variability in Ksl values is high and, even, in some cases -such as the coastal stretch represented by profile 23- it presents a reversal in the transport direction for wave angles greater than the selected one (*i.e.* for waves arriving southwards of 100°).

This variability can also be reproduced by maintaining constant the *representative* wave angle but changing the local coastal orientation and, due to this, it can be used as a measurement of the sensitivity of the local longshore sediment transport to changes in effective wave angle (difference between *effective* wave angle and coastal orientation).

Figure 4. Long-term transport constant K_{sl} along the southern part of the Ebro delta coast as a function of the selected *representative* wave angle.

The coastline model

The effects induced by the net longshore sediment transport pattern along the Ebro delta coast have been modelled through a one-line coastal model.

This first sub-model of the generic conceptual one has been selected due to the good performance of this kind of models to reproduce such effects/changes (associated basically to a longshore sediment transport gradient). Moreover, this approach will permit to include other additional effects/processes to complete the ones already considered in the conceptual model by introducing them into the term representing local sediment sinks/sources and by expanding it to a kind of multi-line model.

Since the entire Ebro delta coastline can be considered as significantly curved (locally, with very strong curvatures as is the case of the apex of both spits), the use of an one-line model in Cartesian coordinates will not properly reproduce the coastline behaviour, specially for the most curved stretches. In order to solve this problem a curvilinear coordinate system (following to Le Blond (1972)) will be used. In this system the orientation of any point P of coordinates (x,y) can be written in terms of local coordinates (normal to and tangential to the shoreline), being θ the orientation between the local axes and the original ones (see Fig. 5).

Figure 5. Curvilinear coordinate system.

Using the complex notation $P = x + iy$, in which $i = \sqrt{-1}$ and, assuming that the movement of any point $P(x,y)$ (induced by a longshore sediment transport gradient along the coast, s) will be perpendicular to the shoreline, the continuity equation can be expressed as (see *e.g.* Suh and Hardaway, 1994)

$$\frac{\partial P}{\partial t} = -\frac{1}{d_c} \left(\frac{\partial Sl}{\partial s} + q \right) \exp(i(\theta + \pi/2)) \quad (5)$$

in which d_c is the closure depth and q a term to include local sediment sources and/or sinks.

Numerical model

The equation (5) is numerically solved by means of an explicit finite-differences scheme using a staggered grid in which shoreline positions are defined in the centre of cells and longshore transport rates are evaluated at cell edges (see *e.g.* Kraus, 1988).

In the selected approach (local coordinates) the cell length, s , is or can be variable along the coast and, to obtain the direction normal to a local point i , an average local orientation is defined considering the orientation upcoast and downcoast of the point of interest.

The finite-differences version of equation (5) for point i along the coast is thus

$$P_{i,j+1} = P_{i,j} - \frac{\Delta t}{d_c} \left(\frac{Sl_{i+1,j} - Sl_{i,j}}{0.5(s_{i+1,j} + s_{i,j})} + q_i \right) \exp \left[i \left(\frac{\theta_{i+1,j} + \theta_{i,j}}{2} + \frac{\pi}{2} \right) \right] \quad (6)$$

where

$$s_i = \left[(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2 \right]^{1/2}$$

The typical time step used in the simulations is of 1 year and the cell length is between 1 and 2 km. The selection of the time step will control the accuracy of the modelling, not only due to stability reasons, but also due to the fact that in any time step the transport rate is updated according to the final coastal orientation and it will be considered as steady during that time step. Thus, the longer the time step is, the smaller the capacity of transport updating will be.

The model requires boundary conditions at both limits of the domain, which in this specific case have been selected (based on the analysis of deltaic coastal behaviour) as *null* transport ($S_{net}=0$) in the southern boundary (apex of the spit) and *free beach* in the northern one.

Model verification

In order to verify the developed model, a hindcast of the Ebro delta coastal evolution has been performed. The selected time frame was from 1973 to 1989 in which detailed coastline configurations, obtained from aerial photographs, were available.

Figure 6. Comparison between modelled and measured coastline evolution between 1973 and 1989 (Jiménez, 1996).

The long-term coastal transport constant, Ksl , obtained from data measured during the period 1988-1992 were used together the Ebro delta coastal configuration corresponding to the year 1973. Fig. 6 shows the comparison between modelled and measured coastlines. As it can be seen, both coastlines are nearly coincident, with deviations measured in terms of the relative error ($|\Delta x_{\text{mes}} - \Delta x_{\text{mod}}| / |\Delta x_{\text{mes}}|$), giving an average relative error of about 15%. This magnitude can be considered as reasonable for the scale of modelled processes.

In any case, the comparison of measured and modelled deltaic coastlines cannot be considered as a model calibration in the sense that no parameter has been fitted. It should be stressed that, the values of the constant (Ksl) along the coast, have been obtained from the analysis of a period (1988-1992) not included in the verification interval (1973-1989).

This fact can be used as a clear indication that the net longshore transport pattern along the Ebro delta coast is the main driving term/process governing the outer coastal behaviour at this scale. The estimated net transport rates for a four year period, which according to the analysis of Jiménez and Sánchez-Arcilla (1993) are representative of the medium-term evolution (over a period of several years), will have a "residual" effect on the long-term/large scale coastal behaviour which is reflected in the observed coastal reshaping (although not contributing to the overall sediment budget). Thus, for the Ebro delta coast, if net longshore sediment transport rates at the medium-term scale are available, and the incident wave climate is steady, the large scale/long-term coastline behaviour can be reasonably predicted by considering the changes in coastal orientation.

Ebro delta coastline evolution under different scenarios

Fig. 7. shows the predicted coastline evolution for the southern part of the Ebro delta from 1989 to 2050 assuming that present conditions (river sediment supply and wave climate) are steady during all that period.

The predicted evolution, in which only longshore sediment transport is considered, shows a spit growth similar to the one observed under present conditions. Moreover, it also shows that the outer coast along the Trabucador Bar will shift landwards towards the present backbarrier coast. In this particular case, it must be taken into account that this implies that this barrier is "sandy rich", *i.e.* no breaching is considered and, in any case, it is assumed that behind the eroding barrier there is always enough sand available. Of course, this will only occur if the effects of overwash processes which permit the barrier rollover are included. Although in this sub-model overwash is not included, existing data on the Trabucador Bar evolution during the last decades, have shown a similar behaviour. Fig. 8 shows thus the barrier evolution from 1957 to 1989 where it can be seen that the barrier outer coast in 1989 occupies the position of the backbarrier corresponding to 1957.

Additionally, the model results can also be used to characterise the barrier as a high vulnerability area in the sense that, if overwash is prevented, the barrier will be prone to be breached due to the existing positive gradient in the net longshore sediment transport pattern.

Figure 7. Prediction of the Ebro delta coastline evolution for the year 2050 under present conditions and assuming two scenarios of wave height change (*W10D0*: 10% increase in wave height, *W-10D0*: 10% decrease in wave height).

The potential of this kind of models to predict some climate effects on coastal evolution can be assessed from Fig. 7. Two climate scenarios, in terms of changes in wave height, have been defined: (i) scenario *W10D0* where an increase of 10% in wave height is assumed and (ii) scenario *W-10D0* with a decrease of 10% in wave height.

To account for these variations in wave height, the local transport constant, Ksl , has been modified for these two scenarios as follows:

$$Ksl_{(W10D0)} = Ksl (1.1)^{2.5}$$

$$Ksl_{(W-10D0)} = Ksl (0.9)^{2.5}$$

As it can be seen from Fig 7, the coastline evolution under both scenarios is similar same from a qualitative standpoint although differing in the magnitude of the predicted shoreline displacements according to the assumed variation in wave height (larger displacements for an increase in the wave height because it implies larger gradients in longshore sediment transport and viceversa).

Figure 8. Evolution of the Trabucador Bar between 1957 and 1989 (modified from Sánchez-Arcilla and Jiménez, 1994b).

Summary and on-going works

A conceptual model to explain and simulate the long-term Ebro delta coast evolution has been presented as well as the approach to be followed to convert this conceptual model into a numerical one able to quantitatively predict the deltaic coast behaviour.

From all the considered modules, a first running sub-model which simulates most of the changes suffered by the outer coast of the Ebro delta, has been described in details. Although this sub-model only considers coastal changes induced by the existence of longshore sediment transport gradients, it has been proven to reproduce most of the observed changes along the Ebro delta coast. This is due to the fact that longshore sediment transport is the main process governing the evolution of the Ebro delta coast at the long-term scale. However, other processes are also important, specially for determined coastal stretches in order to fully explain the coastal behaviour and not only the coastline evolution (*e.g.* overwash processes to explain barrier rollover).

In this way, other different sub-models are being developed and included into a general model able to reproduce and simulate the large scale/long-term evolution of the Ebro delta coast. A first specific module to simulate the effects of overwash, which combined with the effects on the outer coast is able to reproduce different barrier behaviours is nearly operational. The inclusion of this process will permit to eliminate the assumption of a sandy-rich barrier (which in fact implies a quasi-infinity barrier width) as it has been used in the example shown here (Fig. 7). It will be then possible to simulate the

evolution of both barrier coastlines (outer and inner) and this will permit identifying the barrier vulnerability conditions (leading to a barrier prone to breaching).

At present, all other processes considered in the conceptual model have been included in a parametric way (*i.e.* including them in the model as sediment sinks and sources), although a process-oriented approach is being followed to describe these terms in a dynamical manner.

CHAPTER 218

SEA DIKE EROSION AND COASTAL RETREAT AT NAM HA PROVINCE, VIETNAM

Ton That Vinh¹, G. Kant², Dr. Nguyen Ngoc Huan³, Dr. Z. Pruszk⁴

ABSTRACT

Nam Ha Province is situated on the coast of the Red River Delta, immediately east of the mouth of the Red River. The coast of the delta is very dynamic in which large quantities of sediment are supplied by wet season run-off. However, in Nam Ha province the coast is retreating such that successive lines of dikes have been abandoned and a unique 'managed retreat' strategy is underway with double lines of dikes along large parts of the province's coast. This paper reviews and describes the possible causes of the erosion problem and highlights the unique way in which the local coastal engineers are adopting, out of necessity, the classical retreat strategy. Other impacts of the problem such as environmental and socio-economic impacts are also reviewed. Based on the qualitative first order analyses a strategy has been defined towards a sustainable development of this coastal area.

SITE DESCRIPTION

The Delta of the Red River is located in the northern part of Vietnam (Figure 1). The Thao River rises in the Dai Ly Lake in China. In Vietnam, near the town of

Viet Tri, the Thao River becomes Red River and receives flow from two other major contributors: the Da River and the Lo River. The Red River Delta has the classical triangular form downstream of Viet Tri. East of the Red River the Thai Binh River flows onto the Red River Delta. The Red River catchment area is about 155000 km² and reaches into China and Laos, resulting in an average annual discharge of $137 * 10^9$ m³/year, and a total estimated sediment load of about $72 * 10^6$ t/year to the Gulf of Tongking (World Bank, 1994). The sediment is discharged through a large number of branches over a coastline with a length of some 165 km (as the crow flies). The enormous amount of sediment in general leads to accretion in the coastal areas for which the growth of the Red River Delta itself is the most outstanding proof and example.

However, despite this fact there are local stretches of coast on which serious erosion problems are reported. Two provinces where such erosion problems exist are the provinces Thai Binh and Nam Ha. Surprisingly both provinces are directly located at Cua Balat, the mouth of the main branch of the Delta: the Red River itself (Figure 2).

Nam Ha province is bound by the Red River in the north-east and by the Day River in the south west. The coast length is about 60 km and generally faces E to SE. The province has three coastal districts which are separated by branches of the Red River (Figures 2 and 3). One of the branches, Ngo Dong River was dammed in 1955. The middle district, Hai Hau district, experiences a serious consistent widespread erosion. About 75% of the total of 25 km coastline of Hai Hau district is retreating.

The coastline of Hai Hau district is being protected by dikes. In front of the dikes is a very gentle sloping beach. The slope of the beach varies along the coastline from 1:40 on eroding beaches to 1:200 in other places. The beaches consist of very fine sand with an average grainsize of about 80 μm. Measurements show an increase of the grainsize on the eroding sections of the coast.

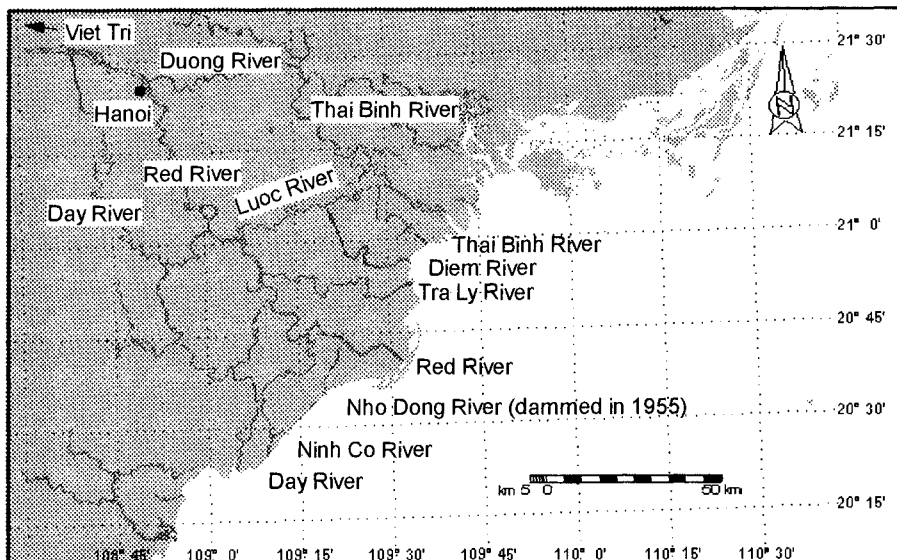

Figure 3 Red River Delta River Branches

HISTORIC SHORELINE DEVELOPMENT

The coastline development this century (from 1905 to 1992) in Nam Ha province is presented in Figure 4. It can be seen that the development of the coast is irregular. Near the mouths of the Red River (right hand side of the figure), the Ninh Co and the Day River (both on the left hand side of the figure) progressive sedimentation has led to accretion. This results in shoreline developments in these areas of 2.5 km to 6.5 km in seaward direction over the 87 year period. However, in Hai Hau district the development is just the opposite. Over the last 87 years a strip some 16 km long and about 2.5 km wide was lost to the sea. This is a time averaged shoreline retreat of about 29 m/year. It appears from this figure, which is based on maps, that the erosion at Hai Hau district started in the beginning of the century and seems to be slowing down after 1966. This indicates that the damming of the adjacent Ngo Dong River in 1955 is not the main reason of the consistent erosion problems.

LOCAL RESPONSE STRATEGY

The present coastal defence at Hai Hau district consists of a double dike system (Figure 5). These parallel dykes, with a separative distance of about 250 m, are constructed along 75 % of the Hai Hau coastline. The area between the dykes has been split into sections alongshore in the range of 500 to 3000 m long. The beach in front of the first dike reaches to about MSL. The slope of the dike is about 1:2 (v:h) and is protected by pitched limestone rock of about 30 cm diameter placed on a clay layer. The crest height is approximately 4 m above MSL. The dike body itself consists of clay and sand. On heavily attacked sections the toe of the dike is reinforced with cement grouting.

Since the erosion is progressing continuously the first defence line is becoming weaker every year. During extreme events the first dike is therefore at some points not strong enough to withstand the attack. In

Figure 4 Shoreline Development

Figure 5 *Double Dike System*

order to prevent inundation the second defence line has been built. When the first dike fails the section behind the first dike is inundated and the second dike becomes the new first dike. Every time the first dike fails a section of land is lost to the sea since there are no resources to repair the old dike. In response to such a breakthrough a new second dike is built behind the new first defence line. On average every ten years a dike section is lost to the sea. This is a typical example of a managed retreat strategy although the Vietnamese authorities are forced by the circumstances. Beside the weakening of the dikes by the continuous erosion, the strength of the first defence line itself is in general insufficient due to problems such as funding and practical construction problems (such as accessibility of roads and availability of vehicles). This results in generally weak dykes, which are also too low, causing severe overtopping problems and revetment instabilities.

As the retreat of the coastline is known for many years evacuation plans are readily available. These plans are started on average every 2-3 years in case of high flooding risks. For maintenance and construction of the sea defences the authorities mobilise local inhabitants. As in the whole country the population has to invest a number of days per year in the community. The national average is about 10 workdays per year. In villages endangered by the erosion able bodied workers are required to work 40 days per year on dike repair, maintenance and construction.

ENVIRONMENTAL BOUNDARY CONDITIONS

The meteorological conditions of the area can clearly be divided into a summer (July and August) and winter (October to March) monsoon period. During the summer monsoon period moderate winds (average force: 3 Beaufort) from south western directions prevail. In winter the predominant wind direction is north east (average

wind force about 4 Beaufort). The summer monsoon period is also known as the 'wet season'. During this season 80% of the yearly run-off is discharged through the Red River system. Peak discharges are to be expected towards the end of the wet season or at extreme storm or typhoon events. On average two typhoons per year hit the coastline of the northern provinces of Vietnam. The typhoon season starts in May and lasts till October with the highest activity in the months July and August.

Similarly, the wave climate is also strongly influenced by the monsoon periods which is typical for this region of the world. The average deep water wave height in the summer months is about 1.5 m (coming from SW directions) whereas the average deep water wave height in winter is about 2 m (NE directions). However, during storms and typhoons the deep water significant wave height can develop to 10 m.

The characteristic range of the diurnal tide at spring tide is about 2.4 m. Currents along the coast are mainly tidally driven with a significant (seasonal) influence of wind and waves. During the last 30 years water levels (astronomic tide plus wind set-up) up to 3.00 m above MSL have been reported in bays and inlets along the shallow coast.

QUALITATIVE MORPHOLOGICAL ANALYSIS

The morphological system of the Red River Delta is very dynamic. During the wet summer monsoon season 80% of the annual sediment load is discharged to the Gulf of Tongking resulting in huge deposits near the River mouths. As the prevailing wave and wind direction is south west most of the sediment will be deposited on the eastern side of the river mouths (Figure 6). Wave conditions in the summer season can

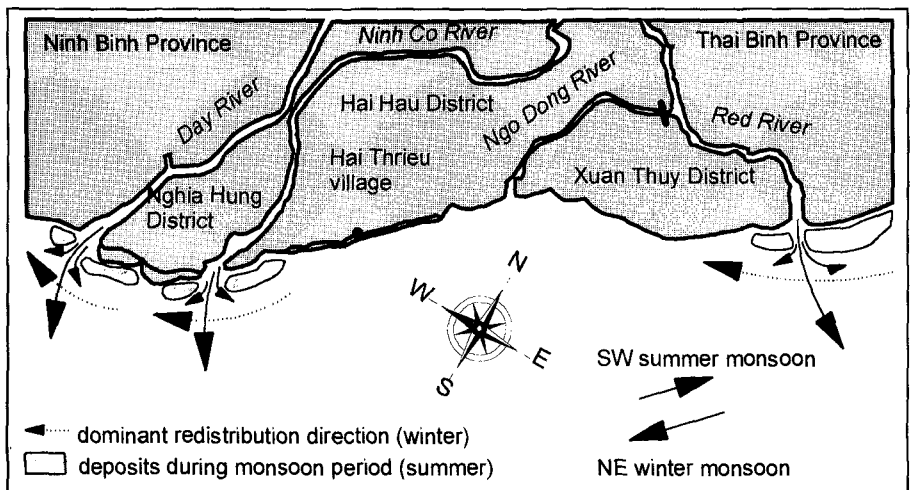

Figure 6 *Sediment Deposits and Redistribution Along the Shore*

be characterized as 'moderate' resulting in some redistribution of sediment in north-eastern direction. However, during the remainder of the year wind and wave conditions from north-eastern directions prevail. Compared to the summer monsoon the north-east monsoon is somewhat stronger and more persistent resulting in higher longshore sediment transports. During the winter season a substantial part of the fresh deposits will therefore be transported further offshore or be redistributed along the shore in south-western direction. The beach sections between the river mouths (beyond the direct influence of the river mouths) are therefore dependent on the redistribution mechanisms of deposited sediment from the nearest river branches.

Up to 1955 the Hai Hau district beaches were nourished by the Ngo Dong River in the north and the Ninh Co River in the south. The net sediment transport is directed to the south-west so the main source of sediment was the Ngo Dong River. With the damming of the Ngo Dong River the main sediment source was blocked resulting in erosion south of the River mouth. From then on the beaches of Hai Hau district had to be nourished from either the Red River or the Ninh Co River mouth (Figure 6). However, due to the shape of the Red River mouth hardly any nourishment took place from the north-east. Nourishment from the Ninh Co River could only develop during the summer months. From the coastline development graph (Figure 4) it can be seen that indeed some nourishment took place resulting in a stable or accreting development of the southern beaches of the Hai Hau district.

However, the erosion of the Hai Hau coastline did not start after the damming of the Ngo Dong River. The erosion started at the beginning of the century or even earlier. The reported erosion rates of 29 m/year over a length of 16 km indicate the Ngo Dong River must have been a major branch of the Red River. A possible explanation would be that at the end of the 19th century the Ngo Dong River lost its importance as a major branch of the Red River. This process, which can either be a natural development or a result of man made channelling works, redirected the discharge to, most probably, the present Red River mouth. The discharge through the Ngo Dong River diminished which allowed the damming in 1955. Damming would have never been possible when the Ngo Dong River was still a major branch of the Red River. This hypothesis of the historic development and importance of the Ngo Dong River is still under investigation.

QUALITATIVE PREDICTION OF THE SHORELINE DEVELOPMENT

Based on the above described hypothesis of the morphological system a prediction of the shoreline development can be made. When no action is taken the coastline will retreat at same pace for the coming years. On a longer timescale it is expected that the accreting coast of the Nghia Hung District will, due to the changing coastline orientation, develop an increasing nourishing effect on the Hai Hau coastline.

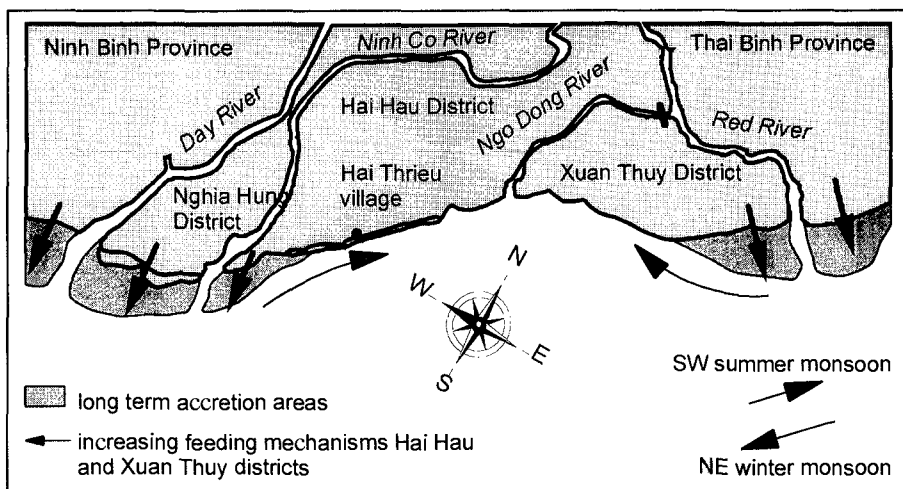

Figure 7 *Qualitative Prediction of Long Term Coastline Development*

The accretion near the mouths of the Ninh Co and Day River will slow down and the retreat at Hai Hau will decrease (Figure 7). This effect will develop along the coast starting in the south of the district.

SOCIO-ECONOMIC IMPACTS

Within Vietnam the Red River Delta (16,000 km²) is the most densely populated region with 1,700 inhabitants per square kilometre. This is also among the highest population densities on arable land in the world (VVA, 1996). The erosion at Hai Hau district causes significant socio-economic impacts. The land in the coastal strip is completely in use for agriculture, aquaculture and salt production. Further, because of the progressing retreat, a number of villages are at risk being located directly behind the sea defence. Hai Thrieu for instance is a commune of which part of the 8000 inhabitants live between the first and second sea defence. At present the second dike is being reinforced as the authority reluctantly have to abandon the first dike in case of a breakthrough. Moving this part of the village requires resources and will include a social problem since practically all the land is presently in use. A more general problem of the coastal region is salt intrusion via overtopping of dikes. In this way storms and typhoons can impact a strip of 750 m wide along the coast with salt (eg. typhoon Wayne, 1986). It takes years after such an event before the original crop yield can be reproduced.

STRATEGY TOWARDS SUSTAINABLE DEVELOPMENT

Based on this qualitative analysis of the erosion at Hai Hau district a number of measures and preliminary strategies can be defined. However, an integrated approach is recommended which includes not only technical aspects but also socio-economics, planning and institutional matters in order to achieve a sustainable development. This Coastal Zone Management approach needs to include more investigations and studies on the mentioned fields in collaboration with the responsible Vietnamese authorities and the local people. The key study would be, in succession on this first qualitative analysis, the extensive investigation of the morphological development. A sound understanding of the processes and developments will result in a quantitative prediction of the shoreline development. This will form the basis for all further strategy decision making.

ACKNOWLEDGEMENTS

CHAPTER 219

BEACH PROFILE ANALYSIS AROUND INDIAN RIVER INLET, DELAWARE, U.S.A.

Kirk F. Bosma¹ and Robert A. Dalrymple²

ABSTRACT: The purpose of this study is to examine the recent shoreline history at Indian River Inlet, Delaware using beach profile data. Indian River Inlet was stabilized in the late 1930's with two parallel rubble mound jetties. The stabilization resulted in considerable modifications to the surrounding beach environment, leading to the construction of a sand bypassing system in 1990. The profiles adjacent to the inlet are first examined with the standard tools, such as shoreline change, volume change, and sand budget. Then, details are given on the use of Principal Component Analysis (PCA) in the coastal field, an explanation of its function, and the differences between the complex and non-complex versions. Results are presented for areas north and south of the inlet in both 2-mode and 3-mode versions of Complex Principal Component Analysis (CPCA). The results illustrate the ability of CPCA to detect moving features within the profile data, including its direction and speed, as bypassed sand is seen moving to the north.

INTRODUCTION

The Delaware Atlantic coastline, a sandy shore that spans approximately 24 miles, is an area of constant transformation. Significant littoral drift rates, man-made structures, remediation efforts, and occasional battering by large storms all effect the coastline. Thus, the beach profiles are 'dynamic' in character, changing continuously. These profile variations occur in both the subaqueous and subaerial elements of each profile, as wave energies constantly move sand on, off, or alongshore. In effect, changes in profiles can reveal a vast amount of information, both long and short term, about the coastline.

The focus of this study is the profiles adjoining Indian River Inlet (as shown in Figure 1), which is one of the most unique features along the Atlantic Coast of Delaware. After several failed attempts to keep the Indian River Inlet open by dredging alone, a 152 meter (500 foot) wide inlet was constructed in the late 1930's. The goal being to establish a stable passage way from the inner bays (Rehoboth and Indian River) to the Atlantic Ocean, increase bay salinity, reduce stagnation, and increase the tide range (Thompson and Dalrymple, 1976). The

¹Graduate Student, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA.

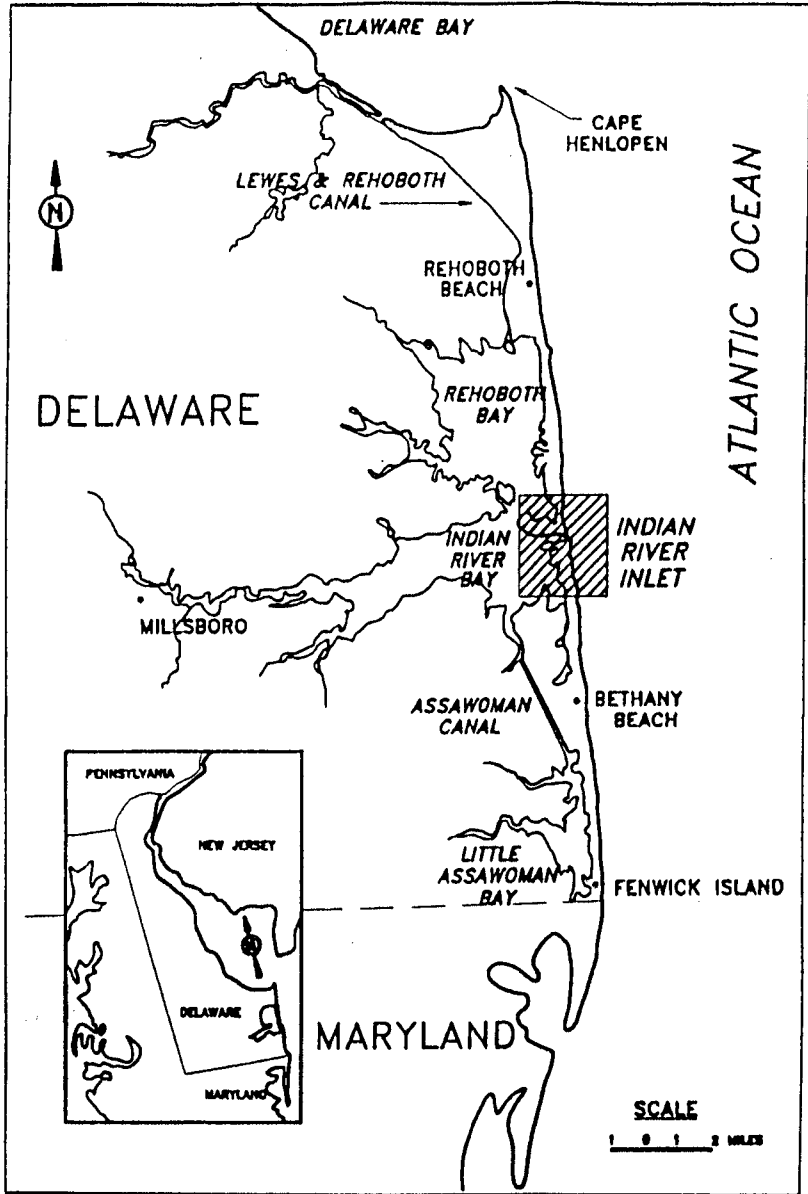

Figure 1: The Atlantic Coast of Delaware

inlet is stabilized by two parallel rubble mound jetties, originally extending a distance of 472 meters (1550 feet). 185 meters (600 feet) of this length extended seaward of the ocean shoreline at the time of construction. There have been significant problems with the engineered inlet over the years, including erosion of channel banks west of the jetties, accelerated scour along the jetties, and massive downdrift erosion, due to the predominant northward drift (Gebert *et al.*, 1992). The main concern related to the downdrift erosion is the threat it poses to the Route 1 highway traveling parallel to the shoreline. In fact, by 1954, a dune scarp had been created that was, in places, less than 60 meters (200 feet) from the roadway. From 1957 to 1990, mitigation of the beach erosion was accomplished by dredging of the flood tidal shoal and back barrier deposits. Approximately $380,000 \text{ m}^3$ ($49,700 \text{ yd}^3$) of sand was placed on the north beach approximately every five years. Since February of 1990, however, a fixed sand bypassing system was constructed to pump sand from the southern shore and "slurry" it across the inlet to the northern shore. The system mines the south accretional fill by using an eduction unit deployed by a crane. Through May of 1995, approximately $350,000 \text{ m}^3$ ($456,000 \text{ yd}^3$) have been pumped across the inlet at a cost of \$2.11 per m^3 (\$1.62 per yd^3). The system is performing well and is relatively inexpensive to run.

The objective of the present study is to investigate many aspects of the beach profile at Indian River Inlet through the use of the newest analytic methods and the most recent field data available. We want to determine what the profiles north and south of the inlet reveal about the region and to answer questions such as:

- What happens to the bypassed sand?
- Is enough sand being pumped?
- Can we identify moving forms or sandwaves?

To do this, we consider the early performance of the bypassing plant through shoreline changes, evaluation of littoral drift, and other standard analytical tools. We also explore the use of complex principal component analysis (CPCA), in both 2-mode and 3-mode versions, to evaluate propagating features that exist within a bathymetry.

FIELD DATA COLLECTION

Profile data sets are considered on both the north and south side of Indian River Inlet collected by the U.S. Army Corps of Engineers, Philadelphia District. The profiles span from 1984 to 1994, with an average of two surveys per year. 28 profile lines are taken in the range from 1524 meters (5000 ft) south of the inlet to 1524 meters (5000 ft) north of the inlet, as shown in Figure 2. 17 of the lines are located in the northern portion of the study area, while 11 are located in the south. As shown in Figure 2, some profile lines extend far offshore, while others only advance to the water line. The station numbers provided are the distance in hundreds of feet (30.5 m), from the respective jetty centerline. Survey points were taken randomly during each survey, thus requiring linear interpolation in both the alongshore and cross-shore directions for much of the analysis. Examples of the bathymetries north and south of the inlet are shown in Figure 3. Notice the scour hole that is evident at the tip of the northern jetty.

Figure 2: Profile lines north and south of Indian River Inlet

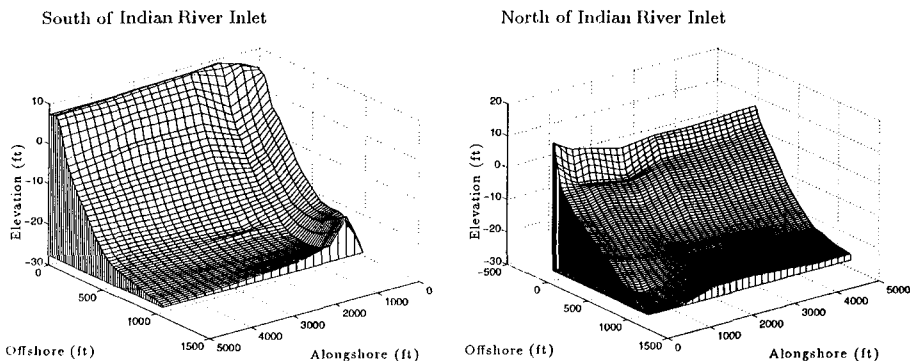

Figure 3: Sample bathymetries (October 1994) for north and south of Indian River Inlet. Offshore grid intervals are 152.4 meters (500 feet); alongshore, 304.8 meters (1000 feet); and elevation, 3.05 meters (10 feet).

SHORELINE CHANGE

The simplest way to examine what is occurring on a given region along the coast is to evaluate the change in shoreline position. This 1-line analysis quantifies beach behavior and allows for comparison of pre- and post-bypassing. Cumulative shoreline change plots for four profile stations in the range extending up to 305 meters (1000 feet) away from the inlet in both the north and south directions are shown in Figure 4. The figure illustrates the shoreline behavior at various stations through time. Watson *et al.* (1993) have computed similar results for a shorter interval of time. For this study, the pre-bypassing interval is from November of 1984 to October of 1989. The initial survey of November 1984 takes place after a large beach fill of 35,781 m³ was placed between stations 0+00 to 30+00. Surveys measured after October of 1989 are considered post-bypassing. Since we only have a total of four years of data after bypassing start-up, only the short-term performance of the system can be determined.

North of the inlet the trend had been towards progressive retreat, as expected due to the influence of the inlet and the northward littoral drift. Only once,

during the winter season from September 1987 to March 1988, did a substantial shoreline advance occur. This was most likely due to the net reversal of littoral drift in the winter months (response to “northeasters”) and thus the trapping of some sediment in the shadow of the jetty. The general shoreline retreat was evident until approximately 1035 meters (3400 feet) from the jetty. At this distance, the effect of the inlet was lessened and larger seasonal variations tended to dominate. The bypassing operation was started with the aid of a 133,800 m³ (175,000 yd³) fill (evident in the March 1990 survey) obtained from the flood shoal. The initial increase in beach width was not retained due to the spreading of the beach fill, but the shoreline for the stations just north of the inlet seems to have stabilized since bypassing initiation.

Figure 4: Cumulative shoreline plots showing relative distance from original shoreline position with time for the first four profile stations both north and south of Indian River Inlet.

South of the inlet, pre-bypassing, the trend had been overall stability with some slight accretion. The accretion, if any, was at a much lower rate than the erosion to the north. Again, at around 1035 meters (3400 feet), the effect of the inlet seemed to be minimized as the overall change in beach width was small. After bypassing start-up, Stations 1+00 and 2+00 exhibited immediate effects of the sand mining. Proceeding southward, the next two stations (6+00 and 10+00) show a slight lag in the response to the mining and a smaller shoreline retreat. Notice as well that all stations recover quickly from the effect of the mining. Sand bypassing influence is also typically seen to about 1035 meters (3400 feet) south of the inlet.

VOLUME CHANGE AND SAND BUDGET

Next, volume changes for the areas between profile stations were computed. From these volume changes, a standard sand budget analysis was calculated for the northern region by assuming that the only sediment entering the area was due to bypassing or beach fills. The results from this analysis, shown in Figure 5, yield a measure of the local transport rate. The littoral drift is found to be dominantly northward, as expected, at a rate of approximately 79,500 m³ (104,000 yd³) per year. This value was found to be consistent with values found in the past by other methods (Lanan and Dalrymple, 1977; U.S. Army Corps of Engineers, 1984).

Figure 5: Local volumetric transport rate for north of Indian River Inlet.

THE HISTORY OF PRINCIPAL COMPONENT ANALYSIS

Many geophysical phenomena derive from interactions between traveling waves of different spatial scales and temporal frequencies. Principal component analysis (PCA) was developed to explore these spatial and temporal relations with the primary advantage of its ability to express the complicated variability of data into the fewest possible number of modes. Thus, applying this idea to beach profiles, beach changes can be described by linear combinations of space and time through the breakdown of data into spatial and temporal dependence (e.g. Winant *et al.*, 1975; Aubrey, 1979). Winant *et al.* (1975) found that most of the variation in a profile configuration is accounted for by the first three eigenfunctions, which corresponded to the "mean beach," "bar-berm," and "terrace" functions. However, PCA detects standing oscillations only, such as the standing phenomena of the shift from summer to winter profiles in seasonally sampled data (Winant *et al.*, 1975), not traveling waves. Therefore, PCA can not identify a coherent form moving through the data, such as a rapidly traveling bar as a sand wave alongshore.

Complex principal component analysis (CPCA) was developed for meteorological applications (e.g. Wallace and Dickinson, 1972; Barnett, 1983) and has been used to detect a fast moving sand bar by Liang and Seymour (1991). CPCA has also been shown to out-perform PCA by capturing more of the variance in fewer terms by Liang, White, and Seymour (1992). CPCA has considerable potential for being widely used to detect propagating features, yet its limitations as an analysis technique have not been well explored.

Both of the methods discussed above account for only one spatial direction when evaluating the temporal changes in the data set. This assumes the movement is directed in two independent directions and therefore, the analysis is limited to looking at only individual cross-shore or alongshore "lines." However, what if there is two dimensional movement of sand, as expected in response to a coastal structure or a beach nourishment? Then the 2-dimensional analysis may be rendered inadequate. So, in a further expansion of PCA, the analysis was carried into a third dimension allowing the break down of data into three separate components. This so-called 3-mode PCA was started for mathematical psychology applications, such as the evaluation of multiple personality patients

(Tucker, 1966; Kroonenberg and DeLeeuw, 1980). For the case of a coastal region, 3-mode PCA allows a bathymetric survey to be divided into two spatial directions (cross-shore and alongshore) and a temporal dependence. The technique was applied to a beach fill site in Spain by Medina *et al.* (1992).

In the next section, we apply the 2-mode CPCA tool to the beach profile data of Indian River Inlet and develop a 3-mode CPCA model to examine movement occurring in multiple directions within a bathymetry. The 2-mode CPCA is shown to not only detect the moving forms as well as standing forms, but also distinguish between them.

2-D COMPLEX PRINCIPAL COMPONENT ANALYSIS

To apply CPCA, the data field must first be augmented in a manner such that propagating features within it may be detected. This is done by deriving a complex data matrix, where the real part is simply the original data field and the imaginary part is the Hilbert transform, which represents a filtering operation upon the data in which the amplitude of each spectral component is unchanged, but each components phase is advanced by $\pi/2$. If $g(t)$ is a real-valued function of time, we can define an analytic function

$$z(t) = g(t) + ih(t)$$

where $h(t)$ is the Hilbert transform of $g(t)$ given as:

$$h(t) = \mathcal{H}(g(t)) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{g(t')}{t' - t} dt' \quad (1)$$

Using the complex data, we can compute complex eigenvectors (functional decompositions of the data) and eigenvalues (portions of the variation represented by each eigenvector). The goal is to expand the data, $z(x, t)$, into two dimensions (in this case offshore and time) as:

$$z(x, t) = \sum_{i=1}^n a_i g_i(t) e_i(x) \quad (2)$$

n =number of desired modes

a_i =normalizing factors (eigenvalues)

g_i =temporal eigenfunctions

e_i =spatial eigenfunctions

This is done through computation of the correlations between the spatial locations to develop a complex correlation matrix, as shown in Equation 3, where n_t is the total number of surveys and the large brackets denote a time average. The eigenvalues and eigenvectors are then determined from the complex correlation matrix.

$$A_{ij} = \langle z_j(t)^* \cdot z_i(t) \rangle_{n_t} \quad (3)$$

The 2-mode CPCA is used to look at an alongshore profile lines north of Indian River Inlet in the hope of identifying migrating features. Because of the random sampling of the data, many profile lines had to be discarded for various reasons (e.g. did not extend far enough offshore, a given survey was missing,

etc.). The results shown below are for an alongshore profile line located approximately 76 meters (250 feet) from the baseline. The complex correlation between the complex time series at given alongshore grid points are shown in Figure 6a. Each complex correlation is plotted in vectorial format where the real portion (magnitude) is indicated in the vertical direction of the vector and the imaginary portion (phase) is indicated in the horizontal direction. A vector pointing upwards (downwards) indicates that the two time series are in-phase (out-of-phase). For example, a vector pointing to the right indicates a lag of 90 degrees. The complex correlation between the time series delineates the propagation of a moving "bump" through the domain. Figure 6b shows the resulting spatial eigenvectors for the alongshore line, plotted in vectorial format as in Figure 6a. The numbers correspond to the percent of variance retained by each eigenvector. The top panel is the first eigenvector which represents the mean alongshore profile and accounts for 98% of the variance. The eigenvector is almost entirely real valued, which signifies that no extensive movement is associated with it, and exhibits a depression in magnitude near the inlet entrance. The second eigenvector identifies a definite progressive feature, which represents 1% of the total variance. Imagine the movement as a spinning motion indicated by vectors "rotating" through space. The second eigenvector then represents a moving form that augments the mean alongshore profile. Similarly, the third eigenvector, which indicates no coherent movement, modifies the mean further.

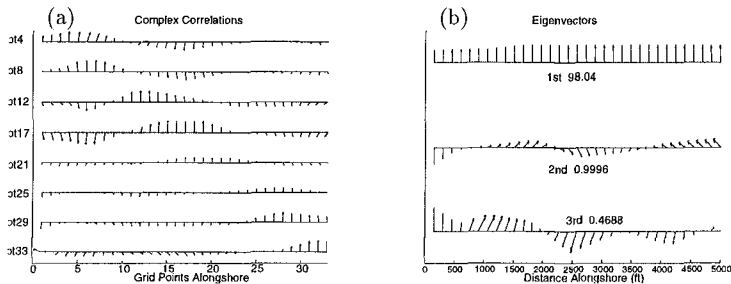

Figure 6: (a) Complex correlation between time series for alongshore grid points. Notice that the vector is normalized to one when a time series is correlated to itself; i.e. the time series of point 4 is perfectly related to itself. (b) Eigenvectors computed by CPCA for an alongshore profile line North of Indian River Inlet. Spacing intervals in the distance alongshore are 152.4 meters (500 feet).

Once the eigenvectors and eigenvalues have been determined, we are able to define both a spatial ($\theta_i(x)$) and temporal ($\phi_i(t)$) phase function as:

$$\theta_i(x) = \arctan \left[\frac{\text{Im}(e_i(x))}{\text{Re}(e_i(x))} \right] \quad \phi_i(t) = \arctan \left[\frac{\text{Im}(g_i(t))}{\text{Re}(g_i(t))} \right] \quad (4)$$

The spatial derivative of the spatial phase function then provides a measure of the "local" wavenumber. Similarly, the time derivative of the temporal phase function is directly proportional to the "instantaneous" frequency. Therefore, CPCA not only allows us to identify a moving form, but also determine the direction and the rate at which it is moving. The spatial and temporal phase functions for the same alongshore profile line, as presented in Figure 6, are shown in Figure 7. The numbers correspond to the approximate wavenumber

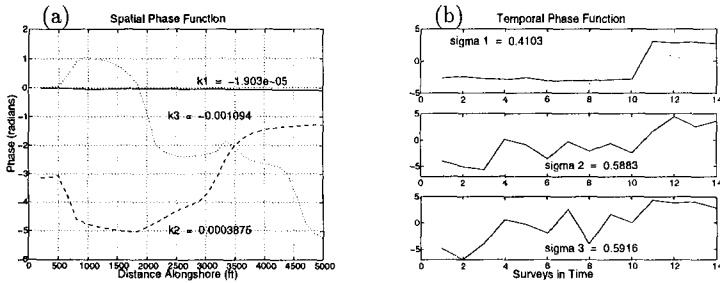

Figure 7: (a) Spatial phase function for alongshore location north of Indian River Inlet. Spacing intervals in alongshore distance are 152.4 meters (500 feet). (b) Temporal phase function for the same location.

and frequency of each eigenvector component. By using these values, the second eigenvector indicates a feature that is moving northward at the rate of around 1.68 meters (5.5 feet) per day. Therefore, over this time period, CPCA reveals that sand was relatively quickly moved out of the area to the north.

3-D COMPLEX PRINCIPAL COMPONENT ANALYSIS

The 2-mode CPCA appears to be very useful for many cases. However, what if 2-dimensional movement of sediment is expected, as mentioned earlier. The 3-mode CPCA is applied to the nearshore region, where significant movement is occurring, for both north and south sides of the inlet. In 3-mode CPCA, we begin with a set of data matrices or rather, a large 3 by 3 cube of data, which can also be thought of as a collection of 2-mode matrices (Figure 8).

Figure 8: Schematic breakdown of a 3-mode data set into 2-mode submatrices.

Again, after Hilbert transforming the data in time to generate a complex

data set, we seek to expand the data in two spatial dimensions and time by:

$$z(x, y, t) = \sum_{m=1}^s \sum_{p=1}^u \sum_{q=1}^v e_m(x) f_p(y) g_q(t) C_{mpq} \tag{5}$$

where

s, u, v are the number of components in the 3 modes, respectively
 e, f, g are the offshore, alongshore, and temporal eigenfunctions, and
 C_{mpq} is the core matrix (normalizing factors)

Rewriting Equation 5 in matrix form we arrive at

$$Z(x \times yt) = E(x \times s)C(s \times uv)[F(y \times u)' \otimes G(t \times v)'] \tag{6}$$

where \otimes denotes the Kronecker product and the dimension of the matrices Z and C are augmented to be two dimensional arrays. The core matrix, C , is no longer a simple diagonal matrix of eigenvalues as in 2-mode analysis, but a complex combination of elements that describe the basic relations that exist between the various collections of variables as expressed through their components (Kroonenberg and DeLeeuw, 1980).

The cross-shore and alongshore eigenvectors for the nearshore region north of the inlet are presented in Figure 9. For simplicity, only the real part of each eigenvector is shown. To illustrate the relative importance between both the variables and components, the eigenvectors shown have been weighted. These eigenvectors can be thought of as the average form of all cross-shore or alongshore profile lines in the region. In the cross-shore direction, we see the mean is easily identifiable. The second component, typically referred to as the “bar-berm” function is significantly reduced in importance due to the larger fluctuations occurring in the alongshore direction. In the alongshore eigenvectors, the mean is characterized by a dramatic depression that occurs near the inlet. The second and third components highlight sizable changes in the alongshore direction.

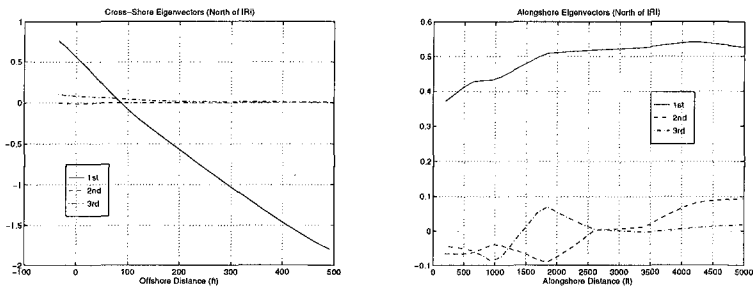

Figure 9: The real portion of cross-shore and alongshore eigenvectors computed from 3-mode CPCA. Offshore distance is spaced at 30.5 meters (100 feet), while the alongshore distance is spaced at 304.8 meters (1000 feet).

The eigenvector components can also be combined to represent various features of the bathymetry. These *eigenvector combinations* are products of the

different alongshore, cross-shore, and temporal components. Similar to a large puzzle, if we have three components in each variable, then there are 27 combinations that make up a complete bathymetry. The three combinations that capture the highest amount of variance are shown in Figure 10. The real part of each combination is shown on the left and the imaginary part of the combination on the right. The top panel shows the combination A1O1, which is defined as the product of the first eigenvector in the alongshore direction (A) and the first eigenvector in the cross-shore direction (O). This combination represents the mean bathymetry and the real part is characterized by the erosion located at nearshore region of the inlet entrance. The middle panel shows the A1O3 combination, corresponding to the product of the first alongshore eigenvector and the third cross-shore eigenvector. This combination modifies the mean bathymetry most notably in the shoreline area where bypassing has a significant effect. The lower panel, which contains the A3O3 combination (same nomenclature as before), is perhaps the most intriguing. A large "bump" appears on the real portion of the bathymetry, while the imaginary portion depicts a wave-like phase rotation. This imaginary "hot spot" of movement indicates that the feature is in motion. Notice that the magnitude of the imaginary bathymetry decreases as we proceed offshore. Therefore, the alongshore movement is strongest at the nearshore area and becomes less severe further offshore.

The eigenvector combinations for the region south of Indian River Inlet are shown in Figure 11. The nomenclature remains the same as for the combinations north of the inlet. Again, the top panel represents the mean bathymetry and shows a build up of sediment in the area adjacent to the southern jetty. The A2O3 and A2O1 combinations illustrate changes that are occurring once again in the neighborhood of the inlet entrance. The difference between the two is that the imaginary portion of A2O3 identifies more of a movement in the alongshore direction, while the imaginary portion of A2O1 identifies more of a movement in the cross-shore direction. This may mean that, after bypassing occurs, the large eduction hole that remains recovers by receiving sediment from both the alongshore and offshore elements of the bathymetry.

CONCLUSIONS AND SUMMARY

An in-depth analysis of the profiles at Indian River Inlet, Delaware has been accomplished by using standard analysis tools and Complex Principal Component Analysis. Early returns of the sand bypassing system seem to be positive. The shoreline analysis reveals that the north shore has been stabilized by the bypassing and the south shore recovers quickly from the eduction process. The littoral drift indicates sand is moving to the north and that a larger amount of sand could be pumped each season. Generally, sand moves quickly to the north as evident from both the shoreline variation and CPCA analysis. As shown, CPCA has considerable potential, but needs further investigation on a more finely sampled data set.

CHAPTER 220

IMPROVED 3-D BEACH EVOLUTION MODEL COUPLED WITH THE SHORELINE MODEL (3D-SHORE)

Takuzo Shimizu ¹, Takahiro Kumagai ¹ and Akira Watanabe ²

ABSTRACT

An improved 3-D beach evolution model coupled with the shoreline model, named "3D-SHORE", was newly developed to estimate both the spatial bottom topography change and the shoreline change. In calculation of the shoreline change, the total longshore sediment transport rate is estimated by integrating the local sediment transport rate in the direction parallel to the shoreline from the breaking point to the run-up point. The applicabilities of the model were verified through comparisons with both the results of the movable bed laboratory experiment and the actual beach evolution.

INTRODUCTION

In recent years, the 3-D beach evolution model which treats only the sediment transport due to nearshore currents have been applied to many practical problems in Japan. This model, based on the depth-averaged nearshore current model, is called "Medium-term 2DH Coastal Area Model" according to de Vriend et al.(1993). The authors have presented a few attempts to quantitatively verify its field applicabilities through comparisons with the actual medium-term topographical changes around a harbor entrance during 1 to 5 years(e.g. Shimizu et al., 1990, 1994). This conventional 3-D beach evolution model have reached the stage of being applicable for engineering use to estimating the volume of maintenance dredging around a harbor entrance and to investigating an effective countermeasure against harbor shoaling. It is, however, difficult to estimate the shoreline change, especially shoreline retreat, because the shoreline is used to be

¹Penta-Ocean Construction Co., Ltd., 2-2-8 Koraku, Bunkyo-ku, Tokyo 112, Japan.

treated as a fixed boundary in the model. Therefore, we cannot assess the impacts due to construction of a harbor on neighbouring beaches with good accuracy. In order to make the 3-D beach evolution model more practically useful, the model should be improved to treat the shoreline as a moving boundary and to properly estimate the shoreline change.

In this study, we developed an improved 3-D beach evolution model, named "3D-SHORE", which is coupled with the conventional shoreline model. The applicability of the model is verified through comparison with the result of movable bed laboratory experiment for the beach evolution around a detached breakwater. And we also tried to simulate the actual bottom topography changes around an offshore man-made island type fishing port during approximately a year.

IMPROVED BEACH EVOLUTION MODEL

Basic Model Concepts

Our interests are focussed on the impact assessment of neighbouring beaches due to construction of a maritime structure. It is demanded to evaluate long-term beach evolution during more than 10 years after the construction. For the beach evolution around a maritime structure, the sediment transport due to nearshore currents plays a predominant role and the contribution from cross-shore sediment transports due to waves and undertow is usually cancelled for a long period beyond approximately a year.

The shoreline model which describes only the longshore sediment transport is widely used in practise for such a case. We have recognized that the shoreline model is applicable to estimating beach evolution caused by the unbalance of sediment budget in the alongshore direction over long time scales and for broad spatial scales. However, in the vicinity of the harbor, where the nearshore circulations occur and the offshoreward sediment transport due to nearshore currents exist, the shoreline model approach has a limited applicability.

The 3-D beach evolution model which treats only the sediment transport due to depth-averaged nearshore currents, "Medium-term 2DH Coastal Area Model", is based on the same concept as that of the shoreline model. This medium-term predictive model can be, therefore, regarded as an improved version of the shoreline model, which has an advantage of estimating the spatial beach topography changes.

Another 3-D beach evolution model is a short-term predictive model which treat both longshore and cross-shore sediment transports. This model is based on the quasi-3D or fully 3D current model which can describe the vertical structure of nearshore current and undertow. In order to properly estimate the beach profile changes, the short interval iterations, probably every one or two hour repetitions are needed. The computations of the wave and current fields are, however, much time-consuming. At present, it is unrealistic to improve the short-term predictive model to properly estimate the shoreline change. We, therefore, tried to develop the 3D-SHORE for practical use by coupling the medium-term predictive model

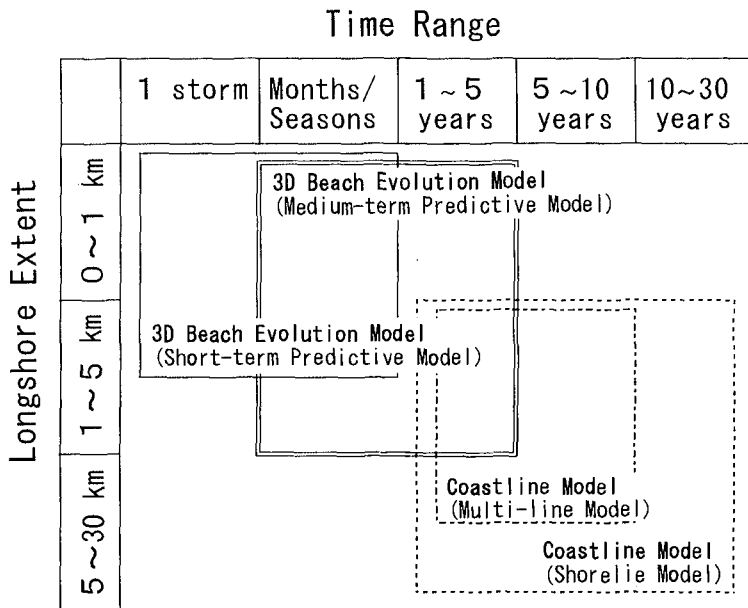

Fig. 1 Classification of numerical models of beach evolution.

with the shoreline model.

Fig.1 shows the classification of numerical models of beach evolution by spatial and temporal scales. The comparisons of the models are briefly summarized in Table 1.

Structure of 3D-SHORE

The flow chart of the improved 3-D beach evolution model (3D-SHORE) is shown in Fig.2. The model consists of four submodels for calculating 1)nearshore waves, 2)nearshore currents, 3)local sediment transport rate and spatial beach change, and 4)total longshore sediment transport rate by integrating local sediment transport rate and shoreline change.

The new bottom topography can be calculated by coupling the calculation results of shoreline change and spatial beach evolution. The new bottom topography is, then, fed back into the wave-current computations with appropriate intervals.

Wave Model

The waves in the swash zone play important roles on the shoreline change. In the nearshore wave model, the run-up height is estimated by the Hunt's formula, assuming the beach-face slope determined by the empirical relationship incorporating wave height, period and sediment grain size proposed by Sunamura(1984). The wave set-up and set-down are estimated by the approximate expressions for a plane beach according to Longuet-Higgins and Stewart(1962). The water depth in the swash zone is given virtually by decreasing linearly from the wave set-up height at the still water level to zero at the run-up point as shown in Fig.3. This virtual water depth is also used for calculation of the nearshore current field. Although this treatment of swash zone is not correct in a strict sense, it is a simple and effective method for engineering use in order to save computational time and take an important factor into consideration.

The parabolic-type equation model proposed by Isobe(1987) is employed in this study to properly estimate the wave field behind the offshore breakwater and man-made island and so on where combined diffraction and refraction occur. This basic equation is derived from the mild slope equation by using the wave ray-front coordinates. The energy dissipation term due to wave breaking is included. Random waves are described as a superposition of component regular waves with different frequencies and directions. The applicabilities of the model to the actual wave field were verified through comparisons with field measurement data (e.g. Shimizu et al.,1992).

Nearshore Current Model

In most of the previous computation of nearshore currents, the friction term is expressed as the general nonlinear form and a constant value has been used for the frictional coefficient C_f in the calculation domain. Its value, however, affects the magnitude of the nearshore current velocity and the resultant sediment transport rate. We, therefore, tried to directly estimate the local values of bottom frictional

term by using the full-range explicit approximate expressions of frictional law for a wave-current coexistent system proposed by Tanaka and Thu(1994). The outline of the nearshore wave and current models is summarized in Table 2.

Sediment Transport and Beach Evolution Model

Fig.4 shows schematically the cross-shore integration of the local sediment transport rate in the direction parallel to the shoreline from the breaking point to the run-up point. The shoreline change is calculated using the mass conservation equation of the shoreline model based on the alongshore balance of the total longshore sediment transport rate.

In coupling the spatial bottom topography changes with the shoreline changes, both results are interpolated near the shoreline. In the area of shoreline retreat, the profile is determined by the smaller depth comparing between the profile extended offshoreward from the new shoreline position with the foreshore slope estimated by empirical formula by Sunamura(1984) and the profile extended onshoreward from the grid point adjacent to the old shoreline position with the local bottom slope. In the area of shoreline advance, in order to prevent the new shoreline calculated based on the mass conservation of total longshore sediment transport rate from advancing the new shoreline calculated by that of local sediment transport, the appropriate local sediment transport rate coefficient and duration of time-stepping are to be selected.

The local sediment transport rate is evaluated by the formula proposed by Watanabe et al.(1986). The outline of the model is shown in Table 3. The formula for local sediment transport rate under combined wave-current action was formulated so as to be consistent with previous studies on both longshore drift and cross-shore sediment transport. The total transport rate vector is divided

Table 3 Outline of the local sediment transport rate formula.

[LOCAL SEDIMENT TRANSPORT RATE FORMULA]

Watanabe Model (Watanabe et al., 1986)

- Seiment transport due to nearshore currentn q_c :

$$\vec{q}_c = A_c (\tau_m - \tau_c) \vec{u}_c / \rho g \quad (5)$$

- Seiment transport due to nearshore current q_w :

$$\vec{q}_w = A_w F_D (\tau_m - \tau_c) \vec{u}_b / \rho g \quad (6)$$

where τ_m : the maximum bottom shear stress under waves and currents,

τ_c : the critical shear stress,

u_c : the mean current, u_b : bottom orbital velocity

F_D : the direction function(+1 for onshore, -1 for offshore)

• Relationships among the coefficients

(Watanabe et al., 1991; Shimizu et al., 1994)

$$A_c = 10 A_w \quad (7)$$

$$A_w = w_o \sqrt{0.5 f_w / \{(1 - \lambda) s' \sqrt{s' g D}\}} B_w \quad (8)$$

where B_w : the nondimensional coefficient of the wave-induced sediment transport rate formula by Watanabe(1982),

f_w : the wave-current friction coefficient proposed by Tanaka and Shuto(1981),

w_o : the fall velocity, D : the grain diameter,

λ : the porosity, g : the gravity acceleration,

$s' (= \rho_s / \rho - 1)$ (ρ_s, ρ : the densities of sand and fluid).

• Determination of local coefficients

- ① Previous studies $\rightarrow B_w \begin{cases} = 3 \sim 5 & \text{for field} \\ = 7 & \text{for laboratory experiment} \end{cases}$
- ② $H, T, \theta, h, D, s' \rightarrow f_w \rightarrow A_w$ at each local point (eq. (8))
- ③ $A_w \rightarrow A_c$ (eq. (7))

into that due to mean currents including both nearshore current and undertow and that due to waves. This formula is based on the power model concept and assume that the sediments set in motion by the excess shear stress under combined wave-current action are transported with both mean currents and wave motion into the respective directions. In this study, only the sediment transport due to nearshore currents is taken into account. The value of the sediment transport rate coefficient is determined by using the empirical relations, according to the previous studies (Watanabe et al.,1991; Shimizu et al.,1994). The local transport rate coefficients depend on local wave conditions and properties of sea-bed material.

MODEL VERIFICATION

Outlines of Laboratory Experiment and Numerical Calculation

The applicability of the newly developed model is investigated on the basis of the movable bed laboratory experiment conducted by Mimura et al.(1983). The experiment was carried out using a wave basin 14m long and 7.5m wide. The sediment grain diameter was 0.2mm and the initial bottom slope was 1/20. After the initial beach was subjected to wave attack for approximately 12 hours, a 1.5m long detached breakwater was placed approximately at the breaker line. The incident wave height was 5.7cm and the period was 0.9s. The verification data used in this study are the beach topography change for about 6 hours after placement of the detached breakwater.

In the calculation of beach evolution, the new bottom topography is fed back into the hydrodynamic and sediment transport computations and the dynamic time-evolution of the seabed is calculated. The calculations of waves, currents and beach topography changes were repeated every 20 minutes and 18 time iterations in total were conducted. The change in the bottom shear stress caused by bottom elevation change is taken into account every 4 minutes in the calculation of beach evolution. The grid spacing is 15cm. The local sediment transport rate coefficient B_w is 7 and the depth of closure D is set to 10cm.

Calculation of Nearshore Wave and Current Fields

Fig.5 shows the alongshore distribution of breaking wave height. The calculations show good agreement with the measurements.

Fig.6(a) and (b) show the examples of the calculated depth-averaged nearshore currents. Fig.6(a) is for initial bottom topography and Fig.6(b) is for that after 5 hours and 40 minutes. The shoreline advance behind the detached breakwater and the strong and sharp nearshore circulations are simulated.

Calculation of Beach Evolution

Fig.7 shows comparisons between the calculated and the measured positions of the shoreline and the depth contours of 2cm and 4cm. The shoreline position calculated by the shoreline model is also plotted. The shoreline change is reproduced better by the shoreline model than by the 3D-SHORE, because the

Fig. 5 Alongshore distribution of breaking wave height.

Fig. 6 Calculated nearshore current fields.

Fig. 7 Comparisons between the calculated and the measured positions of the shoreline and the depth contours of 2cm and 4cm.

computational time of the shoreline model is considerably shorter than that of the 3D-SHORE and it is, then, easy to adjust the parameters to agree with the measurement. The shoreline model, however, can calculate only the shoreline and cannot estimate the spatial bottom topography change. The present improved model, on the contrary, has good accuracy for estimating the changes in both the shoreline and the depth contours for approximately 6 hours.

Fig.8(a) and (b) show the time-evolutions of the shoreline and the 2cm depth contour calculated by the 3D-SHORE and (c) shows the time-evolution of the shoreline calculated by the shoreline model. The shoreline behind the detached breakwater advances gradually and reaches an equilibrium state after 5 hours according to the calculation result of the 3D-SHORE. The contour of 2cm advances faster than the shoreline.

According to the result calculated by the shoreline model, on the contrary, the shoreline advances rapidly and reaches an equilibrium state after only 3 hours. In the shoreline model, the longshore sediment transport rate becomes zero at the equilibrium state, because the breaking wave crest angle to the shoreline becomes zero. This shows that the shoreline model can describe only the static equilibrium. The improved 3-D beach evolution model, on the other hand, can describe

Fig. 8 Time-evolution of the calculated depth contours.

the dynamic equilibrium and is, therefore, more effective for properly predicting the time-evolution of bottom topography.

FIELD APPLICATION

In order to verify the field applicability, we try to simulate the beach evolution due to construction of the Kunnui Fishing Port, an offshore man-made island type fishing port, in Hokkaido, Japan (Kawaguchi et al., 1994). The man-made island is located about 200m offshore from the initial shoreline. The maximum width of the man-made island is about 180m, which approximately equals to the detached distance. Although the bottom contours are straight and parallel to the shoreline in 1985 before construction of the fishing port, they extend offshoreward like a tongue behind the fishing port owing to extreme accretion caused by nearshore circulations. The rapid and extreme beach evolution took place during only a year from 1989 to 1990 after the start of the construction of man-made island. At present, the tombolo is formed behind the fishing port.

The calculation was conducted with the area of 1.0km long in the alongshore direction and 0.8km long in the cross-shore direction. The grid spacing is 10m. The bottom slope is approximately 1/75. The grain diameter is about 0.2mm and the transport rate coefficient B_w is 4. The numerical simulation was performed under simply modelled two series of the storms by repeating the calculations of waves, mean currents and beach changes. The modelled series of waves have the same occurrence frequency in total as that of the observed wave climate data. The depth of closure D was expressed as a function of the incident wave conditions.

Fig.9 shows the comparisons between the calculated and the measured depth contours after a year from 1989 to 1990. The calculations show fairly good agreements with the measurements. The field applicability of the proposed model is also verified.

Fig. 9 Reproduction of the beach evolution around the Kunnui Fishing Port during a year.

CONCLUSIONS

In this study, an improved 3-D beach evolution model coupled with the shoreline model (3D-SHORE) is newly developed. And the applicabilities of the model were successfully verified through comparisons with both results of movable bed laboratory experiment and the actual beach evolution. The 3D-SHORE can describe the dynamic equilibrium of beach evolution and is, therefore, more effective for properly predicting the time-evolution of bottom topography than the conventional shoreline model which can only the static equilibrium. It is concluded that the 3D-SHORE has enough accuracy for practical use.

CHAPTER 221

EVALUATION OF SHOREFACE NOURISHMENTS BY LINE MODELLING

Martin D. Groenewoud¹, Willem T. Bakker^{2,3}, Jan van de Graaff¹,
Ruud Spanhoff³ and Christian Lastrup⁴

ABSTRACT

Shoreface nourishments are sometimes used as an alternative for ordinary beach nourishments. Many aspects of the behaviour of shoreface nourishments are still unknown. Shoreface nourishments affect the morphological behaviour of a coast. Line modelling might be used to study and to predict the behaviour of shoreface nourishments after execution. Although not every detail of the real behaviour can be dealt with, line modelling is still a rather simple but powerful tool. The recent application is discussed of the line modelling technique to study several shoreface nourishments carried out in the NOURTEC framework.

INTRODUCTION

Coastal zone managers may fight undesired structural erosion of coasts either by 'hard' or by 'soft' measures.

With 'hard' measures the basic idea is to interfere in the sediment transports involved in such a manner that the erosion in the stretch of coast under consideration is stopped, or at least reduced. With a well-tuned system of groynes or a number of shore-parallel detached breakwaters this aim can in principle be achieved. That often the erosion problem is shifted to the adjacent lee side beaches is a serious draw-back of these types of countermeasures.

With 'soft' methods (e.g. a beach nourishment [further: BN]) this adverse lee side effect is avoided. The basic idea of artificial nourishments is to accept the losses as observed (no attempts to interfere in the processes which cause the erosion) but replenish from time to time the apparent losses. Often life times in the range of 5 till 10 years are striven after. Although artificial BN's have to be repeated, it often turns out to be a very cost effective method in comparison with 'hard' alternatives.

Structural erosion of a stretch of coast means that the stretch loses sediments at a regular basis. Often a gradient in the longshore sediment transports is the main cause of the erosion problem. In a cross-shore profile the volume of sediments (m^3/m) in that profile in a predefined (fixed) area, diminishes as a function of time. All parts of such a profile (dunes; beach; shoreface) suffer eventually from this type of

erosion. However, the upper part of the profile (beach and dunes) is often considered as the most important part of the entire profile; many important functions of a coast to mankind are concentrated in just this part. Because structural erosion manifests itself most clearly in the upper part of the profile, artificial nourishments are often applied just there. With a BN the 'health' of a beach is directly improved; one clearly can notice the improvements for the time being; e.g. the beach is widened which is favourable for recreational use.

Many methods exist to execute artificial BN's [see e.g. CUR (1987)]; most of them are, however, rather cumbersome in practice. The handling of the sediments from borrow area to fill site is often complicated and thus costly. Because of the recreational use of beaches often the summer period is excluded as execution time.

Instead of applying (cumbersome) artificial BN's, nourishing just the shoreface seems an (easy) alternative. Sediment handling is quite simple; the dredge sails from the borrow area and dumps the load at the shoreface and starts with a new cycle. Because of no (or less) hindrance to the recreational use of the beaches also the summer time can be used for execution. Large cost savings are expected to be achieved with shoreface nourishments [further: SN] in comparison with classical BN's.

In the scope of the NOURTEC project [Mulder *et al.* (1994)] at 3 sites (Terschelling, the Netherlands; Norderney, Germany; and Torsminde, Denmark; see Fig.1) sand has been supplied on the shoreface. The NOURTEC project implies evaluation and comparison of the coastal behaviour at those sites after the SN's.

Bakker *et al.* (1994) made a prediction of the expected coastal behaviour after the SN at the Dutch Wadden island of Terschelling; furthermore the coastal behaviour after the supply at the German Wadden island of Norderney was evaluated. They used the 3-line modelling technique. Later on the nourishments in Denmark and Terschelling have been evaluated with the same technique (Groenewoud 1996a and 1996b). The study has been finished with an overall evaluation of the 3-line modelling technique as a design and evaluation tool (Groenewoud 1996c).

Fig.1 Location of the 3 NOURTEC test sites

In the present paper the application of the 3-line modelling technique in the 3 NOURTEC cases is discussed; strong and weak points of the method are revealed.

SHOREFACE NOURISHMENTS IN PRACTICE

Fig.2 shows in plan view a (shore parallel) SN along a sandy coast. Because a SN is meant to be a substitute of an ordinary BN it is expected that a part of the supplied volume is transported towards the coast. With the notion of the existence of equilibrium profiles one can indeed expect that because of cross-shore transports the extra volume of sand is eventually spread over the entire profile (in onshore as well in offshore direction). Consequently also a part of the supplied volume is thought to reach eventually the beach. For the judgment of the effectiveness of SN's in comparison to BN's it is of course important to know which part of the volume of SN's reaches the beaches, and which time scales are involved. With detailed cross-shore transport calculations these topics are to be evaluated.

Fig.2 (Arbitrary) shoreface nourishment in plan view

In plan view (see Fig.2) a SN is limited; between points A and B the depths contours are just after the execution locally shifted in seaward direction. In the neighbourhood of the points A and B the orientation of the depth contours has changed. With a description of the (local) longshore transport depending on the orientation of the depth contours it is easily understood that near the points A and B a redistribution of the volume of sediments of the SN in longshore direction will take place. Also in the upper part of the profile, as soon as some sediment has reached that part of the profile by cross-shore transports, a similar reorientation of the local depth contours will occur with a consequent redistribution of sediments in longshore direction in the upper part of the profiles of the stretch of coast.

A SN acts, however, also as a (mobile) submerged breakwater. The presence of a SN will affect (reduce) the wave heights in the zone between the SN and the waterline. Consequently the longshore sediment transports in this zone are reduced compared to the original transports along the non-supplied coast at the left-hand side of A and at the right-hand side of B (see Fig.2). Assuming a net longshore transport in the zone behind the SN as indicated in Fig.2 from left to right, it is expected that behind the left side of the SN some accumulation of sediments will occur (salient formation). Right from B it is expected that (additional) erosion of the beaches will occur.

Especially the expected salient formation at the up-drift side behind the SN will confuse phenomenological studies based on bathymetric data. Is the observed

accumulation of sediments in this area because of cross-shore sediment transport effects or because of longshore transport effects?

If a SN is applied in a zone with water depths where in the non-supplied situation still substantial yearly net longshore sediment transports do occur (either wave or tide driven or due to a combination of waves and tidal currents), the mere sudden uplift of the bottom because of the presence of the SN will cause increased sediment transports above the SN (see Fig.2). Induced gradients in the local longshore transport will cause erosion of the SN just right of point A and accumulation of sediments just right of point B. It seems that the entire SN is moving (within the schematization of Fig.2) from left to right along the coast.

In the brief discussion of the different morphological effects of a SN it was presumed that the borrow material of the SN is equal to the native material. In practical applications, however, this presumption might not be true; the borrow material may differ from the native material. It is for sure that consequently the sediment transports involved, will change.

In the previous part 4 morphological effects of a SN have been briefly discussed, viz.:

- i) (straightforward) cross-shore redistribution of the volume of a SN over the entire cross-section;
- ii) longshore redistribution of the volume of a SN due to reorientation of the depth contours in the zone of the SN itself (starts immediately after execution) and in the upper part of the profile (starts when after some time sediments have reached the upper part of the profile);
- iii) salient formation at the up drift side (and erosion at the down drift side) in the zone between SN and waterline because of reduction of the yearly net longshore sediment transport in this zone;
- iv) integral movement of the SN in longshore direction because of yearly net longshore sediment transports in the SN zone.

In the next section the 3-line modelling technique is discussed. It will turn out that the effects i) and ii) can in principle be properly modelled with the present technique; the effects iii) and iv) cannot be accounted for with the present model set up. In the present 3-line modelling approach it is also assumed that borrow and native material are the same. Additional effects due to differences in borrow and native material are not accounted for.

3-LINE MODELLING TECHNIQUE

General

In the present study 3 lines have been used to represent a cross-shore profile. More, or only 2 lines are in principle also possible. The 3-line modelling technique is a rather simple technique which can be used to study the behaviour of a morphological system with time. The approach relies on the assumption that the actual behaviour of a morphological system can be considered as a linear superposition of different sub-systems. In the present application for instance, the autonomous behaviour of the system is assumed to be the same before and after a SN application. Only the additional effect of the SN is modelled. So if the behaviour of the SN with time is

modelled reliably, the eventual behaviour of the system with time is found by adding both sub-systems (autonomous behaviour + behaviour because of the SN).

Schematization of cross-shore profile and cross-shore transports

In a 3-line model the cross-shore profile is schematized by 3 zones with horizontal separation planes (see Fig.3). The volumes of sand in the zones (layers) are characterized by 3 lines which may, contrary to equilibrium profile approaches, develop 'freely' with time. It is assumed that in each zone the mutual distance between the upper and the lower limit remains the same and (thus) that the part of a profile coinciding with the zone moves only horizontally.

The characterizing lines each have a distance to an arbitrary vertical reference line which for L_1 can be defined as (see Fig.3):

$$L_1 = \frac{1}{h_1} \int_{-d_1}^0 y(z) dz \quad (1)$$

For lines L_2 and L_3 similar formulae can be derived.

Fig.3 Schematization of cross-section

The parameters of Eq.1 and Fig.3 are:

- d_1, d_2 = depth of separation plane between zone 1 and 2; zone 2 and 3;
- d_3 = depth of lower limit of zone 3;
- h_1, h_2, h_3 = height of zone 1; zone 2; zone 3;
- L_1, L_2, L_3 = characterizing mean line of upper zone; middle zone; lower zone;
- $y(z)$ = distance of point of profile at depth z to a reference line;
- z = height above the y -axis.

The cross-shore sediment transport rate between the zones is assumed to be proportional to the difference between the actual distances and the equilibrium distance between the characterizing lines. This method of describing cross-shore

sediment transports was originally proposed by Bakker (1968) and further developed by Swart (1974).

Since in the present application the profiles before the SN application are assumed to be equilibrium profiles, the use of L_1 , L_2 and L_3 can be avoided; only perturbations from the initial equilibrium profile are considered. These perturbations are expressed as (see Fig.4) y_1 , y_2 and y_3 respectively.

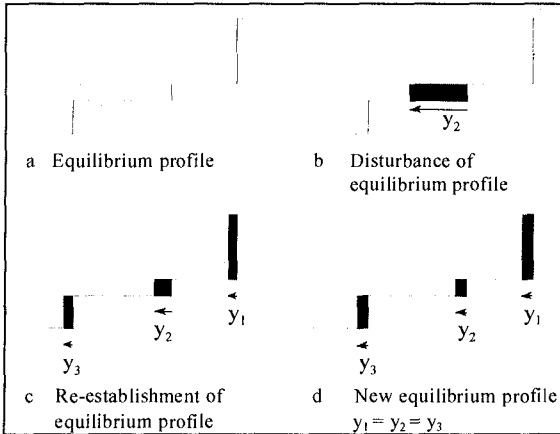

Fig.4 Schematized equilibrium profile (a); disturbance in middle layer (b) and behaviour (c and d)

If the transport rates S_{y1} [and S_{y2}] are assumed to be proportional to the differences ($y_1 - y_2$) for S_{y1} [and ($y_2 - y_3$) for S_{y2}], then the following equation for S_{y1} can be written:

$$S_{y1} = s_{y1} (y_1 - y_2) \quad (2)$$

(For S_{y2} similar formula.)

with: S_{y1} = cross-shore transport from the upper to the middle zone [$m^3/m/year$]
(positive in seaward direction)

s_{y1} = cross-shore coastal constant [$m/year$]

The description of the cross-shore sediment transport relies on a proper estimate of the cross-shore coastal constants. It can be proved that these coastal constants can be rewritten as:

$$s_{y1} = \frac{1}{T_{01}} * \left(\frac{h_1 * h_2}{h_1 + h_2} \right) \quad (3)$$

with: T_{01} = time constant for diffusivity between upper and middle zone (year)

(For the time constant for diffusivity between the middle and lower zone T_{02} a similar formula can be derived.)

The T_0 period is the lapse of time in which a certain value of deviation from the equilibrium distance will decrease with a factor e . The problem of estimating proper values for the cross-shore constants is now shifted to the proper estimate of the T_0 periods.

Schematization of longshore transport

In each zone of the schematized cross-shore profile longshore sediment transports will occur. These longshore transports are indicated by S_1 , S_2 and S_3 for the upper, middle and lower zone, respectively. In the following discussion S_x is generally used.

In the present Nourtec cases the total longshore transport, and the distribution over the different zones, is calculated with the CERC formula; the possible contribution of tidal currents is consequently ignored. The method can, however, also be used if tidal currents are taken into account; the preparatory calculations are only somewhat more complicated in that case.

A gradient in the longshore transport results in the following equation of continuity:

$$\frac{\partial S_x}{\partial x} + h \frac{\partial y}{\partial t} = 0 \quad (4)$$

with h being the thickness of the layer over which erosion or accumulation takes place. The gradient of the longshore sediment transport is due to changes in angle of wave approach.

The wave climate is assumed to be constant along the coast. With small changes of the angle, the longshore transport is assumed to depend linearly on the angle of wave approach.

$$\frac{\partial S_x}{\partial \phi} = s_x \quad (5)$$

with: s_x = longshore coastal constant

The chain rule gives:

$$\frac{\partial S_x}{\partial x} = \frac{\partial S_x}{\partial \phi} * \frac{\partial \phi}{\partial x} \quad (6)$$

Substitution of Eqs.5 and 6 in Eq.4 and assuming small angles ultimately yields:

$$-s_x \frac{\partial^2 y}{\partial x^2} + h \frac{\partial y}{\partial t} = 0 \quad (7)$$

The change of the position of the coastline ($\partial y/\partial t$) due to longshore transport is proportional to the curvature of the coastline. This also applies if the profile is divided into several zones. The equation for the upper zone then becomes:

$$\left[\frac{dy_1}{dt} \right]_{\text{long}} = \frac{s_1}{h_1} * \frac{\partial^2 y_1}{\partial x^2} \quad (8)$$

with: s_1 = longshore coastal constant

Combination of both cross-shore and longshore processes with linear addition gives:

$$\frac{dy_1}{dt} = \frac{s_1}{h_1} * \frac{\partial^2 y_1}{\partial x^2} - \frac{s_{y1}}{h_1} (y_1 - y_2) \quad (9)$$

$$\frac{dy_2}{dt} = \frac{s_2}{h_2} * \frac{\partial^2 y_2}{\partial x^2} + \frac{s_{y1}}{h_2} (y_1 - y_2) - \frac{s_{y2}}{h_2} (y_2 - y_3) \quad (10)$$

$$\frac{dy_3}{dt} = \frac{s_3}{h_3} * \frac{\partial^2 y_3}{\partial x^2} + \frac{s_{y2}}{h_3} (y_2 - y_3) \quad (11)$$

In these equations the longshore transport is determined by the constants s_1 , s_2 and s_3 and the direction of the coast. The cross-shore transport is determined by the constants s_{y1} and s_{y2} and the deviation from the equilibrium position.

These three equations determine the development of y_1 , y_2 and y_3 in time and position along the coast.

Numerical solution

The numerical method used to solve Eqs.9, 10 and 11 is the Euler Explicit Time Forward Central Space method. Time and space steps have to be carefully linked in order to fulfil the stability criterion.

Example

In Fig.5 the results of an arbitrary example are given. Along 2 km a shore-parallel SN is placed in the middle layer. The thicknesses of the layers are respectively: upper: 6 m; middle: 3 m and lower: 3 m. The cross-shore constants are $s_{y1} = 1.33$ m/year and $s_{y2} = 0.3$ m/year. The longshore coastal constants read: $s_1 = 2.65 * 10^6$ m³/year/rad; $s_2 = 0.22 * 10^6$ m³/year/rad and $s_3 = 0$ m³/year/rad. The volume as nourished is 300 m³/m; because of the nourishment just after the nourishment the y_2 values shifted with 100 m in seaward direction.

From Fig.5 it becomes clear that the SN diffuses in all directions. With the constants as used indeed a large part of the SN reaches the upper part of the profile.

The lower zone just seaward of the SN gets some sand directly from the middle zone because of cross-shore transports. In the adjacent lower zones also some sedimentation is noticed. Since the longshore coastal constant s_3 in the present

Fig.5 Development with time of a shoreface nourishment in middle layer

example is zero, this material has reached these zones first via the adjacent middle layers and next by cross-shore transport.

In the present example the autonomous behaviour of the coast is not taken into account; in real life problems the autonomous behaviour has to be added to the computation results. To determine the autonomous behaviour in real cases turns out to be a cumbersome task (see *NOURTEC* examples next section).

NOURTEC EXAMPLES

Torsminde

The Torsminde test side is located along the west coast of Denmark (see Fig.6). Fig.7 shows two typical cross-shore profiles; 1 to 3 offshore bars are present. The site is located in front of a sand dike. A typical value of D_{50} for the sand in the profile is 0.4 mm.

Fig. 6 Location Torsminde test site

Fig. 7 Typical cross-shore profiles

Separate beach and shoreface nourishments took place in 1993. Over longshore stretches of one km each, approximately $250,000 \text{ m}^3$ sand has been nourished in both cases; so approximately $250 \text{ m}^3/\text{m}$. The D_{50} of the borrow sand ($D_{50} = 0.34 \text{ mm}$) for the BN was slightly less than the native sand; the borrow sand ($D_{50} = 0.58 \text{ mm}$) for the SN was coarser than the native material.

The BN was placed between DNN +4 m and DNN -1 m (DNN = Danish Normal Zero); the SN between DNN -4 m and DNN -6 m. The cross-shore profiles have been divided in 3 layers: upper: DNN +4 m to DNN -4 m; middle: DNN -4 m to DNN -6 m; lower DNN -6 m to DNN -10 m.

Estimates of the longshore coastal constants have been calculated using the CERC formula; the distribution of the transport over the different zones have been found by using the Svašek and Bijker (1969) method.

In the modelling the determination of the cross-shore coastal constants is a vital item. In the Torsminde case different sets have been tested using the observed behaviour as criterion. A reasonable set was eventually found.

To judge the quality of the computation, a comparison with the observed behaviour was made. The autonomous behaviour was set on an average coastline retreat of 6.7 m/year. This value was based on measurements in the period 1978 - 1988.

In the example case of Fig.5 y-values are computed for each 100 m along the coast. In the Torsminde case also a 100 m spacing was used in the computations. In order to facilitate comparison of measurements with computations, averaged values for stretches of coast of 1 km length (so-called boxes) have been used.

The fluctuations of the measured y -values turned out to be relatively large compared to the calculated development of the y -values. It is not expected that these large fluctuations are mainly due to the two nourishments.

Overall the comparison between the calculated and the observed development showed in some cases similarities and in some other cases considerable differences. One of the shortcomings of the present model is that the model can not cope with the effects of the different grain sizes on the morphological development.

Norderney

As already discussed by Bakker *et al.* (1994), the Norderney case is in fact too complicated to be modelled properly with a 3-line modelling technique. The complicated bottom topography in front of the test site and the presence of a number of groynes made this site in fact unsuitable for a simple line-modelling technique.

Terschelling

In the Terschelling case (see Figs.8 and 9) the shoreface was nourished in 1993 with a volume of 2.1 million m^3 over a length of 4.6 km at a depth of Datum -7m to -5m. In fact the most seaward trough of the bar system was filled. The SN was located in the middle part of a 12 km long study area.

Fig. 8 Location Terschelling test site

Fig. 9 Typical cross-shore profiles

The native bed material shows a typical distribution over the cross-shore profile: $D_{50} = 0.24$ mm at the beach and gradually decreasing to $D_{50} = 0.16$ mm at the deeper shoreface. The D_{50} value of the borrow material was 0.20 mm. Apart from the yearly profile measurements (since 1964; 200 m spacing), just before and after the execution of the SN many more profile measurements have been carried out. After the nourishment e.g. in a lapse of time of 2 years 11 series of measurements have been carried out.

The shape of the cross-shore profile was schematized in 3 layers. Normally (fixed) depth contours are chosen as layer limits. In the Terschelling case because of the bar system, the upper layer was defined from Datum +3 m to Datum -3 m (most landward contour); the lower layer was defined from Datum -6 m (most seaward contour) to Datum -9 m. All the sediment between the most landward Datum -3 m depth contour and the most seaward Datum -6 m depth contour was considered to belong to the middle layer. So even if a trough of the bar system is deeper than Datum -6 m or a crest is higher than Datum -3 m the sediments (or the lack of sediments) involved belong to the middle layer. With this procedure the entire (with time moving) bar system is confined in the middle layer.

The 3-line model is based on the hypothesis that an equilibrium profile exists in cross-shore direction. It might be questioned whether this concept holds as well in case of a bar system with a cyclic behaviour as for Terschelling.

The longshore coastal constants have been derived with the CERC formula. The cross-shore coastal constants have been derived by trial and error, taking the observed behaviour after the SN into account. Rather short T_0 (time constant for diffusivity) values had to be adopted ($T_{01} = 1.5$ years upper to middle zone; $T_{02} = 5$ years middle to lower zone). It is felt that the rather small value T_{01} of only 1.5 years is partly 'artificially'. As discussed in section 'Shoreface nourishments in practice' some salient formation landward of the SN is expected because of gradients in longshore transport. Although this phenomenon can not be properly modelled with the present technique, the effects are accounted for by the relatively small T_{01} value.

The study area was divided in several (8 in this case) boxes (1.2 km each). Prior to the SN the autonomous behaviour of each box could be determined since many profile measurements are available. In the final judgment of the observed and calculated behaviour of the coast, the calculated autonomous behaviour of each box was taken into account.

The calculated development of the y -values of the upper zones was very similar to the measured development after the application of the SN. The large observed volume increase in the upper zone is, in the present simulation, almost entirely caused by cross-shore transports from the middle zones. It might be questioned whether this is physically correct.

The simulation results for the middle zones were less good. E.g. the observed general movement of the SN in eastward direction could not be properly modelled. The differences between the measured and modelled behaviour of the lower zone were in some cases large.

ESTIMATES OF COEFFICIENTS

In the preceding section the modelling results of the 3 NOURTEC cases have been briefly discussed. The Torsminde and Terschelling cases could be modelled more or less successfully. The Norderney case has been reported by Bakker *et al.* (1994); the complexity of that problem was demonstrated.

The quality of the modelling results depends to a large extent on a proper choice of the coastal constants. Reliable longshore constants could be determined with the CERC formula. The proper choice of the cross-shore constants turned out to be more difficult. Till now a sound theoretical basis is lacking for the determination of these constants. By trial and error (using the observed behaviour after execution of the SN's) useful estimates have been found. With these estimates at least some essential characteristics of the behaviour could be modelled. This procedure makes it difficult to use the model in an *a priori* predictive mode in other cases.

In Table 1 the constants as used in the Torsminde and Terschelling cases have been summarized.

	Torsminde	Terschelling
T ₀₁	5.0 years ($s_{y1} = 0.32$ m/year)	1.5 years ($s_{y1} = 1.33$ m/year)
T ₀₂	5.0 years ($s_{y2} = 0.27$ m/year)	5.0 years ($s_{y2} = 0.30$ m/year)
s ₁	$2.65 * 10^6$ m ³ /year/rad	$3.63 * 10^6$ m ³ /year/rad
s ₂	$0.23 * 10^6$ m ³ /year/rad	$0.96 * 10^6$ m ³ /year/rad
s ₃	$0.00 * 10^6$ m ³ /year/rad	$0.00 * 10^6$ m ³ /year/rad

Table 1 Coastal constants Torsminde and Terschelling cases

The longshore constants for the upper zone for Torsminde and Terschelling are of the same order of magnitude; in the middle zone the constants for Torsminde are somewhat smaller than for Terschelling. This is partly caused by the difference of the height of the upper limit of the middle zone; DNN -4 m for Torsminde and Datum -3 m for Terschelling. Both in Torsminde and in Terschelling no longshore sediment transports are assumed to occur in the lower zone.

The time constants for diffusivity in cross-shore direction are generally 5 years, except for the Terschelling case between upper and middle zone (T₀₁ = 1.5 years). There is no reliable theory available yet to predict time constants. In the Terschelling case the observed cycle for the (offshore) movement of the bar system is 10 - 15 years. It is felt that the time constants should have the same order of magnitude; 5 years is in this respect not too strange. The rather small value of T₀₁ = 1.5 years for Terschelling is probably because in this value also the (not modelled) effects of longshore sediment transport gradients are accounted for.

With the use of mathematical cross-shore transport (and morphological) models in principle estimates of cross-shore constants could be derived. Although this procedure has not yet followed in the present NOURTEC cases, promising results have already been achieved in other Dutch research cases. [See Steetzel (1996).]

CONCLUSIONS

The 3-line modelling technique has proved to be a powerful method to represent the most important characteristics of the behaviour of SN's after placement. Different design alternatives can be easily compared. It is certainly not a technique to answer all questions which might be raised related to the application of SN's.

A serious problem in analyzing the behaviour of SN's after placement is the distinction between the SN-induced behaviour and the autonomous behaviour. Much of the observed differences between model results (added to the estimated autonomous behaviour) and the measured behaviour, is caused by uncertainties about the estimated autonomous behaviour.

The present 3-line modelling technique is not able to cope with differences between borrow and native material.

Although the modelling results were in some respects not fully successful, the study has revealed that modelling attempts can serve as a very fruitful focus point for better understanding of the complex behaviour of shoreface nourishments.

ACKNOWLEDGEMENTS

The study was sponsored by partners in the Nourtec project: Rijkswaterstaat, National Institute for Coastal and Marine Management/RIKZ; the Netherlands (Terschelling case), Coastal Research Station Norderney; Germany (Norderney case) and Danish Coastal Authority; Denmark (Torsminde case). The Nourtec project was co-sponsored by the Commission of the European Union, Directorate General XII, Marine Science and Technology (MaST II) Programme under contract MAS2-CT93-0049.

CHAPTER 222

BEACH MONITORING PROGRAM OF VALENCIA (SPAIN)

José Serra¹, and Josep R. Medina¹

Abstract

The littoral processes and long-term shore protection plans are analysed for the coast of Valencia (Spain). The breakwaters built during this century by the Port Authorities have greatly affected the most Southern beaches by interrupting the natural longshore sand transport. The monitoring program of the beaches of Valencia (Spain) has been established for a precise estimation of the evolution in time of the beaches to the North and South by the Port of Valencia. Periodic topographic surveys provide the basic time-dependent beach description of the area. The two main objectives are the following: **a)** 3-D description of the beach surface, including estimation of reliability and measurement errors of bathymetrics, and **b)** stochastic description of wave climate.

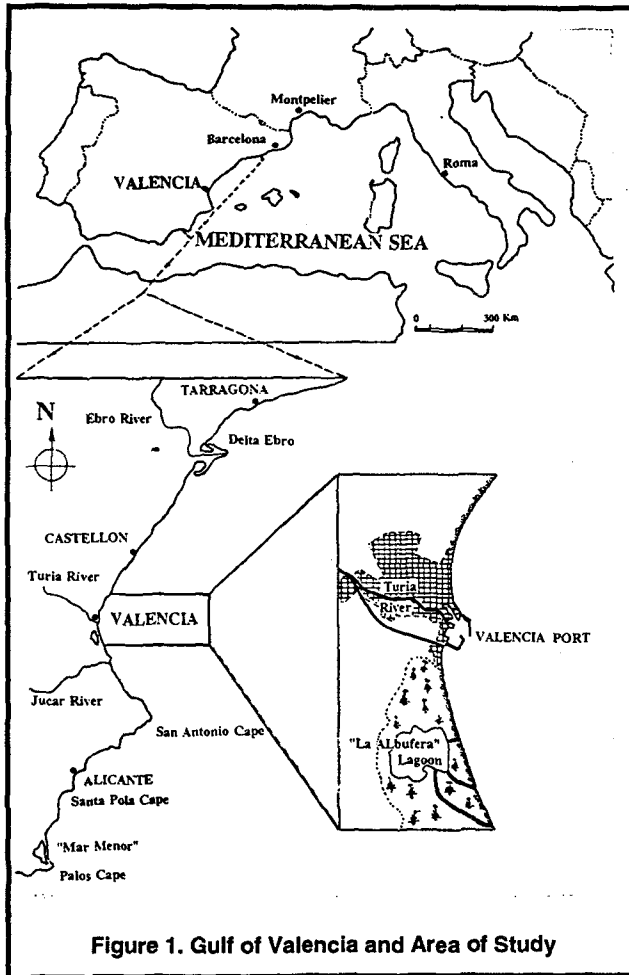

High precision and cost-efficient beach surveying techniques have been developed during the monitoring program of the beaches of Valencia (Spain). Beach profiles and zero-shorelines have been obtained with systems and errors similar to the terrestrial topography. The methods are simple enough to be applied by general land surveyors with a minimum training and may be extended to a variety of beaches for systematic and low-cost monitoring programs.

Introduction

Most beaches of the Gulf of Valencia in Spain suffer an erosion/acretion

¹ **Department of Transportation, Universidad Politécnica de Valencia, Camino de Vera s/n, 46022 Valencia, SPAIN.**

processes induced by inappropriate constructions and unadequate coastal policies. The rivers and the natural littoral sand drift created more than a hundred miles continuous natural sand beach which has been altered in several points by breakwaters, jetties, commercial ports and marinas. According to Yepes (1995), economic, social and political pressures and different kind of lobbies are interacting on the sand beaches, which are considered the most critical production factor of the touristic sector in Valencia (10% of the Spanish GNP).

Cost-efficient beach monitoring programs appears as key elements in developing appropriate shore protection and beach nourishment plans. A high precision low-cost beach profile system developed during the monitoring program of Valencia (see Medina and Serra, 1993) is being applied for beach

monitoring North and South of Valencia and may become a common low-cost system for autonomous and decentralized control of beaches along the Spanish Mediterranean coast

Environmental Characteristics

Figure 1 shows the location of the area of study in the Gulf of Valencia. Serra (1986) analysed the natural morphodynamic unit known as "Ovalo Valenciano" (Gulf of Valencia), located in the Western Mediterranean Sea, between the Delta Ebro (North), and the San Antonio Cape (South); it is almost a continuous sand beach of approximately 270 kilometers.

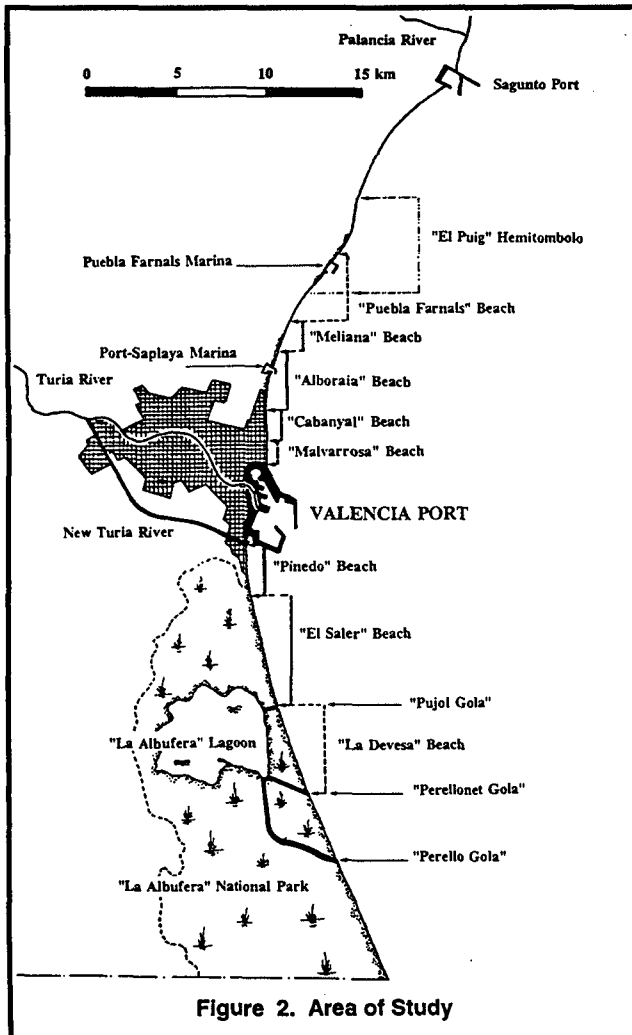

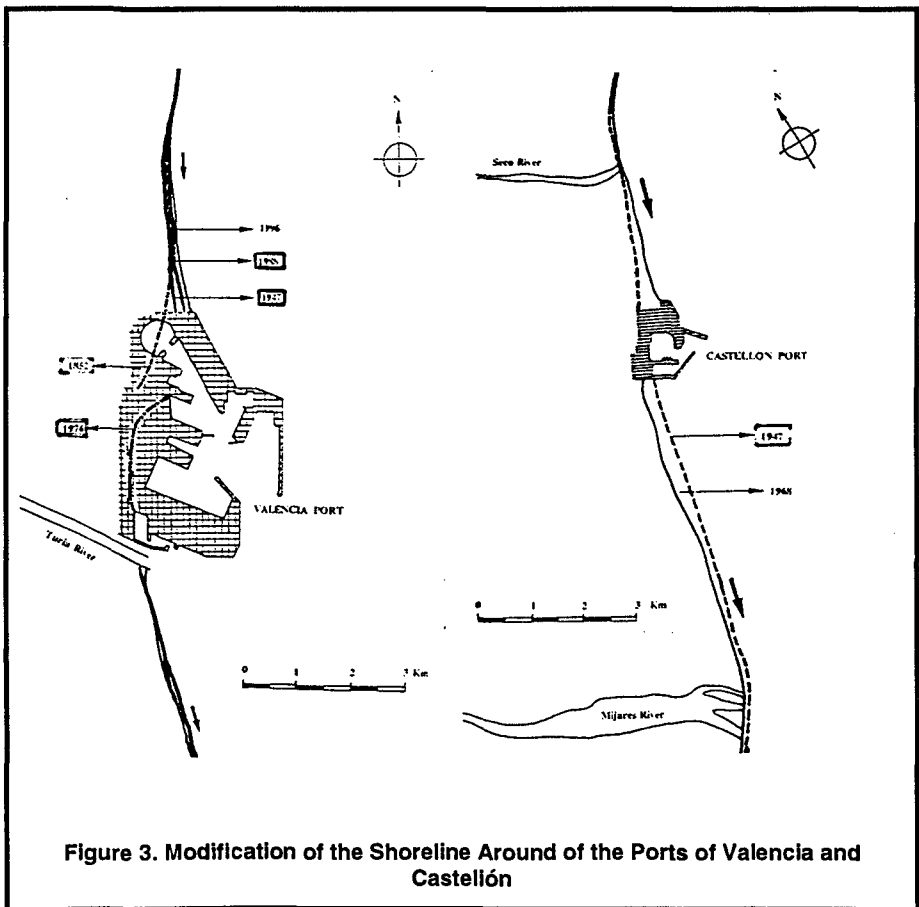

Figure 2. Area of Study

Figure 2 shows the monitorized area located in the "Ovalo Valenciano", between the "Puebla Famals" marina on the Northern limit and de inlet of the "La Albufera" lagoon, known as "Gola del Perellonet" on the Southern limit, littoral stretch length approximately 30 kilometers. The longshore transport of the coast of Valencia is about $500.000 \text{ m}^3/\text{yr}$ North to South and $200.000 \text{ m}^3/\text{yr}$ South to North.

During centuries, there was not enough construction and dredging capacity to build up breakwaters and docks able to resist a sand current of half a million m^3/yr , and a variety of projects enlarging the ancient Port of Valencia failed because of the sand sedimentation processes. Nevertheless, modern construction techniques and the economic development of this century altered the traditional conditions.

A barrier to the littoral drift was established on the sandy coast and an

erosion process was generated since then on the beaches South of the harbor, where the shoreline is retreating about one meter per year. Not only the Port of Valencia, but also the dams built in the Turia river and marinas North of Valencia are contributing to the beach erosion process.

Unfortunately, neither the Port nor the dams are expected to be removed as barriers in the near future, because they are key elements to the economic development of the region. Additionally, the urban development of the Southern beaches (El Saler) has affected the natural mobility of dunes resulting in a significant retreat of the shoreline during the last three decades.

The case of the Port of Valencia and the accretion on the Northern

beaches and erosion of the Southern beaches is similar to other cases along the Gulf of Valencia. The figure 3 shows the modification of the shoreline during this century around of the Ports of Valencia and Castellón.

The coast South of the Valencian Port has two different stretches. The one next to the Port is under erosion and the furthest from the Port is stable. On the other hand, the coast North of The Port of Valencia, presents stretches in accretion and others in erosion. The erosion is located South of the barriers of the marinas; the areas in accretion are located North of the marinas, and on the beach North of the breakwater of the Port of Valencia.

The coast to the North, (figure 4), is characterized by the high number of constructions of coastal and nearshore works: the Puebla Farnals and Port-Saplaya marinas, and various coastal work fenders, emphasizing the longshore revetments which protect the A-7 motorway against direct action from strong waves.

Beach Monitoring Program of Valencia

The sand deposits at "El Saler" is in the order of dozens of millions of cubic meters, and short term problems of vital structures caused by erosion is not expected. However, the construction of a new container terminal in the Port of Valencia and the social and economic value of the beaches in the area of Valencia (1.300.000 inhabitants) has favored the establishment of a systematic beach monitoring program. This monitoring will be the basis of the long-term planning and shore protection works on the coast of Valencia.

The Valencia beach monitoring program focuses on two main points: 1) the topographic and bathymetric description of the beaches, and 2) the description of wave climate. Figure, shows the location of the wave recording equipment and in the twenty beach profiles that define the beach morphology to the North and to the South of the Valencia Port.

Bathymetric Survey

From the theoretical point of view, it is relatively simple to describe the beach erosion process. The aerial topography and bathymetry of the beach defines the surface of the sedimentary deposits or rocks along the coast.

The common equipment for systematic bathymetries are echosounders on boats with GPS which are affected by temperature, salinity, and calibration method. The bathymetries on boats must be related to a "zero level" which requires a high precision topographic network and a continuous measurement of the mean water level during the beach survey; it is a difficult to estimate the

error level of the survey because the high precision measurement techniques, when available, are low-efficient.

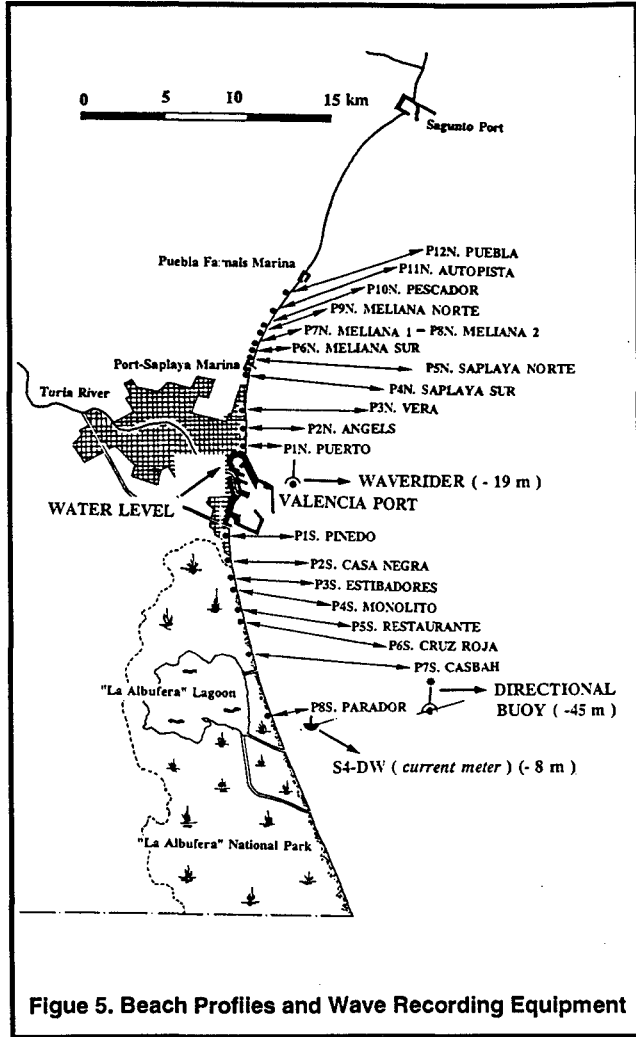

Figure 6 shows a scheme of the three different surveying techniques commonly used in the beach monitoring programs of Valencia. The first technique is a systematic automated method based on an echosounder boat mounted with GPS. The second technique is a manual method based on a small dinghy and chain; and the third technique is a manual method based on a land rod readapted for marine purposes, this technique is known as *Beach Profiler (BP)*.

The Beach Profiler (BP) Within the last decade new measuring systems for bathymetric survey with a common criteria of moving land topography to marine topography have been considered by different research groups. Following this research line the Laboratory of Ports and Coast of Univerisidad Politécnica de Valencia has developed the denominated Beach Profiler (BP) represented in Figure 7. The unit has proved its effectivity as a precise unit for beach profile measuring in beach monitoring. A basic idea is that, in the long-term, cost-efficient beach monitoring techniques appear to be key elements in developing apropiate shore protection and beach nourishment plans.

BP is a high precision and low-cost beach profiler system developed

during the first monitoring program of "El Saler" which is being also applied for monitoring the beaches North of Valencia, and may become a standard low-cost system for regional and decentralized control of beaches along the Spanish Mediterranean coast.

Figure 7. Beach Profiler (BP)

The BP system only requires a two man work team aboard to a small boat, and a land surveyor with a conventional infra-red equipment. The especial designed element to measure the level of the sea botton was a self-floatable aluminium bar, with a crow on the top on which the infra-red reflectors are fixed covering all directions and an articulated led plait in the botton. The BP shows the following characteristics: high precision (error < 2 cm), high efficiency (about 60 points/hour), low cost, and simplicity. Figure 8 shows a typical enveloped and standard deviation of the elevation of the measured profiles using BP.

Figure 8. Profile Envelope and Standard Deviation in Elevation (P7N.MELIANA1) Using the BP

Beach Profiles: Errors

Esteban (1993) and Esteban et al. (1995) analysed the problems associated with the use of different bathymetric systems in beach monitoring. Table 1 shows a comparison of different bathymetric techniques, incorporating the results obtained by the BP.

Bathymetric Technique	Sources of Error	Estimated Error	Cost
ECHOSOUNDER	⇨ Mean water level: <i>Tides</i> <i>Strong surges,...</i> ⇨ Calibration: <i>Temperature (° C)</i> <i>Salinity (g/l).</i> ⇨ Boat movement: <i>Heave, Pitch, Roll.</i>	$\approx 10 \text{ cm}$ <i>(Mediterranean)</i>	High
CHAIN	⇨ Mean water level: <i>Tides</i> <i>Strong surges,...</i> ⇨ Manual operation	$\approx 20 \text{ cm}$ <i>(Mediterranean)</i>	Low
SLED <i>Stauble et al. (1993)</i>	⇨ Terrestrial topography ⇨ Positioning	$\sigma \approx 7 \text{ cm}$ (Atlantic)	High
CRAB <i>Birkemeier et al. (1993)</i>	⇨ Terrestrial topography ⇨ Positioning	$\sigma \approx 1 \text{ cm}$ (Atlantic)	Very High
BEACH PROFILER	⇨ Terrestrial topography ⇨ Positioning	$\sigma \approx 2 \text{ cm}$ (Mediterranean)	Low

Table 1. Sources of Error Corresponding to Different Bathymetric Techniques

Conclusions

High precision and cost-efficient beach surveying techniques have been developed during the monitoring program of the beaches of Valencia (Spain).

The BP method is simple enough to be applied by a general land surveyor with a minimum training and may be extended to a variety of beaches for systematic and low-cost monitoring programs. The technical characteristics are:

- 1.- *High precision (1 cm < error < 2 cm).*
- 2.- *High efficiency (about 60 points/hour).*
- 3.- *Maximum length profile: 1000 m.*
- 4.- *Maximum water depth: 10 m.*
- 5.- *It does not require specially trained personnel.*
- 6.- *The BP may be considered a simple terrestrial topography system adapted for monitoring beaches.*

Continuous mean water level measurements during surveys are unnecessary, neither is special equipment nor highly trained personnel required.

Therefore, the BP is adequate for manual beach monitoring and the problems of the BP are similar to terrestrial topography.

CHAPTER 223

BAR MIGRATION AND DUNEFACE OSCILLATION ON DECADAL SCALES

Marcel J.F. Stive^(1,2), Jorge Guillen^(1,3) and Michele Capobianco⁽⁴⁾

Abstract

While structural erosion or accretion of a coastal stretch is of primary concern to coastal management, knowledge of coastline oscillations on larger time scales relative to the erosional or accretional trend would allow for a more efficient management practice. Our analysis of more than thirty years of observations of dune, beach and nearshore evolution reveals some of the typical oscillatory behaviour in time and space on a decadal scale. We have focused on the behaviour of the duneface and analyzed the possible relation between the duneface behaviour and that of the nearshore morphology. Amongst our results are the findings that the demeaned oscillatory duneface evolution on a decadal scale is not only correlated with the recurrence frequency of the migratory bar system, but also with a cumulative measure of episodic wave events.

Introduction

Moderate rates of structural erosion or accretion only become apparent on larger time and space scales, because of the dominance of shorter scale oscillations caused by natural processes. Most evident is that due to episodic wave events, which can cause strong erosion and associated steepening of the duneface, while the eroded sediment is deposited on the beach and nearshore profile, resulting in a more weakly sloping and wider beach. After these events a

restoration may occur due to aeolian and hydrodynamic processes. Our interest is typically into the scales intermediate to the short term, event related, behaviour and the long term, structural trend of erosion or accretion associated with gradients in cross-shore and longshore directions over a coastal stretch.

These intermediate scales concern the temporal behaviour on decadal scales, leading to duneface amplitude oscillations of magnitudes comparable to those of the structural trend. Our objective has been to develop an understanding of the mechanisms behind this behaviour, based on the "working-hypothesis" that a relation may be expected between the bar dynamics and the duneface behaviour. The JARKUS data-set, comprising more than thirty years of field observations of the duneface, beach and nearshore profile along the central Netherlands coast, has revealed typical and unexpected properties of subaqueous bar morphodynamics on a decadal scale. Amongst the most recent analyses is that of Wijnberg and Terwindt (1995) pointing towards the existence of four distinct morphodynamic regimes, each characterized by their own particular bar dynamics. These regimes occur in four coastal stretches, each constrained by coastal engineering structures. While the precise physical interpretation and explanation remains to be resolved, our objective (stimulated by the findings of Guillen and Palanques, 1993) has been to investigate and explain the possible relation between the above described bar behaviour and the duneface dynamics.

It is clear that the dune system and the bar system interact through the dynamic processes of the coastal area; they are both subject to the same wave and tidal forcings and, at same time, they are part of an interconnected system. We recall the fact that not only tides have clearly defined astronomic cycles with a periodicity ranging from hours to decades, but also wave climate has at least a seasonal cycle and, on a long term basis, longer cycles linked to climate oscillations. These are still active subjects of investigation; think for instance to the so-called Bruckner cycles, basically consisting of the recurrence in northwestern Europe of periods of cold and damp alternating with warm and dry years, the average interval between successive maxima being 34.8 years (as calculated by Bruckner in 1890), though individual cycles vary from 25 to 50 years. However there is an increasing evidence that, when looking at large scale and long term evolution of the coastal system, we need to highlight the long term character of the forcing factors.

Study area

Our study area is the Holland coast (Fig. 1), bounded by Rotterdam harbour and the port of Den Helder. It is characterized by an almost uninterrupted dune system, without barrier islands and tidal inlets. The main human interventions along this stretch of 120 km are the harbourmoles of Scheveningen and IJmuiden, the sea dike of Petten and the dike of Den Helder.

During the last three hundred years this coast is erosive in the north (approx. 1 m/yr), and the south (approx. 0.3 m/yr) and accretive in the centre (approx. 0.2 m/yr). Sediment grain sizes are 200 to 250 microns in the dunes and 250 to 300 microns on the beach. The tide ranges from 1.7 m near Scheveningen to 1.4 m near Den Helder. Mean wave heights and periods are 1.2 m and 5 s respectively, with approaches from south-west and north-northwest mainly.

Foredunes are regressive, stable or progressive over the last decades, with widths ranging from 500 to 2500 m. The subaerial beach averages 43 m in width, with a mean slope of 1:15 (Short, 1991). The bar-beach system commonly consists of a beach-bar, attached to the beach as a ridge and runnel system, an outer bar, highly rhythmic and rip-dominated and a longshore bar (Short, 1992). Their temporal and spatial behaviour has been analyzed by Wijnberg (1995). A common characteristic is that of a cyclic two or three bar system, initiated

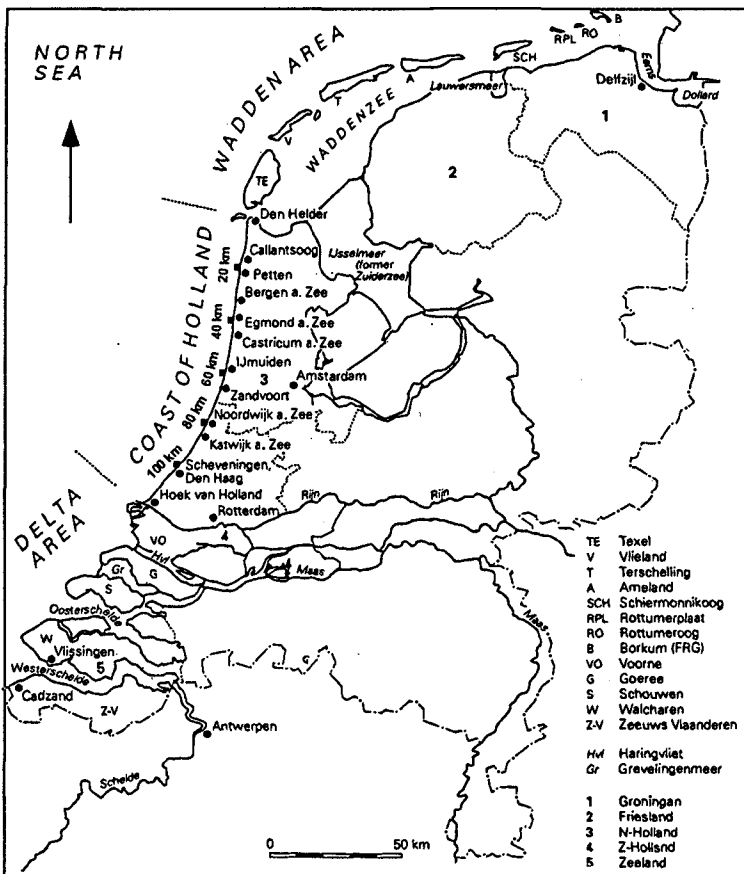

Figure 1 Study area

nearshore, migrating and growing through the surfzone and then decaying offshore. Apparent return periods range between 4 and 15 years.

Methodology

The medium-term dune, beach and nearshore profile evolutions were analyzed using the JARKUS data-set. It consists of (about 3,000) fixed measuring rays extending along the Dutch North Sea coast. The distance between the profiles is 200-250 m and yearly profiles approximately from the foredune to 1,000 m seaward are available since 1964. Profiles are usually surveyed between early April and late September. It is expected that the biased sampling does not affect a decadal analysis of the shapes of the profiles (Wijnberg and Terwindt, 1995).

Our morphometric analysis of the dune and beach system concerns first the determination of temporal and spatial oscillations on decadal scales in the dunefoot, and second the possible relation of this behaviour with the shoreface slope and the behaviour of bar and trough systems. Our parameters are the dunefoot position, the duneface slope and the beachface slope.

Qualitatively it is clear that the shoreface slope plays a fundamental role in the dynamics of the coastal system. Firstly, in the sense that in the steeper slope area, the bar system needs longer return period waves to be moved offshore. Second, in the steeper slope area, the dunefoot is subject to larger wave impact under storm conditions. In addition, residual tidal currents will determine a relatively larger speed of motion for the shallower part of the bar system with respect to the deeper part, which is a clear mechanism of introduction of a "structural modification" in the coastal system. If we consider two adjacent zones with different profile slope, this is clearly a mechanism for the introduction of a longshore mechanism of motion.

Following Wijnberg (1995) we distinguish four distinct spatial sectors (Fig. 1), viz. (I) km 8-20, (II) km 28-52, (III) km 63-95 and (IV) km 104-114. These sectors are bounded by structures, the Hondsbossche dike (km 23) and the harbours of IJmuiden (km 55) and Scheveningen (km 102), and have been found to exhibit a uniform bar behaviour within them. In our analysis we further concentrate on Zones (II) and (III), which contrary to (I) and (IV), are virtually without human interference.

Our initial effort has been to derive a representative duneface and dunefoot definition, such that it is not affected by local and instantaneous processes occurring immediately before the survey. A heuristic procedure, based on hydrodynamic and morphologic considerations, using two constant planar surfaces and a sediment volume balance was chosen (Fig. 2). By using this procedure the temporal changes in the calculated dunefoot position indicate the changes in the volume of sediment stored in the dune-beach system between +1 and +5 m NAP heights, allowing a comparison between all the profiles in a coherent way. The

choice of the +5 m NAP height as the upper boundary is based on the storm surge design level height for dune erosion in Holland.

Figure 2 Dunefoot definition procedure

In the analysis the dunefoot and nearshore profile evolution has been based on space-time diagrams. Linear temporal trends were calculated in each profile and the "residuals" with respect to this trend were extracted. This approach has been complemented by application of Empirical Orthogonal Function (EOF) analysis techniques, the presentation of which has been omitted here because of space limitations. We have used the EOF's to derive periodicities more clearly.

In analyzing possible effects of wave forcing we have used a time history of 1,090 "storm events" during the period 1979-1991 (De Valk, 1994). They have been characterized by two parameters, viz.

$$A = H_{m0} * \text{SQRT}(t), \text{ and}$$

$$B = SL * \text{SQRT}(t),$$

where H_{m0} is the average significant wave height during the storm event, SL the average surge level and t the duration of the storm event. Furtheron we have summed these parameters over the period in between soundings to account for the cumulative effect of storm events.

Results and analysis

Dunefoot data

Following our derivation of a morphologically equivalent and stable duneface profile, we find that the average maximum duneface slope is nearly

constant along the different zones ($\tan b = 0.14$ to 0.15). The average beach slope between the + 1 m NAP and the - 1 m NAP ranges from 0.025 to 0.030, implying a mean beachface width of 70 to 80 m.

The linear trend of the dunefoot position shows a high longshore variability (Fig. 3), but the average over several kilometres is less than 1 m/yr, while the accretional and erosional character is not very different from that over the last few hundred years. Standard deviations relative to the trend also show a high longshore variability (Fig. 4), while the average over several kilometres is between 5 and 10 m.

We now describe the behaviour of Zones II and III, showing a general erosive and accretive trend respectively, which are relatively untouched by human intervention.

The evolution of the residual dunefoot position in Zone II exhibits longshore and temporal oscillations (Fig. 5). Spatially, alternating accretional and erosional stretches of 2 to 3 km are observed alongshore. Temporally, this longshore rhythmicity may be viewed as a shoreline wave propagating towards the south with a propagation velocity of 150 to 200 m/yr. The amplitude of the oscillation is approximately 20 m and its periodicity 15 years.

In contrast the evolution in Zone III shows virtually no longshore oscillations (Fig. 6). Temporally, periods of relative accretion and erosion alternate simultaneously along the coast.

Figure 3 Trend in the dunefoot position (positive is seaward, negative is shoreward)

HOLLAND COAST, 1964-1992 PERIOD

Figure 4 Standard deviation of the dunefoot position

Figure 5 and 6 Residual dunefoot position relative to the trend for zones II and III respectively (dark shading is shoreward, grey shading is seaward)

Also, in spite of the above differences, inspection of Fig. 5 and 6 reveals some simultaneous occurrences of relative erosion and accretion. This may be more clear from Fig. 7, comparing the spatially averaged residual position over time in the two zones. Although our extreme event data only cover the period 1980 to 1991 (Fig 8), we note that we expect that these simultaneous occurrences are related to the decadal variation of the cumulative extreme events. For instance, the relative accretion between 1985 and 1988 appears to correspond to a relative minimum in the extreme events.

A preliminary analysis of the periodicity of the first empirical orthogonal function of the dunefoot position for the whole coast has also been performed. It consists of applying a simplified non-linear model as a reference concept. In practice the temporal evolution of the first and the second empirical orthogonal functions has been considered as determined by the sum of a linear (sinusoidal) term and two nonlinear terms related to the amplitude of the first one. Using empirical process-oriented considerations we assume that, under erosive conditions, the dunefoot is less mobile (composed by less mobile sediments), while under accretive conditions, the dunefoot is more mobile (composed by more mobile sediments). This way three fundamental periods have been identified: 51 years for the oscillation of the mean dunefoot position; 7.5 years for the oscillation of the dunefoot during erosive periods; 2 years for the oscillation of the dunefoot during the accretive periods. These results (see Figure 9) need to be further examined mainly because of the short duration of the dataset with respect to the longer period of oscillation. The results also need to be further examined with respect to the cycles in the forcing factors. We note that the dunefoot evolution is recovered by multiplying the "reconstructed" temporal orthogonal functions and the spatial temporal orthogonal functions. In case the results will be confirmed by further analyses, it is clear that, with a very simple modelling concept we are able to gain some predictive value.

Profile data

A main morphological feature of the profile along the Holland coast is the existence of migrating breaker bars. A comprehensive analysis of their behaviour was recently made by Wijnberg (1995), using EOF analysis. In each of the four coastal stretches the bar behaviour is found to be temporally and spatially different, but internally (i.e. within a particular stretch) coherent. The explanation of this is as yet undetermined.

Zone II and III both exhibit an offshore migratory behaviour of the bars. The average number of bars is constant in time, where the offshore decay of the outer bar is followed by the appearance of a new bar at the shoreline. The temporal behaviour is thus similar, only the recurrence frequency is different, viz. approximately 15 years in Zone II and 4 years in Zone III. Their spatial behaviour is significantly different, however. Whereas in Zone III the relative

Figure 7 Longshore-averaged mean dunefoot position versus time

Figure 8 Normalized year-cumulative storm event parameters

Figure 9 Normalized first temporal eigenfunction of the dunefoot displacement of all four zones (full line observed, grey line modelled)

position is homogenous alongshore, without any longshore rhythmicity, Zone II has two specific spatial features. First, at a large spatial scale, the bar migration is not in phase, exhibiting an obliquity relative to the shore. Apparently, the bar initiation first occurs in the south and this initiation propagates towards the north. The obliquity creates a discontinuity. Second, on a smaller spatial scale, longshore discontinuities (of a length of 2 to 3 km) in bar position exist, which are caused by the crescentic morphology of the bar systems here.

Discussion and conclusions

The standard deviation of the mean shoreline position has been termed beach mobility (Dolan et al., 1978). Short and Hesp (1982) found it to be a function of the morphodynamic beach state: dissipative, intermediate and reflective beaches correspond to low-moderate, moderate-high and low beach mobility respectively. On Australian shores beach mobility ranges between 5 and 14 m from data taken over 1 to 5 years. Shoreline mobility along the Holland coast, averaged over several km (as inferred from the + 1 m NAP depth contour) over the period 1964-1992 amounted to some 20 m, suggesting an increase of mobility over longer time scales. On the other hand, dunefoot mobility, such as defined here, is approximately half that of the shoreline. Apparently, the shoreline evolution exhibits more "noise" than that of the dunefoot. Further, it is noted that the dunefoot mobility on shorter time scales, e.g. due to extreme events, can be nearly an order-of-magnitude larger, i.e. 25 to 75 m of duneface retreat (Stetzel, 1993). While longer term erosive or accretive trends are relevant for long term nourishment policy, our findings of mobility are relevant to medium term (decadal) coastline management.

While the order-of-magnitude of dunefoot mobility has been found the same along the Holland coast, its spatial and temporal nature is quite different in the two, virtually unmanaged, Zones II and III. Our findings suggest that the dunefoot behaviour is strongly influenced by the subaqueous bar behaviour, confirming earlier suggestions by Bruun (1954).

In Zone III, both the dunefoot and the subaqueous bar behaviour behave spatially homogeneous alongshore. Erosional-accretive oscillations appear to correlate with the cumulative parameters describing the storm events.

The latter effect is also found in Zone II, but here most interestingly is the occurrence of the longshore rhythmicity and of the recurrence frequency. It exhibits spatially the same scale as that of the crescentic bar morphology (2 to 3 km) and temporally the same recurrence frequency as that of the migratory bar behaviour (15 yr). Clearly, there exists a strong signature of the bar dynamics in the shoreline and dunefoot behaviour.

A comparison of earlier observed temporal oscillations and -if present- their alongshore propagation speed is given in Table 1. We note the study of Verhagen (1989), who interpreted from long term shoreline observations the presence of 'sand waves' along the Holland coast, moving northwards.

Table 1. Observed shoreline oscillations

Our final conclusion is that our interpretation of shoreline mobility on decadal scales for the Holland coast indicates that the dunefoot, according to our definition, shows an oscillatory amplitude of some 20 m. It is quite moderate compared to other studies, and its behaviour is clearly related to the dynamics of bar behaviour on the one hand and to the cumulative effect of extreme wave events on the other hand.

CHAPTER 224

Morphological development of the Terschelling shoreface nourishment in response to hydrodynamic and sediment transport processes

Abstract

The Terschelling shoreface nourishment was studied over a period of about 2.5 years. The nourishment was originally designed to act as a feeder berm. Since its implementation, the nourishment has completely satisfied the design objectives. However, the nourishment only partly acts as a feeder berm and the actual success of the nourishment is also based on its breaker berm function. The creation of a wave shadow zone leads to an interception of part of the longshore drift and the development of a salient effect.

Introduction

The Dutch barrier island of Terschelling is part of the northern coastline of the Netherlands. The island is facing the North Sea and separates the North Sea from the backharrier system of the Wadden Sea (Fig. 1). The North coast of the island consists of a sandy shoreface, flanked by sandy beaches and dunes. In the last decades the central part of this coastline has chronically suffered from erosion. Over an alongshore distance of 5 km, the average annual coastal retreat was about 2-3 m/yr. This corresponds with an estimated, average annual loss of sand of 110.000 m³. In 1993 a shoreface nourishment was implemented along the Terschelling coast to stabilize the existing coastline. The main design objective of this nourishment was (and is) "to return the Transient Coastline to a position seaward of the Basal Coast Line (Dutch BKL concept; NOURTEC, 1995) and to ensure that this Transient Coast Line will not retreat landward of the Basal Coast Line during the next 8 years" (Biegel and Spanhoff, 1996). In terms of design dimensions in total 2.1 million m³ of sediment was involved and this sediment was supplied to the nearshore zone, filling up the trough between the middle and outer breaker bar (Fig. 1).

Figure 1. The North coast of the island of Terschelling with the study area. The beachpole (RSP)-line indicates the location of the cross-shore transects; the main measuring array is located in section 17

For the nourished zone, the amount of sediment supplied was equivalent to an average, vertical change in sea bed elevation of about 1 m and, in a longshore direction, the amount of nourished sediment per cross-section was in the order of 450 m³/m. The nourishment, with a total length of about 4.4 km and extending from km section 13.7 to 18.1 (Fig. 1), is located in the depth interval between -5 and -7 m below NAP (Dutch Ordnance Datum; the zero - NAP level approximately equals mean sea level).

In 1993 the EC-MAST2 programme NOURTEC was launched to study and explain the behaviour of shoreface nourishments in different European coastal environments (Hoekstra et al., 1994, Knaack et al, 1997 and Laustrup et al, 1997). The final objective of the NOURTEC programme is to study, determine and explain the feasibility, effectiveness and optimum design characteristics of shoreface nourishment techniques for different environmental conditions.

The basic assumption underlying the design and implementation of the Terschelling shoreface nourishment is that eventually sand will be carried to the shore. The nourishment is expected to act as a feeder berm. In case of a feeder berm there has to be a significant net onshore directed sediment transport due to the presence of the nourishment.

Apart from being a potential feeder berm, a shoreface nourishment may also start acting as an offshore located breaker berm or as a combination of these two features. A shoreface nourishment acting as a breaker berm is able to reduce the erosional power of the waves by increasing the degree of wave energy dissipation, in particular due to wave breaking. The nourishment creates a "wave-shadow zone" landward from the

nourishment which will locally reduce the strength of the wave-driven longshore current and the littoral drift.

This paper will focus on the developments at the Terschelling site in the first 30 months after the implementation of the nourishment. The aim of the present study is to analyse and evaluate the potential role as both a feeder berm and submerged breakwater. First of all, the bathymetric data set is used to determine the main morphological evolution in the nearshore zone and to compute changes in sediment volumes for specific horizontal and vertical control sections. The second way of addressing the problem is by analyzing the available process measurements and model computations on (suspended) sediment transport in the nearshore zone. It comprises an analysis of the dominant role of wave- and flow-driven processes in generating cross-shore (and landward-directed) and/or longshore fluxes of sediment.

Methods of research

Bathymetry

Bathymetric surveys were frequently carried out with varying time intervals and the total number of surveys until January 1996 is 12. After the nourishment the time interval varied from 53 to 182 days between two consecutive soundings. The surveyed area North of Terschelling covers approximately 25 km² and measurements were performed along survey lines perpendicular to the coast. Inside the nourished area the longshore spacing of these survey lines varied from 25 to 100 m; outside the nourished area the longshore spacing was about 200 m. The supra- and intertidal part of the cross-shore survey line, starting at the dunefoot, was done by leveling. The subtidal section until a depth of at least 10-12 m was measured by a Rijkswaterstaat survey vessel using a digital acoustic depth sounder (ATLAS DESO, 210 kHz), in combination with an accurate positioning system (Syledis and dGPS).

Hydrodynamics

The hydrodynamic field measuring programme of Terschelling consisted of two main activities: a long-term, continuously recording monitoring network and a series of process-oriented measuring campaigns (4). The monitoring network has been operational for about 2.5 years and almost all measurements were more or less concentrated around cross-sectional transect 17 (Fig. 1), covering the central part of the nourishment. Tidal water levels have been measured by a tide station, located in cross-section 14.60 and in a water depth of approximately 10 m. Every 10 minutes a mean value of the water level has been recorded. Offshore wave conditions were registered with a wave-directional buoy (WAVEC) positioned in the central measurement section in a water depth of about 15 m. The WAVEC measured continuously with a frequency of 1.28 Hz. Each block of 10 minutes was automatically processed using standard zero down-crossing and spectral methods. Information on the time-dependent variation in water levels (waves and tides) was also obtained from 2 measuring poles positioned in the surfzone (section 17.00; Fig.2). Both poles were equipped with a pressure transducer and a capacitance wire, measuring water levels for 40 minutes per hour with a frequency of 4 Hz. The fourth element of the monitoring network consisted of an instrumented tripod, equipped with 2 electro-magnetic flow meters at about 0.25 and 1.2 m. above the bed and with a pressure sensor. Occasionally, the tripod also carried two Optical Back Scatter (OBS) sensors to measure suspended sediment concentrations (0.15 and 0.25 m above the bed).

The instrumented tripod measured in a burst mode sampling scheme with a burst interval of one hour, a burst length of 2048 s. and a sampling frequency of 2 Hz. The tripod was located at the seaward margin of the nourishment, at a water depth of approximately 5.5 m.

During the process-oriented measuring campaigns the monitoring network was substantially expanded and consisted of the following configuration: 2 offshore located wave directional buoys, 6 instrumented tripods in the nearshore zone - including 3 tripods with OBS's - and 2 poles. Emphasis in the measuring programme was given to processes operating in a cross-shore direction and, consequently, a cross-shore array of instruments was installed in section 17 (Fig. 2). Four concentrated measuring campaigns were carried out in the period November 1993 until November 1995; each campaign lasted for approximately 5 to 6 weeks. Data calibration, validation and analysis is discussed in further detail by Houwman and Ruessink (1997) and Hoekstra et al (1996).

Hydrodynamic boundary conditions

Tidal conditions

Tides along the North coast of the island of Terschelling are semidiurnal and are characterized by a mixed micro- to mesotidal range. A maximum range of about 2.8 m is recorded at spring tide whereas the neap tide range is about 1.2 m. Associated tidal currents are basically flowing shore-parallel. The tidal flow during flood is in an ENE direction and the ebb tidal flow is directed towards the WSW. Especially at neap tide, the tidal ellipse is almost flat and rectilinear.

As expected, tidal flow is considerably modified by the presence of wind- and wave-driven currents (compare Whitford and Thornton, 1993). Earlier observations (Hoekstra et al., 1994) make clear that during moderate winds ($< 8 \text{ Bf}$) wind-driven flow has the same order of magnitude as the tidal flow. During storm and heavy storm conditions, the wind- and wave-driven longshore flow, in combination with cross-shore (mean) flow patterns, will even fully dominate the nearshore flow regime.

Wind and waves

The wind climate of Terschelling shows a clear predominance of westerly winds with a prevailing wind force of 4 to 5 Bf. In the period 1984-1994 the predominant wind direction for each year is in the sector between 210 and 300 degrees. This is more or less parallel to the coastline in the nourished zone (Kruyt, 1995). More than 12% of the total number of observations is in the sector 210-240 degrees. In addition, wind forces between 3 and 6 Bf make up 79% of the total number of observations in the data set. The year 1994, just following the nourishment, appears to be a year with a relatively large number of storms with a considerable duration (Kruyt, 1995).

The wave climate of Terschelling has been analysed by Van Beek (1995). Nearly 65% of the total number of wave observations is related to obliquely incident waves from the West to North (270-360 degrees; Fig. 3). The most energetic wave fields are incident from the NW to NNW. This almost coincides with a shore-normal direction (Fig. 3). The average annual significant wave height ($H_{1/3}$) and significant wave period ($T_{1/3}$) for 1994 are 1.08 m (st.dev. \pm 0.67 m) and 7.0 s (st.dev \pm 1.4 s), respectively. For only 2% of the total distribution, wave heights are higher than 3 m (Van Beek, 1995). However, as already mentioned before, in the first three months following the nourishment a number of significant storm events with high seas and swell have been recorded in the study area: November 15, 1993 ($H_{1/3}$ = 5.50 m; data correspond to peak of the storm), December 10, 1993 ($H_{1/3}$ = 5.50 m), December 20, 1993 ($H_{1/3}$ = 5.00 m), January 24, 1994 ($H_{1/3}$ = 4.25 m) and January 28-29, 1994 ($H_{1/3}$ = 8 m; all data based on WAVEC observations offshore).

Figure 3. Offshore wave climate for the coast of Terschelling

Morphological evolution and sediment volumes

Coastal behaviour prior to the nourishment

The natural behaviour of the nearshore zone before the nourishment was studied in detail by Ruessink and Kroon (1994). Herein, both the alongshore and cross-shore tendencies of especially the long-term evolution of the nearshore breaker bars was discussed. In particular, the (geometrical) properties and dynamics of these bars, like their position and depth, were documented in time from 1965 to 1993. With the results of this study, the following conclusions were obtained:

- The cross-shore behaviour of bars is strongly influenced by an alongshore migration of bar attachment-points. Migration rates of these attachment-points are highly variable and can be in the order of $1200 \text{ m}\cdot\text{year}^{-1}$.
- The cross-shore behaviour of a bar is schematized in *three phases*:
 1) generation close to the shore; 2) seaward migration from 300 to 1300 m offshore and 3) bar degeneration when the crest of the bar is at a depth of about -5.5 m NAP. There is a coupling mechanism involved: as soon as the outer bar disappears the inner is triggered, leaves phase 1 and enters phase 2.

This typical cyclic behaviour, also found along other parts of the Dutch coast (see for example Wijnberg, 1995), has a total period of about 12-15 years (Ruessink and Kroon, 1994).

Morphological response of the nourishment

The morphological behaviour of the nearshore zone in the post-nourishment conditions has been studied and reported by e.g. Kroon et al (1995) and Westlake (1995) and summarizing their results indicates the following trends (Hoekstra et al, 1996):

Figure 4. Morphological development of the cross-shore profile of section 17 after the nourishment

- the nearshore morphology inside and outside the nourished zone is becoming strongly 3-dimensional due to the presence of crescentic bars, the presence and migration of bar attachment points and drumstick-shaped nearshore breaker bars, separated by obliquely oriented rip channels. Such a pronounced development of a 3D morphological system has never been experienced in the past (Ruessink and Kroon, 1994);
- the disturbed bar-trough morphology caused by the nourishment is quickly adjusting itself and the former bar-trough pattern appears again (Fig. 4); the time of adjustment is rather short and the strongest response is visible in the first 150 days following the nourishment and the process slows down afterwards;
- the initial morphological response results in an extreme growth of the landward located middle bar and the adaptation of the profile is associated with a dominantly onshore movement of sediment (Fig.4);
- the western part of the nourishment is predominantly eroding whereas the eastern part shows accretion: the nourishment clearly migrates in an alongshore direction, towards the ENE (Fig. 1) at a variable rate of 280-320 m/yr (1994) or 400-420 m/yr (1995; Westlake, 1995).

As a matter of fact, (nourished) sediment is dominantly moving in an onshore and longshore (eastward) direction.

Sediment volumes

The consecutive bathymetric maps are now used in a more quantitative sense to identify areas of erosion and deposition and to compute the change in sediment volume in well-defined control sections. The computations have been reported previously by Westlake (1995). The selected control-sections are presented in Fig. 5 and are related to the nourished zone itself, areas landward and seaward of the nourishment and "reference" areas in both the East and West.

Figure 5. Control sections for volumetric computations of sediment budgets

The analysis of individual soundings occasionally shows the presence of systematic errors in the data sets and related bathymetric maps which may cause substantial inaccuracies in volume calculations. To reduce the effect of individual errors, results concerning the behaviour and effectiveness of the nourishment are based on the average linear trends in volumes, deduced from the total sequence of soundings, rather than the individual difference calculated for just two separate soundings (Westlake, 1995). In total, the nourished volume of sediment is about 2.0 million m^3 . In general it's rather difficult to assess whether there is an overall conservation of sediment volumes in the entire research area. For the most important sections though a number of trends are very consistent, as illustrated by Fig. 6. The nourishment area clearly shows erosion and the areas landward of the nourishment are definitely accreting. Remarkably though is the fact that the area landward of the nourishment is accreting at about twice the rate the nourishment is eroding. The nourished surface has lost about 560.000 m^3 of sediment. Part of this sediment - a conservative estimate is approximately 100.000 m^3 - is related to the alongshore migration of the nourishment. Meanwhile though, landward of the nourished zone a total gain of about 1.1 million m^3 of sediment is observed. And even if potential survey errors are taken into account, the order of magnitude of the difference suggests that the landward gain of sediment is not simply explained by a cross-shore redistribution of sediment. Significant longshore sediment transport gradients have to exist as well.

Figure 6. Cumulative sediment volumes for the nourished zone and the section landward of the nourishment

The frequent occurrence of storms and heavy storms in the period after the nourishment is predominantly held responsible for the relative rapid evolution of the nourished profiles and sediment volumes. This rapid response of the nearshore morphology is probably not fully representative for average conditions along the Terschelling coast.

The onshore directed redistribution of sediment certainly implies that the Terschelling shoreface nourishment has satisfied the design objective: the momentary or yearly computed coastline is estimated to have migrated seaward over a distance of about 16 m/yr (Biegel and Spanhoff, 1996). This totally reverses and exceeds the assumed retreat over the same period which should have been approximately 3 m/yr.

Based on the results of the present analysis, the Terschelling shoreface nourishment *only partly acts as a feeder berm*. Approximately 40% of the total gain of sediment in the inner nearshore can be explained by direct losses in the nourished zone. The success of the nourishment is not simply the result of the onshore movement of sediment from the nourishment. Accretionary processes in relation to longshore sediment transport gradients are probably equally important.

Cross-shore sediment transport processes

The partially, onshore-directed movement of sediment from the feeder berm has to be the result of cross-shore sediment transport processes. The transport study carried out in the framework of the Terschelling shoreface nourishment has focussed on both the dominant processes as well as dominant conditions that are mainly responsible for the onshore-directed fluxes of sediment. In this sediment transport analysis (Houwman and Ruessink, 1997) four main issues are addressed:

- 1) the contribution of oscillating and mean suspended transport to the net suspended transport;
- 2) the relative importance of high- and low-frequency suspended transport to the total oscillating suspended transport;
- 3) the ratio between bedload and suspended load;
- 4) the transport conditions under which most sediment is transported on the time scale of months to years.

Sediment transport measurements carried out in October and November 1995 (T4 campaign) at location F3 (Fig. 2) are selected to illustrate a number of features. Location F3 is one of the most interesting positions with respect to the hydrodynamic and sediment transport processes affecting the behaviour of the nourishment.

Some additional information is given here (Houwman and Ruessink, 1997):

- time series of u (cross-shore), v (longshore) and c (concentration) were divided in a mean and oscillating part; the net cross-shore suspended sediment transport, for example, is given by:

$$\langle u \cdot c \rangle = \langle \bar{u} \cdot \bar{c} \rangle + \langle u' \cdot c' \rangle$$

The net suspended sediment transport (left hand side) is based on the transport by mean currents (first term right hand side) and the oscillating transport (e.g the effect of wave asymmetry; 2nd term on the right). A positive cross-shore and longshore transport is onshore and eastward directed, respectively;

- the oscillating term is sub-divided into a high- and low-frequency part; the separation frequency between both was set to 0.04 Hz;
- cross-spectral analysis was applied to yield information about phase and coherence between u' and c' as a function of frequency.

Figure 7. Cross-shore sediment fluxes measured at tripod F3 at 0.15 m above the bed (T4 campaign): high- and low-frequency ($f < 0.04$ Hz) fluxes and mean fluxes, respectively

Burst-averaged values (burst: measuring series of 34 minutes per hour with a sampling frequency of 2 Hz) of the high- and low-frequency oscillating fluxes in a cross-shore direction and at a height of 0.15 m above the bed are plotted in Fig. 7 as a function of local relative wave height ($Hm0/h$). The factor $Hm0/h$ accounts for both variations in wave climate as well as (tide-induced) fluctuations in water depth. Non-zero fluxes only occurred for $Hm0/h$ larger than about 0.30-0.35, in other words, during situations that were just outside, or inside the surfzone. High-frequency fluxes were in an onshore direction and were associated with the horizontal asymmetry of the incident short waves, i.e. the difference in magnitude between onshore and offshore orbital velocity. Low-frequency fluxes were seaward directed and were caused by the dominance of bound long waves in the total long wave field (Ruessink, 1996). For this sensor height, the low-frequency sediment flux was only about 16% of the high-frequency one, averaged over the entire campaign.

Burst-averaged values of the mean flux for the T4 campaign are shown in Fig.7 as well, again as a function of relative wave height $Hm0/h$. The largest fluxes, which were in a seaward direction, occurred for situations with the ratio $Hm0/h$ above 0.3-0.35. This indicates that these negative fluxes were associated with wave-driven undertows. The mean flux was larger than the total oscillating flux (i.e. the sum of high- and low-frequency flux) averaged over the entire campaign. Consequently, the net flux was in an offshore direction. In addition, it is also clear that the (high-frequency) oscillating fluxes can not be neglected.

To estimate the long-term bedload and suspended load transport in the surfzone, the sediment transport is calculated with the Bailard model (Bailard, 1981) and the adapted Van Rijn/Ribberink model (Van Rijn, 1993). The suspended load component of the Van Rijn model does not include the oscillating suspended load transport. For that reason, Houwman and Ruessink (1997) incorporated an oscillating suspended load term in the model in a parameterized way.

Summarizing all measurements and modelling results (Houwman and Ruessink, 1997) it becomes obvious that the measured and computed cross-shore sediment transport fluxes (for Terscheling) are reasonably related to a dimensionless wave height ($Hm0/h$). This term can also be interpreted as a breaker coefficient and it turns out that sediment fluxes increase with $Hm0/h$. By making use of a probability density function for the term $Hm0/h$, it appears that the suspended sediment transport on a time scale of months to years is typically related to breaking wave conditions ($Hm0/h > 0.33$); in other words is limited to situations inside the surfzone. It also supports the view that the relative rapid

evolution of the Terschelling shoreface nourishment is partly related to the frequent occurrence of storms in the period just following the nourishment.

Both measurements and modelling efforts also demonstrate that wave asymmetry is primarily responsible for the potential onshore movement of sediment; this sediment is mainly transported as suspended load by the oscillating flow related to seas and swell (high-frequency oscillating suspended load). Bedload, according to results obtained with the Van Rijn/Ribberink model, is of lesser importance.

However, the actual fate of the feeder berm is determined by a delicate balance of offshore directed mean fluxes and onshore directed oscillating fluxes. Paradoxically, in these conditions the contribution of some minor transport components, such as bedload and the effect of low-frequency waves, may eventually explain the success or failure of the nourishment. It's clear though that there is no significant and consistent net landward directed sediment transport in the nearshore zone. Therefore, it's not surprising that only part of the nourished sediment is moving in an onshore direction.

The observations make clear that it's not realistic to come up with a proper and reliable sediment balance for the area, based on sediment transport measurements and model computations.

Longshore sediment transport processes

Breaker berm and longshore sediment transport

The classic concept of a feeder berm is the idea that a cross-shore redistribution of sediment is mainly responsible for nourishing the upper part of the profile. Meanwhile, for the Terschelling coast, it's becoming quite evident that longshore processes are expected to be equally important. This is, for example, illustrated by the computations of sediment budgets inside and landward of the nourished zone, the longshore migration of the nourishment and the potential breaker berm function of the combination shoreface nourishment/nearshore breaker bar.

The breaker berm function is evaluated by using the UNIBEST-TC model. UNIBEST-TC is a morphodynamic coastal profile model (Roelvink et al, 1996). Application of the model required quite a lot of validation and calibration runs. During this process the model was further modified by using Terschelling data. Results of wave decay were obtained with the UNIBEST-TC model after considerable tuning of the model for wave heights using the breaker index (H/h) and the bottom friction factor f_w (Bakker, 1995 and Roelvink et al, 1996).

Model computations were carried out using measurements and conditions observed during the T2 campaign (May-June, 1994). The morphological boundary conditions are presented in Fig. 4. For all computations it is clear, that there commonly is a gradual reduction in wave heights across the seaward side of the profile and over the nourished zone. The wave dissipation is primarily due to bottom friction. A rapid decay in wave heights, though, is observed across the landward located middle bar (Fig. 1 and 4; Hoekstra et al, 1996). Here, wave breaking is the prime reason for a rapid decay in wave heights. In the landward located trough the wave field propagates without any major modifications. The model simulations definitely indicate that the design of the present shoreface nourishment not necessarily leads to an increase in wave energy dissipation: it is essentially the interaction of the shoreface nourishment with the nearshore breaker bars (Fig. 4) that is effective in reducing the landward propagating wave energy. Indirectly nourishing the middle bar is considered to be an effective method to construct or maintain

a natural breaker berm.

The longshore transport module of the UNIBEST-TC model is further applied to study to what extent longshore sediment transport rates and gradients in these rates are initially affected

by the presence of the nourishment. The influence of the nourishment on longshore sediment transport patterns was determined by computing the cumulative longshore transports for a profile with (T1-condition) and without (T0-condition) a nourishment (Fig. 8). The measured wave climate for approximately the first 160 days since the implementation of the nourishment was used as input for the model, in combination with the recorded (tidal) water levels. The effect of tidal currents, however, was omitted. Every 3 hours a longshore transport computation was carried out; results are given in Fig. 8.

Figure 8. Cross-shore distribution of cumulative longshore sediment transport for conditions with and without a nourishment and for a period of about 160 days just following the nourishment

The net longshore sediment transport in the nearshore zone is predominantly towards the East (compare Fig. 3). Going from West to East - or from a non-nourished profile to a nourished one - longshore sediment transport in the trough is smaller than on the nourishment (Fig. 8). As a result, the West side of the nourishment will be eroding.

Sediment transport on the middle bar, by contrast, will be lower upon entering the nourished zone, which creates accretion on top of the bar (Fig. 8). On the nourished surface no transport gradients are expected to develop due to the longshore uniformity. On the downdrift side, however, longshore sediment transport patterns change again. The sediment transport on the nourished surface is larger than in the trough and the trough is gradually filled up with sediment. Simultaneously, the top of the middle bar shows erosion. The net effect is a gradual longshore migration of the nourishment towards the East, as observed for the Terschelling case.

The leeside deposition on the updrift side of the nourishment or breaker berm is commonly referred to as the salient effect. It probably partly explains the fact that the accretion in the cross-shore profiles landward of the nourished zone may exceed the losses from the nourishment. A salient is also frequently associated with erosion at a downdrift section of the coast. For the time being, no clear erosional patterns have developed yet.

In conclusion, longshore sediment transport gradients are important for understanding the behaviour of the nourishment. These gradients are responsible for the longshore migration of the nourishment and they can also partly explain the additional input of sediment in the inner nearshore zone.

Conclusions

The Terschelling shoreface nourishment has completely satisfied the design objectives in the first 2.5 years since the implementation. The nourishment not only compensates for the annual coastal retreat of about 3m/yr, but results in a net seaward migration of the momentary or yearly computed coastline of about 16 m/yr. The nourishment only partly acts as a feeder berm and the actual success of the nourishment is also based on the "interception" of longshore sediment transport due to the creation of a wave shadow zone and the salient effect. The combination of middle bar and shoreface nourishment effectively acts as a breaker berm.

Wave asymmetry is primarily responsible for the potential onshore movement of (nourished) sediment. This sediment is mainly transported in the form of a high-frequency oscillating suspended flux due to seas and swell. Bedload transport is of minor importance. In addition, the long-term suspended sediment transport from the nourished zone into an onshore direction is mainly related to breaking wave conditions ($H_m0/h > 0.33$). The net cross-shore suspended load flux, however, is determined by a very sensitive balance of two large components: a large offshore directed mean suspended flux due to currents is opposed by a large onshore directed oscillating flux due to waves. In these conditions the contributions of some minor transport components, such as bedload and the oscillating flux due to low-frequency waves, may eventually determine the behaviour of the nourishment.

CHAPTER 225

JUSTIFICATION FOR BEACH NOURISHMENT

by John G. Housley, PE, M.ASCE ¹

ABSTRACT

Sand balance of the littoral system determines whether erosion or recession will occur. Adding sand to the system is the only engineered way to restore the balance and prevent erosion or recession. Justification of beach nourishment as a shore protection measure depends on the benefits criteria used in the analysis, and societal goals will decide the criteria.

INTRODUCTION

Mankind, in its love affair with the coast, has often encroached on sandy areas which are basically unstable - at least as far as lines on a map are concerned. Sandy coasts are particularly attractive as recreation sites, and in the last half century they have been the target of intensive development. In the United States, about 50 percent of the population lives within 30 miles of a coast. Erosion of those shores has become a national concern.

THE EROSION PROBLEM

Sand is in constant motion along the shores of this country due to waves, currents, and wind. As long as the sand leaving a stretch of beach is balanced by the same quantity of sand arriving on the beach, there is no erosion or recession. But if the balance is not maintained (either by the arriving sand being interrupted by a structure such as a jetty or by a lack of sand on the updrift beach), erosion/recession will result.

When the user of a beach wants to construct some fixed structure in the immediate vicinity, such as a road or a house, then, if the shoreline moves in the direction of the fixed structure, that is called a problem.

¹Coastal Engineering Consultant, Michael Baker Corporation, Alexandria, VA 22304

There are three basic responses to an erosion threat: reduce the hazard, adjust human use, or accept the cost. Only the first one is amenable to an engineering approach; the others are either management options or the do-nothing alternative with its attendant increased costs. To reduce the hazard, the choices are to modify the physical process or to reduce the impact. From an engineering viewpoint, it is usual to pursue some combination of those hazard-reduction options.

A BEACH NOURISHMENT SOLUTION

For developed coasts, the serious problem of coastal erosion is caused by a deficit of sand in the littoral system. Adding sand to the system (beach nourishment) is the only engineering solution that remedies the basic problem. All other potential engineering solutions (groins, seawalls, breakwaters, etc.) may stop the erosion at a particular point, but the deficit of sand in the littoral system will cause erosion to occur at some other location. And the cost of mitigation of those adverse effects is one of the strong reasons for a beach nourishment approach.

When sand is first installed as part of a beach nourishment project, it is placed on the existing beach to raise it to a higher elevation and to widen the dry beach in the seaward direction; the seaward face is thus on a steep slope. The filling procedure is dictated by the least total cost of the operation. If the fill is made from the land side, say by truck haul, then the trucks dump near the waters edge and continually push that edge seaward. If the fill is by hydraulic dredge, then the pipes are positioned so that the effluent moves the edge of the fill seaward. If the fill is by offshore mounding, a split-hull hopper dredge or barge is maneuvered as close to shore as the draft of the vessel will allow, and the fill is placed in shallow water so that waves will move the sand toward the shore.

When first placed, the sand slope in the water is not at the equilibrium slope. As waves work on that slope, the sand tends toward the equilibrium position, that is, a slope which is stable under the wave regime present. Since the waves are not of constant height, period, or direction, each wave climate tries to put the beach slope in an equilibrium position for that instant. Seconds later, the regime has changed, thus the process of equilibration is continuous.

So as the sand pile is reshaped by waves, some of the dry beach sand is moved into the water to provide the material for a flatter equilibrium slope. And the perception that the beach was "lost" comes to those who only consider the subaerial beach. Without the subaqueous beach, surely the beach *is* lost.

BENEFITS

The recent study by a blue-ribbon committee of the Marine Board of the National Research Council found that, when used in appropriate situations, beach nourishment does indeed become a cost-effective measure to combat the effects of coastal erosion. The key is to determine what are the appropriate situations for the use of beach nourishment. First, a determination must be made of the benefits to be derived from such a project. Those benefits are not only in terms of dollars of increased revenues and decreased losses, but also social and environmental benefits. The costs associated with the project are not only the planning, design, construction, and maintenance costs, but also the social and environmental costs.

In an effort to stem what many consider unwise development on pristine shores in this country, the Coastal Barrier Resources Act precludes (with some exceptions) the federal government from expending funds on undeveloped coastal barriers. For developed shores, the rules for U.S. federal participation in shore protection projects are quite explicit about how and how much benefits can be claimed. The benefits in the category of storm damage reduction must be at least one half the costs of design and construction. After that benefit requirement is fulfilled, other benefits (such as recreation) can be added to bring the total benefits up to something greater than the total costs. However, these are not all the benefits that should be considered.

Justification usually has the connotation of financial break-even or better. Justification on the national, state, local, or personal levels uses different yardsticks and different elements of measure. Measures that would justify a project on the local level may not be counted on the national level, since benefit gains in one region may be offset by losses in another. And on the personal level, hard to quantify aesthetics may be the most important element for some people. And for environmentalists, the fill material as habitat for birds, turtles, and other creatures may be the important elements.

One of the major benefits not considered in beach nourishment cases involving federal participation are those benefits outside the project boundaries caused by sand being transported to property beyond those boundaries. In the recreation benefit category, the benefit to the non-federal sponsor is usually far greater than that allowable under U.S. federal rules. Those rules require the benefits to be national economic development (NED) benefits, but the local entities realize benefits in addition to NED benefits. An often overlooked cost is a navigation project that causes a sediment deficit in the littoral system by trapping sand in the channels and harbor areas, or in ebb-tide deltas that effectively divert sand away from a beach area.

CONSTRAINTS

The major problem with beach nourishment is not technical, but perception. The person who views a beach nourishment project has a certain expectation from that project. If it is a property owner in the vicinity, he looks for protection. If it is visitor, he looks for a recreation site. And if it is a taxpayer from a distant location, he looks for a return on his investment.

Beach nourishment mimics what nature does, so that sand is not held in one place but is allowed to move under the influence of the waves and current. Although beach nourishment is not appropriate for all locations, it is the preferred option in many problem areas. A beach nourishment project is sacrificial; that is, it is designed so that sand is removed from the beach rather than buildings being removed from the backshore. Sand replenishment restores the beach to the design dimensions upon which the benefits are derived, and if the project is well designed, constructed, and maintained, and if there is the political and financial will to continue the periodic renourishment program, the benefits will continue to accrue. While hard structures (groins, seawalls, etc.) require a large, up-front, construction-cost investment, beach nourishment involves a smaller, periodic expenditure for construction over the life of the project. In almost all cases, the benefits of beach nourishment outweigh those of hard structures.

It was once said that anyone could build a bridge, but it took an engineer to build one economically. The same can be said for beach fills.

Beach nourishment projects need to use state-of-the-art engineering principles, which includes a thorough understanding of shore processes. It is not enough that an adequate supply of sand is available to a project for it to be successful; there must also be an understanding of the goals of the project and the criteria for success. If the public does not understand how success is measured, and that beach nourishment is meant to be sacrificial, then when some of the subaerial beach is lost during a storm, the project may be labeled a failure, even when much of the sand is returned to the dry beach by natural processes in a few months, and the engineer has expected those results.

So beach nourishment (or renourishment) is the preferred solution to the sand deficit problem. To properly engineer the sand fill, the characteristics of the native sand and the proposed fill material must be known, as well as the forces acting on it, i.e., waves, current, wind, etc.

A recent (1995) legislative proposal by the Clinton administration would redefine the US Army Corps of Engineers' (the federal agency charged with

shore protection) mission as "nationally significant missions." If enacted, the cost sharing for federally-funded water resources projects would change to 25/75 (federal/non-federal), and the benefit/cost ratio would be at least 2. Federal participation in storm damage reduction projects would be eliminated on the basis that these projects are local (not national or interstate), and should be paid for by non-federal dollars. As of the date of this paper, the proposal has been rejected by the Congress, but the administration is using the budget process to put shore protection in a low priority position.

CONCLUSION

The expense of a nourishment program (initial plus subsequent re-nourishments) is not inconsequential. However, the loss of property during storms and loss of revenue from tourism on a neglected beach can be much greater.

ABSTRACT

The problem of coastal erosion in Russia became especially urgent in 50th-60th during the extensive river damming, taking place mainly in the regions valuable for society. To prevent erosion, which spanned thousands of kilometres of new shoreline different shore protection techniques were used, including hard structures, shoreface and beach nourishment as well as hybrid methods. Most if not all of these techniques were previously applied on Novosibirsk Reservoir, one of the first Russian large man-made lakes. Long-term observations of structures state and recent studying of response of the coastal environment on the projects emplacing testify the greater efficiency of coastal stabilization by beach nourishment programs and hybrid structures.

INTRODUCTION

Novosibirsk Reservoir was created in Western Siberia in 1956 when the Ob River was dammed ca. 20 km upstream the city of Novosibirsk (latitude 55° N, longitude 83° E). It is a freezing reservoir which ice season lasts about 180-190 days from November till April or May. Like many man-made lakes seasonal changes in water level of Novosibirsk Reservoir occur because of the river flow fluctuations; they reach more than 5 m/yr in amplitude and include: (i) Water level rise in May-June: mean duration - ca. 50 at a rate of ca. 0.1 m per day, (ii) Water level stabilization: mean duration - ca. 120 days, and (iii) Water level subsidence in October-April: mean duration - ca. 195 days at a rate of ca. 0.02 m per day.

The fetch of Novosibirsk Reservoir is 220 km from northeast to southwest up to town of Kamen-on-Ob, its minimal, mean, and maximum width are 2, 10,

¹ Institute for Water and Environmental Problems, Siberian Branch of the Russian Academy of Sciences, 105, Papanintsev Street, 656099, Barnaul, Russia; e-mail: khabidov@iwep.altai.su

³ Scientific and Research Center of Marine Coasts; 1, Jan Fabritsius St., 354002 Sochy, Russia

and 22 km, respectively, water plane area is 1070 km², depth is up to 25 m, total storage is 8.8 km³, effective storage is 4.4 km³, and shoreline length is 550 km.

The principle basin morphometries of Novosibirsk Reservoir are: a shallow area in the south-western edge of the lake basin under fetch of about 60 km, an area of transitional depths, and a deep-water area with typical depths exceeding the average reservoir depth in the north-eastern part of the lake basin under fetch of 100-120 km. These areas correspond to main types of dynamical relief-forming and depositional sedimentary environments of the lake basin, namely: the deltaic/fluvial-dominated environment, the wave-dominated one with significant influence of the channel flows, and wave-dominated environment itself.

The wave heights are among the most significant features of dynamic relief-forming and depositional sedimentary environments of the reservoir. Within delta-like environment wave heights do not exceed 0.5 m even under severe storm. As for transitional zone the waves of up to 1.5-1.7 m height occur, while the waves of more than 3.5 m were observed in deep water area.

High rate of erosion of Novosibirsk reservoir coasts is primarily caused by wave. Two more factors contribute to erosion. First, the reservoir coasts are formed mainly of loose and soft grounds - sands, sandy loam, and loss-like loam. Second, like natural lakes and other man-made lakes, its beach berms are narrow or even absent at all. That is why the mean erosion rate reaches here 7-10 m/yr and more and the extension of eroding shores makes up 350 km.

Coastal erosion caused the most serious problems in wave-dominated area of Novosibirsk Reservoir. It is precisely here where the coast protection started before the reservoir filling. At present more than 40 km of its coasts have been protected already. As this takes place different shore protection techniques, including hard structures, shoreface and beach nourishment as well as hybrid methods were used.

Long-term observations of structures state showed considerably different reliability and effectiveness of hard structures, filled natural and artificial beaches as well as hybrid projects which combine a shoreface and/or beach nourishment with stabilization of sand by breakwaters, groins, artificial headlands, etc.

Recent studying of response of the coastal environment on the different projects emplacing allowed to reveal some causes of these phenomena.

METHODS

The work on the project began from the studying of data on long-term visual and tool supervision of seawalls, bulkheads, revetments, filled natural and artificial beaches as well as other coastal engineering sites of Novosibirsk Reservoir. This allowed to determine the key sites for special investigations. These investigations include repeated topographic surveys, continuous meteorological observations, synchronized with measurements of waves and studies of swash interactions by wire gauges, measurement of nearshore currents by omni-directional and two-component impeller current meters, measurement of bedload and suspended sediment concentration by *in-citu* samplers, sand tracers movement observations and piezometric studies of beach groundwater interactions.

For comprehensive evaluation of the affect of protective measures on coastal environment, all observations are conducted not only on the coastal engineering sites, but on the upcoast and downcoast areas as well. Investigations on the key sites started a year ago. In this connection only the preliminary results of the observations are presented here.

BEACH MORPHOLOGY AND NEARSHORE PROCESSES NEAR A SEAWALL

As development increases along the shoreline and property is lost, engineers, developers as well as planners need quantitative descriptions and models of how coastal processes affect the shoreline (Dean, 1987) and how the projects, emplaced to protect the threatened structures, affect the surrounding coastal environment. In recent years, many of the investigations were devoted to the studying of the nearshore processes near a seawall and the resultant beach morphology under marine conditions (Kraus, 1988; Tait and Griggs, 1990; Plant and Griggs, 1992, and others). The definite severity of the environment occur at the man-made lakes, because of the long-term water level fluctuations from weeks to months.

Just as the seawalls, so bulkheads and revetments were built at the Novosibirsk Reservoir; as this took place, the first hard structure was emplaced before its initial filling. The concrete curved-face seawalls, concrete combination inclined and curved-face seawalls and rubble-mound seawalls as well as concrete and rubble-mound revetments had common occurrence at the reservoir. Since 1956 more than 25 km of the seawalls were built here, but only about 12 km still persist to date.

For an understanding of the reasons of improper operation and destroying of the structures, beach morphology and nearshore processes were studied near seawalls of several types. The noted effects were both seasonal and long-term ones. According to observations, in the case typical for natural and man-made lakes, when a seawall is placed on the water edge or near it, and the adjacent beaches have a narrow berm or have not it at all, these effects are: (a) the bottom erosion rate increases after the seawall construction and on the fronting beach and its value is always higher than on the adjacent beaches without structures, (b) the bottom erosion in front of seawall before erosion on the protected beaches, (c) the coastal erosion increasing downcoast of seawalls. Near the seawall placed at the backshore, the erosion of beach berm in front of the structure had arised before equivalent erosion on the flanked beaches, because the erosion increses with the reflectivity of the seawall and the mobility of the fronting beach as the result of altering of the pattern of groundwater flux.

That is why, though under such sea-wall position the beach slows down the scour at the toe and ends of the structure, however as the result of the berm erosion the final response of the coastal environment will be equivalent to the first case.

In this manuscript the attention is focused on the effect of the nearshore currents on beach processes near a seawall that protrude into the surf zone. Dean (1976), Berkemeir (1980), and McDougal et al, (1987) noted, that structures of such type can effect longshore currents; trap sand upcurrent of wall and, perhaps, induce scour in front and downcoast of the seawall. However, the

observations, conducted by Plant and Griggs (1992) in Monterey Bay, did not reveal this effect neatly.

The study site on Novosibirsk Reservoir consisted of a gently curving shorelines and a 350 m concrete combination inclined and curved-face seawall flanked by the continuous natural beaches at the upcoast and a 200 m beach at the downcoast. The flanked beaches, all backed by 3-5 m escarpment, had the berm the slope of which is 1:35, the width from 3-5 m (downcoast) up to 10 m (upcoast) and initial bottom slope was of order 1:25. The seawall protrude into the surf zone by 2:1 sloping revetment at its toe. The present investigation involved the pre-storm, storm, and post-storm beach surveys to capture morphological changes as well as measurement of the longshore and cross-shore currents at 10 cm level above the bottom in front of the seawall and in the flanked beaches. The storm surveys were carried out under the waves of Hsig 0.5 m, 1.2 m, and 2.3 m; the angle between wave crest and shoreline varied from 35° to 42° in all three events.

The beach surveys in the upcoast, seawall-backed, and downcoast sections of the site showed that the behavior of morphological changes within these sections differs greatly. Total losses of the bottom sediment per one metre of the shoreline made up 0.15, 2.75, and 4.25 m³ within the upcoast section, 1.00, 5.14, and 8.00 m³ within the seawall-backed section and 2.5, 4.25, and 6.25 m³ for the 1st, 2nd, and 3rd storm events, respectively (Table 1).

Table 1.

Beach profile changes near the seawall and on the flanked beaches under different storm events

Beach profile area	Storm event	Net total volumetric changes in beach erosion and sediment accretion, m ³		
		Upcoast section	Seawall-backed section	Downcoast section
Beach Berm	1	+120	-	-150
Breaker Zone	1	-850	-1650	-1000
Offshore	1	+700	+1300	+1000
Beach Berm	2	-350	-	-450
Breaker Zone	2	-1500	-3900	-1900
Offshore	2	+1300	+2100	+1500
Beach Berm	3	-500	-	-650
Breaker Zone	3	-2450	-6700	-3400
Offshore	3	+2100	+3900	+2800

Note. Sign <+> corresponds to accretion, sign <-> corresponds to erosion

Measurements of the nearshore currents during the storms in the front of seawall and on the flanked natural beaches correlate with beach surveys data, and to all appearances, explain the observed morphological changes. The absolute values of time-averaged longshore and cross-shore current velocities at the seawall-backed and downcoast sections of the study site were higher

than the current velocities within the upcoast beach during the steady stage of all the storms (Table 2). Alongside, it is hard to state, that the observed rather higher rates of the nearshore currents at the downcoast beach are directly related to hydrodynamic processes in front of the seawall. It is stipulated by the fact that under small width of beach berm at the downcoast section, the backed cliff can induce nearshore processes, in principal similar to the processes caused by the seawall.

Table 2.

The range of the absolut values of time-averaged longshore (V) and cross-shore current (U) velocities near the seawall and on the flanked beaches during the steady stage of storms

Beach profile area	Storm event	Longshore and cross-shore current velocities, m/s

V				
U		<0.10	<0.10	<0.10

Notes. 1) Time averaging interval by hardware is of 30 sec.
2) Time of continuous measurement is of 5 hours for all the storm events.

Visual observations of the seawall reliability started immediately after construction of Novosibirsk Reservoir. During the period of observation the most typical were the cases of seawalls destroy during several years or decades. At this time some events were noted, when the wall was completely destroyed under a prolonged severe storm with Hsig exceeding 3-3.5 m or under series of 2-3 such storms.

The survey of the walls destroyed showed that the main reasons of their destruction were not the construction failures but a scour at the toe and ends of the structures. No doubt, the scour was caused not only by the nearshore currents, but by wave reflection from a seawall, and the effect of groundwaters as well. However, in all cases of wall breakdown on the reservoir nearshore currents appeared to be of a prime consideration.

COASTAL ENVIRONMENT RESPONSE TO BEACH NOURISHMENT AND EMPLACING OF HYBRID PROJECTS

The first event of seawall damage on Novosibirsk Reservoir occurred in 1959 near the Novosibirsk Academic Center. This wall was constructed in an effort to protect the shore site associated with federal highway and railway as well. Thus at this site renovation of shore defence, wherein the combined shoreface and beach nourishment were used for the first time in Russia, began.

At Novosibirsk Academic Center stretching 3 km alongshore, approximately 5,000,000 m³ of sand have been nourished during three years. The constructed open artificial beach was located within the curved shoreline site where the longshore transport rate is not more than 20,000-25,000 m³/yr. Owing to appropriate location the beach provided a powerful shore protection for 25 years without renourishment.

In spite of reasonable results of shore protection by beach nourishment, this technology became widely used on Novosibirsk Reservoir only at the end of 70th . At present there are more than 7 km of the open artificial beaches on the man-made lake.

The continuous monitoring of the beach morphology changes showed that under the environmental conditions of Novosibirsk Reservoir the equilibrium beach profile has shapes of several years. The process of profile formation usually begins from intensification of beach face erosion and is followed by cross-shore sediment transport. Superimposed terrace is formed in consequence of the sediment accretion at the outer border of the beach profile. As development progress of the profile the terrace edge is shifting to the seaward direction and the beach profile becomes level out. When two-three years elapse the terrace edge position has become fairly stable and the longshore sediment transport begins to dominate among the nearshore processes (Table 3). It seems likely that profile formation is completed.

The occurrence of abnormal conditions with erosion of the accretive terrace at the outer border of the beach is mainly stipulated by severe storms effects during the lake's water level subsidence in autumn or water level rise in spring. It resulted in increasing of bottom slope (Table 3), that finally brought to intensification of berm beach erosion, cross-shore sediment transport and decreasing of longshore sediment rate.

Table 3.

Temporal morphological changes and prevailing trends in the nearshore processes on the nourished beach near the Novosibirsk Academic Center

Year	Total amount of the sediment losses			Total amount of the sediment accretion		Observed trends of the sediment transport
	Beach berm, m ³	Nearshore, m ³	Outer border of the beach, m ³	Near-shore, m ³	Outer border of the beach, m ³	
1	-82,000	-63,000	-	+21,000	+110,000	Cross-shore
2	-81,500	-52,000	-	+24,000	+97,000	Cross-shore
3	-78,000	-51,000	-	+54,000	+64,000	Cross-shore
4	-49,300	-51,000	- 5,000	+53,000	+35,000	Longshore
5	-46,500	-52,000	-35,000	+70,000	+15,000	Longshore
6	-54,500	-63,000	-	+38,000	+73,000	Cross-shore
7	-48,000	-54,000	-11,000	+49,000	+42,000	No clear trend
8	-46,700	-52,000	-27,000	+61,000	+21,000	Longshore
9	-39,200	-47,000	-	+34,000	+45,000	Cross-shore
10	-45,000	-54,000	- 4,000	+51,000	+34,000	Longshore
11	-40,500	-51,000	-31,000	+54,000	+19,000	Longshore
12	-46,100	-55,000	-23,000	+62,000	+20,000	Longshore
13	-59,200	-64,000	-16,000	+55,000	+49,000	No clear trend
14	-35,000	-40,000	-10,000	+54,000	+11,000	Longshore
15	-40,300	-53,000	-21,000	+59,000	+20,000	Longshore
16	-42,500	-55,000	-37,000	+53,000	+23,000	Longshore
17	-46,100	-57,000	-	+40,000	+47,000	Cross-shore
18	-45,400	-58,000	-9,000	+57,000	+25,000	Longshore
19	-45,500	-54,000	-10,000	+64,000	+18,000	Longshore
20	-53,000	-65,000	-23,000	+65,000	+30,000	Longshore
21	-62,500	-78,000	- 7,000	+68,000	+47,000	Longshore
22	-63,000	-83,000	-10,000	+64,000	+58,000	No clear trend
23	-70,300	-81,000	-14,000	+68,000	+62,000	No clear trend
24	-69,000	-86,000	-15,000	+71,000	+65,000	No clear trend

Within the wave-dominated region of Novosibirsk Reservoir the net longshore transport rate at the open shores varies from 25,000 m³/yr to 150,000-200,000 m³/yr. In term of this, the priorities in policy of beach nourishment are established as following:

1. Initial beach nourishment and periodic replenishment after ten and more years existence of protective beach.
2. The accomplishment of hybrid projects, which combine beach nourishment with the use of isolated groins, breakwaters or their systems.

Practically all attempts to prevent erosion along the Novosibirsk Reservoir shores by beach nourishment and hybrid structures were rather successful and these projects offer numerous benefits. Firstly, unlike the seawall and similar hard structures the main part of nourishment-based projects are in good condition (Table 4). Secondly, groin systems and/or detached breakwaters retain the desired shape of beach berm. Thirdly, the longshore transport of borrow material from filled beaches allowed tangibly to mitigate the coastal erosion at downcoast areas and the costs on shore protection were reduced by virtue of this phenomenon.

Table 4.

General results of the Novosibirsk Reservoir shore protection

Shore Protection Type	Length km	Modern condition		
		Destroyed km	Indamage, km	In good condition, km
Seawalls and similar hard structures	11.88	5.51	4.50	1.87
Beach nourishment	7.50	–	0.50	7.00
Hybrid projects:				
protective beach + groins	9.00	–	1.50	7.50
protective beach + segmented breakwaters	5.20	–	1.20	4.00
protective beach + segmented breakwaters + groins	3.30	–	–	3.30
protective beach + artificial headlands	5.00	–	–	5.00

CONCLUSION

Preliminary data based on over one year of observations provide some information that can assist in future efforts to mitigate shoreline erosion. The construction of hard structures like seawalls under a man-made lake's environmental conditions marked by strong storms and long-term water level fluctuations had failed measure. This type of shore protection structure presumably will be admissible only in case of feeder beach creation on the upcoast area.

Beach nourishment and fulfilling of hybrid projects are considered to be the most efficient ones. There are numerous benefits providing these measures, among which are the significant mitigation of the shoreline erosion, fair reliability, and improvement of coastal environment on adjacent shore sites. It resulted in serious changes in shore protection policy in Russia, because Novosibirsk Reservoir is a study site for a full-scale testing of various ideas in applied coastal engineering.

ACKNOWLEDGEMENTS

The portion of this research was conducted under the support of Russian Foundation of Basic Research, the project # 96-05-64448.

CHAPTER 227

COMPARISON OF BEACH AND SHOREFACE NOURISHMENT TORSMINDE TANGE, DENMARK

Christian Lastrup¹, Holger Toxvig Madsen², Per Sørensen³, Ida Brøker⁴

Abstract

Within the framework of the EU-sponsored programme Marine Science and Technology (MAST), a full-scale test was implemented in 1993 in Denmark, Germany and the Netherlands with the aim of evaluating the use of shoreface nourishment.

In this paper the background, the set-up and the results of the Danish part of the NOUR-TEC project are presented.

1. Introduction

Nourishment has been used by the Danish Coastal Authority (DCA) on the Danish North Sea coast since 1974. The volume of sand has been gradually increased and has now reached a level of about 3 mill. m³/year distributed along 150 km of the coast. Most of the nourishment has been beach nourishment but shoreface nourishment has also been used occasionally.

There has always been and there still is a considerable difference in the unit price of the two ways to protect the coast. The inevitable question is therefore which nourishment method has the best benefit/cost ratio.

Qualitatively, the following relative advantages are seen for the two nourishment methods:

Beach nourishment

– gives a better dune foot protection

1) Deputy Director, Danish Coastal Authority, Box 100, 7620 Lemvig, Denmark

2) Chief Engineer, Danish Coastal Authority, Box 100, 7620 Lemvig, Denmark

3) Project Engineer, Danish Coastal Authority, Box 100, 7620 Lemvig, Denmark

4) Chief Engineer, Danish Hydraulic Institute, Agern Allé 5, 2970 Hørsholm, Denmark

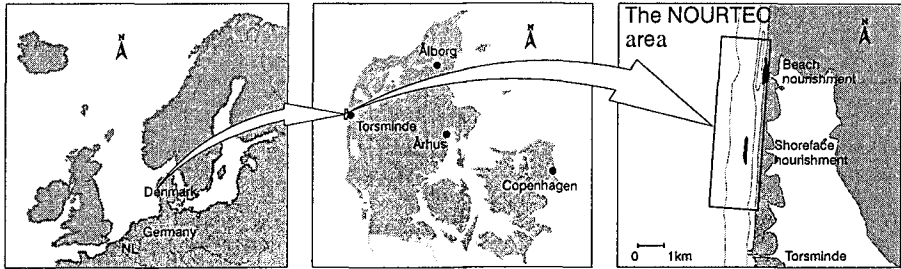

Fig. 1 Nourtec site, Torsminde Tange.

- gives a more well-defined local effect within the problem area
- is politically more attractive because a direct result of the nourishment can easily be seen

Shoreface nourishment

- is about 30% cheaper per m^3
- can be carried out without machinery on the beach
- is applicable to small nourishment projects because the mobilization costs are low

However, to our knowledge no quantitative methods exist which can be used to make a rational choice in the design situation. The design has been based on experience and on the use of rules of thumb.

The Danish Coastal Authority therefore decided to initiate a full-scale test on beach and shoreface nourishment, see Fig. 1. Together with similar projects in the Netherlands and Germany, the Danish project constitutes the NourTEC project.

2. Research questions

In the planning and design of the test nourishment projects, the three NourTEC partners agreed upon the following general design objectives [Niemeyer et al. 1995]:

- stabilization of the coastline
- coastal protection
- widening of the beach

Each of the design objectives is evaluated in terms of a corresponding design parameter, see section 4.2. The evaluation should end up giving the answers to these research questions:

- Does the nourishment fulfil the design objectives?

- What is the relative effect of the two nourishment projects? Here the benefit/cost ratio should be included.
- What is the importance of the grain size of the nourishment sand?

Besides, the project should give an improved understanding of the morphological changes induced by placing large volumes of sand in a coastal environment.

3. Experimental set-up

3.1 Test site description

Torsminde Tange is a 300 – 500 m wide barrier located north and south of Torsminde on the North Sea coast of Denmark, see Fig. 1. The barrier is a sand dune system on a clay layer. The top of the dunes is at +8 m DNN (Danish normal zero). The top of the clay layer is found at approximately –4 m DNN along the beach. The beach is 100 m wide and consists of sediment ranging from fine sand to pebbles. The beach slope is 1:20. A 2 – 3 bar system is found offshore and the sediment D_{50} range is from 0.3 to 0.8 mm. The closure depth is at –16 m DNN. The depth contours are straight and parallel to the coastline and the profile slope is 1:100. The average coastal retreat is 2.6 m/year.

3.2 Nourishment and survey programme

The shoreface nourishment is located on the outside of the outer bar in the southern sector and the beach nourishment is located from the dune foot to the shoreline in the northern sector. The nourishment volume in both nourishment projects was 250,000 m³ of sand distributed with 250 m³/m. Each of the stretches was 1 km long and 2 km apart from each other. The D_{50} of the beach nourishment sediment was 0.32 mm while the D_{50} of the shoreface nourishment was 0.57 mm. A red fluorescent tracer was mixed with the shoreface nourishment in a ratio of 1:100,000. Similarly, a blue tracer was mixed into the beach nourishment [Madsen et al. 1995].

The survey area is 7 km long and 1.5 km wide located symmetrically around the nourishment projects. The survey lines span from dune top to –12 m DNN with a mutual spacing of 100 m giving a total of 70 survey lines. A single beam echo sounder was used to survey the bathymetry and GPS was used to survey the topography and the zone from 0 to –2 m DNN. The survey accuracy was 0.04 m. A total of 17 survey campaigns were carried out during the 2–year *NOURTEC* period.

In every fifth of the survey lines 9 – 10 sediment samples were taken by hand on the beach and by a Van Veen grab offshore in predefined positions. All samples were sieved and analysed for content of tracer grains.

3.3 Boundary conditions

The water level is recorded at a groyne at Torsminde and at a groyne 5 km north of the survey area once every 15 min. The tidal range is 0.6 m and the 100 year water level

is 3.40 m DNN. Wind speed and direction are recorded at Torsminde once every 15 min. Wind from the north west is dominant and the 100-year wind speed is 33 m/s. Wave height and direction are recorded by a waverider just north of the survey area at 18 m depth. Wave characteristics have also been recorded by a current meter, at first placed at 14 m depth just seaward of the NOURTEC area. Later it was placed at 4 m depth on the shoreface nourishment. Waves were recorded once every 3 hours. The dominant deep water waves come from NW and the 100-year significant wave height is 8.1 m. Current has been measured at the above described locations once every 15 min. At both locations the current meter was placed 1 m above the bottom. At 14 m depth the dominant current is the tidal current with an amplitude of 0.2 m/s. At 4 m depth the current is also significantly influenced by waves but still the tidal current is dominant.

4. Effectiveness analysis

4.1 Introduction

The surveys showed that the beach nourishment was eroded after about 3/4 year while the shoreface nourishment only lost about 40% of its volume in the whole monitoring period. The morphological description and interpretation of the development in the monitoring area is presented in section 6.

Here the results are presented of a strictly mechanistic method to analyse the survey data. This so-called effectiveness analysis gives objective results easy to compare with the results produced by the other two partners in the NOURTEC project.

The analysis is based on the use of a number of common design parameters. The parameters are calculated for each bathymetry and the development of the parameters is compared to the estimated development of the parameters in the absence of the nourishment projects. The difference between this so-called autonomous development and the actual development represents the net effect of the nourishment. Here it is assumed that the autonomous development and the nourishment effect can be superimposed.

4.2 Definition of the design parameters

In section 2, the general design objectives were presented. Each of these objectives is evaluated by means of one of the following three common design parameters:

- position of the coastline
- position of the upper part of the profile
- beach width

In Fig. 2 it is shown how the design parameters are calculated. Apart from the “beach width” the parameters are calculated on the basis of a volume divided by the height of the zone used in the volume calculation. The result is a horizontal distance to the reference line. The level DNN +4 m is considered to be representative of the beach level at the dune foot.

Fig. 2 Definition of the common design parameters.

4.3 The autonomous development

For practical reasons it was not possible to estimate the autonomous development in the monitoring area for the NOURTEC period 1993 – 95 from the development of a nearby reference stretch. So instead, historical data were used.

The wind rose for the monitoring period 1993 – 95 is nearly identical to the wind rose for the period 1985 – 92. This indicates that the meteorological boundary conditions are about the same for the two periods. On this basis it was decided to calculate the design parameters for the period 1985 – 92 and consider the slope of the corresponding trend lines as good estimates for the autonomous development in the monitoring period.

4.4 Results

The effect of the nourishment projects can be calculated for any section along the coast. Here it has been chosen to show the results for 3 km stretches located symmetrically around the two project areas. The reason for this choice is that the analyses have shown that the effect of the nourishment projects is not limited to the nourished 1 km stretches themselves.

The development of the three design parameters for the southern and the northern 3 km stretches is shown in Fig. 3. The autonomous development is shown as well.

From the figure it appears that in the 2-year monitoring period the beach nourishment stabilizes the coastline and improves the coastal protection level. On the other hand, the beach width has not been improved. For the shoreface nourishment there is a positive net effect on all three design parameters. Hence, the shoreface nourishment has fulfilled all the design objectives.

Quantitatively speaking the shoreface nourishment has an effect on the coastal stability of 10.4 m or 250,000 m³ for the 3 km stretch while the similar effect of the beach nourishment is 2.8 m or 67,000 m³. The effect on the coastal protection is 9.0 m or 189,000 m³ for the 3 km stretch for the shoreface nourishment and 5.4 m or 113,000 m³ for the beach nourishment.

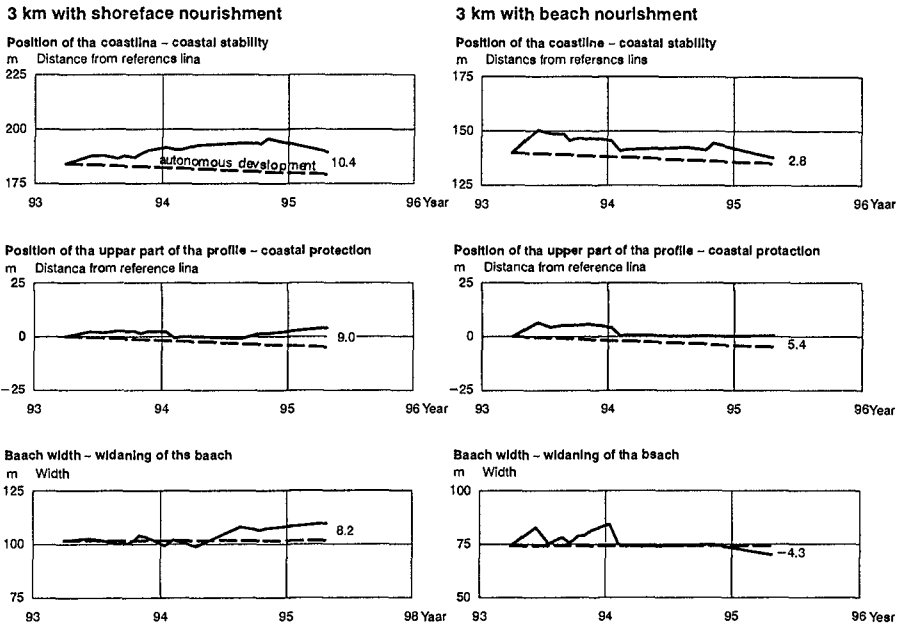

Fig. 3 Nourishment effect on the design parameters.

A direct comparison of the two nourishment projects is shown in Fig. 4. It appears that the shoreface nourishment gives the better stabilization of the coastline over the whole period. However, in the first 3/4 year the beach nourishment is the more effective. Concerning coastal protection the shoreface nourishment is the better option. Again the beach nourishment is the better option at the beginning of the period. For the beach width the result is similar. At the beginning, the beach nourishment is better but over the whole period the shoreface nourishment ends up being better.

Also in Fig. 4 the benefit/cost ratios are shown for the effect of the nourishment projects. Because it is about 30% cheaper to nourish on the shoreface than on the beach, the better relative effect of the shoreface nourishment mentioned before is increased when the costs are included in the evaluation.

5. Modelling

The 1-dimensional numerical model LITPACK and a 2-dimensional numerical model MIKE 21 have been used. Both models have been developed by the Danish Hydraulic Institute. The purpose of using the models is to analyse the effect of using coarse sand in the shoreface nourishment and to extrapolate the results to other boundary conditions.

5.1 1-dimensional modelling

LITPACK has been used to calculate the longshore sediment transport during the entire NOURTEC period and the results have been used in the calibration of MIKE 21. The

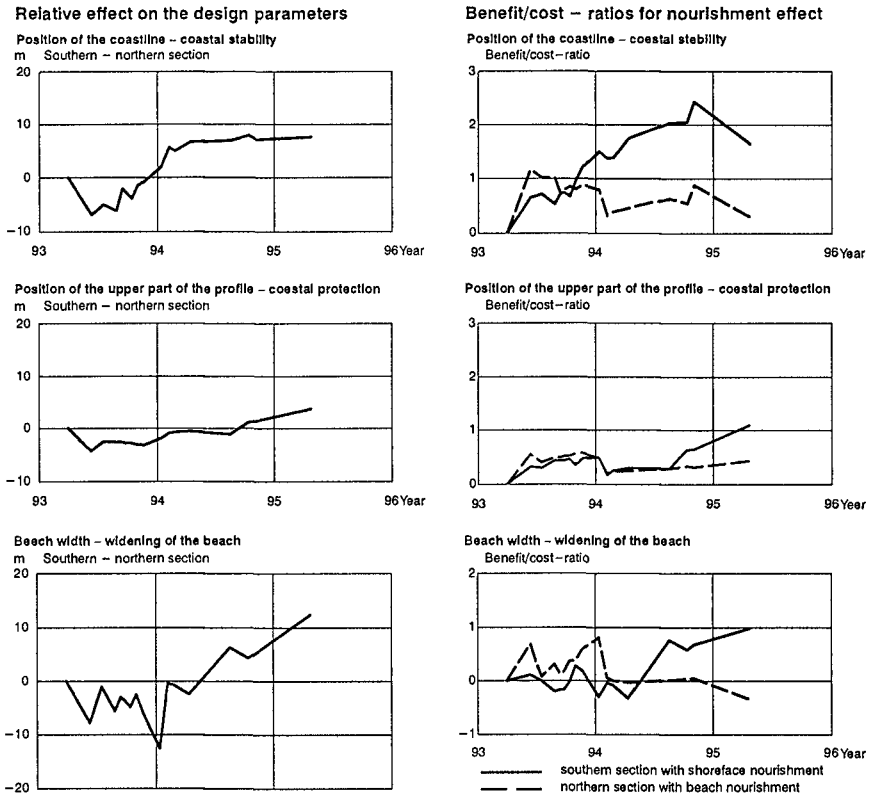

Fig. 4 Relative effect of the two nourishment methods and benefit/cost ratios for the nourishment effect.

nourishment projects are included in the two areas S(horeface nourishment) and B(each nourishment), see Fig. 5. For each area there is one survey line on both sides of the nourishment and 3 lines which include the nourishment.

First, LITPACK was calibrated to the annual littoral drift. The annual littoral drift has been calculated by accumulating the profile erosion from the nodal point for the littoral drift to the NOURTEC area by using three different approaches. Based on these calculations the south-going net littoral drift was estimated to be in the interval of 550,000 – 850,000 m³/year. Secondly, LITPACK was calibrated to the measured volume changes in the areas S and B in the entire NOURTEC period, including the variation intervals due to survey inaccuracy.

In LITPACK, uniformity of the coastal profiles is a basic assumption. The applicability of LITPACK for quantification of erosion/accretion along a coastline depends entirely on the fulfillment of this assumption. This assumption was not completely met, which

was confirmed by the 2-dimensional modelling, and must be taken into account when the results are analysed.

In Fig. 5 the results of the calibration are shown. It appears that the calibration is good for the area S and less good for the area B but still within the variation intervals which are given by the measured data. The problems with area B are caused by an extremely large erosion that took place during the winter of 1994 – 95 outside the beach nourishment.

Fig. 5 Calibration and validation of LITPACK.

After the calibration, the model set-up has been verified for the two halves of the monitoring period, each about 1 year long. The results are also shown in Fig. 5. Again good agreement is seen for area S and for area B, less agreement is seen for the second half of the period. Although the results have not been quite perfect, the model set-up is assumed to be calibrated and validated as far as possible and the model set-up can be used in a descriptive and prognostic mode.

The cross-shore distribution of the longshore sediment transport in the NOURTEC period has been analysed and it is found to be very sensitive to the local shape of the shoreface nourishment on the outer bar. A decrease in the water depth above the nourishment causes extensive wave breaking and hence increased sediment transport on the bar and decreased transport near the coastline. The sediment transport distribution is not particularly affected by the the beach nourishment because only a small part of the nourishment is under influence of waves.

For both the shoreface and the beach nourishment area it is found that during the NOURTEC period waves with a significant wave height of 1 to 2 m cause most of the sediment transport and the net sediment transport direction is southward.

In order to quantify the effect of nourishment sediment characteristics on the sediment transport, the dependence of D_{50} is analysed. For the shoreface nourishment $D_{50} = 0.57$ mm and for the beach nourishment $D_{50} = 0.32$ mm. It is done by averaging the longshore sediment transport for the NOURTEC period in each of the areas S and B for each D_{50} . For the shoreface nourishment the ratio between $D_{50} = 0.32$ mm and $D_{50} = 0.57$ mm was found to be 2.3. Similarly for the beach nourishment, the ratio was found to be 1.2.

5.2 2-dimensional modelling

MIKE 21 is a 2-dimensional modelling complex. In the present case a parametrised wind wave model, a depth integrated hydrodynamic model and a deterministic, intra wave period sediment transport have been applied. The intention of using MIKE 21 is to calibrate the model so that it will reproduce the sediment transport in the NOURTEC period.

The simulated conditions had to be limited to 3 wave heights and corresponding water levels, 2 wave directions, 3 bathymetries and 4 different types of sediments due to computer time consumption and with that the costs. The wave heights are chosen from knowledge gained in the LITPACK study about which waves are significant for the sediment transport. Wave directions from south- and northwest were chosen as a minimum. Both are 40° off the coast normal. As a minimum, a bathymetry taken prior to the nourishing, one describing a "summer" bathymetry and one describing a "winter" bathymetry were chosen. Finally, the sediment range from natural sand to the coarse shoreface nourishment sand was described by the D_{50} parameter. The same sediment spreading was used to reduce the number of variables. These parameters were combined in 18 sets of data, each set representing a typical combination of boundary conditions.

The 2-dimensional modelling complex consists of a large wind wave model with a resolution of 20 by 100 m, which gives boundary conditions to the local model area. Here the resolution of the wave modelling is 4 by 20 m. The resolution of the hydrodynamic and sediment transport model is 20 by 20 m.

The results show that even small morphological changes are reflected in the sediment transport pattern so it was difficult to distinguish between the sediment transport caused by natural variations and the sediment transport caused by the nourishment volumes. An attempt has been made to eliminate all other changes but the ones caused by the nourishments by integrating the longshore transport in depth intervals of +4 m to -4 m ("coastline") and of -4 m to -8 m ("6 m depth"). It was found that the changes introduced by the nourishments are nearly insignificant compared to the natural variations both in space and time.

Fig. 6 shows examples of sediment transport fields calculated for 3 different bathymetries. Here the 2-dimensional effect of the nourishments are clearly seen. The longshore sediment transport components have been integrated within the intervals "coastline" and "6 m depth". The calculated integrated sediment transport rates are compared for a) the bathymetry just before nourishment and the "before nourishment bathymetry" supplemented with the "after nourishment bathymetry" within the area S and B, and b) for a "summer" bathymetry and a "winter" bathymetry.

Another result was that of migrating bed forms on deep water (15 – 20 m) influence the direction of the incoming waves and effect the longshore sediment transport. The effect is most pronounced in the most seaward part of the NOURTEC area.

The effect on the integrated longshore transport of using coarse sand for the shoreface nourishment was calculated. For the shoreface nourishment the ratio between the longshore sediment transport rates for $D_{50} = 0.32$ and 0.57 mm was found to be 1.17. Similarly for the beach nourishment, the ratio was found to be 1.11.

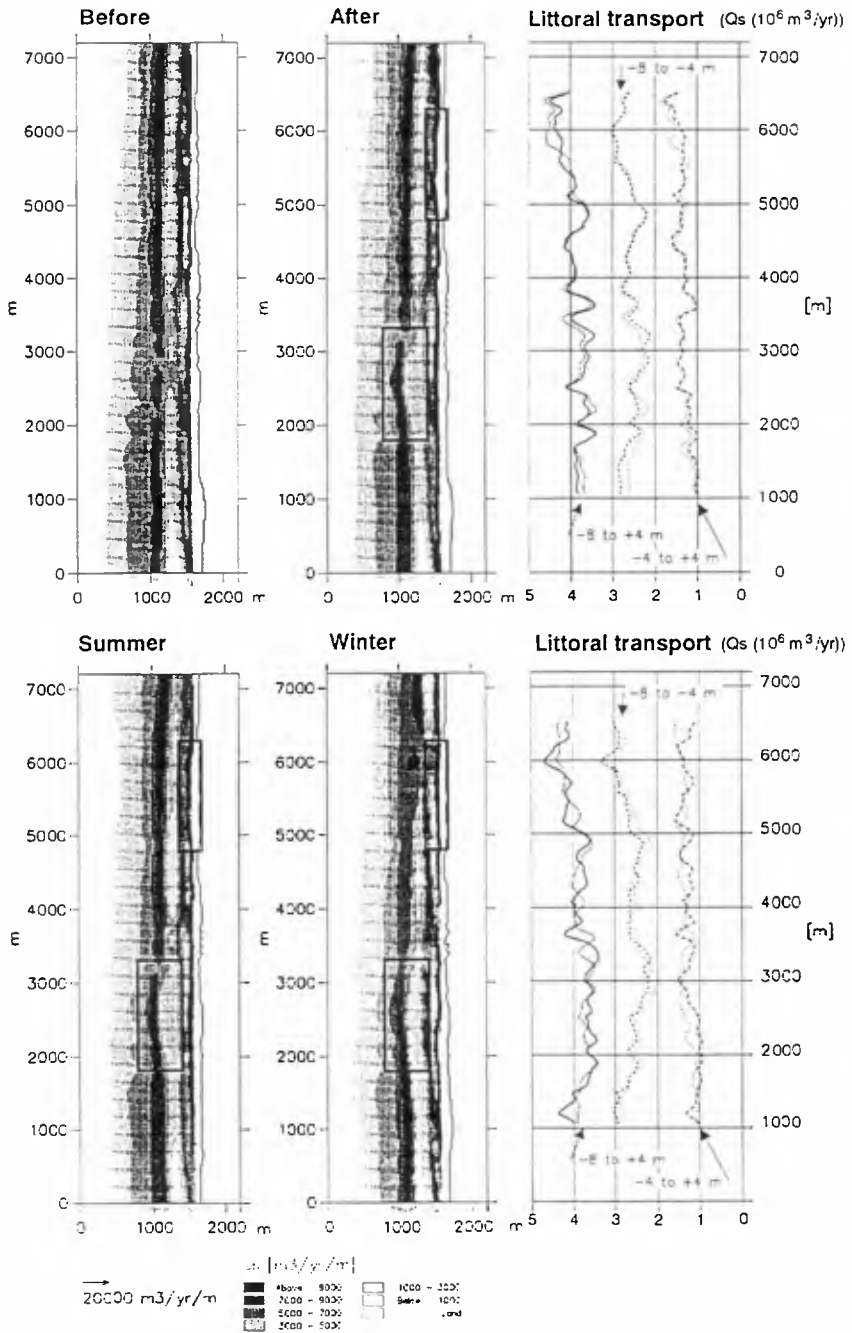

Fig. 6 Calculated, 2-dimensional sediment transport fields and integrated longshore sediment transport components for the intervals +4 m to -4 m, and -4 m to -8 m.

Finally, attempts were made to combine the MIKE 21 calculated volume changes in a system of 12 boxes by which the Nourtec area is described to reproduce the development in the Nourtec period. The longshore sediment transport variation with wave direction calculated by LITPACK was used to extrapolate the volume changes. The morphological changes were taken into account by using the "summer" or "winter" bathymetry. Fig. 7 shows the MIKE 21 weighted and measured accretion in 1 km long boxes. In 3 of the 6 boxes good agreement is seen but poor agreement is seen in the other boxes.

Fig. 7 Weighted Mike 21 and Measured volumes from south to north.

6. Morphological analysis

The volume changes in the monitoring area have been analysed by use of a system of cells with fixed horizontal boundaries. For each cell the volume development has been calculated.

In Fig. 8 the system of cells is shown together with the volume curves for selected cells and combinations of cells. The shoreface nourishment is located in cell H. For this cell there is a volume increase just after completion of the nourishment. From here the volume is stable with some fluctuations. In the cells A–B–C landward the shoreface nourishment there is a gradual volume increase over the whole monitoring period. For the beach nourishment in cell E a gradual volume decrease is seen over the monitoring period. After about 3/4 year the beach nourishment has been eroded. Tracer results indicate that part of this sand migrates towards south in the coastline zone.

Although the volume is constant in cell H, some morphological changes are seen. Over the monitoring period the nourishment migrates about 50 m onshore and the level of the top of the nourishment is reduced by about 0.5 m.

In Fig. 9 an overview is given of the horizontal development of the bar system. Just south of the shoreface nourishment the bar becomes continuous shortly after completion of the nourishment, probably because of the surplus of sand transported on the bar at the nourishment. It can also be seen that a weakening starts after a year at the northern end of the nourishment. Corings in the nourishment area show that about 60% of the nourishment sand is still in the initial position at the end of the monitoring period.

The 40% loss of the nourishment sand is only about 1/3 of the total accretion landward of the nourishment. It means that the accretion effect of the shoreface nourishment is

Fig. 8 Volume development in selected cells.

much larger than the nourishment volume itself. The reason is the breakwater effect of the nourishment. Like a breakwater, the nourishment reduces the longshore transport landward with an accretion as result.

An interesting result of this project is the better stability of the shoreface nourishment compared to the beach nourishment. Part of the explanation of this fact is the coarser sand in the shoreface nourishment. However, a reason which is even as important is the specific position of the shoreface nourishment. The position in the bar zone is a natural position for a perturbation so to say. Therefore the nourishment quickly becomes an integrated part of the bar system instead of being eroded away.

Outside the monitoring area migrating bed forms have been observed. However, it has not been possible to verify if the bed forms cause a longshore variation in the sand transport from the outer to the inner part of the profile.

7. Conclusions

The effects of a beach nourishment and a shoreface nourishment have been analysed and compared. Because the weather conditions in the monitoring period were about average, the results are considered to be valid for average weather conditions.

By use of a mechanistic analysis approach it has been determined if the nourishment projects fulfil three design objectives: stabilization of the coastline, coastal protection and widening of the beach. It was found that the beach nourishment stabilizes the coastline and improves the coastal protection but the beach width has not been improved. On the other hand, the shoreface nourishment fulfils all the design objectives.

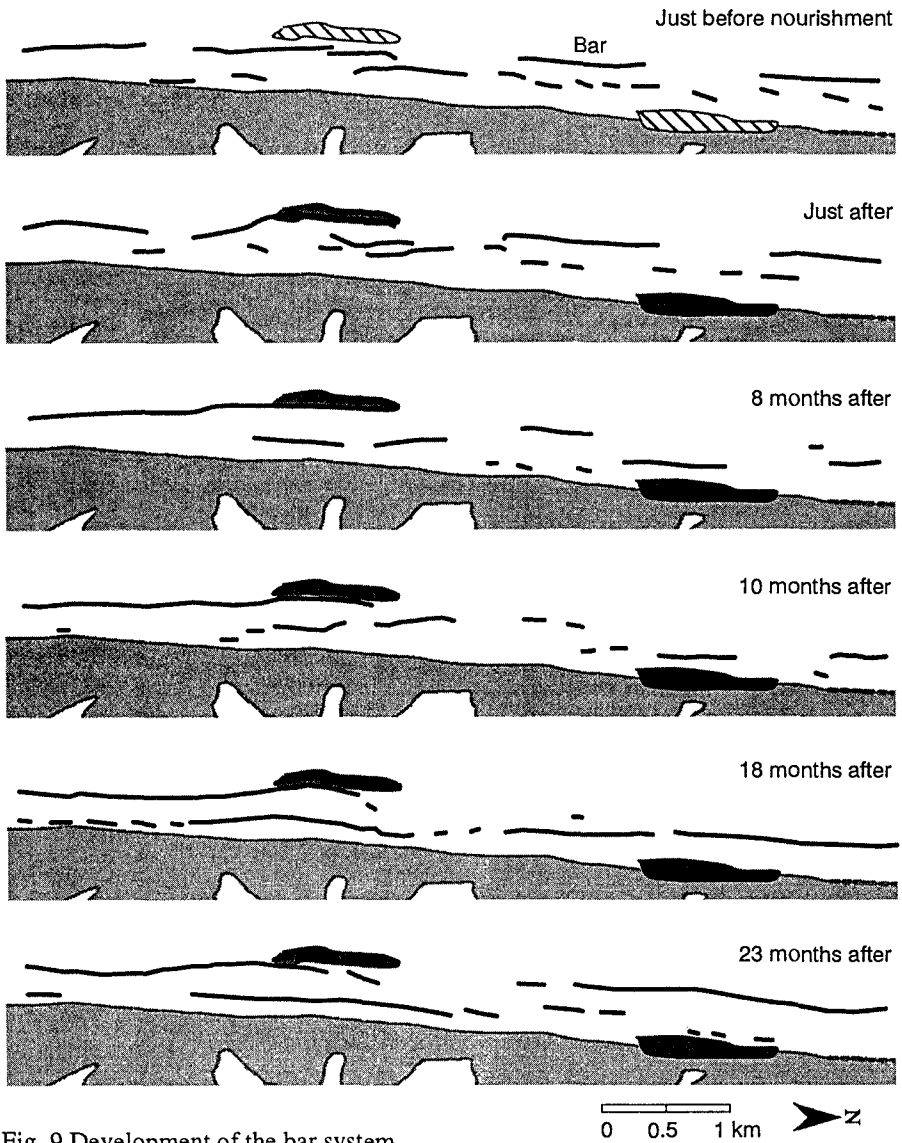

Fig. 9 Development of the bar system.

The relative effect of the two types of nourishment has also been analysed. For all three design objectives, shoreface nourishment is the better option at the end of the monitoring period but beach nourishment is the better option at the beginning. When the price of the nourishment sand is taken into account, the relative effect of the shoreface nourishment is improved because this nourishment type is cheaper.

The 1-dimensional model LITPACK has been calibrated and verified to the monitoring data. LITPACK was then used to calculate the sediment budget and the effect of grain size.

The 2-dimensional model MIKE 21 has shown that the processes in the surf zone are highly 3-dimensional and that the natural variations of the longshore transport are large compared to the changes introduced by the nourishment.

It was concluded that the 2-dimensional calculations of 6 wave conditions combined with 3 bathymetries have been helpful in understanding details of some of the processes which contribute to the natural re-shaping of the investigated area. However, partly due to a limited number of simulated conditions and partly due to the fact that the processes in the surf zone are highly three dimensional, the results cannot be combined in such a way that the observed losses and gains of sediment are reproduced.

The two nourishment volumes have shown a clear difference in stability. The beach nourishment was eroded after 3/4 year. For the shoreface nourishment about 60% of the sand was still in the initial position two years after completion of the nourishment. One reason for the stability is the coarser sand. It was found that the shoreface nourishment sand with $D_{50} = 0.57$ mm is about 2.3 times as stable as sand with $D_{50} = 0.32$ mm. However, a reason which is probably just as important is the position of the nourishment in the bar zone.

The accretion effect of the shoreface nourishment is much larger than the nourishment volume itself. The reason is the breakwater effect of the nourishment. Like a breakwater, the nourishment reduces the longshore transport landward resulting in an accretion.

Acknowledgement

This work was carried out as part of the NourTEC project. It was funded jointly by The Danish Coastal Authority and by The Commission of the European Communities, Directorate General for Science, Research and Development under Contract no. MAS2-CT93-0049.

CHAPTER 228

Mathematical and Physical Modeling of Beach Nourishment Projects

W. Erick Rogers¹ and Paul A. Work², Associate Member, ASCE

Abstract

This paper evaluates the utility of mathematical models for prediction of the planform movement of beach nourishment projects. The results of one-line models (analytical and numerical) are compared to the evolution of nine laboratory-scale model beachfills. Several methods of planform modeling are evaluated, varying in complexity. Comparison of planform modeling suggests that, in some circumstances, using a simple analytical treatment of refraction may be a feasible alternative to using more rigorous numerical wave modeling for shoreline modeling purposes. The relative ability with which different equations for net longshore sediment transport rate reproduce observed beachfill evolution is discussed. Information on the effect of wave climate and beachfill geometry on beachfill lifetime is extracted from the laboratory study. The observed effect of lower wave height, greater beachfill length, and the tapering of a beachfill is a greater beachfill lifetime, in agreement with conventional wisdom. Increasing beach slope and decreasing wave period are both observed to cause a slight decrease in beachfill lifetime.

Introduction

A beach nourishment project is an attempt to widen the dry portion of a beach and offer protection from storms to existing nearby structures by adding large quantities of sediment to some portion of the beach. They are sometimes appropriately referred to as "sacrificial beachfills." This emphasizes the fact that beach nourishment projects are rarely expected to stay in place for more than a decade without losing a large portion of the placed material. Any improvement in the ability to predict this redistribution of beachfill material, through the use of better modeling techniques, allows for more cost effective design and more efficient coastal zone management.

Laboratory Study

A laboratory study was conducted, with two primary purposes in mind: 1) to observe in detail longshore sediment transport patterns in the presence of beach nourishment projects, and 2) to provide prototype beachfills for validation of mathematical shoreline models. Similar studies have been conducted. Kamphuis et al. (1986), Kamphuis (1991), and Nielsen (1988) studied longshore sediment transport in a laboratory setting. Kamphuis and Meyer (1976) studied beachfills using physical models. Dean and Yoo (1994) conducted a laboratory study of beach nourishment projects in front of seawalls and compared the results to mathematical models.

Nine laboratory beachfills were monitored. A paddle-type wave-maker was used to generate nominally shore-normal, monochromatic waves. A set of parameters were compiled which were expected to have an effect on beachfill lifetime: project length, degree of beachfill tapering, breaking wave height, wave period, and beach slope. In a laboratory setting these parameters are easily controlled; each case was assigned a different set of values for these parameters. For each case, a beachfill "lifetime" was calculated based on the amount of beachfill remaining in place, by volume, after wave attack. Lifetime is defined as the time period required for a significant percentage of material to be eroded; loss of 5% of beachfill volume was used. Beachfill material which was dispersed in the longshore direction, outside the original location of the beachfill, was considered "lost" sediment volume. Based on these calculations, the effect of each of the important parameters on beachfill lifetime was inferred (see Table I). Comparison is made to mathematical models employing the "CERC equation" for longshore sediment transport rate (U.S. Army Corps of Engineers 1984).

Table I
Effect of Parameters on Beachfill Lifetime

Parameter	Mathematical Models (with CERC formula)	Physical Model Observations
H_b , wave height at breaking \uparrow	Lifetime \downarrow	Lifetime \downarrow (significant effect)
T , wave period \uparrow	No effect	\uparrow (slight)
L , project length \uparrow	\uparrow	\uparrow (moderate)
m , beach slope \uparrow	No effect	\downarrow (slight)
Tapering of fill	\uparrow	\uparrow (moderate)

Figure 1 shows the location of two typical beach profiles from one of the laboratory cases. Figure 2 is a beach profile located at the "shoulder" of one of the beachfills; the profile experiences a net loss of sediment. Figure 3 shows a beach profile located in the adjacent, unnourished region; accretion occurs due to beachfill material deposited there via longshore transport.

Figure 1. Locations of Laboratory Beach Profiles A and B

Figure 2. Laboratory Beach Profile A

With any physical model, scale effect is a major concern. Due to the relatively small scale of this laboratory study, it is unreasonable to expect accurate quantitative information. However, if the physical model behaves in a manner similar to full scale beachfills, useful qualitative information can be gained, like that shown in Table I. Figure 4 is a beach profile from the shoulder of a full-scale beach nourishment project (Perdido Key, FL). The similarity to Figure 2 is encouraging.

Figure 3. Laboratory Beach Profile B

Figure 4. Beach Profile from Full-Scale Beachfill (Perdido, FL)

Shoreline Models

The shoreline model used in this study was a "one-line model", a tool which has been used extensively by researchers and engineers (e.g. Pelnard Considère 1956, Hansen and Kraus 1989). One-line models are used to predict the movement of a single elevation contour of a beach, typically the still water line. These models are governed by the sediment continuity equation,

$$\frac{\partial y}{\partial t} + \frac{1}{h_* + B} \frac{\partial Q}{\partial x} = 0, \tag{1}$$

and an equation for longshore sediment transport. In equation (1), $h_* + B$ defines the vertical extent of the active beach profile.

If a one-line model is used to provide the shoreline location, $y(x,t)$, the assumption must be made that the shape of a beach profile does not change, but that the profile only shifts onshore or offshore as erosion or accretion occurs (implying zero net cross-shore sediment transport over the time period of interest). However, a recently constructed beachfill typically has an overly steep beach slope, resulting in significant offshore sediment transport. Shoreline models were used to calculate longshore distributions of longshore sediment transport gradients, $\partial Q/\partial x$. A longshore sediment transport gradient can be directly compared to the time averaged rate of change of beach profile area $\partial A/\partial t$, which can be inferred from laboratory and field beach profile measurements:

$$\overline{\frac{\partial Q}{\partial x}} = \overline{\frac{\partial A}{\partial t}} = \frac{\Delta A}{\Delta t}. \tag{2}$$

Here, the overbar denotes time averaging. This method of comparison removes the effect of cross-shore sediment transport from calculations, provided that the entire "active" portion of the beach profile is included in area calculations.

Sediment Transport Equations used in Mathematical Shoreline Models

Three basic equations for longshore sediment transport were tested with the shoreline change models of the laboratory beachfills: the "CERC equation," the "Kamphuis equation" (Kamphuis 1991), and the "GENESIS equation" (Hansen and Kraus 1989). The CERC equation states that longshore sediment transport is proportional to the longshore component of wave energy flux:

$$Q = \frac{KH_{sb}^2 C_{gb} \sin 2\theta_b}{16(SG-1)g(1-p)}. \tag{3}$$

Here K is an empirical coefficient.

The GENESIS equation is a slight modification of the CERC formula, with an added term to account for longshore sediment transport driven by longshore gradients in wave height caused by the presence of structures or (less significantly) irregular bathymetry:

$$Q = (H^2 C_g)_b [a_1 \sin(2\theta_b) - a_2 \cos\theta_b \frac{\partial H}{\partial x}]_b, \quad (4)$$

where

$$a_1 = \frac{K_1}{16(SG-1)(1-p)(1.416)^{\frac{5}{2}}}, \quad (5)$$

and

$$a_2 = \frac{K_2}{8m(SG-1)(1-p)(1.416)^{\frac{7}{2}}}. \quad (6)$$

The Kamphuis equation is an empirically-based equation, developed by a power fit analysis using data from lab and field studies:

$$Q = KH_{ab}^2 T_p^{1.5} m_b^{0.75} D_{50}^{-0.25} \sin^{0.6}(2\theta_b). \quad (7)$$

Inclusion of Refraction in the Numerical Shoreline Model

Longshore sediment transport rate is generally accepted to be dependent on the angle between the wave orthogonal and the local shore normal. This suggests that the inclusion of refraction is requisite for any numerical modeling of irregular shorelines, such as a coastline with a trapezoidal beachfill. In most beach nourishment scenarios, inclusion of refraction will lead to a lower predicted rate of evolution, as it tends to decrease wave obliqueness at breaking.

The numerical wave transformation model REFRACT (Dalrymple 1988) was used to calculate breaking wave conditions for use in the shoreline model. This wave model includes shoaling and refraction (but not diffraction).

As an alternate method for including refraction in a numerical one-line model, a modified form of the CERC equation for longshore sediment transport (Work and Dean 1995) was employed. This equation is based on a two-line, analytical approach to wave transformation, which is much simpler than using a numerical wave model to supply breaking wave input data. The equation is a generalized form of an equation proposed by Dean and Yoo (1992). It can be stated as:

$$Q = K \frac{H_R^{2.4} g^{0.4} \cos^{1.2}(\beta_R - \alpha_R) C_{G_R}^{1.2}}{8(SG-1)(1-p)\kappa^{0.4} C_*} \left[\frac{C_* \sin(\beta_R - \alpha_R)}{C_R} - \beta_t \left(1 - \frac{C_*}{C_t}\right) + \beta_s - \beta_R \frac{C_*}{C_t} \right] \quad (8)$$

The notation is illustrated in Figure 5. Subscript *t* denotes the location of the "toe" of the beach nourishment.

Figure 5. Notation used in Equation (8)

Inclusion of Diffraction in the Numerical Shoreline Model

Diffraction acts to reduce along-wave wave height gradients and thus tends to counter the effects of refraction. Without the inclusion of diffraction, a wave transformation model may tend to yield exaggerated focusing of wave energy near the "shoulders" of a beach nourishment project, which would compromise the predictive capability of the one-line model. The numerical wave model REF/DIF1 (Kirby and Dalrymple 1994) was used to generate breaking wave conditions (for use in the one-line model) including the effects of the shoaling, refraction, and diffraction of waves.

Comparison of One-Line Model Results to Laboratory Results

Laboratory data and numerical model results were compared based on longshore gradients of longshore sediment transport rate ($\partial Q/\partial x$), rather than shoreline evolution; thereby the effects of cross-shore sediment transport on shoreline movement were removed. Time-averaged longshore gradients of longshore sediment transport were inferred from beach profile measurements using equation (2).

Several shoreline modeling schemes were used, varying in complexity:

1. analytical calculation of shoaling (using conservation of wave energy flux), CERC equation for longshore sediment transport (equation (3));
2. analytical calculation of shoaling (using conservation of wave energy flux), Kamphuis equation for longshore sediment transport;
3. analytical treatment of the shoaling and refraction of waves in CERC equation (equation (8));
4. analytical treatment of shoaling and refraction in Kamphuis equation (analogous to equation (8));
5. shoaling and refraction determined by numerical wave model REFRACT, CERC equation for longshore sediment transport;
6. shoaling and refraction determined by numerical wave model REFRACT, GENESIS equation for longshore sediment transport; and
7. shoaling, refraction, and diffraction determined by numerical wave model REFDF1, CERC equation for longshore sediment transport.

Figure 6 shows the longshore gradients of longshore sediment transport calculated by the one-line model for one of the laboratory cases. Note the similarity between the results using the numerical and analytical treatment of refraction.

Figure 6. Comparison of Shoreline Modeling Schemes (1, 3, and 5)

Figure 7 compares longshore sediment transport gradients inferred from measurements for a laboratory beachfill to model output using option (1) above. This plot is representative of most comparisons of the one-line model results to lab results: though quantitative agreement is somewhat artificial due to calibration of the longshore sediment transport equation, qualitative agreement is good.

Figure 7. Comparison of Laboratory Results to One-Line Model Results

Using standard "field" values for coefficients of proportionality, none of the longshore sediment transport equations yielded good quantitative agreement. With standard coefficients, the equations typically greatly over-predicted longshore sediment transport. This is almost certainly due to scale effect, and has been observed by other researchers (e.g. Komar and Inman 1970).

The ability of the calibrated numerical one-line model to duplicate laboratory results was determined for each of the variations of the shoreline model. This comparison indicated that the use of the numerical wave models did not provide any added accuracy over method (1) above. On the other hand, use of the longshore sediment transport equation with an analytical treatment of refraction did yield a slight improvement in results.

In this comparison of methods, the Kamphuis equation yielded slightly better qualitative agreement than the other two basic equations for longshore sediment transport. The added term in the GENESIS equation did not result in any improvement over the CERC equation, probably because longshore gradients in wave height were not large in the laboratory.

Comparison to Field Data

Numerical one-line model results were compared to data from a well-monitored beach nourishment project at Folly Beach, South Carolina (Figure 8). The method for analytical treatment of refraction (method 3 above) was used with a standard calibration factor for the CERC equation ($K=0.77$ using H_{ms}). 2.1 million cubic meters of beachfill material were placed during the first four months of 1993 (Ebersole, et al., 1996). A 25-month period was investigated, from July, 1993 to August, 1995.

Figure 8. Location of Folly Beach

For the shoreline model initial condition, the "ad hoc transformation" method was used. This method is suggested by Dean and Yoo (1992) for situations "where substantial perturbations (human or natural) have placed the system out of balance." The initial planform used was simply the deviation from an assumed equilibrium planform caused by the placement of the beachfill.

Nine groins located northeast of the Holiday Inn (see Figure 9) were renovated at roughly the same time that the beachfill was placed. These groins were not included in the model results presented in this paper. For the time period modeled, the groins were thought to have a minor impact on shoreline movement; the groins are relatively short and were dry at low tide. Offshore wave data for 1993 and 1994 were obtained from a Wave Information Study (WIS) hindcast database (Brooks and Brandon 1995) for shoreline model input.

Comparison of the one-line model results to measured data is shown in Figure 10. The one-line model provides a reasonably good prediction of erosion and accretion, in both a quantitative and qualitative sense. Close inspection of Figure 10 suggests that the inclusion of the groins in the numerical model may have improved the model's accuracy--erosion was overpredicted by the model inside the groin field, and underpredicted downdrift (southwest) of the field.

Volume calculations indicate that 413,000 m³, or 19% of the beachfill volume which existed in July 1993 was lost from the nourished region by August, 1995. Volume calculations include both the subaerial and submarine portions of Folly Beach; beachfill material deposited immediately offshore of the beach (above

-3m to -4m NGVD) was not considered a sediment loss, even though, by some measures, this cross-shore sediment transport would decrease the value of the beach. A majority of the 413,000 m³ should therefore represent a loss of sediment due to longshore gradients in longshore sediment transport. However, other factors such as aeolian sediment transport, transport by tidal currents, and sand deposition well offshore of the beach could have contributed to the loss or gain of sediment. The shoreline model predicted a loss of 302,000 m³ for the same time period. Had a larger empirical sediment transport coefficient been used, to account for the relatively fine sand at Folly Beach, this volumetric prediction would have been more accurate.

Figure 9. Map of Folly Island, S.C.

Conclusions

The laboratory observations regarding wave height and beachfill geometry shown in Table I agree with conventional wisdom on beach nourishment design. The observed weak dependence of sediment transport (and beachfill lifetime) on beach slope is not widely accepted, though it has been observed by other researchers, such as Kamphuis (1991). On the other hand, the observed positive correlation between wave period and beachfill lifetime is contrary to Kamphuis (1991). This discrepancy merits further study; though shorter waves impact on the shoreline with greater frequency, longer waves possess greater energy.

Results of the laboratory study suggest that relatively small-scale physical models of coastal sediment transport can yield useful qualitative information on shoreline and beach profile changes, though the magnitude of sediment transport rates may be greatly influenced by scale effects. The laboratory models cited in this study evolved similarly to prototype projects.

Figure 10. Comparison of One-Line Model Results to Field Measurements

The use of simple, one-line shoreline models in this study indicates that such models are adequate tools for predicting the volumetric redistribution of beachfill material. More rigorous, three-dimensional models of beachfill evolution are a worthy goal; however such models are equally, if not more, limited by present uncertainties in prediction of sediment transport.

The CERC equation for longshore sediment transport is adequate for predicting qualitatively the longshore trends of longshore sediment transport at both laboratory and field scale. The equation is a fair predictor of the magnitude of longshore sediment transport at field scale but requires calibration at small scales. Comparison to laboratory data suggests that the Kamphuis equation for longshore sediment transport is slightly more accurate than the CERC equation. Because of the possibilities of measurement error and scale effect with the laboratory study, this finding is inconclusive.

Based on limited laboratory and field-scale beach nourishment modeling, the analytical treatment of refraction seems to be an efficient method of including wave transformation in one-line models. This method may be considered by engineers for use in lieu of more rigorous, numerical approaches to wave transformation. However, in cases where a complex bathymetry exists (and accurate, high resolution survey data are available), a good numerical wave model is likely to give a better representation of the spatial variability of the wave climate. But again, the beachfill modeling as a whole is only as good as the "weakest link," so unless longshore sediment transport can be reliably predicted, extensive efforts at wave modeling may be unwarranted.

List of Symbols

The following symbols are used in this paper:

A =cross-sectional area of beach profile;
 B =berm height;
 C_g =wave group velocity;
 C_r =wave celerity at toe of beachfill;
 C_c =wave celerity at depth of closure;
 D_{50} =representative grain size;
 g =acceleration of gravity;
 H_s =significant wave height;
 h =depth to which longshore sediment transport affects beach profile;
 K =empirical longshore sediment transport coefficient;
 L =length of beach nourishment;
 m =beachface slope;
 p =sediment porosity;
 Q =volumetric longshore sediment transport rate;
 SG =sediment specific gravity;
 T =wave period;
 T_p =wave period at peak of frequency spectrum
 t =time;
 x =longshore coordinate;
 y =cross-shore location of shoreline;
 β =local contour or shoreline orientation, relative to North;
 κ =ratio of wave height to water depth at breaking;
 θ =angle between wave orthogonal and local shore normal.

CHAPTER 229

COASTAL ZONE DYNAMICS DURING ARTIFICIAL NOURISHMENT

Elżbieta Zawadzka¹

Abstract

The nearshore zone of the Hel Peninsula has a hydro-geomorphological system which, together with the influence of the port at Władysławowo, causes permanent erosion of the basal and central part of the peninsula's sea coast. After a period during which traditional methods of coastal defence (seawalls, groynes) were used, a massive artificial nourishment of the dune and beach was realised in the years 1989-1995. The borrow material used was of lagoon and marine origin. The progress of morpho- and lithodynamic processes was evaluated basing on quantitative analyses of changes in topography and granulometry. In the land part of the coastal zone, accretion of deposits resulted in rebuilding of the dunes and beaches. In the nearshore zone, accretion occurred on the beach slope, and resulted in the development of shore terraces and breaker bars (especially the outer breaker bars). This was accompanied, by related with the accretion, processes of erosion in the form of U-shaped troughs. These processes proceeded at small changes in the erosion/accretion (e/a) system of the nearshore zone in the whole region. Smaller input of sandy material into the nearshore zone resulted in gradual return of the e/a system to initial state. If the safety of the peninsula is to be maintained, artificial nourishment must be executed every year. Frequency and volumes of renourishment will depend on the quality of used material. Therefore new sources of borrow material must be sought.

Introduction

Artificial beach nourishment, considered as one of the most environment friendly methods of coastal defence, was used in Poland several times (Basiński, 1992; Basiński & Szmytkiewicz, 1991; Mierzyński, 1985). However, these were experimental pilot projects, realized in small temporal and spatial scale, using rather small amounts of material. In this paper are discussed results of investigations of changes in the coastal environment caused by a large-volume nourishment project implemented on the Hel Peninsula coast (Fig. 1). The decision to use artificial nourishment resulted from the catastrophic state of the basal part of the peninsula, and from the imminent danger of flooding of the hinterland of the narrow and

intensely eroded dune, at limited width of the spit. Strong storms in the autumn and winter of 1988/1989 resulted in a danger of breaking of the peninsula at 2-3 places.

The Hel Peninsula is an accumulative spit of 36 km length, which is an extension of the mainland to SE, and which shelters from the north the Gulf of Gdansk. In historical times it was broken several times. Analysis of maps from the period 1908-1978 (Zawadzka, 1994) has shown that the average rate of coastline retreat along the peninsula is -0.6 m/year (Fig. 2a). Processes of erosion in the period 1980-1987, directly preceding the nourishment project, are characterized by a similar spatial distribution as in the 70-year period 1908-1978 (Fig. 2b). The foredune became nearly completely eroded in the basal and central part of the peninsula along 17 km of coastline, resulting in a danger of breaking of the peninsula, especially at these stretches where the width of the spit did not exceed 100 m. In this situation, the decision was taken to use artificial nourishment as the most effective and least ingereventive method of coastal protection (Cieślak, 1994).

In the years 1989-1995 the largest project of artificial nourishment of a dune coast in Poland was realized. On the seaward coast of the Hel Peninsula, along a length of 23.4 km, 8 mln. m^3 of sand was supplied, gradually widening the range of sand suppletion works, which in total were executed along 14 km of the coastline. The material for nourishment was taken from the Puck Bay, from the sand trap at the port at Władysławowo, and from borrow sites at sea located to NE of the central part of the peninsula and to NE of Cape Rozewie (Zawadzka, 1993). In order to determine the effectiveness of the method, a comprehensive program of measurements and investigations was systematically realised. It included investigations of sediments and morphology of the seabed, beach and dune along the first 23 km of the peninsula's coastline. Each year 800-1000 sediment samples were analysed. Analyses of the variability of the dune, beach, beach slope, breaker bars, interbar troughs and of the deepwater slope to 10 m water depth were made. Comparison of maps of statistical grain size indicators (median diameter, sorting, skewness, steepness) on the background of proceeding changes in the shape of the nearshore bed and of its morphological forms, and taking into account the hydrodynamic conditions, has

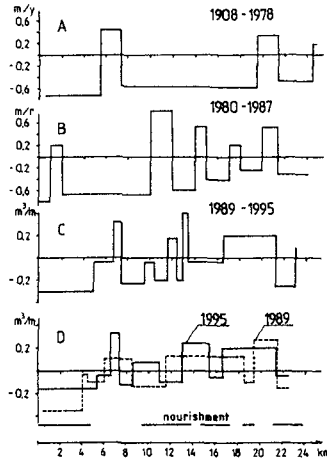

Fig. 2 Changes of coastline position, Hel Peninsula, 1908-1978, 1980-1987 and changes of the fill coefficient of the nearshore zone to -10 m MSL, 1989-1995. A-B - Zawadzka, 1990; C-D - Dubrawski, 1995.

shown that independently of the local short term changes connected with artificial sand supply, in the coastal zone there is a hydro-geomorphological system, which forms relatively stable erosion/accretion trends in the coastal zone - also in conditions of artificial nourishment. Nourishment works carried out for 7 years have not resulted in a basic change of the general trend within the erosion/accretion system in the Hel peninsula region. Generally erosion has decreased, but its spatial distribution remained almost the same (Figs. 2c, 2d).

Characteristics of supplied material

For the nourishment material dredged from the Puck Bay and from sea borrow sites located at sea was used (Fig. 1). Deposits accumulated in the Puck Bay consist of fine and medium sand, well and medium sorted, and the median diameter (M_d μm) ranged between 139 and 237 μm . Marine material consists of medium sand of M_d 290 μm , medium sorted. Comparative analysis of the "bay" borrow material and native material, using the R_j and R_A indicators (Manual, 1990), shows that these two sands do not fit satisfactorily. Highest stability of the supplied material may be attained when 2-3.5 larger quantities of material are nourished than the volumes resulting from calculations of deficiency of sand material in the basal part of the peninsula. In the central part, material borrowed from marine sources may be used in 1:1.5 (2) proportion. Grain size parameters of borrow material from the Puck Bay suggest that mass transport of that sand may proceed at speeds of 12-20 cm/s.

Nourishment started in 1989 at two sites: at Chałupy (km H3.5-4.5) and at Kuźnica (km H11.9-13.7). By 1993, about 5.85 mln. m^3 of sand were supplied, and the nourishment works were executed on 5 stretches of total length of 11.1 km. At the Chałupy nourishment field the resultant average volume of nourishment per metre of coastline was 510 m^3 , at Kuźnica it was 730 m^3 . On the other fields the average

volume of nourishment per metre of coastline ranged between 100 and 330 m³. In the next two years, until 1995, the length of directly nourished coastline grew to 14 km, and the total amount of sand supplied since 1989 increased to 8 mln. m³. Most intensive nourishment was still realized at Chałupy and Kuźnica due to the highest deficit of sediments in the nearshore zone, and because of the limited stability of the nourished material.

Morphodynamics and lithodynamics of the region

The shore and the nearshore zone of the Hel Peninsula are characterized by a semistable erosion/accretion system, with a strong predomination of erosional trend resulting from the hydrodynamic conditions in the region (Fig. 2).

The stable predisposition to erosion along given stretches of the coastline are caused by trough-like forms present in the sea bottom, which are obliquely oriented at an angle of 25-27° to the shoreline. In the western part of the peninsula they are of glacialfluvial origin (Tomczak, 1994), in the eastern part they are remnants of the Yoldia Sea coastal systems (Musielak, 1989). Location of these forms influences the occurrence of areas with permanent erosion of the sea bottom and shore. The stability of the erosion/accretion system is confirmed both by cartometric analysis of coastal change (Zawadzka 1990, 1994) and by means of modelling of hydrodynamic processes in the nearshore zone (Skaja & Szymkiewicz, 1995). When wind blows from the west and north sectors, dangerous to the west and central part of the peninsula wave and current systems are generated. In extreme conditions current velocity may reach 2 m/s. Wind from the east results in higher energy supply to the east and central parts.

The variability of sediment transport characteristics in natural conditions, in the different zones of bottom and shore, influences the intensity with which the artificially nourished material is displaced in given meteorological conditions, resulting in different reactions of the erosion/accretion system of the coastal zone.

Transformation of morphological forms of the coastal zone

The caused by artificial nourishment increase of volume of the beaches resulted in adaptive transformation of the adjoining forms of the shore and nearshore zone.

Accretion of nourished material on the beach and dunes was accompanied by an appearance of erosion along stretches east (downstream) of the nourishment fields. Gradually these phenomena moved also into the nearshore zone.

After the first season of nourishment, along 14% of the observed coastline well developed shore terraces were present, and their average width was 75 m (Dubrawski, 1995). After 4 years terraces occurred along 45%, and after 6 years - even along 76% of the coastline (Table 1).

The intensive development of inner and outer bars took place after four years of artificial nourishment, during which 5.8 mln. m³ of sand were supplied. One of the most significant features of the transforming during the artificial nourishment seabed was the generation of rarely occurring in the natural bottom profile U-shaped troughs. Maximum development of the interbar U-troughs also was observed after 4 years of

nourishment. The maximum number of shore U-troughs appeared after 6 years of nourishment, suggesting increased current velocities in the shallow part of the nearshore zone.

Table 1. Changes of parameters of morphological forms in the nearshore zone, 1989/1995 (Dubrawski, 1995)

Year	Shore terraces		Shore slope		shore U-trough		Inner bar lower class		interbar U-trough		Outer bar higher class	
	%	l [m]	l [m]	slope	%	l [m]	%	[m ²]	%	l [m]	%	[m ²]
1990	14	75	133	1:33	4	76	26	37	8	144	33	303
1993	45	76	141	1:37	11	80	12	43	21	108	52	332
1995	76	81	135	1:33	19	85	17	43	9	71	45	335

The decreased volumes of nourishment in the period 1994-1995 resulted in stronger erosion on the beach and in smaller differentiation of morphological forms in the nearshore zone and of grain size composition within these forms, which suggests a gradual return to the state before artificial nourishment (Dubrawski, 1995). Analysis of the average crossshore profile showed stabilisation of the volume of the inner bar after 4 years of nourishment, and a steady development of the outer bar where redeposition of fine sands occurs. The shore slope increased its volume by 4.8% of the volume of nourished material, attaining maximum after 4 years of nourishment. Similarly to shore terraces, in the next years it was subjected to gradual reduction.

Fig. 3 Nourished stretches and net beach volume (1 - sum of annual suppletion; 2 - changes of dune and beach volume; 3 - sum of annual losses)

The balance of changes of the shore, evaluated basing on measurements carried out twice every year, shows that during the first 3.5 years, in spite of repeated nourishment, the volume of dunes and beaches remained at the level of 1989 (Fig. 3). When intense nourishment was carried out after strong storms of winter 1992/93, and after the relatively mild wind and wave conditions of the 1994/95 season with higher than average percentage of winds from the east, did result in stabilisation accretion on the beach and dune. After the annual amount of nourished material was reduced, the volume of material contained in the beach and dune decreased in spite of a

consecutive mild winter season. In effect of 6.5 years of artificial nourishment, the volume of the shore (beach and dune) increased by about 1 mln. m³.

Lithodynamics in conditions of artificial nourishment

Grain size analysis of bottom surface samples, taken each year from the seabed in the whole region before each annual nourishment works, show that the mean value of the median diameter has not changed significantly. Before the nourishment works began, the belt-like distribution of mean and fine sands was locally disturbed by zones of coarse sand and fine gravel, which indicated areas with higher wave and current activity. In these areas erosion of shore and bottom was observed (Fig. 4).

Fig. 4 Plan of median diameter (M_d mm) of bottom surface sediments in the coastal zone of Hel Peninsula, 1990

After 6 years of artificial nourishment, grain size composition shows changes of sediment parameters in the central part of the peninsula, which became supplemented with fine sands, at maintained erosional trend in the central part and at development of erosion along the basal part. The grain size composition of bottom surface sediments in the 10-12 m water depth zone was characterized, after 6 seasons of nourishment with sand from the Puck Lagoon (Puck Bay), by a slight decrease of the median diameter from 253 μm to 238 μm in 1993 and to 225 μm in 1995. The median diameter of beach deposits, which were successively supplemented with mean and fine sand, was after three years of artificial nourishment nearly the same as in prenourishment conditions.

The average grain size composition of deposits in the nearshore zone remained nearly unchanged through 3 years of nourishment. In the fourth year, due to erosion of nourishment fields during strong storms of the 1992/93 season, beach deposits

became slightly coarser and the nearshore zone was supplemented with large amounts of fine sand, and the median diameter of bottom surface deposits in the nearshore zone decreased to $206 \mu\text{m}$. It may be supposed that the stability of nearshore zone

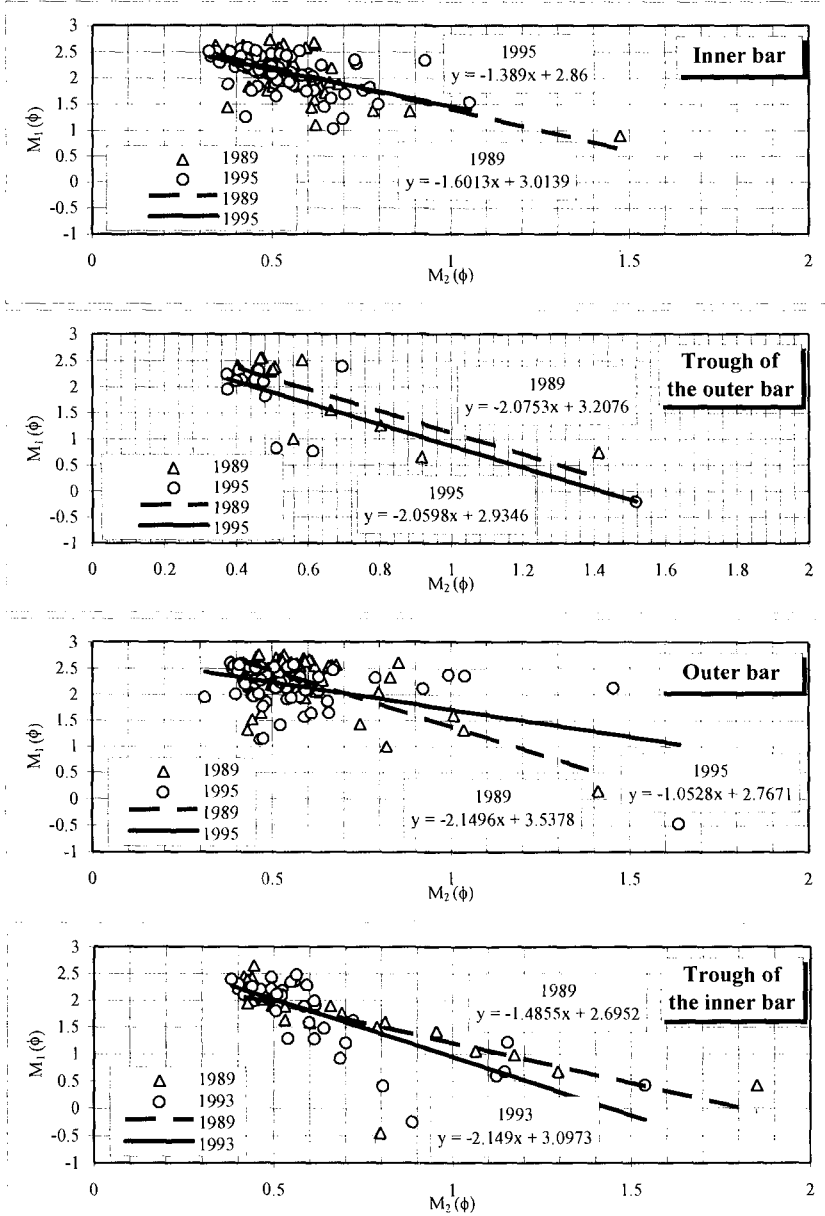

Fig. 5 Relationship between mean diameter (M_1) and standard deviation (M_2) of sediments in breaker bars and bar troughs, Hel Peninsula, 1989-1995

forms built of artificially supplied material, which was finer than the natural material, is smaller than in case forms built of material present before the nourishment project, and that they will quicker undergo transformation.

Small changes in the grain size (evaluated using mean parameters) of the nearshore forms during the nourishment are proof of an inner stability of the hydrogeomorphological system and that the finest particles are displaced outside the active zone. However, at the same time within each of the morphological forms in the nearshore zone proceeded distinct granulometric changes, indicating a different distribution in the wave and current field (Basiński & Szmytkiewicz, 1991). Development of the shore terraces and the breaker bar zone was accompanied by deepening and widening of the troughs. Increased nearbottom current velocities in the troughs, which increase is largest in the trough between the inner and outer bar, suggest a transformation of the erosion/accretion system (Fig. 5). The development of interbar troughs is connected with the existence of gradient currents (Pruszek & Zeidler, 1995). Probably gradient currents increased in the nourished areas, and in effect U-shaped troughs developed.

The median diameter in the interbar troughs increased by 150 μm , from 280 μm in 1989 to 430 μm in 1995, in spite of relatively mild hydrodynamic conditions in the last winter season. After the strongest storm season 1992/93 the median diameter in the troughs was even up to 480 μm . In areas of most distinct development of U-shaped troughs, the median diameter exceeded 1000 μm , which could be related with current velocities of over 1 m/s (current velocities require confirmation by field measurements).

The decrease from 260 μm to 220 μm of median diameter of sediments building the breaker bars indicates that the accumulated in them material will be moved at lower initial current velocities. This fact may be the reason of quicker transformation of the outer breaker bars.

In conditions of a growing amount of supplied artificially material, of steadily growing length of nourished stretches, and of variable hydrodynamic conditions, the lithodynamic system of the Hel Peninsula nearshore zone was characterized by a variable spatial distribution of fields of erosion and accretion. Basing on analysis of the changes of median diameter of sediments and their mean values, calculated for each of the morphological zones (beach, shore slope, interbar troughs, breaker bar zone and deepwater slope), areas with finer or coarser sand were determined. This allowed to draw plans of the surface erosion/accretion system of the nearshore zone, and to evaluate its dynamics.

Before artificial nourishment works started, there were 4 erosional areas along the basal part of the peninsula, covering all morphological zones: the shore slope, breaker bar zone and the deepwater slope. Along the central part of the peninsula, the shore slope and the breaker bar zone were eroded. Along the eastern part, alternately located zones of erosion and accretion occurred, indicating routes of sediment transport to the deepwater slope and then out of the observed area.

In spring 1990, after the first artificial nourishment campaign, the initial system of erosion/accretion areas did not change along the basal and central part of the peninsula, though local accretion of the supplied material in the breaker bar zone and

on the shore slope was observed. East of the fill field at Chałupy and Kuźnica (central part) the breaker bar zone was supplemented with fine sand material, at simultaneous erosion of the deepwater slope (Fig. 6). Influence of the fill material was observed in the interbar troughs and on the outer bar to 8 m water depth and up to 1.5 km from the fill field. On the other hand, segregation of the nourished material resulted in an increase of coarse sand and gravel on the beach and at the water line. No significant change of grain size was observed on the outer breaker bar.

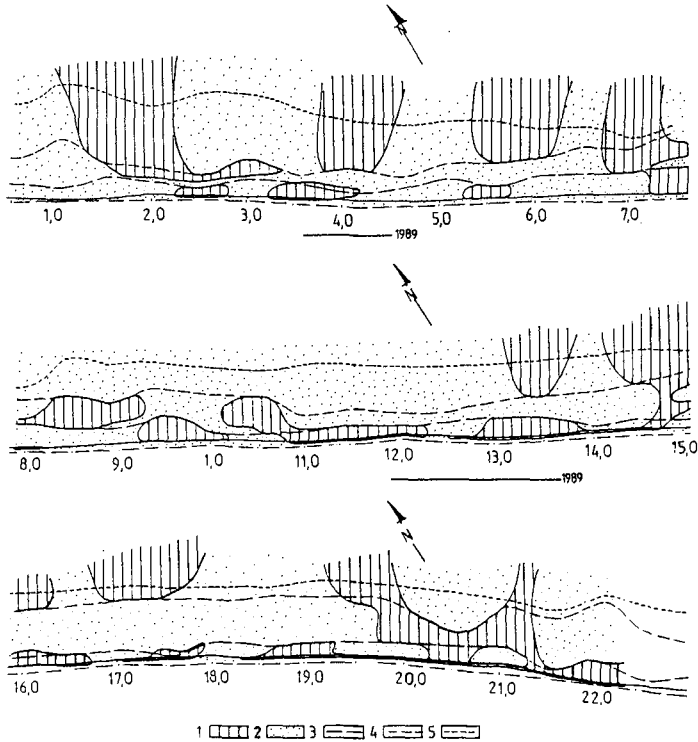

Fig. 6 Erosion/accretion system of surface sediments, Hel Peninsula, 1990
(1 - areas with erosive trend; 2 - areas with accretional trend; 3 - range of shore slope; 4 - range of breaker bar zone; 5 - 10m depth contour)

After two years of nourishment (in 1991), while distinct accretion occurred in the shallow water and breaker bar zones, also development of areas of erosion of the breaker bars and deepwater slope was observed east of the fill field located in the basal part of the peninsula. In the central part, zonal accretion on the shore slope and on the breaker bars was observed, accompanied by erosion in the same zones east and west of the fill field. Rhythmically occurring erosion/accretion surfaces, encompassing the breaker bar zone occurred in the eastern part, suggesting a development of circulation cells of 1 km order. In the Chałupy area, in effect of segregation of the material, the beach became saturated with mean and fine sand, while percentage of mean and coarse sand grew on the shore slope. The process of washing out of the shore slope proceeds at simultaneous enriching of the breaker bar zone and of the deepwater slope with fine sediments. The influence of the fill material was observed

in the breaker bar zone 2 to 3 km east of the fill field. Further migration of the fill material is limited by a convex bottom form at km H7.0-7.5, which is considered to be a natural boundary of a lithodynamic unit of the nearshore zone. Observations at Kuźnica showed that the fill material is transported over larger distances than in case of the Chałupy field. Within the shore slope and inner bar zones the material was transported 3 km, and in the outer bar zone - about 5 km to the east of the fill field. East of the Kuźnica fill field two independently occurring in 1990 areas of scour, one on the shore slope and the other on the deepwater slope, were transformed into an oblique to the coastline and cutting through the breaker bars zone of intense transport.

After the third year (in 1992) of artificial nourishment of the western stretch of coastline with material from the Puck Bay, supplemented with material from the sand trap at the port at Władysławowo, the inner bar and its inner trough became richer in fine sand. Deposition of sediments grew also locally in the outer bar zone. The large supply of material from the fill resulted in a shallowing of the interbar trough and in supplementing the balance of sediments up to about 1.5 km east of the fill field. Areas of bottom scour formed in 1991 became filled with sands of 225-250 μm diameter. Finer material (less than 150 μm) was deposited in the 8-10 m water depth zone about 3 km east of the fill field. Accretion in the area of transport of the fill material was always accompanied by erosion, which indicates a nonuniform character of the transport. In 1992, due to the continuing suppletion of the shore at Kuźnica, the system of shore terraces became distinctly developed, and the median diameter of sediments accumulated in them was 275-300 μm . The shallowing of the shore slope was accompanied by deepening of the trough before the inner bar and in its transformation from a V shape to a U shape. Suppletion of the inner bar occurred at a distance of 1 km and of the outer bar - at a distance of 2.5 km east of the fill field. The change of zones of wave energy dissipation resulted in a local rebuilding of the double bar profile into a single bar profile, which was built of medium sands. The new system of eroded and accreting bottom surfaces suggests a distinct stabilisation of lithodynamic processes over a stretch of 5-6 km east of the fill field at Kuźnica.

Intensive development of large erosive forms, encompassing nearly all the morphological zones appeared after 4 years of nourishment (1993), pointing to the development of oblique to the coastline routes of sediment transport. The field at Chałupy still supplemented the coastal zone to a distance of 2.5-3.0 km east of the field, and to a water depth of 6 m. In the nearshore zone a strip of 350 m width seaward of the water line, and reaching to 4 m water depth, was supplemented at a length of about 3.5 km. Predominance of wind from the NW sector in autumn and winter of 1992/93 resulted in the generation of distinct "upstream" zones and of new routes of sediment transport out of the nearshore zone. The obliquely situated erosive areas were characterized by larger grain sizes than the average values determined for the whole observed area, and crossed all analysed nearshore zones. The larger rates of loss of fill material over the deepwater slope occur, among others, along the defined routes of intensive transport (Fig. 7).

In the last year of observations (1995), in the nearshore zone of the basal part of the Hel Peninsula accretion occurred over large areas of the shallow water zone adjacent to the fill field. Locally in the central part erosive areas appeared, independently of the development of massive breaker bars, which are a transient zone

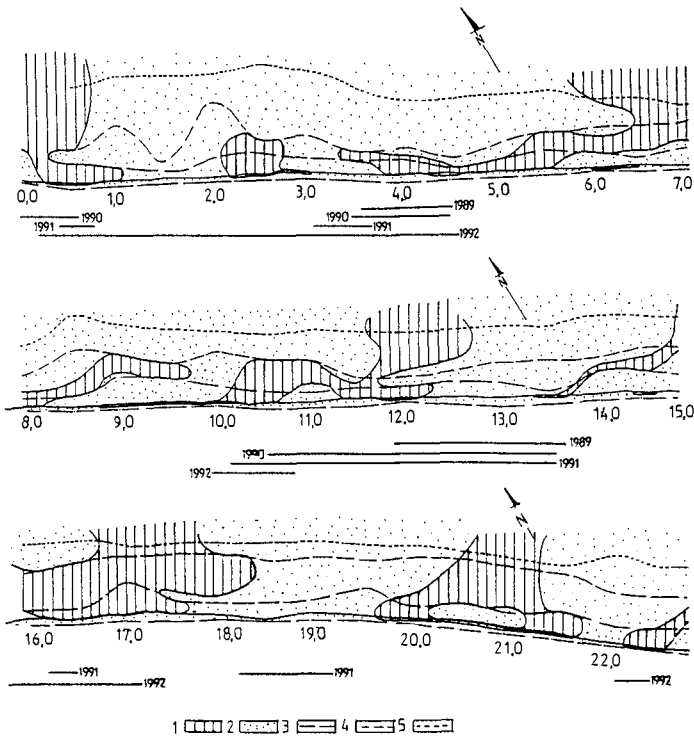

Fig. 7 Erosion/accretion system of surface sediments, Hel Peninsula, 1993 (explanations as in Fig. 6)

of deposition. Also distinct zones of higher energy appeared, which caused scouring of breaker bars east and west of the fill field at Kuźnica, formation of deep interbar troughs, and erosion on the deepwater slope. Hydrodynamic conditions at the break of 1994/95 resulted in the formation of two distinct circulation cells in the central and eastern region (Fig. 8). The direction of sediment transport out of the intensely artificially nourished region in the central part suggests an influence of a trough form situated obliquely to the coastline. A very similar arrangement of sediment transport routes (accretion in the central part of the system and erosion in the outer zones) was observed in the Jastarnia-Jurata region. The distribution of the eroded and accreting surfaces in the nearshore zone suggests that bottom forms farther offshore and deeper situated influence the nearshore zone, steering circulation at winds from the NW to NE sector.

The highest percentage of nearshore surface, subjected to processes of erosion in the breaker bar zone and on the shore slope, occurred before artificial nourishment began (Table 2). The area of redeposition of the sediments was located on the deepwater slope below the breaker bar zone. Accumulation on the beach, shore slope and in the breaker bar zone caused increased erosion of the deepwater slope. After a period of strong storms at the break of 1992/93, processes of erosion increased again in the shallow part of the nearshore zone (shore terraces and breaker bars), but weakened below the breaker bar zone due redeposition of the sediments.

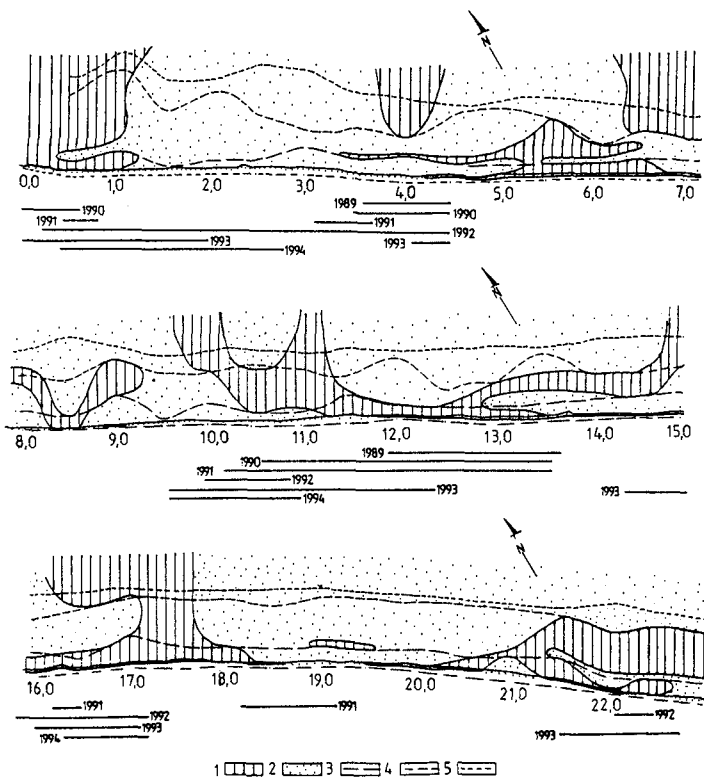

Fig. 8 Erosion/accretion system of surface sediments, Hel Peninsula, 1995 (explanations as in Fig. 6)

Table 2. Percentage of eroded nearshore zone surface, Hel Peninsula, period 1989-1995 (on the basis of granulometric parameters)

Year	Erosion (in %) of nearshore zone (to 10 m water depth)		
	Whole nearshore (0.0±-10.0 m MSL)	Shore slope & breaker bar zone	Deepwater slope
1989	35.2	46.5	20.5
1990	21.0	16.9	33.7
1991	22.0	21.1	27.5
1993	29.0	36.4	19.4
1995	23.4	22.6	27.9

Obtained results show that in intensive hydrodynamic conditions the shallow part of the nearshore zone and the breaker bar zone was being destroyed over 36 to 46 % of its surface. Stabilisation on the shore slope and breaker bars is connected with development of processes of erosion on the deepwater slope, indicating that in the erosion/accretion system proceed compensatory processes.

Summary

The six years of artificial nourishment along the Hel Peninsula, due to the restoration of dunes and to the improvement of sediment balance in the coastal zone, resulted in higher safety of the coast and its hinterland. The total volumetric change in the strip from dunes to breaker bars inclusive was over the whole period 1.8 mln. m³, i.e. about 28% of the total volume of the nourishment in the period 1989-1994 (Cieślak et al, 1995), in that about 12.5 % remained in the dunes and beach, and 15.5 % remained in the shore terraces and breaker bar zone. The rest was transported outside of the investigated area. Significant amounts of fill material were accumulated in the developing shore terraces, which at the end of the analysed period covered 3/4 of the length of the observed coastline. Terraces improve the stability of beaches and dunes because they dissipate wave energy.

Breaker bar height increased by 11.8%, and cross-section area by 22% in reference to the 1989 state. Formerly present stretches with no breaker bars disappeared. A decisive change in the shape and volume of breaker bars took place. Participation of small breaker bar forms decreased. Massive breaker bar forms developed, especially after the fourth year of artificial nourishment. During the last two years of suppletion, when volumes of supplied fill material were reduced, the percentage of breaker bars of each of the volumetric classes began to stabilise at the levels of the period preceding the nourishment works, indicating a predominant influence of hydrodynamic processes. The grain size composition of fill material indicated that it may nourish especially zones with lower hydrodynamic activity. Gradual reduction of massive breaker bars caused by reducing the volume of annual artificial nourishment will result in the future in higher levels of danger to the coast. Development of shore terraces and breaker bars was connected with local changes in the erosion/accretion system, which appeared especially through the generation of U-shaped troughs and areas of scour downstream of the fill fields and terraces.

Observed morpho- and lithodynamic changes of the coastal zone during artificial nourishment are of adaptative character and proceed within an existing, well established hydro-geomorphological system of the Hel Peninsula. Gradual reduction of the volume of artificially supplied to the erosion/accretion system material will result in a slow return of the shore and seabed forms to the state present before artificial nourishment began. In the conditions of prevailing winds from the west sector and of generated by them waves and currents, and of the system of macroformations of the outer part of the coastal zone and of the breaker bar zone, there is a natural predisposition to transport a part of the sediments of the dynamic layer to east and north. This requires repeated artificial nourishment in the west and central part of the peninsula, in order to ensure relative stability of permanently eroded stretches, especially when too fine fill material is used. In periods when prevail winds from the east, morphodynamic processes in the erosion/accretion system become stabilised.

The basic recommendation, resulting from grain size and sediment transport analyses, is that borrow sites with grain sizes better fitted to open sea hydrodynamics should be sought. Sand from the Puck Bay is very easily moved, and only for a short period supplement the areas with sediment deficit. Material with parameters ensuring 40-50% better stability in the whole strip from shore to outer bar than the

presently used sand should be used. Maintaining the present state of the coast requires annual nourishment of the order of 0.6-1.0 mln. m³.

The presented results show that artificial nourishment, as any other method, has a limited range of application, and - as any other technical ingerence into the coastal zone - causes changes in the wave and current system which result in a development of negative morpho- and lithodynamic effects.

CHAPTER 230

Dune Damage Curves and Their Use to Estimate Dune Maintenance Costs

David R. Basco¹ and Cheol S. Shin²

Abstract

A beach profile numerical model is employed to calculate the change in dune cross-section for a wide range of increased, water level events. The volume loss in dune cross-section increases with relative increase in storm surge elevation above the design water level. These "damage curves" for dunes are analogous to rubble mound damage curves created by excessive wave energy above the design wave height.

The results are applied in the design of a protective, beach-dune structure (with buried seawall as a safety factor) at Dam Neck, Virginia for the US Navy. The damage curves are used to estimate annual dune maintenance costs and hence, total life-cycle costs for this "soft" alternative to shore protection. Interestingly, the dune-beach-buried seawall alternative costs less than a concrete structure using artificial units for armor.

Construction is complete and a three year monitoring project begun so that actual versus theoretical dune damage curves can be determined in the future.

1.0 Introduction

Dunes are "soft" coastal structures that quickly lose cross-sectional volume during elevated, storm surge events. Cross-shore sediment transport, beach profile models permit the development of dune "damage" curves showing the percent dune cross-sectional change, ΔV (damage) versus the relative storm surge level, S compared with the design storm surge, S_D . The dune damage curves can then be used in the classical, convolution integral method to compute annual dune maintenance costs. Life-cycle

¹ Professor of Civil & Environmental Engineering and Director, the Coastal Engineering Centre, Old Dominion University, Norfolk, Virginia 23529 USA

² Instructor, Department of Civil Engineering, Dongshin University, Daeho-Dong, Naju-City, Jeonranam-Do, 520-714 Korea

costs of the "soft" solution for coastal protection (dune-beach alternative) can then be compared with the "hard" alternatives (seawalls, dikes, etc.) on an equal, total annual cost per unit shoreline length basis.

The objective of this paper is to present the results of one analysis using the SBEACH model (Larsen and Kraus, 1989) for the design of a dune-beach restoration project to protect \$95 million of structures and property at the US Navy's, Fleet Combat Training Center (FCTC), Dam Neck, Virginia. Section 2 briefly reviews the available models and key independent variables. The dune damage curves are summarized in Section 3 including safety factors used in dune design. Maintenance costs are determined in Section 4 and a cost comparison with an armored seawall design presented in Section 5. Construction of the entire project has recently been completed and a three year, beach profile monitoring project begun so that the theoretical versus actual dune damage curves can be determined in the future.

2.0 Beach - Dune Erosion Models

Recently, ten cross-shore sediment transport models have been evaluated by Schoonees and Theron (1995). The model developed by Larsen and Kraus, 1989 called SBEACH was found to be "acceptable" on its theoretical basis and in the "best group" category based on the extent of verification with prototype data. It allows sand overwash during elevated water level events so that the total, cross-shore sectional volume is conserved.

The probabilistic design of dunes with examples from the Netherlands are presented by van de Graaff (1989) as illustrated in Figure 1. It was learned (Table 1) that storm surge elevation accounted for about 83 percent of the total variance associated with dune erosion. Wave height, particle size, initial profile shape, storm duration and other factors were far less important. The change in dune cross-sectional area (per unit width) was primarily related to elevated water levels during storm surge events.

Dune damage curves are thus analogous to rubble mound damage curves created by excessive *wave energy* above the design, wave height.

3.0 Dune Damage Curves for Dam Neck, Virginia

Figure 2 shows the location of the Navy's FCTC at Dam Neck, Virginia on the Atlantic Ocean below the City of Virginia Beach.

Using a 50 ft. (15.2m) crest width at elevation +22ft (6.7m) above the City of Virginia Beach datum and 2:1 side slopes produces a unit volume of 30cy per foot ($75\text{m}^3/\text{m}$) above the one percent chance, storm surge event (9.1 ft., 2.8m). This dune cross-sectional (Figure 3) is essentially that originally designed by Headland (1991) and contains fifty percent more sand than the minimum requirement of $540\text{ ft}^3/\text{ft}$ ($50\text{m}^3/\text{m}$) as established by the Federal Emergency Management Agency (FEMA) for breaching of natural dunes.

A nearshore survey taken in May, 1990 was considered representative for the existing bathymetric conditions in the model. The SBEACH model was run with eleven successively higher water level events to cover the return periods between 1

The objective of this paper is to present the results of one analysis using the SBEACH model (Larsen and Kraus, 1989) for the design of a dune-beach restoration project to protect \$95 million of structures and property at the US Navy's, Fleet Combat Training Center (FCTC), Dam Neck, Virginia. Section 2 briefly reviews the available models and key independent variables. The dune damage curves are summarized in Section 3 including safety factors used in dune design. Maintenance costs are determined in Section 4 and a cost comparison with an armored seawall design presented in Section 5. Construction of the entire project has recently been completed and a three year, beach profile monitoring project begun so that the theoretical versus actual dune damage curves can be determined in the future.

2.0 Beach - Dune Erosion Models

Recently, ten cross-shore sediment transport models have been evaluated by Schoonees and Theron (1995). The model developed by Larsen and Kraus, 1989 called SBEACH was found to be "acceptable" on its theoretical basis and in the "best group" category based on the extent of verification with prototype data. It allows sand overwash during elevated water level events so that the total, cross-shore sectional volume is conserved.

The probabilistic design of dunes with examples from the Netherlands are presented by van de Graaff (1989) as illustrated in Figure 1. It was learned (Table 1) that storm surge elevation accounted for about 83 percent of the total variance associated with dune erosion. Wave height, particle size, initial profile shape, storm duration and other factors were far less important. The change in dune cross-sectional area (per unit width) was primarily related to elevated water levels during storm surge events.

Dune damage curves are thus analogous to rubble mound damage curves created by excessive *wave energy* above the design, wave height.

Figure 1 Schematic of Dune Erosion by Elevated Water Levels: Dutch Practice (from van de Graaff, 1986)

Table 1 Relative Importance of Independent Variables on Dune Erosion (from van de Graaff, 1986)

Contribution parameters to variance reliability function

Parameter	Contribution variance reliability function (%)
surge level	82.8
wave height	0.9
particle size	7.3
initial profile	1.3
surge duration	2.6
gust bump	0.0
accuracy computation	5.0

3.0 Dune Damage Curves for Dam Neck, Virginia

Figure 2 shows the location of the Navy's FCTC at Dam Neck, Virginia on the Atlantic Ocean below the City of Virginia Beach.

Using a 50 ft. (15.2m) crest width at elevation +22ft (6.7m) above the City of Virginia Beach datum and 2:1 side slopes produces a unit volume of 30cy per foot (75m³/m) above the one percent chance, storm surge event (9.1 ft., 2.8m). This dune cross-sectional (Figure 3) is essentially that originally designed by Headland (1991) and contains fifty percent more sand than the minimum requirement of 540 ft³/ft (50m³/m) as established by the Federal Emergency Management Agency (FEMA) for breaching of natural dunes.

A nearshore survey taken in May, 1990 was considered representative for the existing bathymetric conditions in the model. The SBEACH model was run with eleven successively higher water level events to cover the return periods between 1 on Southeastern Coastline, Atlantic Ocean and 1000 years (Table 2). Wave heights associated with these water levels were established from measured and extrapolated values at the Corps' FRF, Duck, NC. As illustrated in Figure 3, the original dune section was modified by sand moving offshore ΔV_3 , sand overwash ΔV_1 , and the dune volume ΔV_2 . Dune damage is the volume change (loss) ΔV_2 and here after simply ΔV as found in Table 2. The total volume change above mean low water (MLW) accounted for all but less than 1cy per foot which moved offshore.

Dune Volume loss in cy/ft (ΔV in Table 2) and the percent loss (damage) are plotted against the S/S_D ratio as shown in Figure 4a and 4b, respectively. These curves are conservative in that they do not include the renourished beach in front of the dune as discussed blow.

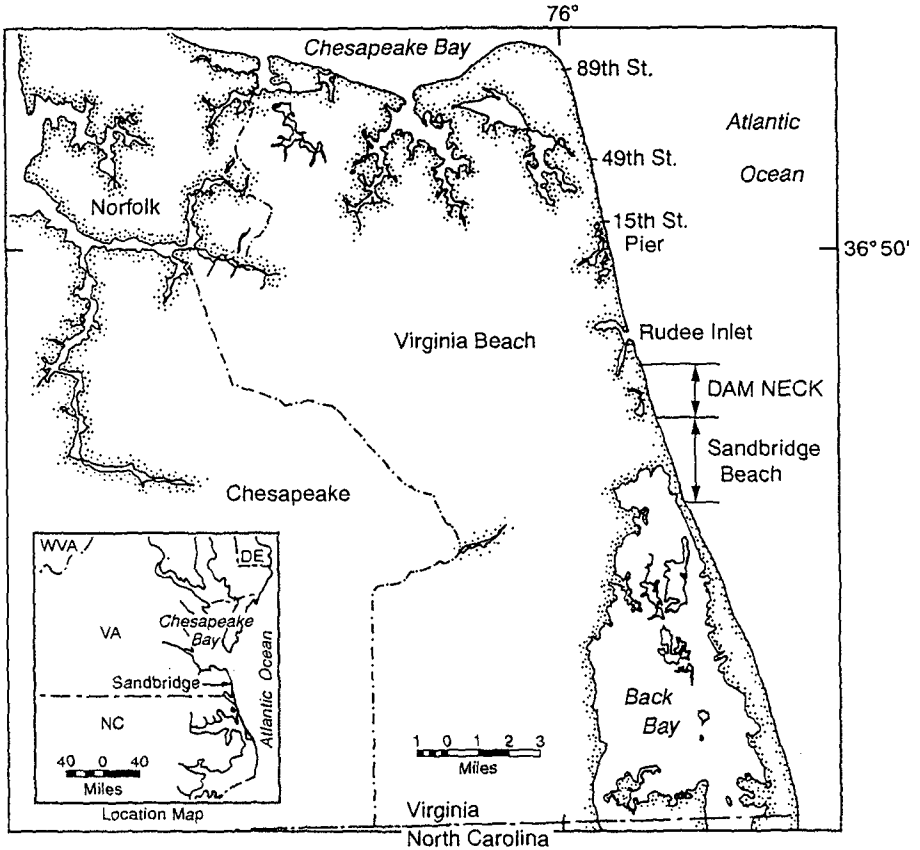

Figure 2 Location of US Navy, Fleet Combat Training Center, Dam Neck, Virginia on Southeastern Coastline, Atlantic Ocean

ΔV = Volume Loss Without Seawall

ΔV_w = Volume Loss With Seawall

P = Percent Damage Without Seawall

P_w = Percent Damage With Seawall

(P, P_w) = 100*(ΔV , ΔV_w)/V, V=Total Volume of the Dune, 30 cy/ft

Dutch design practice for dunes (TAW, 1984) includes a safety factor or "remanent" dune volume remaining after a major storm event. Headland (1991) replaced this minimum remanent volume by an equivalent volume of rubble-mound seawall buried beneath the dune. Should a second major storm occur the same winter season, the buried seawall will be in place to protect the structures behind the dune. A similar buried seawall structure as shown in Figure 5 has been incorporated in the constructed project. Its effect on the damage curve is ΔV_w in Table 2 as illustrated in Figure 4b. The buried seawall acts to reduce dune volume loss at high water level events.

Figure 4a Dune Volume Loss (cy/ft) Versus S/S_D

Figure 4b Dune Damage Curve: Percent Loss Versus S/S_D

Figure 5 Dune-Beach-Buried Seawall Design for Dam Neck, VA

However, as illustrated in Figure 6, a major reduction in dune volume loss (percent damage) occurs when the beach is also renourished seaward of the dune. As an example, when the constructed beach width is 75ft (23m) damage curves for a design width after equilibration of 40 ft (12m) and with one-half life remaining of 20 ft (6m) are presented in Figure 6. Dune maintenance costs are obviously impacted by the volume of beach remaining over time to protect the dune system. The results of these computations are summarized in Table 3.

4.0 Dune Maintenance Costs

Simply stated, higher water elevations produce greater damage but have lower probabilities of occurrence each year. Annual dune maintenance costs are computed using the classical, convolution integral method of Kreeke and Paape, 1964 as illustrated in Figure 7. The dune damage curve was divided into eight subregions with damage greater than 70 percent requiring complete rebuilding of the dune structure. the storm surge probability curve was also divided into eight comparable subregions and then annual dune repair costs computed. As shown, subregion 2 for 10 - 20 percent damage from storms in the 0.2 - 0.35 probability of occurrence range accounted for the highest increment of maintenance expense. The total annual repair costs per unit foot of dune summed to about \$74 per foot (Table 4).

Using a 25 year design life and 9.5 percent interest rate in the present worth method of economic analysis resulted in annual dune maintenance costs of \$695 per foot. The value is conservative because the damage curve *without* the protective beach (Figure 4b) was used in the analysis. This can also be considered as a safety factor in the design and economic analysis.

Monitoring of the entire dune system and beach to closure depth will provide the requisite feedback information over a three year period to insure that dune maintenance is performed at appropriate intervals.

Figure 6 Effect of Beach Renourishment on Dune Damage Curves (Example for design beach width of 40 feet)

5.0 Cost Comparison With Armored Seawall

The dune damage curves used to compute dune repair costs permitted total, life-cycle cost estimates to be made for the dune-beach-buried seawall system (DBBS). Initial, unit costs for the dune of \$15/cy or \$450 per foot together with the maintenance costs of \$695 per foot produced a total cost of \$1145 per foot for the dune system. Using an offshore borrow area (Sandbridge shoal) for beach renourishment, one renourishment after 10-12 years and realistic, unit cost estimates for sand and rubble materials (buried seawall), the "soft" alternative system totalled about \$1820 per foot on an annual, life-cycle cost basis.

The original, engineering study (Cummings and Basco, 1995) also considered a conventional, large armor unit, revetment structure as the "hard" solution for storm damage mitigation.

Table 3 Summarized Computations of ΔV Values for Various Water Elevations at Dam Neck, Virginia

Return period in year	Water Level, ft	S/S _D	H _{ms} , ft	T _p , sec	Volume Loss, cy/ft					Percent Damage, %

Z = repair cost factor (say 1)

INITIAL COSTS, I.C.

$$IC = \$15/cy * 30 cy/LF = \$450/LF$$

MAINTENANCE COSTS, M.C.

$$i = 9.5\%$$

$$T = 25 \text{ yrs}$$

$$pwf = 9.4376$$

$$MC = \$73.62 * 9.4376 = \$695/LF$$

TOTAL COSTS, T.C.

$$TC = IC + MC$$

$$= \$450/LF + \$695/LF$$

$$TC = \$1145/LF$$

For a proper design study, the water depths at the toe of the stone revetment were estimated as those at the *end* of the 25 year design life. The historic, long term erosion rate, seasonal beach variations and toe scour during storms were all considered to determine the design water depth. In effect, at the end of 25 years, the beach would be gone in front of the seawall and the design water depth would be far different than today's conditions. The SBEACH model and others were used to calculate the surf zone wave conditions and design wave height for the armor layer. Artificial armor units (core-loc) were selected and resulted in total costs (minimal maintenance) of about \$2350 per foot.

Interestingly, the dune-beach-buried seawall alternative costs *less* than a concrete structure using artificial units for armor. This was primarily because the lowered beach elevations at the end of the design life permitted in large waves to directly attack the armor units with no beach remaining. Full details can be found in Cummings and Basco, 1997.

Costs are only one criteria in the decision matrix for choosing the "soft" or "hard" alternative for shore protection. Table 5 summarizes these decision criteria at Dam Neck. The only advantage of the armored revetment is lower annual maintenance costs. All others favored the dune-beach-buried seawall system. The primary benefits of this design are also that:

- a beach is present in the year 2020 at the end of the design life;
- the new sand spreads north and south to benefit all Dam Neck;
- the permitting agencies favor the "soft" alternative;
- the general public favors the "soft" alternative;
- the Navy's image will be enhanced by these efforts to protect/improve the environment.

6.0 Recommendations

Research is needed to develop generic damage curves and equations for use by coastal engineers for a wide range of practical applications. This dune design information could be developed through the systematic application of numerical models (e.g. SBEACH) plus confirmation of the results using large scale laboratory experiments and field data. The influence of the beach width should be quantified and design recommendations presented to aid the coastal engineer in dune design.

More case studies are needed comparing the life-cycle, costs of "soft" versus "hard" solutions for shore protection.

CHAPTER 231

HURRICANE OPAL INDUCED CHANGES ON NATURAL AND NOURISHED BEACHES, WEST-CENTRAL FLORIDA

Richard A. Davis, Jr.¹ and Ping Wang²

ABSTRACT

Twenty-six beach profiles were surveyed immediately after the passage of storm conditions and were compared with pre-storm situations. They include 1) eleven locations spread throughout the entire 60 km reach of the Pinellas County coast including wide, narrow, natural and nourished sites, with and without seawalls; and 2) 15 locations confined to three adjacent nourishment projects along 14 km of Sand Key.

The overall behavior of the nourished and natural beaches along the 60 km reach of coast was similar, displaying a general trend of 1) shoreline erosion ranging from 2 to 10 m, 2) upward and landward migration of the nearshore bar, and 3) backbeach accumulation and increase in the berm height. Shoreline orientation and beach sand composition played no significant role in beach performance during the storm. The technique of dry beach replenishment using a dragline and conveyer belt may contribute to the more severe shoreline erosion at the Indian Shores nourishment project as compared to the traditional pumping technique used at Indian Rocks Beach and Redington Beach.

Temporary berm accumulation and shoreline accretion were recorded at two chronically eroding locations downdrift of structures. The shoreline accretion was caused by the landward sand transport induced by the storm waves. The storm accumulation was eroded by the normal-weather longshore sediment transport within three months after the storm.

The current version of SBEACH model (Larson and Kraus 1989) failed to reproduce the Opal-induced beach changes in the surf zone. The unsuccessful prediction was attributed to the uncertainties in offshore wave measurement, and morphological and computational complications caused by the exposure of hard bottom in the nearshore region.

INTRODUCTION

Hurricane Opal passed about 250 km to the west of the west-central Florida coast in its northerly path toward the Florida panhandle in early October, 1995. The speed of the hurricane center (Fig. 1) in the central Gulf of Mexico was relatively slow. The slow speed generated abnormally long-period, high waves in the Gulf. A storm surge of about 1 m was measured in the study area along the west-central Florida coast (Fig. 2). The energetic conditions and the storm surge lasted for approximately two days during spring tide conditions.

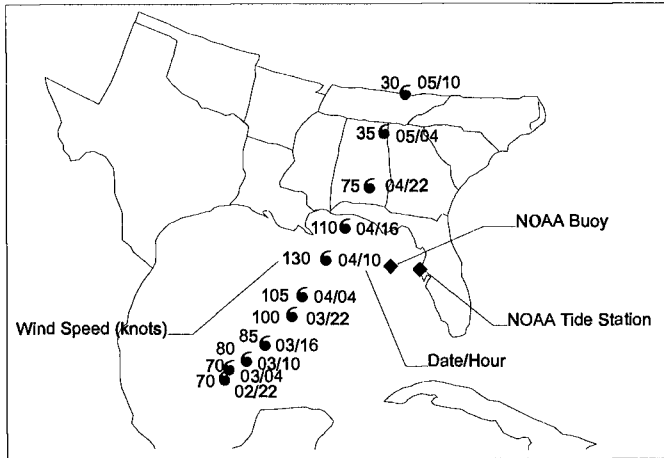

Figure 1. Storm track of Hurricane Opal and NOAA's wave buoy and tide gage.

Figure 2. Measured significant wave height, average wave period, and storm surge by the NOAA buoy station 42036 and Clearwater tide station.

The significant wave height measured by the NOAA wave buoy (Fig. 1) reached a maximum over 9 m. Although the average wave period as shown in Figure 2 was less than 10 s, the dominant wave period reached 13 to 14 s during the peak of the storm. A storm surge of nearly 1 m was measured by the NOAA Clearwater tide station at the northern boundary of the study area (Fig. 2).

Twenty-six beach profiles were surveyed immediately after the passage of storm conditions and were compared with pre-storm profiles which were surveyed 1 to 2 months before the storm. Each profile was surveyed to a depth of 1.5 m below NGVD along a shore-normal transect. The 26 profiles are located along nearly 60 km of coast in Pinellas County, Florida and are part of an ongoing, long-term study of beach dynamics. Both natural and nourished beaches were included with construction ranging from 2 years old to nearly 10 years. The study area has a coastal orientation that ranges over about 40 degrees with a broad headland in the middle (Fig. 3). The shoreface gradient ranges from about 1:400 to 1:700 with the steepest being at the headland.

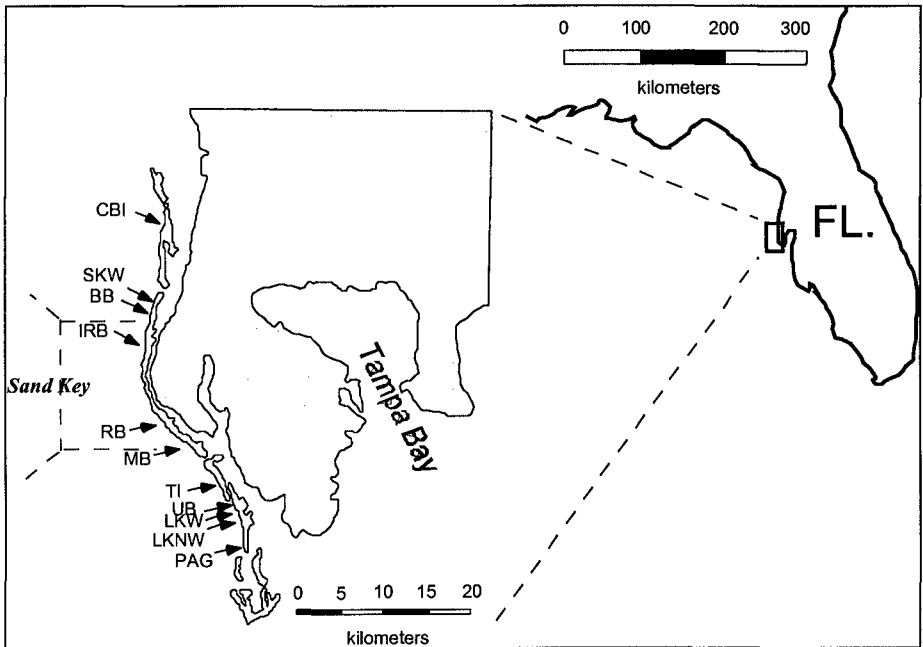

Figure 3. Study area in Pinellas County, Florida. The eleven sites are indicated by the lettered arrows. The 15 nourished locations are equally spaced at 300 m intervals on central Sand Key.

The objective of this study was to examine the hurricane-induced beach morphology changes through the comparison of profiles surveyed before, immediately after, and 4 to 8 months after Hurricane Opal. Different types of

beaches with different orientations and different degrees of human activities including natural and nourished, with and without seawalls, were examined and compared. Dominant direction of sediment transport during storm and normal-weather conditions is discussed. The application of the SBEACH model in predicting the storm induced beach changes along west-central Florida coast is also examined.

STUDY AREA

Two sets of profiles were surveyed: 1) eleven locations spread throughout the entire 60 km reach of coast including wide, narrow, natural and nourished beaches, with and without seawalls; and 2) 15 locations confined to three adjacent beach nourishment projects along 14 km of Sand Key (Fig. 3). The dominant longshore sediment transport along the entire coastal reach is toward the south, but there are local reversals. Two locations (SKW and UB), downdrift of structures, are experiencing severe beach erosion. SKW (Fig. 3) is currently protected by seawalls. The chronically eroding Upham Beach (UB in Fig. 3; Leonard et al. 1989, Dixon and Pilkey 1989) was protected by sand bags and renourished for the fifth time in the last 20 years in May, 1996.

Three adjacent beach nourishment projects were constructed on Sand Key. Five locations, R74, R75, R78, R80, and R81, were surveyed on Indian Rocks Beach which was nourished in 1990. The middle project at Indian Shores (R86, R87, R89, R91, and R92) which is located on the protruding headland was nourished in 1992 and the southern project at Redington Beach (R98, R99, R106, R107, and R108) was nourished in 1988. The nourishment at Indian Shores was constructed differently from the two adjacent projects. Instead of using the conventional pumping, the sand was replenished dry with a dragline and conveyer belt. The less expensive dry fill resulted in a looser packing than the wet pumping. The nearshore wave energy is usually higher at the Indian Shores headland due to the steeper shoreface gradient than at the adjacent Indian Rocks Beach and Redington Beach.

Sediment properties on natural beaches are different from those on the nourished beaches. Natural beaches or beaches that have not been nourished for the last decade or so are typically composed of well-sorted fine sand with less than 10% shell gravel. Nourished beaches, especially the two recently constructed at Indian Rocks Beach and Indian Shores, have significant amount of shell gravel, generally more than 20 %, inherited from the borrow material. Sediments in the swash zone have even higher shell-gravel concentration.

OPAL-INDUCED CHANGES ON NOURISHED BEACHES

All the nourished sites showed shoreline erosion of 2 to 10 m (Fig. 4A). The protruding 4-year old Indian Shores suffered the most shoreline loss, ranging from 8 m to over 10 m. The 8-year old Redington Beach lost the least shoreline, from 2 to 8 m. The 6-year old Indian Rocks Beach lost between 5 to nearly 10 m. The severe

shoreline erosion at Indian Shores headland is believed to be caused by a combination of high wave energy and loose packing.

The sand-volume change above the -1.5 m NGVD datum was generally small, ranging from 15 m³/m gain to 17 m³/m loss (Fig. 4B). Although most of the locations lost 2 to 17 m³/m sand, five of the 15 locations gained various amount of sand. The trend of volume change was not as apparent as the shoreline change. The reason for the less distinctive trend of volume change as compared to shoreline change was that the volume loss at the shoreline was compensated by the landward and upward migrations of the nearshore bar and the accumulation on the backbeach, forming a higher berm (Fig. 5).

Figure 4. Shoreline (A) and volume (B) changes on the nourished beaches.

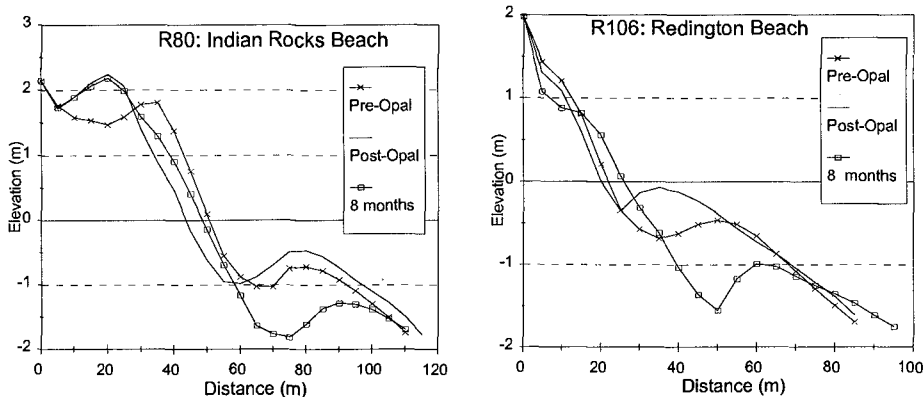

Figure 5. Beach profile changes: before, immediately after, and 8 months after.

It is generally assumed that large storm waves induce seaward migration of the breaker-point bar (e.g., Komar 1976, Dean 1995). This hypotheses which was developed from the original beach cycle study of Shepard (1950) has been used

broadly in shoreface-development studies (e.g., Pilkey et al. 1991). Larson and Kraus (1994) documented landward sediment transport during 3 of the 4 examined storms in 1989 and 1991 at Duck, North Carolina. Landward and upward migration of the nearshore bar induced by Hurricane Opal was measured on all the barred locations in the present study along the 60 km study area (Fig. 5). This landward migration of nearshore bar was also observed by Stone et al. (1996) on the Florida panhandle. Shoreline recovery and seaward migration of the nearshore bar was measured 4 and 8 months after Opal, indicating a seaward transport during the normal-weather conditions.

Seasonal beach cycles like those observed along the U.S. Pacific coast (e.g., Shepard 1950, Inman et al. 1993) are not observed along west-central Florida coasts. The landward migration of the nearshore bar observed in this study cannot be explained by the seaward shift of breaker point during high-energy storm wave conditions, which would result in seaward migration of the breaker-point bar. The unexpected upward and landward bar migration indicates that in addition to the wave steepness and the location of breaker point, the nearshore bar migration may be also controlled by other factors. Further study is needed to understand the mechanism of landward bar migration during storm conditions.

Another morphological change that was observed at all the profile locations except the "hot spot", R106 (Fig. 5B), was the accumulation on the backbeach. A large amount of sand was deposited landward of the previous berm crest. The berm crest was shifted landward and higher than before. The thickness of the wedge-shaped accumulation decreased landward and terminated, at most of the nourished locations, before the accumulation reached the seawalls. The backbeach accumulation was the thickest, up to 1 m thick at the storm-berm crest, on the high-energy Indian Shores headland, and the thinnest on the relatively low-energy Redington Beach.

Significant shoreline recovery and the seaward migration of the nearshore bar were observed 8 months after the storm (Fig. 5). The shoreline recovery resulted in more gentler beach than the storm beach, especially in the vicinity of the shoreline. The backbeach accumulation remained unchanged because the storm berm crest is beyond the reach of wave uprush under normal weather conditions.

Natural beaches or those that have not been nourished in the last decade or so (CBI, MB, TI, LKNW, and PAG in Fig. 3) showed a similar general trend, i.e., shoreline erosion, landward migration of nearshore bar, and backbeach accumulation, across the entire 60 km study area. The amount of shoreline retreat, ranging from 2 to 10 m, was similar to that measured on Indian Rocks Beach and Redington Beach and was less than that on Indian Shores (Fig. 6A) headland. Volume change above -1.5 m NGVD was generally small, mostly less than 15 m³/m, and showed similar trend (Fig. 6B) as that observed on nourished beaches in Sand Key.

Figure 6. Shoreline (A) and volume (B) change of the 11 locations along Pinellas County, Florida.

OPAL INDUCED CHANGES ON THE CHRONICALLY ERODING STRUCTURED BEACHES

Two of the beaches that are historically erosional, SKW and UB (Fig. 3), are both downdrift of structures. Scour behind the seawall and damage to the adjacent residential buildings occurred due to storm wave over-topping at both locations. A significant amount of sand accumulation was measured in front of the seawall at SKW, and the sand bags at UB were buried by sand that was deposited on the beach (Figs. 6, 7). As much as 26 m of shoreline accretion with nearly 60 m³/m volume gain was measured at SKW immediately after the storm. Ten meters of shoreline accretion and 35 m³/m volume gain were measured at UB just south of the wave-dominated inlet, Blind Pass (Davis and Gibeaut 1990). Large carbonate rock fragments characteristic of the Tampa Limestone which is exposed offshore were found on the storm beach, indicating that the sediment was transported landward from offshore during the storm. It is believed that the seawalls and sand bags induced significant energy dissipation during the storm surge. The fast rate of energy dissipation resulted in backbeach accumulation above the normal wave uprush limit.

The temporary sediment accumulation induced by Opal was eroded completely within four months after the storm (Fig. 7). The longshore transport under normal weather and the lack of updrift sediment supply are believed to be responsible for the erosion. The southward transport is evident at Upham Beach (UB) from the most recent beach nourishment. A profile, LKW (Fig. 3), about 150 m south of the UB location, was surveyed as part of a long-term beach monitoring program. A large amount of sediment was replenished on the Upham Beach about 7 months after the storm. The LKW location was about 80 m south of the nourishment project. Significant shoreline erosion was measured at UB only 3 months after the nourishment (Fig. 8). Remarkable accumulation was measured at the LKW location during the same period. The shape and slope of the shoreface at Upham Beach

remained fairly constant, suggesting that the shoreline retreat was not caused by the cross-shore profile adjustment. It is evident that the southward longshore transport is the cause of the long-term beach erosion at Upham Beach as well as the erosion of the storm accumulation from Opal.

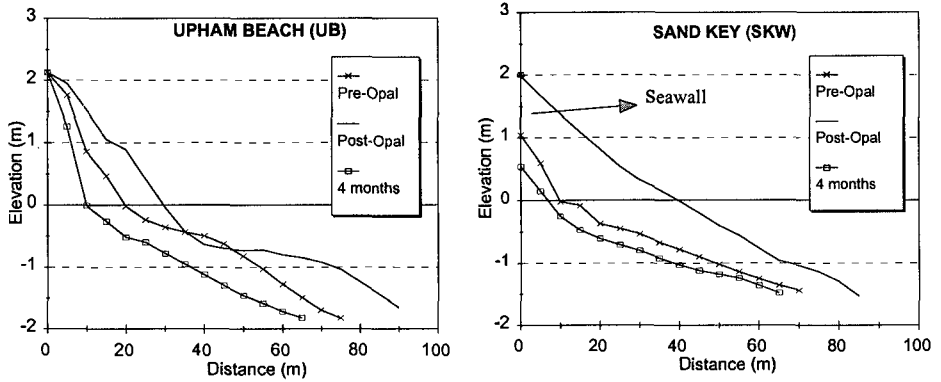

Figure 7. Temporary accumulation induced by Hurricane Opal on structured beaches.

Figure 8. Shoreline erosion at the recently nourished Upham Beach and sand accumulation at the downdrift beach. Note the differences in scale.

The seawall and stabilizing sand bags effectively protected the coast and dissipated a significant amount of wave energy during Hurricane Opal. The structures are not capable of controlling regional and long-term beach changes caused by longshore sediment transport. Beach nourishment not only provides a

buffer for normal weather shoreline erosion caused mainly by longshore sediment transport but also protects the coasts against dramatic storm events.

SBEACH MODELLING OF THE BEACH PROFILE CHANGES

SBEACH, the numerical model for simulating storm-induced beach change (Larson and Kraus 1989), was applied to reproduce the Opal-induced beach profile changes along west-central Florida coast. The offshore wave condition measured at the NOAA's 42036 wave buoy and the water level measured at the NOAA's Clearwater tide station (Fig. 2) were used as the key hydrodynamic input data. The numerical modeling was applied to the 15 locations on Sand Key. An average grain size of 0.33 mm obtained from over 1100 samples was used to represent the sediment. The model was calibrated at two locations, one at the northern Indian Rocks Beach and one at the southern Redington Beach.

Examples of SBEACH modeling are illustrated in Figure 9. The trend of shoreline erosion induced by Hurricane Opal was successfully reproduced by the SBEACH model, although the magnitude of the shoreline erosion was over predicted. The backbeach accumulation and the unexpected upward and landward migration of the nearshore bar were not predicted. The bar/trough features were basically absent from the predicted profiles. The increased berm height and the wedge-shaped sediment accumulation on the backbeach were not predicted, on the contrary, significant berm erosion and a much gentler beach slope near the shoreline, as compared to the pre-storm situations, were predicted.

The unsatisfactory SBEACH modeling is believed to be caused by the uncertainties in input wave data and regional morphological and geological complications. A significant wave height of over 9 m with a relatively short wave period of less than 10 s was measured by the NOAA's 42036 wave buoy offshore west-central Florida. The 9 m significant wave height was much larger than that observed in the nearshore (3 to 4 m, as printed on the local newspaper). The over-predicted backbeach erosion is believed to be caused by the possibly exaggerated wave height. This assumption was proved by using an arbitrary smaller wave height of 3.5 m. Much less backbeach erosion was predicted with the smaller input wave height.

The nearly horizontal hard bottom composed of Tampa Limestone violated the bottom boundary condition of movable sand assumed in the current version of SBEACH. The depth of the hard bottom decreases from north to south. At northern Indian Rocks Beach, the hard bottom is exposed at 7 m, the depth decreases to about 3 m at the southern Redington Beach. Based on the wave breaking criterion used in the SBEACH model (Larson and Kraus 1989), the nearly horizontal hard bottom is within the breaker zone during the peak of the storm conditions with over 9-m waves. The current version of SBEACH is not capable of incorporating the non-erosible hard bottom, especially when the hard bottom is within the breaker zone. The above situation will be an ideal field test for the updated SBEACH model (N.C. Kraus, personal communication; available:

December 1996, Randy Wise, personal communication) which will incorporate the influences of non-erosible bottom.

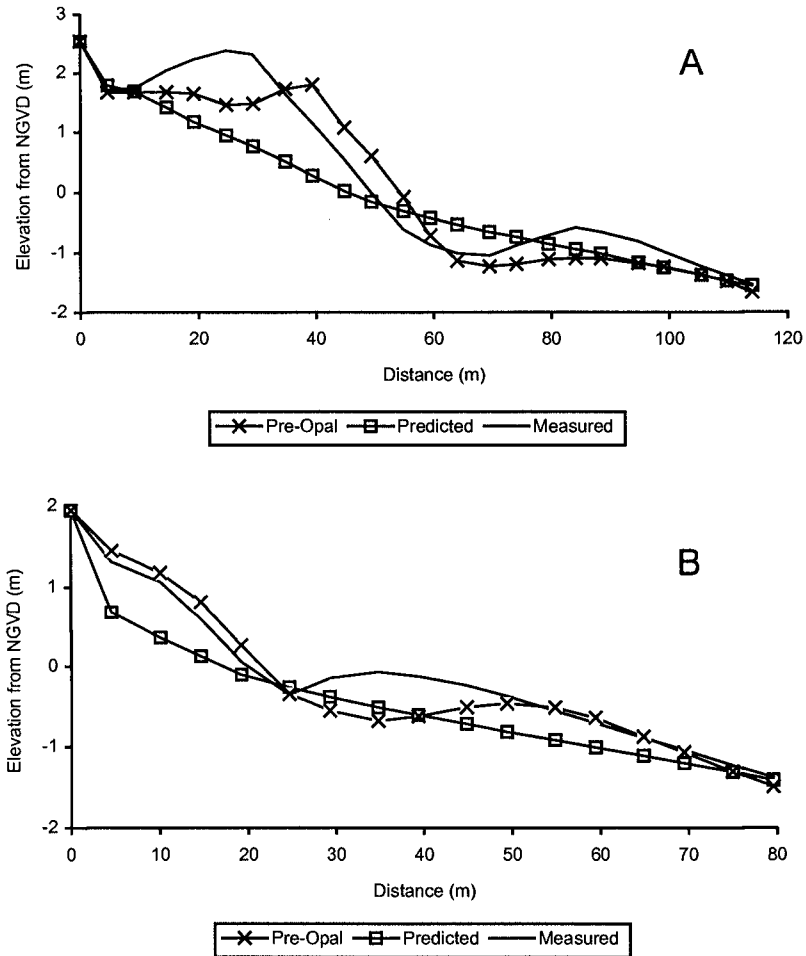

Figure 9. Measured and predicted beach profiles; A) R74, Indian Rocks Beach; and B) R106, Redington Beach.

SUMMARY AND CONCLUSIONS

The overall behavior of the nourished and natural beaches during the passage of Hurricane Opal is similar. All surveyed beaches along the 60 km reach of coast displayed a general trend of shoreline erosion, upward and landward migration of the nearshore bar, and accumulation on the backbeach resulting a higher berm. This

trend was observed on beaches with different orientations and different sediment compositions, ranging from less than 10% shell gravel on natural beaches to greater than 30% shell gravel on nourished beaches. This indicates that shoreline orientation and sand composition played no significant role in beach performance under storm conditions.

It is apparent from the data collected on the three adjacent and differently constructed nourishment projects on Sand Key that they behaved differently. The oldest showed least change and the most recent showed the most. The most recent project was also constructed without the benefit of dredging and pumping, thus creating a loosely compacted beach. The loose packing contributed to the greater rate of erosion.

The two chronically eroding locations downdrift of structures behaved differently from the nourished and natural beaches. Significant shoreline accretion was measured at the two locations, with one protected by seawalls and the other protected by sand bags, immediately after the storm. A large amount of sand accumulated on the beach in front of the structure resulting from the storm-induced landward transport. The temporary storm accumulation was eroded by the normal-weather longshore sediment transport within 3 months after the storm.

The current version of SBEACH model failed to reproduce the Opal-induced beach changes along west-central Florida coast. The unsuccessful prediction is attributed to uncertainties in input wave data and the model's limitation in incorporating the non-erosible hard bottom in the study area into the computation.

ACKNOWLEDGEMENTS

This study was supported by Pinellas County, Florida and Florida Department of Environmental Protection. The authors would like to thank the graduate students in the Coastal Research Laboratory at the University of South Florida for their assistance in the field work. The SBEACH model was kindly provided by Randy Wise at the Coastal Engineering Research Center.

CHAPTER 232

Modelling Sand Transport and Profile Evolution on Macrotidal Beaches

Paul.R.Fisher¹ & Tim.J.O'Hare²

Abstract

An empirical model is presented which simulates the effect of tidal translation of cross-shore sediment flux patterns, in support of a hypothesis that wave height *and* tidal range are the key influences in the formation of characteristic macrotidal beach profiles. The energetics-based model is based upon field observations of cross shore currents and sediment fluxes from three high-energy macrotidal (tide range >4m) locations around the U.K, chosen as representations of dissipative, intermediate and reflective environments (after Wright and Short, 1984). The observed depth-dependant flux patterns are translated across linear beach profiles, with gradients modelled from sediment characteristics (Dean 1977, Kriebel et al 1991), the evolution of characteristic macrotidal beach profiles and the development of attendant features such as break-point bars, low tide terraces, and steepened foreshores are observed.

Introduction

The morphological significance of tidal translation of the swash, surf and shoaling wave zones across the beachface has received increasing attention over the last fifteen years (Wright et al (1982), Short (1991), Masselink (1993), Masselink and Short (1993)). It has been suggested that the continual variation in water depth by the tidal signal in a *macrotidal* environment is responsible for temporal variations in local dynamics. Furthermore, the intermittence of swash and surf processes in the high-tidal zone modifies the dynamics of that zone, whereas the mid and low-tidal zone dynamics are more similar to nearshore and offshore zones on micro-tidal beaches (Wright et al, 1982).

This contribution sets out to give some insight into the effects of asymmetric residence times of the water level on the beachface within macrotidal regimes.

¹Research student, ²Senior Lecturer, Institute of Marine Studies, University of Plymouth, Drake Circus, Plymouth, Devon, UK, PL4 8AA

According to the classification of Bird (1969) macrotidal regimes are those locations where the mean maximum tidal range during a month is greater than 4 metres, mesotidal regimes experience a mean maximum tidal range between 2 and 4 metres, and microtidal regimes are between 1 and 2 metres. While much work has been done relating the effects of a varying wave field on sediment transport processes in macrotidal regimes, (e.g. Wright et al (1982), Wright and Short (1984)), it is not clear how transport processes are modulated by a continual rise and fall of the water level by the tidal signal. This effect is pronounced within macrotidal environments where migration velocities and widths of swash, surf and wave shoaling zones are variant during the tidal cycle dependant on (a) the phase of

Figure 1. Tidal translation of swash, surf and shoaling zone processes across a beachface of exponential form. Because of the shoreward increasing beach gradient swash, surf and shoaling zones narrow significantly at high tide levels.

the tide and (b) the local gradient of the beach. The tidal variation in magnitude and position of these zones is illustrated in Figure 1 for the case of an exponential beachface. The approach taken in this study is to oscillate simple empirical models of cross-shore sediment transport across a beachface, allowing the profile to respond to the resulting patterns of erosion and deposition. The empirical model used is constructed from field observations of water and sediment dynamics at a variety of high energy macrotidal locations around the U.K during the British Beach and Nearshore Dynamics (B-BAND) experiment.

A useful overview of the B-BAND experiment is given by Davidson et al (1993). This three-year experiment investigated surf zone processes at three high

energy macrotidal locations around the UK. The sites were chosen to represent dissipative, intermediate and reflective beaches following the morphodynamic classifications of Wright and Short (1984). The locations are illustrated in Figure 2 along with typical beach profiles and are described briefly in turn.

Llangennith: A dissipative high energy beach with a shallow beach gradient (0.014-0.020) with fine to medium quartz sands ($D_{50}=0.21\text{mm}$). This beach is west facing, has a tide range up to 9 metres, and broad surf (up to 350m) and intertidal ($\sim 500\text{m}$) zones.

Spum Head: An intermediate beach located near the end of a 5km long spit facing the North Sea. The beach profile comprises a steep high tide beach ($\tan\beta \sim 0.0975$) and a low tide terrace ($\tan\beta \sim 0.023$, and $D_{50}=0.35\text{mm}$). This beach has a tide range up to 6m and experiences strong longshore tidal currents which have a significant effect on surf zone dynamics.

Teignmouth: A reflective beach site facing south-east into the English Channel sheltered from Atlantic swell. The beach is backed by a sea wall, and has a gradient of 0.067-0.142. Cross-shore variation of sediment size at this location is significant, with a D_{50} value of 0.24mm. Tidal range is 6 metres.

Figure 2. Location of B-BAND field sites around the UK, showing typical cross-sectional profiles.

Shape Function Approach To Sediment Transport

Foote (1994), Foote et al (1994), and Russell and Huntley (1996) examined field measurements of cross-shore sediment transport from these three locations. They calculated velocity moment contributions to sand transport, by assuming the instantaneous velocity field to be composed of the following contributions:

$$\bar{\mathbf{u}} = \bar{\mathbf{u}} + \mathbf{u}_S + \mathbf{u}_L \quad (1)$$

where \bar{u} is the mean flow, u_s is the incident wave component of velocity, and u_L is the long wave component. Using Bagnold's (1963, 1966) uni-directional stream flow total load sediment transport model, modified by Bailard (1981, 1987) for cross shore sediment transport under bi-directional flow, Guza and Thornton (1985) used field measurements to examine the relative importance of the velocity moment terms in Bailard's model, and found the transport significant terms to be (in normalised form):

$$\overline{|u|^2 u} / \left(\overline{u^2} \right)^{3/2} \quad \text{for bedload transport, and} \quad (2)$$

$$\overline{|u|^3} / \left(\overline{u^2} \right)^2 \quad \text{for suspended load transport} \quad (3)$$

Foote et al (1994) examined the cross-shore distribution of the significant moments for bedload and suspended load and found in both cases that the sum predicted a net onshore movement shoreward of the breakpoint and a net offshore movement seaward of the breakpoint. To clarify this pattern for each case they normalised the water depth by the depth of wave breaking. The position of wave breaking was determined from the position of maximum wave height from pressure transducer records and this was checked with visual observations in the field. Combining data from all three field sites they noted that not only was there a pattern of net onshore transport shoreward of wave breaking and a net offshore transport seaward of it, but that a curve could be reasonably fitted through the velocity moments calculated for the interim positions.

They subsequently proposed the existence of quasi-universal, cross-shore sediment transport spatial distribution curves for bed load and suspended load on high energy beaches. These sediment 'shape functions' are illustrated in Figure 3. Third order polynomials are fitted through each data set, with one root at $x=0$, $y=0$ (zero transport at the shoreline). O'Hare (1994) proposed that this 'shape function' approach be adopted to develop a tentative cross-shore sediment transport model, suggesting that the patterns observed in the B-BAND data are in fact required by the break-point bar hypothesis, and that characteristic macrotidal profiles may be constructed by the repeated tidal excursion of the shape function. This contribution presents the preliminary results from the development of such a model.

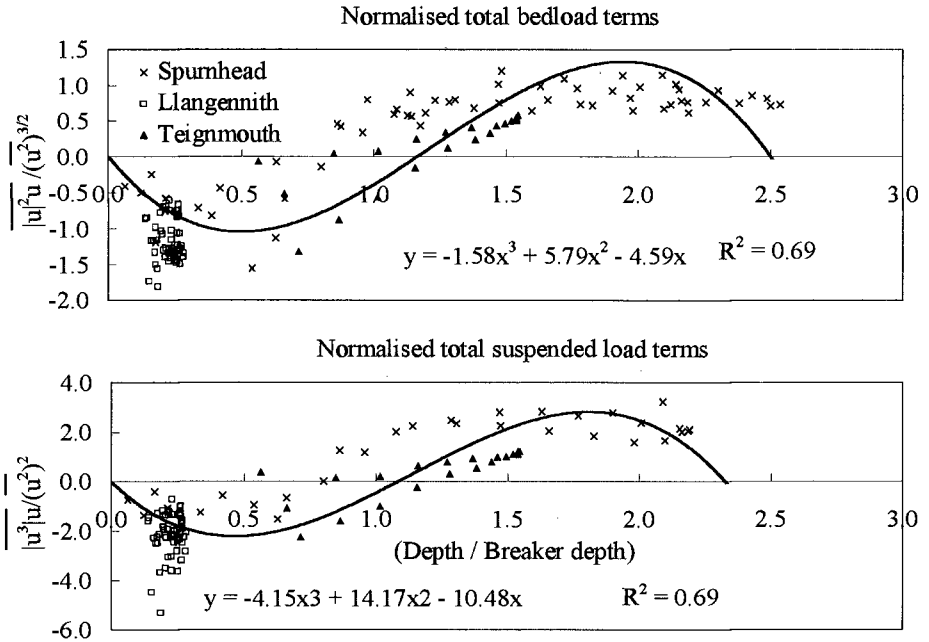

Figure 3. Sediment transport shape functions obtained from the B-BAND data.

Model Description

The simulation model migrates the proposed shape functions for bed and suspended load across a beachface. The input parameters for the model are breaker height H_b , grain diameter ϕ , tide range, wave period T , sediment and fluid densities ρ_s and ρ , gravity, kinematic fluid viscosity ν , bed drag coefficient C_d , and bed and suspended load efficiencies ϵ_b and ϵ_s . Related parameters such as sediment repose angle, $\tan\phi$, and sediment porosity, n , are evaluated using an empirical model (Allen, 1970).

The first stage for the simulation model is to evaluate the grain buoyancy and fall velocity of the beach sediment according to the CERC Shore Protection Manual procedures (US Army Corps of Coastal Engineers, 1984):

$$\text{Grain buoyancy (A): } \frac{(\rho_s - \rho) g D^3}{\rho \nu^2} \tag{4}$$

Sediment fall velocity (w):

$$w = \frac{1}{18} \frac{(\rho_s - \rho) g D^2}{\rho v} \quad \left\{ \frac{(\rho_s - \rho) g}{\rho} \right\}^{0.7} \cdot D^{1.1} \quad \left\{ \frac{(\rho_s - \rho) g D}{0.91 \rho} \right\}^{0.5} \quad (5)$$

(for $A < 39$) (for $39 < A < 10^4$) (for $A > 10^4$)

Breaking depth is then calculated iteratively according to the model of Le Mehaute (1961) using an initial estimated value for breaking depth (taken as 5m):

$$d_b = \left[\frac{H_b (g d_b T^2)^{0.5} g T^2}{0.12 \tanh 2\pi d_b} \right] \quad (6)$$

Next breaker coefficient (γ) and breaking wavelength (L_b) are evaluated from:

$$\gamma = \frac{H_b}{d_b} \quad (\text{from Galvin, 1972}) \quad (7)$$

$$L_b = \sqrt{g d_b T^2} \quad (\text{assuming shallow water}) \quad (8)$$

The preliminary (linear) gradient of the profile is evaluated at closure depth, d_c , (the outer root of the transport polynomial) from Dean (1977) and Kriebel et al (1991):

$$\tan \beta = \left(\frac{2.25 \left(\frac{w^2}{g} \right)^{\frac{1}{3}}}{d_c} \right)^{\frac{3}{2}} x_c^{-1} \quad \text{Where } x_c \text{ is the offshore distance to closure.} \quad (9)$$

The model starts at high tide with a vertical increment of 0.1 metres. Water depth is simply calculated by subtracting the profile level (initially linear) from the still water level. Next a simple model of shoaling wave height is used to determine velocity scales to apply to the polynomial coefficients. The model, again using shallow water approximations is linear from the shore to the breakpoint (depth = 0:gd), and offshore of the breakpoint, takes the form

$$H = \left(\frac{d_b}{d} \right)^{\frac{1}{4}} H_b \quad (10)$$

The shoaling wave heights are used to calculate cross-shore varying maximum orbital velocities from:

$$u_{\max} = \frac{H}{2} \sqrt{\frac{g}{d}} \quad (11)$$

u_{\max} is used to evaluate $\overline{u^2}$ by assuming a sinusoidal variation in u within the wave period. $\overline{u^2}$ is then used to scale the transport coefficients. Normalised depth, i.e. depth over breaking depth, is calculated cross-shore, so that bedload and suspended load velocity terms may be calculated from the B-BAND derived coefficients giving the $\overline{u^2|u|}$ term for bedload transport and $\overline{u^3|u|}$ for suspended load transport. The transport coefficients from the B-Band field data are then:

$$I_{\text{bed}}_{\text{coeff}} = \frac{\overline{|u^2|u}}{(\overline{u^2})^{3/2}} \left\{ -1.58 \left(\frac{d}{d_c} \right)^3 + 5.79 \left(\frac{d}{d_c} \right)^2 - 4.59 \left(\frac{d}{d_c} \right) \right\} \quad \text{bed load} \quad (12)$$

$$I_{\text{sus}}_{\text{coeff}} = \frac{\overline{|u^3|u}}{(\overline{u^2})^2} \left\{ -4.15 \left(\frac{d}{d_c} \right)^3 + 14.17 \left(\frac{d}{d_c} \right)^2 - 10.48 \left(\frac{d}{d_c} \right) \right\} \quad \text{suspended load} \quad (13)$$

The expression for bed and suspended load transport, i , from Bagnold (1966) and Bowen (1980) is:

$$i_{\text{bed}} = \frac{\varepsilon_b C_D \rho I_{\text{bed}}_{\text{coeff}}}{\tan \phi - \frac{u\beta}{|u|}} \quad (14)$$

$$i_{\text{suspended}} = \frac{\varepsilon_s C_D \rho I_{\text{sus}}_{\text{coeff}}}{W - u\beta} \quad (15)$$

where ε_b is a bedload efficiency factor, C_d is the drag coefficient for the bed, ρ the density of fluid, $\tan\phi$ is the angle of repose of sediment and $\tan\beta$ the beach slope. Similarly for suspended load transport ε_s is a suspended load efficiency factor, w is the sediment fall velocity and u is the instantaneous orbital velocity. Because our data provides a time averaged expression for $\overline{u^2|u|}$ and $\overline{u^3|u|}$ respectively, it is difficult to isolate the instantaneous orbital velocity to evaluate the slope terms in the denominator of the two expressions. In this contribution they are ignored (i.e. $u\beta$ is set to zero in the denominators).

The total cross-shore immersed weight sediment transport rate is the sum of expressions (14) and (15), and the total volumetric transport rate, Q , is thus determined by:

$$Q = \frac{i_{\text{bed}} + i_{\text{suspended}}}{(\rho_s - \rho_w)g(1-n)} \quad (16)$$

where ρ_s and ρ_w are the sediment and fluid densities, g is gravity and $(1-n)$ is the packing of settled grains (where n is the void ratio).

The sediment is then moved across the profile on the basis of the gradient of the volumetric transport rate, and the submerged part of the new profile is smoothed so that each point on the new profile is elevated or lowered to the mean of the height of its two neighbours. Having completed all these calculations for a particular tide level, the tide is moved at intervals of 1/100th of a tidal cycle through a simple sinusoid, and the process repeated.

Clearly the model works on several underlying assumptions, which may be summarised as follows:

1. The energetics model is valid.
2. Downslope and upslope transport are equal.
3. Airy wave theory is appropriate.
4. There is transmission of wave energy through bars.
5. Longshore transport is ignored.
6. Swash zone transport is ignored.
7. Sediment supply is unlimited.
8. No avalanching can occur.
9. There is a sinusoidal monochromatic tide signal.

Model Results and Discussion

Figure 4(a) shows the results of a model run with zero tidal range and a 2m breaking wave. Sediment is continually eroded at the shoreline and deposited offshore. The transport convergence point gradually moves offshore, the rate of movement being governed by the asymmetry of the transport profile in the surf zone, and the magnitude and asymmetry of the transport profile in the shoaling wave zone. As the profile evolves what started initially as an area of onshore erosion in the shoaling wave zone gets filled in by the offshore movement of sediment due to broadening of the surf zone. The plateau corresponds to the level of peak offshore transport, as modified by the wave energy profile. The onshore transport region quickly narrows into a spike as the beach gradient in the shoaling zone becomes steeper and steeper. Profile changes from cycle to cycle get smaller, suggesting that the model is approaching an equilibrium state.

Figure 4(b) shows what happens in the model when a tide range is introduced, so that the water surface is continually fluctuating and the transport zones migrate up and down the beachface. A pronounced high water bar forms, but

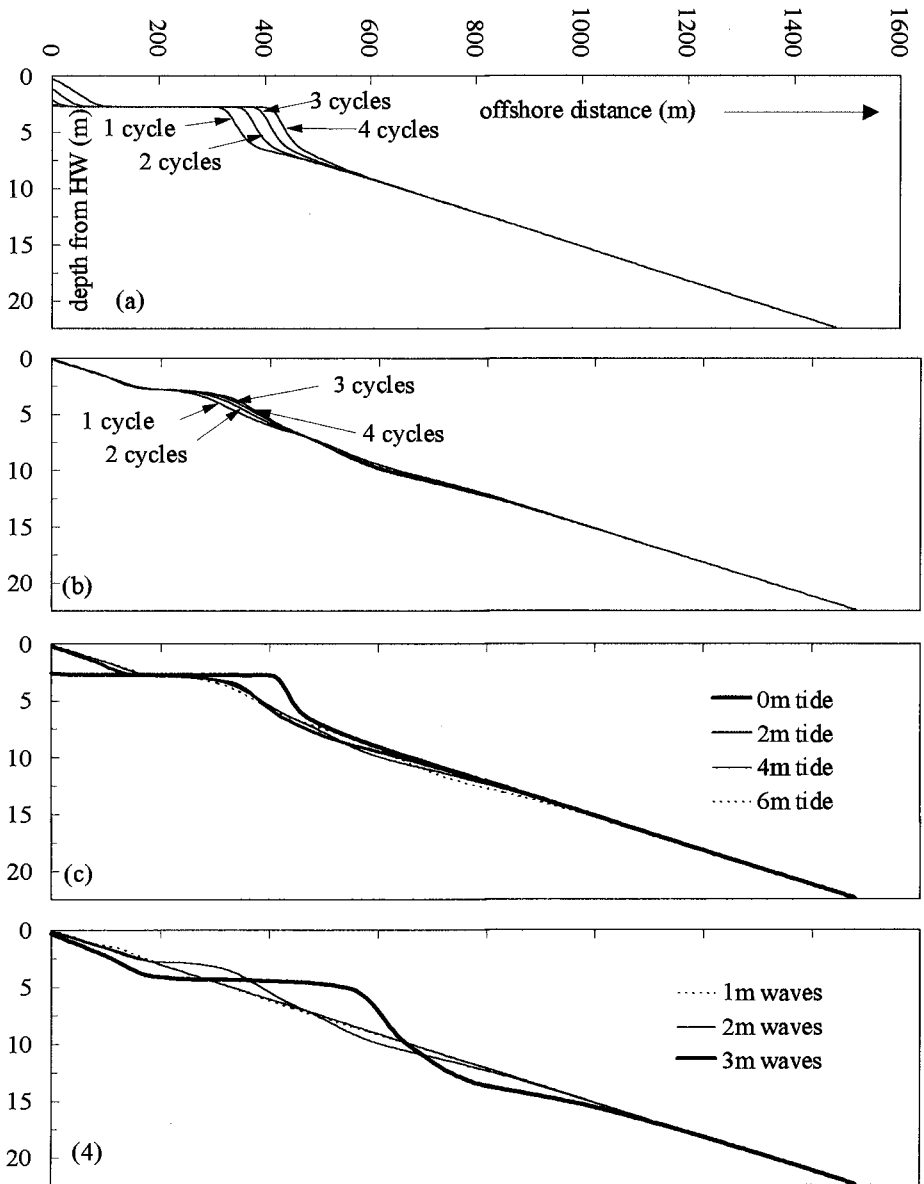

Figure 4. (a) Profile evolution through four tidal cycles with no tidal range and 2m wave height. (b) With 4m tidal range and 2m wave height. (c) Model sensitivity to tidal range 2, 4 and 6m tides (all with 2m waves). (d) Model sensitivity to wave height: 1, 2 and 3m breaking waves (all with 4m tide range).

the low water bar, corresponding to a depth from high water of approximately 6 metres, appears to be suppressed as a result of residence in both offshore and onshore transport zones. The area shoreward of the high water bar only ever resides in a zone of offshore erosion. Again the pattern of erosion and deposition is determined by the total effect of the transport profile, as modified by the shoaling wave energy profile. As the profile develops it appears to be approaching an equilibrium, and changes through time become progressively smaller. Because of the smoothing technique used, what is happening at the shoreline and in the offshore regions is that the elevation of cells outside of the transport zone is being modified by those inside, simulating a slumping effect. This model will only run for approximately 4 tidal cycles before it demands sediment from the very top, or very bottom of the profile, and fails a volume continuity test.

Figure 4(c) shows the evolution of the model profile under different tidal regimes after 4 tidal cycles, with 2 metre waves. The figure demonstrates the suppressing effect of larger tide ranges, with morphological change being the least for the 6m tidal range. In addition with the 6m range the high and low water bars become separated from each other. The position of the high water bar is similar for all cases except for the case of no tide range, where the amount of erosion has pushed it slightly further offshore.

Figure 4(d) shows the sensitivity of the model to wave height, it can be seen that the effect of increasing the wave height is similar to a reduction in tidal range - an increase in the magnitude of wave height leads to tendency for the profile to resemble the non-tidal case. 1m waves have a negligible effect on the profile even after 4 tidal cycles, while with 3m waves the erosion is so substantial, that, as with the zero tide case, the bar is moved offshore by the erosion, to the extent that it becomes indistinct from onshore accretion at low water.

Conclusion

At this stage in its development the model is not able to *quantitatively* simulate the cross-shore profile evolution on 2-dimensional beaches from a knowledge of the wave and tide regimes and sediment characteristics, although that is a possibility with further development. What has been shown is that, using quantitatively accurate flux profiles, the model produces realistic beach profiles within reasonable time-scales. Also, as has been observed by researchers examining field data from macrotidal beach sites (e.g. Wright et al (1982), Jago & Hardisty (1984), Short (1991), Masselink (1993), Masselink and Short (1993)), the model is able to confirm that wave height and tide range are the key influences on the form of the cross-shore profile.

The qualitative appearance of realistic features (offshore bar, intertidal terrace) indicates that the scale of macrotidal beach profile features can be predicted by the tidal translation of a transport shape function across the beachface. The

model will now be used to explore more complex scenarios such as profile response to tide & wave field variations, and examine the effect of spring/neap variations within the tidal cycle.

CHAPTER 233

BEACH EVOLUTION UNDER RANDOM WAVES.

Patrick Holmes¹, Thomas E. Baldock², Ray T. C. Chan³ and M. Ahmad L. Neshaei³

ABSTRACT

This paper considers the evolution of steep mobile sediment beaches under random waves and results from a new experimental investigation are presented. Both hydrodynamic data obtained over fixed beds and the resulting profile evolution of fine, coarse and bimodal sediment beaches are discussed. Wave heights and undertow in the inner surf zone are found to be poorly predicted by commonly used numerical solutions. In addition, the undertow appears to be strongly influenced by wave grouping in the nearshore. The behaviour of the fine, coarse and bimodal sediment beaches are compared and contrasted. The fine sand beaches tend to erode in the inner surf and swash zones, with the sediment moving predominantly offshore to form a bar. In contrast, onshore sediment transport dominates over the coarse sand beaches, resulting in the formation of a berm above the initial still water level. The bimodal beaches show a similar evolution to the fine sand beaches. However, considerable sediment sorting occurs, with the swash zone largely denuded of fines and the coarser sediment deposited between the still water line and the bar. The data suggests that the stability of the coarse material is significantly reduced by the presence of fines, with little evidence of armouring effects under high incident energy conditions.

1) INTRODUCTION

The hydrodynamics within the nearshore region and the subsequent evolution of beaches under wave attack are important elements governing the stability of the coastal zone. However, numerical modelling of these processes has yet to result in consistent and realistic predictions of beach behaviour. The present

study addresses this issue and considers two key aspects of the problem; the undertow and the sediment particle size. The time mean flow, or undertow, is considered one of the dominant mechanisms in the erosion of beaches (Svendsen, 1984). However, particularly under random waves, significant difficulties remain in the modelling of the undertow. This may in part be due to the difficulties in successfully predicting the wave motion in the inner surf zone (Hamm et al., 1993). In the present study, a comprehensive series of measurements of both the wave heights and near bed horizontal velocity are compared to a deterministic numerical model of nearshore processes (Southgate and Nairn, 1993).

Sediment size has a significant effect on both the magnitude and direction of sediment transport under wave action but the mechanics of the process are still poorly understood. Recent work by Work and Dean (1991) considered the effects of varying grain size on equilibrium beach profiles and showed that steeper profiles were found on beaches with larger grain sizes. However, most beaches exhibit a range of grain sizes, with frequent cross-shore sorting of sediment sizes. Moutzouris (1991) found that the coarsest sediments on a beach were generally found just seaward of the shoreline, while the finest sediments tended to be deposited on offshore bars. Mechanisms for this process have been considered by a number of authors (see Horn, 1991), but numerical models have so far resulted in little success.

Bimodal sediment transport under unbroken waves over a flat bed was considered by Mansell (1992). This work indicated a transient process, whereby the winnowing of fine grains from the bed surface led to the formation of a coarse armour layer. Using model beaches, Quick and Dyksterhuis (1994) found some evidence of an armouring process at low energy conditions. In contrast, at higher energy conditions the coarser sediment had little effect on the profile evolution and the fines controlled the beach steepness. The beach permeability therefore appeared to have a controlling influence on the beach behaviour. However, previous experimental work has not considered the sediment sorting process on beaches and, in particular, the cross-shore distribution of sediment sizes. The present study considers this process and identifies key features that appear consistent with field observations.

2) HYDRODYNAMICS

The experiments were carried out in a large wave flume in the Civil Engineering Department at Imperial College. This flume is 60m long, 3m wide and was used with a working depth of 0.9m. Waves are generated by a hydraulically driven bottom hinged paddle with the facility to absorb wave components reflected from the far end of the flume. The end of the flume is subdivided into three sections to minimise cross-tank motions and consists of a composite beach, with an initial slope of approximately 1/20, rising to 1/10 at the

shoreline. Jonswap spectra with three different significant wave heights and wave periods were used (table 1). Data was collected over 330s at 25Hz, giving 8192 points in each run. The water surface elevation was measured with standard surface piercing resistance type wave gauges and the wave heights calculated from the zeroth spectral moment ($H_{rms} = \sqrt{8m_0}$). The horizontal velocity 6mm above the fixed bed was measured using LDA and an acoustic Doppler velocimeter (ADV). The ADV was less sensitive than the LDA to noise from air bubbles generated by breaking waves, and allowed velocity data to be obtained in very shallow water.

Spectrum	H_{rms} (mm)	f_p (Hz)	T_z (s)
L	90	0.68	1.47
P	70	0.68	1.47
K	45	1.0	1.0

Table 1. Random wave spectral characteristics.

Wave heights

Figures 1a&b shows the H_{rms} wave height across the surf zone for cases P and K respectively. In the outer surf zone, the numerical solution (based on the Battjes and Janssen (1978) approach) gives good results. However, in the inner surf zone the variance and, consequently the wave height, does not decrease to zero at the shoreline. Indeed, the wave height only reduces to about half that of the initial offshore wave height. This is because the steep beach slope allows waves to travel close inshore before breaking and forming bores. The set-up just shoreward of the initial shoreline position is found to be small (of order 5mm) and this is therefore not the reason for the observed increase in wave height in the inner surf zone. It is interesting to note that calculations of the wave height based on the spectral approach and a zero crossing analysis give very similar results in the inner surf zone. This is despite the fact that the wave heights frequently exceed the water depth.

The measured spectra for case P are shown on figure 2, together with the smoothing interval and 95% confidence limits. Offshore of the breaker zone there is little energy in either the lower or higher harmonics, while just seaward of the initial shoreline the energy in the lower harmonics increases significantly. This is expected due to the generation of non-linearities by the shoaling process and the amplification of low frequency waves in shallow water. There is also a small frequency downshift of the spectral peak. However, the spectrum close to the shoreline is still dominated by energy close to the initial spectral peak frequency. The inner surf zone spectra are therefore significantly different from those observed on low slope beaches, where low frequency energy often dominates (e.g.

Holland et al., 1995). The present data are consistent with both the measured wave heights and the formation of bores with a frequency close to f_b .

 ——— $x=-2\text{m}$ ($d=200\text{mm}$), - - - - $x=-0.05\text{m}$ ($d=10\text{mm}$).

Undertow

The time-mean flow, or undertow, averaged over the total run time is shown in figures 3a&b. For both cases P and K, the undertow in the outer surf zone is very well predicted. However, for case P, the maximum value of the undertow is over-estimated but the undertow close to the shoreline is under-predicted. The over-estimation of the maximum is probably due to the difficulty in determining the depth over which the forward mass flux should be averaged and the less well defined breakpoint (see figure 1a). In shallow water, and particularly with a significant degree of turbulence, it may be more realistic to average the mass flux over the mean water depth, rather than just below trough level as is usual (e.g. Svendsen, 1984). The under-estimation of the undertow in the inner surf zone is consistent with the presence of larger waves than predicted by the numerical solution. A similar effect may be observed for case K (figure 3b), where, in addition, the principal breakpoint is also closer to the shore than predicted (figure 1b). This is likely to increase both the maximum value of the undertow and the undertow close to the shoreline. It therefore appears that a more realistic model for the nearshore wave heights is required for beach slopes of this steepness.

Recent field measurements have suggested that suspended sand concentrations are strongly correlated with the occurrence of wave groups (e.g. Hay and Bowen, 1994). This prompted a closer examination of the velocity field beneath the random waves used in the present investigation. The measured Eulerian horizontal velocity, averaged over either one or three wave periods, shows significant variations in the "local mean" flow, which may be an order of magnitude greater than the long term mean. Figure 4 shows the velocity averaged over three wave periods, the wave height averaged over the same time period and the long term mean velocity.

Figure 3a. Undertow. Case P.

— Depth, —□— data points, —◇— Numerical solution.

Figure 3b. Undertow. Case K.

— Depth, —□— data points, —◇— Numerical solution.

The variation in the “local mean” flow is strongly correlated with the occurrence of incident wave groups, which suggests that the groupiness of the wave field may be an important feature in suspended sediment transport. Note that the sign of the mean velocity has been inverted to show the correlation with wave height more clearly. The data show that large onshore mean velocities generally occur during the passage of smaller waves, while offshore mean velocities are found under the largest waves. If these variations in the mean flow are combined with coherent fluctuations in the concentration of suspended sediment, then a much large volume of sediment may be moved in suspension than a volume based on the product of the mean velocity and mean sediment concentration.

Figure 4. Temporal variations in the “local mean” flow. Case P.

 — · — long term mean, $\langle U \rangle$ (inverted).

3) Beach evolution

Beach evolution experiments were carried out under random waves for a fine sand beach, a coarse sand beach and a bimodal sediment beach. In order to facilitate the experimental study, the sediment sizes needed to satisfy three criteria:

1. Both sediment sizes should be mobilised by the maximum velocity in the inner part of the surf zone.
2. The ratio of the two sizes should be large enough to result in significantly different profile evolution as well as allowing them to be readily separated from the bimodal mixture.
3. Each sediment should be well-sorted so as to produce the bimodal characteristics in the resulting grain size distribution of the mixture.

Using these criteria, the sediment size for the coarse and fine sand respectively were chosen to be $D_c = 1.5$ mm and $D_f = 0.5$ mm. The grading curves for the two sands and a 50:50 mix are shown in figure 5. Sediment beds with a thickness of 100 mm were laid over the existing solid beach and the water level in the flume raised by the same amount, resulting in the same initial beach profile as used while collecting the hydrodynamic data. The profile evolution experiments were conducted for a total duration of 240 minutes, using repeated 30 minute runs of the spectra shown in table 1. The flume was allowed to settle after each 30 minute run and there was no evidence of the build up of significant seiche due to wave reflections. The experiments were carried out on the coarse and fine grained beaches separately to serve as controls and to provide comparison with the evolution of the bimodal beach.

Figure 5. Grading curves.

Profile evolution with uniform sediment size

Several general observations apply to the beach profile evolution for each of the three spectra. Firstly, the coarse sand beaches tend to form a distinct berm shorewards of the initial SWL. The berm appears steepest for case P, which has the lowest deep water wave steepness. For the fine sand beaches, the formation a bar flattens the beach slope in the surf zone. Seaward migration of the bar was evident and the bar moves further offshore as the wave height increases. The SWL recedes shoreward in all cases, except for the coarse beach using case P. Examples of the cross-shore changes in bed level are shown on figures 6&7. A predominant onshore transport is observed in the case of coarse sand while the fine sand bed suffered much erosion around the shoreline, with sediment transported offshore to form a bar.

Fine sand

Coarse sand

Fine sand**Coarse sand**

Figure 7. Change in bed elevation from original profile, case P.

Bimodal sediment sampling methods

A 50:50 mix of coarse and fine sand was chosen for the bimodal beach. Two sampling devices were used to determine the changes in the composition of the bimodal beach after wave action. The first was a 25mm square spot sampler, which was used to take sediment samples along the centre line of the bed. The second was an in-situ section sampler, placed in position before laying the beach and used to lift whole sections of the bed material from the beach. The section sampler allowed a section of the bed to be removed with minimal disturbance of the sample and enabled the vertical section of sediment sample to be analysed layer by layer (with layers as small as 5 mm). A calibrated fall tube was employed to sort the sampled material, allowing the change with depth in the mix ratio of the beach material to be ascertained. Further details of the sampling method will be available shortly in the Ph.D. thesis of R. T. C. Chan. In order to establish the

variability of initial bed composition a trial experiment was performed to sample the bimodal beach after it was laid. The sampling procedure included taking a section of the bed out (using the section sampler) at six different locations on the beach and 10 layers, each of 5 mm thick, were analysed at each location. The mean in-situ initial mix ratio was found to be 0.515 (coarse/total), with variations of less than 1% by volume between the different locations.

Profile evolution with bimodal sediment

Comparisons of the final beach profiles (after 240 minutes of wave action) for the fine, coarse and bimodal beaches are shown on figures 8a&9a for cases K and P respectively. The original profile in each case is also shown as a reference. The numbered circles at the top of each graph indicate the locations of the section samplers. Figures 8b&9b show the change in bed level from the original profile, where the positions of the section samplers are shown by the numbered triangles. The variation of the mix ratio (coarse/total) with depth at different sections of the beach is shown on figures 8c&9c. The experimental data show several features of particular interest.

In the inner surf zone and swash zone, the final profiles for the bimodal beach resemble the fine sand profiles much more closely than those for the coarse sand. This is the case for all three wave spectra and is confirmed by the bed level changes (figures 8b&9b). The bar positions on the bimodal beach are shoreward of those found in the fine sand beach. Recalling that a seaward migration of the bar was observed on the fine sand beach, it is apparent that there is a tendency for the coarse sand to curb the bar from migrating offshore. On the bimodal beach, the surface of the shoreward slope of the bar is dominated by coarse sediment (refer to section 4a on figures 8c and sections 4,5 and 6 on figure 9c). This is in marked contrast to the higher proportion of fines found on the seaward slope of the bar (section 4b on figure 8c, section 7 on figure 9c). Finally, the foreshore (just above the SWL in the lower swash zone) of the bimodal beach tends to be denuded of coarse sand (sections 2 and 3 on figures 8c&9c).

In summary, the results show that, although the bimodal sediment beach behaves in a similar fashion to the fine sand beach, in agreement with Quick and Dyksterhuis (1994), considerable sediment sorting has also been observed. The present data show that the region between the shoreline and the bar tends to be dominated by the coarse sediment. This appears consistent with the field data of Moutzouris (1990), which showed that the largest grain size often occurred just seaward of the shoreline. Within the swash zone, the fine sand within the mixture seems to destabilise the coarser sand. This facilitates the erosion of coarse sand on the foreshore, and is most conspicuous at the position of the steepest slope. A similar process is also evident on the seaward slope of the bar. This suggests that the mobility of the coarse sand in the mixture is substantially increased due to a

greater exposure and a reduction in friction in the presence of fines. This appears consistent with the results of Miller & Byrne (1966), who found that there is a reduction of the angle of repose when large grains sit on a bed of smaller grains.

The difference in the evolution of the fine and coarse sand beds may be due to a combination of factors. The most dominant are probably a different threshold condition and a difference in the permeability of the beach material. A higher threshold condition for the coarse sand will tend to result in a greater net shoreward transport of sediment. The high permeability of the coarse sediment is also likely to lead to greater infiltration within the swash zone, reducing the backwash and leading to or increasing the asymmetry in the swash zone velocities. This hypothesis is consistent with the much larger berm formation observed on the coarse beaches. In contrast, the bimodal beach permeability will be largely controlled by the finest 10% of sediment within the mix (e.g. Hazen, 1892). Consequently, both the fine sand beaches and the bimodal beaches have a similar permeability. Since both beaches evolve similarly, the permeability appears to be the dominant controlling factor, as suggested by Quick and Dyksterhuis (1994). This has important implications for both numerical modelling of swash processes and beach recharge schemes. For example, if the fines control the beach permeability, and as a consequence the beach behaviour, the addition of coarser supposedly more stable sediment may have little effect on the overall stability of the beach. On the other hand, if the permeability is a controlling factor, beach drainage should be an effective method of beach stabilisation, although some questions remain as to its effectiveness.

CONCLUSIONS

The results of a new experimental investigation have been presented. Hydrodynamic data obtained over a steep fixed beach show that the wave heights and undertow in the inner surf zone are under-estimated by the numerical solution. In particular, the wave heights in the inner surf zone are not depth limited to the expected degree. This is a consequence of the steep beach slope, with insufficient time for wave breaking fully to establish. Significant wave grouping is evident in the nearshore. This leads to large local fluctuations in the “mean flow”, which are strongly correlated with the wave groups. The profile evolutions of fine and coarse sediment beaches were found to be very different, with the fine sand beaches tending to erode to form a bar, while the coarser beaches generally accreted, resulting in the formation of a berm. The profile evolution of bimodal beaches

was found to be similar to that of fine sand beaches, although considerable sorting was observed. The data suggest that the permeability of beaches is of particular importance, in agreement with some previous studies. The presence of fines appeared to destabilise the coarser material within the bimodal beach, with little coarse material present on the bed surface in the swash zone and on the bar crest. In contrast, the coarse material appeared to have little effect on the movement of the fine sediment, with little evidence of armouring. Clearly there is a need further to investigate the influence of the fine/coarse ratio in bimodal sediments and to consider continuously-graded sediments.

BEACH PROFILE SURVEYS ALONG THE U.S. PACIFIC COAST 1945 – 1947

Nicholas C. Kraus¹, M. ASCE, Robert L. Wiegel², Hon. M. ASCE, Willard N. Bascom³

ABSTRACT: The Wave Project at the University of California at Berkeley was established in 1944 to develop a relationship between nearshore waves and the underlying topography for supporting amphibious military landings. The project was continued for scientific purposes until 1952 under the more general name of “Wave Observation and Beach Surveys,” including the Amphibious Oceanography Project. These early field observations are a central part of the genesis of coastal engineering in the United States. Beach profiles were surveyed by stadia and by amphibious vehicle along the coasts of Washington, Oregon, and California, and the results were documented in University of California, Fluid Mechanics Laboratory, reports in the HE-116 series. The profile survey measurements, now 50 years old, are still the only such data available for many beaches along the U.S. Pacific Coast. The data set thus comprises a valuable baseline for documenting change in the coast, and it is a resource on the morphology and grain size for high-energy beaches that are extremely difficult to survey. The profile survey plots in the limited-circulation reports have been digitized and are available for general access in the present study. This paper reviews the early measurement program and the available data set.

INTRODUCTION

The Wave Project of the University of California at Berkeley, sponsored by the Navy Department, was established in 1944 to develop a relationship between nearshore waves and the underlying topography for aiding in WWII beach landings. The project was continued for scientific purposes until 1952 under the more general name of “Wave Observation and Beach Surveys (WOBS),” including the Amphibious Oceanography Project. These early field observations are the genesis of coastal engineering in the United States, and a typical objective was “... to relate wave characteristics to beach changes and to collect sufficient data on surf, beach, and meteorological conditions to make a comparison with the results of

existing forecasting procedures and general wave theory” (Stump and Bascom 1947). Beach profiles were surveyed by stadia and by amphibious vehicle (Dukw – pronounced “duck”) along the coasts of Washington, Oregon, and California, supplemented by measurement of numerous types of coastal processes. The Wave Project and WOBS are believed to have made the first systematic and comprehensive field measurements of the beach profile, sediment, waves, and water level. The results were documented in the HE-116 series of Laboratory Memorandums of the Fluid Mechanics Laboratory, Department of Civil Engineering, U. of California, Berkeley. In the early years, this pioneering program was planned, financed, and directed by Dean Morrough P. O’Brien (U. of California, Berkeley) and by John Isaacs (U. of California, San Diego). Isaacs (1947) made all the surveys in 1945, when he invented the system, and Willard Bascom made virtually all the rest, many at the risk of life. The profile survey measurements have been described authoritatively by Bascom (1964, 1980). The principals responsible for the work were M. P. O’Brien, J. D. Isaacs, W. N. Bascom, D. McAdam, D. Patrick, and R. L. Wiegel.

Surprisingly, the profile survey measurements, now 50 years old, are still the only data available for many beaches along North Pacific coast. In fact, Dean O’Brien had insisted that the northern beaches be surveyed in the winter when there was violent surf (see Bascom 1987 for further discussion), and it remains a challenge to repeat such measurements. The data set thus comprises a valuable baseline for documenting change in the beach that has occurred since that time, and it also serves as a rare resource on the morphology of high-energy beaches that are extremely difficult to survey. The data exist in limited circulation HE-116 reports as distance-elevation plots and have been little accessed, one exception being an article by Komar (1978), who discussed data from HE-116-229 (Isaacs 1947) and HE-116-247 (Bascom and McAdam 1947) for the Washington and Oregon coasts.

The objective of the present work was to capture and preserve the profile data taken on the U.S. West Coast over the period 1945-1952. However, only data for the period 1945-1947 could be recovered in the present effort. For our study, the available profile survey data were digitized manually from the original drawings and the information transferred to magnetic media. This paper presents an overview of the data set, including the institutions and personalities behind the WOBS projects. The paper was prepared as a contribution for the celebratory theme “Coastal Engineering Heritage” (Kraus 1996) of the Twenty-fifth International Coastal Engineering Conference. Further information about the history of coastal engineering in the United States can be found in Wiegel and Saville, Jr. (1996).

RESOURCES CONSULTED

For this study, the originals of ten HE-116 reports were borrowed from the Water Resources Center Library, Department of Civil Engineering, University of California, Berkeley. Of these, five reports contained beach profile survey data. Table A1 of the appendix lists by report the beaches, years, and ranges for which profile data are available from these reports. The data set developed in the present study contains 216 profile surveys from nine beaches in Washington, six in Oregon, and 16 in California.

Many of the reports contain black and white photographs, most taken from the ground, but with some from the air by military planes. HE-116-223 (Fluid Mechanics Laboratory 1946) includes pictures and captions with the location and date for “...various beaches which were not at the time subjects of intensive study.” In order to preserve the photographic record of west-coast beaches in the late 1940s and early 1950s, for the present project more than 100 photographs compiled from the different reports were scanned to create digital files.

After making three sets of copies of the reports, including the oversize plots of the profile plots, the originals were returned to the Water Resources Center Library. A complete set was sent to the Coastal Engineering Archive at the University of Florida, Gainesville, Florida; the University Library at Oregon State University, Corvallis, Oregon; and the Technical Library at the U.S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi.

Many of the profile surveys extended from the upper beach to a depth of approximately 10 m, although surveys to wading depth were also made. Bascom (1980) gives a vivid first-hand account of the surveys made by amphibious vehicle (Dukw, Fig. 1). Horizontal position was measured by triangulation, and measurement points were marked through radio communication when a lead-line was heaved overboard. The sum of the water depth measured beneath the trough of a wave and one-third of the estimated wave height were reported by radio to a recorder on shore as an estimate of total water depth. The depths were converted to mean lower low water tidal datum by reference to either a tide gauge or predictions. Komar (1978) has summarized the measurement procedures and cites primary documents and reports not discussed here.

Other measurements or observations routinely made by the field parties included visual "surf observations" of the wave height and period, breaking wave type, and the nearshore current – both the longshore and rip currents. Measurements were sometimes made of the water table. Sediment samples were taken, but the authors were not able to locate the substantial information that should have been compiled. Other interested parties should continue in that search. An interesting aspect was documentation of the depth of tire impressions in the beach sediment made by the field-reconnaissance vehicles. Both military applications and relation of compaction to beach change were of interest, as was operation of the Dukws in future data collection.

In remainder of this paper, we focus on the beach profile survey data.

DIGITIZATION PROCEDURE

The original reports were unbound to mount the individual plots of the beach profiles on a digitization table. At first, it was planned to trace the profile lines by cross hair sighting on a high-resolution electronic digitization tablet. However, most of the pages containing the plots had become warped, making standard digitization mapping on to electronic axes inaccurate.

As an alternative to rubber sheeting through software, which would have introduced or distributed errors, distance-elevation pairs on the plotted profiles were located manually by placing a straight edge parallel to the grid lines on the plots and reading corresponding intersection values on the two axes. The locations of actual survey points on the plots were almost always unambiguously evident by discontinuities in the lines joining the points. Because of the presence of the grid lines on the plots, errors that might have been introduced by warping of the paper are believed to be minimal.

After manual digitization of the profile survey data, the distance-elevation pairs were entered into the computer and plotted to the same scale as the original drawings. Plots of the digitized data drawn on transparent paper were laid on top of the original drawings and visually compared for discrepancies, which were corrected. The resultant quality-controlled data set is believed to be an accurate representation of the original measurements. These data are available as ASCII files. The data are in the original American customary units (feet), but in this paper results are presented in metric units for the international audience.

EXAMPLE RESULTS

In this section we give examples from Washington, Oregon, and California, from the data set compiled. Locations of many of the sites encompassed by the total data set are shown in Fig. 2. Appendix A gives the locations of all the beaches for which survey data were compiled.

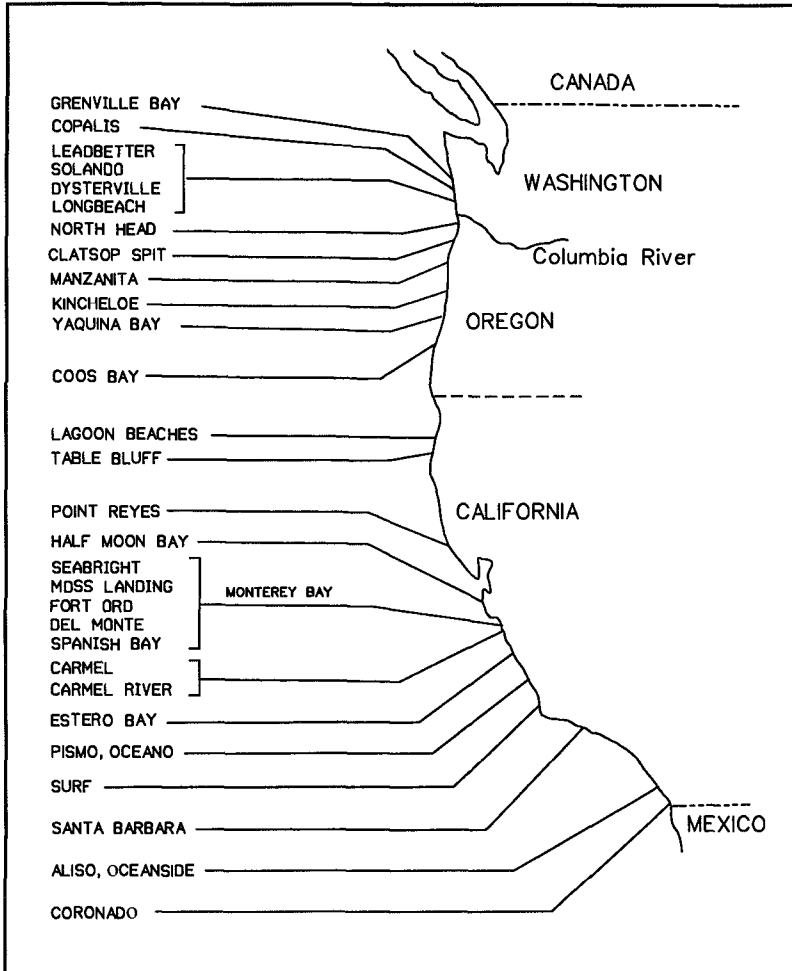

Fig. 2. Location of Pacific Coast beaches investigated (after Bascom 1951a).

Comparison to Echo Sounder

Depth soundings were typically made by lead line as described above, because echo sounders blanked out in the surf zone where air bubbles are present. Patrick and Bascom (1950) discuss technical details of the lead-line method and echo sounder measurement methods as applied in the Wave Project and subsequent studies. Many of the considerations are still valid today for making beach-profile surveys. As an example, we quote "After the ground control is established, the remaining field work is accomplished in two parts: water soundings during high tide and beach land profiles during low tide. The method gives *an overlap* (emphasis added here) of the data obtained and provides a check on the accuracy of the work." Lack of appreciation for the necessity of overlap of land and water surveys is found in some works today, which introduces ambiguity in collection of expensive data.

Patrick and Bascom (1950) compare the two methods "...made at Carmel (California, in 1947) and the results for one range line...", which is reproduced in Fig. 3 here. Although the lead-line method did not pick up detail of the bars on the profile, the comparison indicates remarkable skill in the lead-line survey that was consistent to almost 10-m depth, giving confidence in the reliability of the overall data set. The maximum difference in readings between the two methods is on the order of 1 m beyond the 6-m contour (MLLW).

Fig. 3. Comparison of sounding methods (adapted from Patrick and Bascom 1950).

Point Grenville, Washington

This beach is located north of the mouth of the Columbia River and north of Grays Harbor, Washington. The two profiles plotted in Fig. 4 were surveyed approximately 1 year apart, with the 1945 survey made by a party led by Isaacs (1947) and the 1946 survey made by a party led by Bascom and McAdam (1947). Quoting from Isaacs: "(Between August 27 and September 27, 1945) ...the field party of the University of California Wave Investigation Project made surveys of the beach and surf characteristics at a number of beaches of the Pacific Northwest. These beaches are noted for their gentle slopes and fine grained materials." Further in the report, it is stated for the Point Grenville, South Station: "About 2 miles (3.2 km) south of the Cape (Cape Grenville) a section of the beach existed where the beach face was comparatively steep. No berm existed and it was apparent that high water reached the low clay banks in this region. The profile there showed a slope of beach face of about 1:20. The breaker zone was quite irregular but the bottom offshore was smooth and of gentle slope." This description fits Fig. 4 well. Wave breaker heights tabulated by Bascom and McAdam (1947) at the approximate time of the 1946 survey were approximately 1.5, 2, and 3 m for the inner, middle, and outer bars, respectively.

Grain-size information is not given for Point Grenville in the two aforementioned reports. However, Bascom (1951a) indicates that a representative median grain size might be on the order of 0.17 mm. As an example of a possible use of the profile data, we fit an equilibrium profile following a "distance to the 2/3 power law" (Dean 1991) to the 1945 profile survey. The grain size of 0.14 mm was inferred from the shape parameter (Moore 1982) of the equilibrium profile, which is seen to describe the survey measurements well from MLLW shoreline to the survey limit (7-m depth). This small exercise confirms the concept that profile shape is governed primarily by sediment grain size on an open-coast beach (see Bascom (1951a) for a conclusions about a wave-sheltered beach).

Fig. 4. Profile surveys approximately 1 year apart, Pt. Grenville, South Station, Washington.

Clatsop Spit Beach, Oregon

This beach is located south of the Columbia River, Oregon. The two profile surveys shown in Fig. 5 were taken only 3 days apart and within approximately 300 m of each other. A substantial bar-and-trough topography existed on the profiles. Komar (1978) speculated on mechanisms that might be responsible for the substantial trough. Clatsop Spit is presently experiencing moderate erosion, and data such as shown below will be useful for understanding the coastal processes acting at the site.

Fig. 5. Profile surveys on two range lines, Clatsop Spit Beach, Oregon.

Carmel Beach, California

The beach at Carmel, California, was studied intensively while the surveying parties "...would rest in the spring to recover from winter encounters with the northern surf" (Bascom 1980). Fig. 73 in Bascom (1980) illustrates seasonal shifts in the berm at Carmel, which were measured to be more than 60 m. Figs. 6 and 7, taken from data given by McAdam and Bascom (1947), reproduce some of the profiles in Bascom (1980) and display the remarkable seasonal changes at Carmel Beach. Bascom (1951a) indicates that a representative grain size for Carmel Beach is about 0.35 mm. This beach was one of those analyzed by Bascom (1951a) in a seminal paper on the relation between beach slope, grain size, and exposure to waves. In Fig. 6, it is interesting to note that little profile change occurs below approximately 4-m depth (MLLW) as compared to the elevation changes above that depth.

Fig. 6. Seasonal change in the berm and foreshore, Carmel Beach, California.

Fig. 7. Close-up view: seasonal change in the berm at Carmel Beach, California.

Miramar Beach, California

Discussion of the survey range lines along Halfmoon Bay, California, including Miramar Beach (Fig. 8) is given by Wiegel (1947). In the present study, it was originally intended to recover the locations of such range lines and reestablish survey monumentation. However, lack of funding prevented us from undertaking this task. Fig. 8 is provided to inform others that the HW-116 reports do contain information with which to reoccupy many of the survey ranges. Although recovery of the vertical datum may be impossible because of loss of benchmarks, location of many of the range lines along the beach will be straightforward because of the excellent photographic documentation.

CONCLUDING DISCUSSION

This study has attempted to capture and preserve, in digital form, beach profile survey data obtained on the Pacific Coast of the United States during the inception of the discipline of coastal engineering, the mid-1940s through mid-1950s. Ten original reports from that era were consulted, of which five contained plots of the survey data, which were digitized and quality checked. Approximately 100 photographs were also scanned to create digital copies. The basic product is a data base consisting of 216 profile surveys for 31 beaches in Washington, Oregon, and California, taken during the years 1945-1947.

The data set is expected to be valuable for coastal engineers, planners, and researchers because of its uniqueness – profile surveys extending to 10-m depth on high-energy beaches of various grain sizes. The data set allows study of fundamental aspects of beach morphology, including summer-winter profile change, time scales of profile change, bar size and movement, and beach slope versus grain size. Early analysis of the data (Bascom 1951a, 1951b) has yielded now-classic results on beach behavior. Many more insights and uses of the data can be expected.

The quest should not end for additional data from the WOBS project. Bascom (1951a) reports that approximately 500 beach profile surveys were made on some 40 beaches, so that the present study has located less than half of the available surveys. In addition, in this unfunded project we were not able to find much of the data for the approximately 600 sediment samples taken (see Bascom 1951a, 1951b for some data). Our goal of recovering all the beach profile survey ranges was not achieved, and we hope that this paper will serve as a stimulus for researchers to locate and preserve the remaining data, and for Federal, state, and local agencies in Washington, Oregon, and California, responsible for the coast to locate and reestablish the range lines.

ACKNOWLEDGEMENTS

This study would not have been possible without the cooperation of the Water Resources Center Library, Department of Civil Engineering, University of California, Berkeley, which permitted long-term loan of the HE-116 original reports. Digitization of the profile survey data was carried out at the Conrad Blucher Institute for Surveying and Science, Texas A&M University-Corpus Christi, while the first author served as Director of the Institute. The digitization and quality-control checks were performed by Ms. Karen Bridges and Ms. Margie Langely, both undergraduate students. The day-to-day work was supervised by Ms. Deidre Williams, graduate student in charge of the Blucher Institute Geographic Information Systems Laboratory. Permission was granted to N. C. Kraus by Headquarters, U.S. Army Corps of Engineers, to publish this information.
