By the use of data on long-term shoreline change in the reduction process of the river delta on the Shizuoka coast, we found that there exist two modes of shoreline change, namely shoreline change as a diffusion phenomenon and variation from shoreline change as a wave phenomenon. We name these erosive waves, which are defined respectively as erosive wave (D) and erosive wave (W) for the two modes of shoreline change. We conclude that the erosive wave (D), the first mode of shoreline change, expands down-coast as a diffusion phenomenon; but the erosive wave (W), the second mode of shoreline change, propagates down-coast as a wave phenomenon faster than the erosive wave (D). The shoreline change in the river delta coast can then be described as a diffusion-wave phenomenon.

The generation of the erosive waves was considered in terms of the sediment input from the river and local change in the submerged river-mouth delta. Finally, a theory for the diffusion-wave phenomenon of shoreline change was attempted using a set of equations of longshore sediment transport rate and continuity of shoreline change. From these the dispersion relation of the phenomenon was found. Further theoretical investigations are now being made to establish a predictive method for shoreline change.

Acknowledgments

I thank Mr. K. Ishida, Chief, Planning Section, Technical Division, Suruga Konsaru Ltd. for his cooperation in the collection of long-term shoreline change data at the Shizuoka coast. Part of this investigation was supported both by Grants-in-Aid for Scientific Research (No. 07555164) from the Ministry of Education, Science, Sports & Culture of Japan, and Research Fund (No. 7-1-4-25) of the Foundation of River and Watershed Environment Management.

CHAPTER 313

DELILAH, DUCK94 & SandyDuck: Three Nearshore Field Experiments

William A. Birkemeier, M. ASCE, Charles E. Long and Kent K. Hathaway¹

Abstract

Two major field experiments have recently been conducted, and a third is being planned, at Duck, NC, along the mid-Atlantic coast of the USA, to investigate nearshore dynamic processes. Named DELILAH, DUCK94, and SandyDuck, these experiments take advantage of logistical efficiency and relatively uncomplicated, open-coast field conditions provided by the Field Research Facility of the US Army Engineer Waterways Experiment Station. DELILAH occurred in 1990, and emphasized hydrodynamics measurements. DUCK94, in 1994, added measurements of sediment transport and morphologic evolution, and was planned as a comprehensive pilot study for SandyDuck, the most ambitious experiment in the series, scheduled for 1997. Scientific motivation, instrumentation plans, participants, and representative climatic conditions of DELILAH and DUCK94 are described, as are sources of further information and data.

Introduction

Since 1979, the Coastal and Hydraulic Laboratory (formerly the Coastal Engineering Research Center) of the US Army Engineer Waterways Experiment Station has hosted a series of increasingly complex, multi-investigator, multi-agency nearshore field experiments at its Field Research Facility (FRF) located in Duck, North Carolina, USA. Two recent experiments, *DELILAH* and *DUCK94*, and a planned third experiment, *SandyDuck*, all evolved from scientific and pragmatic successes of prior work at this site, and have the basic objectives of improving fundamental understanding and modeling of surf zone physics. The emphasis in *DELILAH* was surf zone hydrodynamics in the presence of a changing barred bathymetry. *DUCK94* and *SandyDuck* have added components to resolve sediment transport and morphologic evolution at bedform scales from ripples to nearshore bars. *DUCK94* was designed as a pilot effort to test instruments and procedures required for the more comprehensive *SandyDuck* experiment. The purpose of this paper is to summarize the two completed experiments, including participants, environmental

conditions, data collected, and data availability, and thereby suggest the plan for the future experiment.

DELILAH

The DELILAH (*Duck Experiment on Low-frequency and Incident-band Longshore and Across-shore Hydrodynamics*) design (Figure 1) was to make surf zone hydrodynamics measurements to augment directional wave measurements being made in 8-m water depths by the FRF and in 13-m depths during the concurrent SAMSON (*Sources of Ambient Micro-Seismic Ocean Noise*) experiment (Herbers & Guza, 1994; Nye & Yamamoto, 1994). By agreement among investigators, DELILAH objectives were:

To measure the wave- and wind-forced three-dimensional nearshore dynamics with specific emphasis on infragravity waves, shear waves, mean circulation, set-up, runup, and wave transformation, and to monitor bathymetric response to these processes.

Table 1 lists DELILAH investigators, their organizations at the time of the experiment, and general areas of scientific interest.

The DELILAH array of in situ instruments (Figure 1) consisted of a primary

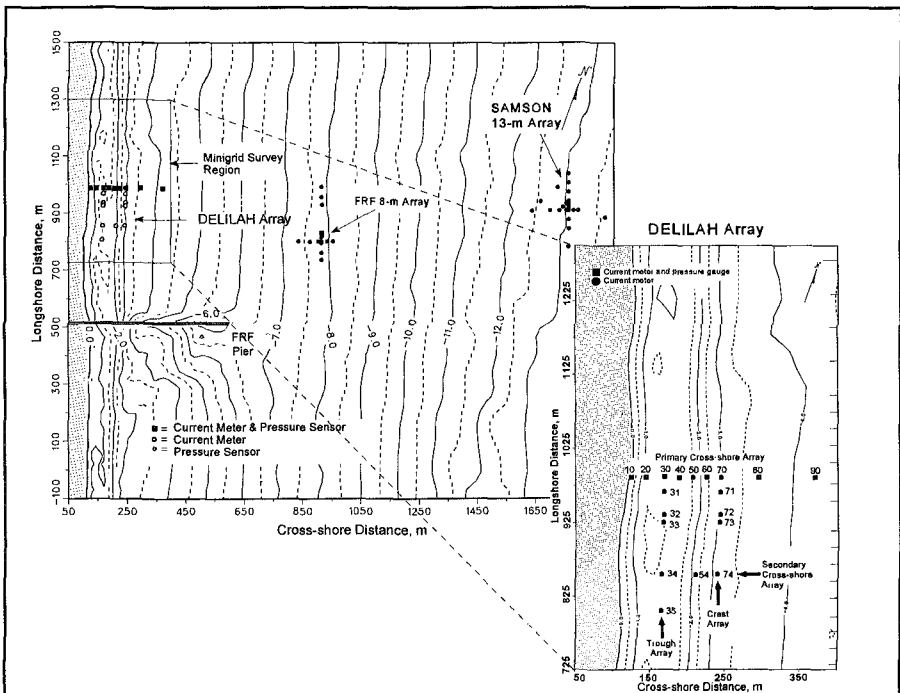

Figure 1. Instrument array locations during the SAMSON & DELILAH experiments

cross-shore array of nine current meters to obtain mean and fluctuating currents, with collocated pressure gauges to enable directional wave measurements. A secondary cross-shore array of three current meters provided long-shore redundancy. Long-shore coverage was provided by an array of six current meters in the nearshore trough, and a second array of five current meters located just seaward of the inner bar crest. Instruments were provided by the Naval Postgraduate School (NPS), Scripps Institution of Oceanography (SIO), and the FRF. The DELILAH array was designed by E. B. Thornton, J. M. Oltman-Shay, and P. A. Howd, with Dr. Thornton having primary responsibility for data collection.

Additional instruments augmented information from the stationary, in situ array. A mobile sled equipped with a vertical array of five current meters, a pressure gauge, and a surface-piercing wave staff was

deployed by J. M. Smith and K. K. Hathaway. Seven video cameras operated by R. A. Holman recorded swash and ocean surface images in the surf zone. D. B. Trizna used five Naval Research Laboratory (NRL) radar systems for remote sensing of waves, currents, and bathymetry. Bathymetric changes were measured daily by the FRF in the 550-m by 400-m minigrad area (Figure 1) using the Coastal Research Amphibious Buggy (CRAB).

A wide range of conditions were encountered during the 21 days of data collection (Figure 2). A short-duration wave event on 1-2 October was followed by several days of low waves ($H_{mo} < 1$ m). On 9-12 October, a "southeaster" built waves of about 2-m height, and induced north-flowing longshore currents that peaked near 1.5 m/s. Passage of Hurricane Lili well offshore on 12-14 October resulted in 2.5-m swell under low-wind conditions. Following Lili, moderately energetic waves and currents continued until the end of the experiment.

In the above conditions, nearshore bathymetry underwent significant changes. Figure 3

Oregon State University	Rob Holman - morphology, runup, shear waves, infragravity waves, video remote sensing Peter Howd - infragravity waves, morphology Tom Lippmann - morphology, infragravity waves, video remote sensing Todd Holland (also with the US Geological Survey) - runup, cusp formation
Scripps Institution of Oceanography	Robert Guza - cross-shore and longshore currents, infragravity waves, wave transformation, (also SAMSON PI)
Northwest Research Associates	Joan Oltman-Shay - shear waves, infragravity waves (also SAMSON PI)
Washington State University	Steve Elgar - incident and reflected directional wave spectra (also SAMSON PI)

Figure 2. Conditions during DELILAH

Figure 3. Profile change adjacent to the DELILAH cross-shore array

shows bathymetric profiles along the primary cross-shore array at five times during the experiment, illustrating the offshore migration of the nearshore bar, and notably the extensive deepening of the nearshore trough on 10-13 October. The CRAB surveys also revealed the presence of megaripples in the nearshore trough and on the seaward bar flank. Figure 4 illustrates four of the 20 minigridd surveys. Vertical lines in this figure indicate current meter locations. Bar topography undulated rhythmically in the alongshore direction until 9 October, when it began to assume a more uniform, linear shape. It reached maximum uniformity by 11 October, and retained this shape through the end of the experiment. Well correlated with shoal parts of the nearshore bathymetry in Figure 4 are time exposures of breaking waves patterns shown in Figure 5. Such remote images are used to extend spatial and temporal coverage provided by measured bathymetry.

DUCK94

Success of DELILAH, and the evident need for more detailed information about sediment transport and morphologic evolution that results from hydrodynamic forcing, initiated interest in further field work to be supported by the US Army Corps of Engineers, ONR, and the US Geological Survey. A plan for two additional field experiments developed. The first, DUCK94, was intended as a test run for new instrumentation, a more formal experiment organization, and more complicated logistics in preparation for SandyDuck, the second experiment. DUCK94 was scheduled for August and October 1994 to take advantage of the synergy offered by the National Science Foundation's Coastal Ocean Processes (CoOP) experiment (Butman, 1994), being conducted at the FRF during that time. The following focus topics were established as fundamental to improved understanding of surf zone sediment transport:

Figure 4. *Minigrid* evolution during DELILAH

Figure 5. Time-exposure video images showing DELILAH morphology.

- a. *small and medium scale sediment transport and morphology;*
- b. *wave shoaling, wave breaking, and nearshore circulation;*
- c. *swash processes including sediment motion.*

Considerable interest was expressed for DUCK94. Table 2 lists the 19 organizations that conducted 31 experiments involving more than 100 scientists, students, and technicians. Instrument measurements were complemented by observations from ground- and aircraft-based radar and video systems. Table 3 lists the 31 basic studies, along with the principal investigators, their primary focus areas, and experiment durations. The extensive instrumentation resulted from consideration of relevant measurement scales required to address SandyDuck science objectives. Guidance was provided by using measured velocity data from DELILAH and sediment transport modeling. Based on this analysis, a general nearshore instrumentation array was designed (Birkemeier & Thornton, 1994). The full array, shown in

Figure 6, was used during the October phase of DUCK94. An abbreviated form of this array was used in the August segment of the experiment. Formal dates for DUCK94 were 8-24 August and 1-24 October, though some investigations (Table 3) of various durations were underway between June and November.

A wide variety of instrumentation was used in DUCK94. Conventional total-station surveying techniques were used in subaerial morphology studies (29, referring to investigations by experiment number in Table 3), minigrid surveys (15), and positioning of all stationary instruments. Central to the main layout were cross-shore arrays of instrument clusters (11), each containing an electromagnetic current meter, a pressure gauge, an acoustic altimeter, and a thermometer (Fedderson, et al., 1997). The altimeters permitted the first comprehensive real-time measurements of bottom changes (8) (Gallagher, Elgar & Guza, 1997). A large number of suspended sediment concentration gauges were deployed, including optical backscattering sensors (16, 22, 26, 30), and less intrusive fiberoptic backscattering sensors (1). The Coherent Acoustic Sediment Probe (Stanton & Thornton, 1997) was mounted on a mobile sled along with eurrent meters, pressure gauges, scanning sonars, and void fraction sensors (20, 25, 26). Figure 6. DUCK94 Instrument layout identified by investigator

located on the FRF pier, provided a stable, mobile platform for sediment transport measurements during high-energy conditions (1, 22). In situ (16) and CRAB-mounted (25) side-scan sonars provided observations of bottom bedforms, including megaripples. Most array positions included one or more current meters (1, 3, 11, 12, 13, 15, 16, 18, 22, 26, 30). Incident wave conditions were monitored with directional wave buoys (6, 19), and a direction-sensing array of pressure gauges (21).

Dynamics measurements were complemented by a series of geologic studies that included surface sediment samples (24) (Stauble & Cialone, 1997), short cores, box cores, and vibracores (4). Several remote sensing systems were used. Surf zone and swash processes were observed with tower-mounted video systems (14, 17, 20). Observations were also made with land-based marine radar systems (27), coherent radar systems (10), airborne synthetic aperture radar, topographic lidar, visible and hyperspectral light imaging, and scanning radar altimetry (5, 7, 28). Three studies examined fundamental nearshore acoustic behavior (16, 23, 31).

Environmental conditions during the October phase of DUCK94 are illustrated in Figure 7. Two high-wave events occurred. The first was on 2-4 October, wherein wave

Figure 7. Conditions during the October phase of DUCK94

heights exceeded 2.5 m. Wave heights reached 4.5 m during the second storm, an eight-day event beginning on 10 October. During the larger storm, large bottom changes were accompanied by a complex nearshore circulation pattern wherein wave-driven currents in the surf zone were opposed by strong wind-driven longshore flows offshore. As shown in Figure 7, currents in the nearshore trough changed from about 1 m/s to the south at the beginning of the storm on 10 October to about 1 m/s to the north just prior to the peak of the storm on 15 October.

Figure 8 illustrates four of the 12 minigrad surveys collected during October. Following a pattern similar to that observed in DELILAH, the bar moved offshore and became more linear in the initial part of the 10 October storm. High waves prevented daily surveys until 21 October, when the survey revealed that a very large rip channel had developed. Evolution of this channel is evident in video time exposure images depicted in Figure 9. Sequences of profile data through the region of the rip are shown in Figure 10, where it is seen that the bar crest moved 100 m seaward, causing 1.2 m of deposition at its most seaward observed location on 18 October. By 21 October, the bar crest had begun migrating landward.

DUCK94 data are being analyzed, and research results are beginning to appear in the literature. Preliminary findings were discussed at a post-experiment meeting (summarized by Long & Sallenger, 1995), where adequacy of the DUCK94 experiment plan was also evaluated in preparation for SandyDuck.

SandyDuck

SandyDuck will take place from 22 September to 31 October 1997. Most of the core DUCK94 experiments are being repeated, with improvements based on experience gained in DUCK94, both in keeping with the basic tenets of physics research, and to take advantage of two major improvements in the basic experiment design. DUCK94 revealed that nearshore dynamics is far less uniform alongshore than had previously been assumed. Consequently, instruments will be added to expand longshore coverage of currents, bottom changes, and sediment transport. Missing from all Duck experiments has been accurate, spatially detailed measurements of sea surface elevation, the gradient of which is an $O(1)$ force in the surf zone. As the second change in the experiment plan, new instruments will be deployed to resolve this very important component of nearshore dynamics.

Further Information and Data Availability

More information about these experiments can be found on the World Wide Web at <http://frf.wes.army.mil> under the heading "projects." Summary data and statistics from DELILAH are available through the above web site, or via anonymous FTP at <ftp://frf.wes.army.mil/pub/delilah>. A DELILAH summary report will be published in 1997 by the US Army Engineer Waterways Experiment Station, Vicksburg, MS.

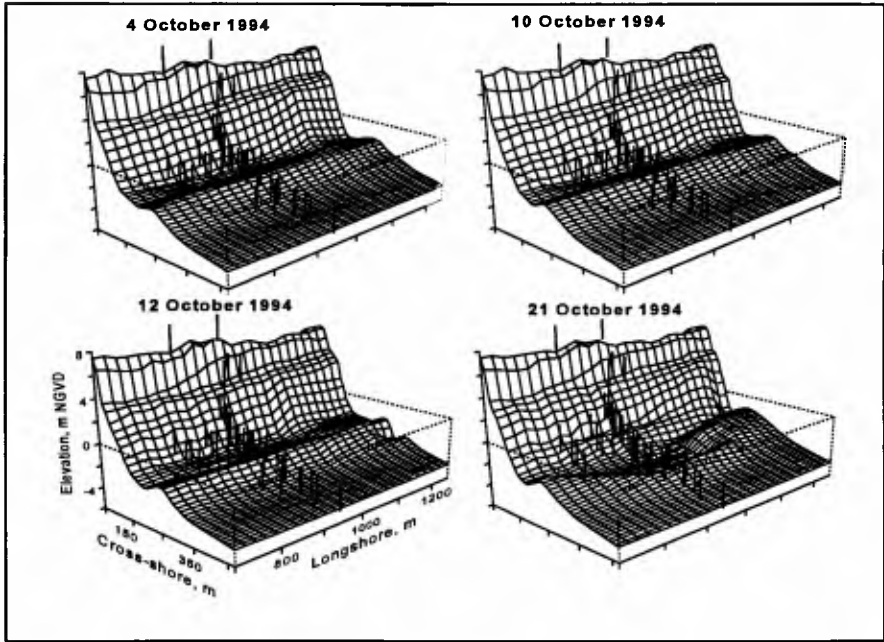

Figure 8. Minigrid evolution during DUCK94

Figure 9. Time-exposure images showing DUCK94 morphology

Figure 10. Profile change along the Elgar & Guza cross-shore array during DUCK94

Data from DUCK94 are not yet generally available. The investigators have agreed on a data sharing policy that offers protection of data by collecting investigators, encourages collaboration, and provides for eventual public release. This policy is:

- a. global release of all data three years after the experiment;
- b. responsible investigators will be identified when data sets are used by others;
- c. prior to three-years, data shared by agreement between individual investigators;
- d. any manuscript based on shared data must be approved by all responsible investigators prior to submission;
- e. no third-party data dissemination;
- f. principal investigators control use of their data.

An extensive discussion of the DUCK94 experiments, including tables listing sensors, data sets, and a summary of results, findings and publications, is available through the above web site. It is anticipated that DUCK94 data will become generally available late in 1998, and that SandyDuck data will be released near the turn of the century.

Acknowledgments

This paper was funded through the Field Research Facility Analysis Work Unit of the Coastal Research and Development Program of the US Army Corps of Engineers, Mrs. Carolyn Holmes, program manager, and the Coastal Dynamics Program of the Office of Naval Research, Dr. Thomas Kinder, program manager. We wish to acknowledge the

large group of investigators, students, staff, committee members and others who dedicated incredible amounts of time and effort in pursuit of these experiments. Permission to publish was granted by the office Chief of Engineers.

CHAPTER 314

EULERIAN MEAN VELOCITIES UNDER NON-BREAKING WAVES ON HORIZONTAL BOTTOMS

Peter Nielsen¹ & Zai-Jin You²

Abstract

A model is presented for the Eulerian time-mean velocities in combined wave-current flows. The typical, measured profiles of weak currents are well modelled. This includes the “toe” of forward drift in the wave boundary layer and the very flat (as opposed to the parabolic shape of laminar models) current profile between the bottom boundary layer and the wave trough. The model relies on a local force balance like Longuet-Higgins’ (1953) diffusion solution rather than on advective influence from the end conditions. This seems justified by experiments, probably because a sufficient amount of turbulent diffusivity is present even for very weak currents. In its present form the model can only handle currents which are so weak that their influence on the wave motion is negligible. However, agreement with measurements of stronger currents can be obtained by modification of the wave Reynolds stress to account the influence of the current on the wave motion. Application to surf zone conditions also require modifications, but the essential structure of the model is globally applicable.

Introduction

Several authors eg. van Doorn & Godefroy (1978), van Doorn (1981), Kemp & Simons (1982), Kaaij & Nieuwjaar (1987), Kampen & Nap (1988), Heiboer (1988), Villaret & Perrier (1992) and Klopman (1994) have found that Eulerian mean velocities under progressive, non breaking waves show different distributions from what has been expected. Following currents reach a maximum value and subsequently decrease towards the surface. See Figure 1. The trend is found for all current strengths as long as the time averaged bed shear stress is in the direction of wave propagation ($d\bar{u} / dz > 0$ for $z \rightarrow 0^+$) but is not found for currents in the opposite direction. Opposing currents show the opposite anomaly. That is, compared with a logarithmic profile, the opposing current grows more rapidly towards the surface.

¹ Reader, Department of Civil Engineering, University of Queensland AUSTRALIA 4072, Fax +61 7 3365 4599, ² Victorian Institute of Marine and Freshwater Resources.

Thus, observations of both following and opposing currents contrast with the existing simple wave current boundary layer models, e.g. Grant and Madsen (1979), Fredsoe (1984), Coffey & Nielsen (1986) or You (1994) which all predict logarithmic, i.e., monotonically increasing current velocities above the wave boundary layer.

It is obvious from Figure 1 that the depth averaged current velocity $\langle \bar{u} \rangle$ may be significantly overpredicted by the old type of models for following currents. The elevation at which the current maximum occurs depends on the relative strength of the current. For very weak currents, e.g. flume experiments with zero net flow, it occurs very close to the bed, i.e., below or near the top of the wave boundary layer. For stronger currents, it occurs closer to the mean water surface. This trend was clearly shown by the measurements of Kemp and Simons (1982). The data in Figure 1 were obtained over a fixed bed but numerous profiles over sand beds, measured by Heijboer (1988) and Villaret & Perrier (1992) show the same trends.

Figure 1: Eulerian mean velocities measured under non breaking waves. van Doorn (1981) test V00, V10, V20. In all tests the wave parameters were $(D, T, H_s) = (0.3m, 2.0s, 0.12m)$, and the bed roughness was artificial ripples with Nikuradse roughness $r = 2.1cm$.

The current maximum is not seen in velocity profiles from U-tube experiments like those of van Doorn (1983). It was therefore suggested by Nielsen (1992) that the profile type in Figure 1 can be understood in terms of the wave Reynolds stress $-\rho \bar{u} \bar{w}$ which exist under a progressive wave with a bottom boundary layer but not in the U-tubes. The tilde indicates periodic components with zero mean, corresponding to the definition $u(t) = \bar{u} + \tilde{u}(t) + u'(t)$.

Figure 2 shows corresponding examples of following and opposing currents superimposed on the same waves (same period and same wave height) measured by Klopman (1994). Klopman's data show very clearly the difference in profile shape

caused by the wave Reynolds stress $-\rho\overline{u'w'}$. Wave basin measurements by Havinga (1992) with angles of 60° , 90° and 120° between current and wave propagation show intermediate stages of this phenomenon.

The following outlines a model of current profiles in the presence of waves which takes $-\rho\overline{u'w'}$ into account explicitly in order to explain the shape of the velocity profiles in Figures 1 and 2. The model can successfully predict the distributions of weak currents as in a flume with no recirculation. For strong currents adjustments are needed to the distribution of $-\rho\overline{u'w'}$ which are as yet not understood. They are most likely due to non linear wave current interaction.

Figure 2: Current profiles in the presence of no waves (+), following waves (o) and opposing waves (triangle) of the same size. Depth $D = 0.5\text{m}$, wave period $T = 1.4\text{s}$ and wave height $H = 0.12\text{m}$. After Klopman (1994).

Shear Stresses and Shear

In the following the notation of Nielsen (1992) will be followed. Thus, the symbol τ represents the total shearing force per unit area of a cross section or the total transfer of x -momentum in the z direction. Hence, in a two dimensional flow with steady, periodic and random velocity components $(u, w) = (\overline{u} + \tilde{u} + u', \overline{w} + \tilde{w} + w')$ in the x and z directions we have

$$\tau = \rho v \frac{d\overline{u}}{dz} - \overline{\rho u w} = \rho v \frac{d\overline{u}}{dz} - \rho \overline{u w} - \rho \overline{u'w'} - \rho \overline{u'w'}$$
 (1)

where, as usual, ν is the kinematic viscosity and ρ is the fluid density. The total normal stress (positive as tension) or horizontal transfer of x -momentum is corresponding given by

$$\overline{\sigma} = -\overline{p} - \rho \overline{u'^2} + \rho v \frac{\partial \overline{u}}{\partial x} = -\overline{p} - \rho \overline{u'^2} - \rho \overline{\tilde{u}^2} - \rho \overline{u'^2} + \rho v \frac{\partial \overline{u}}{\partial x}$$
 (2)

and these two satisfy

$$\frac{\partial \bar{\tau}}{\partial z} + \frac{\partial \bar{\sigma}}{\partial x} = 0 \quad (3)$$

in a steady, two dimensional flow, i e,

$$\frac{\partial}{\partial z} \left[v \frac{d\bar{u}}{dz} - \bar{u}\bar{w} - \overline{u'w'} \right] = \frac{\partial}{\partial x} \left[\frac{\bar{p}}{\rho} + \bar{u}^2 + \overline{u'^2} - v \frac{\partial \bar{u}}{\partial x} \right] \quad (4)$$

Here we assume, for the situation of waves and a weak current, that the second term on the left can be neglected and that the first and the third term are dominant on the right hand side so that we have

$$\frac{\partial}{\partial z} \left[v \frac{d\bar{u}}{dz} - \overline{u'w'} \right] = \frac{\partial}{\partial x} \left[\frac{\bar{p}}{\rho} + \bar{u}^2 \right] \quad (5)$$

which is integrated with the bottom boundary condition $\bar{\tau}(0) = \bar{\tau}_o$ to give

$$v \frac{\partial \bar{u}}{\partial z} - \overline{u'w'} - \overline{u'w'} = \frac{\bar{\tau}_o}{\rho} + \int_0^z \frac{\partial}{\partial x} \left[\frac{\bar{p}}{\rho} + \bar{u}^2 \right] dz \quad (6)$$

Here we may write the first and third terms on the left in terms of a current eddy viscosity ν_c and solve for the current gradient

$$\frac{\partial \bar{u}}{\partial z} = \frac{1}{\nu_c} \left(\frac{\bar{\tau}_o}{\rho} + \int_0^z \frac{\partial}{\partial x} \left[\frac{\bar{p}}{\rho} + \bar{u}^2 \right] dz + \overline{u'w'} \right) \quad (7)$$

This equation will then directly give the current distribution by integrating with the boundary condition $\bar{u}(0) = 0$.

If the main emphasis is on the flow near the bed, it is justified to assume that the mean pressure is hydrostatic. However, in order to get a good representation of the flow closer to the surface it is necessary to use $\bar{p} = \rho g(\bar{\eta} - z) - \rho \bar{w}^2$ in which case Equation (7) can be written.

$$\frac{\partial \bar{u}}{\partial z} = \frac{1}{\nu_c} \left(\frac{\bar{\tau}_o}{\rho} + g \frac{\partial \bar{\eta}}{\partial x} z + \int_0^z \left[\frac{\partial}{\partial x} (\bar{u}^2 - \bar{w}^2) \right] dz + \overline{u'w'} \right) = \frac{1}{\rho \nu_c} \left(\bar{\tau}_o - \int_0^z \frac{\partial \bar{\sigma}}{\partial x} dz + \overline{u'w'} \right) \quad (8)$$

This general expression explains qualitatively the shape of the current profiles in Figure 1. For all three cases, $\bar{\tau}_o$ is positive and hence the current gradient is positive at the bed where the other terms are zero. Those terms will however grow in magnitude with increasing z and they are all initially negative for non-breaking waves over a horizontal bed. Thus, the right hand side and hence the current gradient will change sign at a certain level and the current velocity shows a maximum, see Figure 3.

The mean bed shear stress

The bed shear stress $\tau_o = \bar{\tau}(0)$ can be determined from

$$\tau_o = \tau_w - \rho g D \frac{d\bar{\eta}}{dx} - \frac{d S_{xx}}{dx} \quad (9)$$

where $\bar{\tau}_w$ is the time averaged wind stress, D is the local mean depth, $\bar{\eta}$ is the mean surface elevation and S_{xx} is the wave radiation stress in the direction of wave propagation calculated from a suitable wave theory.

The radiation stress term

Assuming linear wave theory, the radiation stress term of Equation (8) is evaluated as

$$\int_0^z \frac{\partial}{\partial x} [\bar{u}^2 - \bar{w}^2] dz = \int_0^z \left[\frac{1}{2} \frac{\partial}{\partial x} \left(\frac{\pi H}{T \sinh kd} \right)^2 [\cosh^2 kz - \sinh^2 kz] \right] dz$$

$$= H \frac{dH}{dx} \frac{\pi^2}{T^2 \sinh^2 kd} z \tag{10}$$

In general the wave height may also vary due to breaking, refraction, diffraction and shoaling, but if only bottom friction is important, the wave height gradient is given by

$$H \frac{dH}{dx} = - \frac{8}{3\pi g} \frac{f_e (A\omega)^3}{c_{g,r} + \langle \bar{u} \rangle} \tag{11}$$

where f_e is the energy dissipation factor ($\approx f_w$), $c_{g,r}$ is the wave group velocity relative to the current and $\langle \bar{u} \rangle$ is the depth averaged current velocity. See e.g Nielsen (1992) p 77. By inserting into (10) we obtain

$$\int_0^z \left[\frac{\partial}{\partial x} (\bar{u}^2 - \bar{w}^2) \right] dz = \frac{-8\pi}{3gT^2 \sinh^2 kd} \frac{f_e (A\omega)^3}{c_{g,r} + \langle \bar{u} \rangle} z \tag{12}$$

Hence, the radiation stress contribution to the current shear in Equation (8) has the same form as the surface slope term, i.e., both grow linearly in magnitude with distance from the bed. Consequently, the general picture which determines the level of the current maximum ($\frac{\partial \bar{u}}{\partial z} = 0$) is as shown in Figure 3. The current maximum occurs where the terms due to $\frac{\partial \bar{\sigma}}{\partial x}$ and $\bar{\tau}_w$ are balanced by the wave Reynolds stress.

Figure 3: The current shear and the terms that generate it, cf Equation (8), for a typical situation of following current ($\bar{\tau}_0 > 0$). The (lowest) current maximum will occur close to the bed for small $\bar{\tau}_0$ and closer to the MWS for larger $\bar{\tau}_0$, cf the measurements in Figure 1.

The wave Reynolds stress

The wave Reynolds stress $-\rho\overline{u\tilde{w}}$ may be seen as consisting of three components as shown by Bijker et al (1974). One due to the phase shifting of velocities in the boundary layer, one due to wave height decay and one due to bed slope.

Longuet-Higgins (1956) derived an expression for the first one for boundary layers with constant eddy viscosity. It varies through the wave boundary layer as

$$-\rho\overline{u\tilde{w}} = \rho \frac{1}{4} (A\omega)^2 k\delta \left[1 - e^{-\zeta} (2\cos\zeta - e^{-\zeta} + 2\zeta\sin\zeta) \right] \quad (13)$$

where

$$\zeta = \frac{z}{\delta} = \frac{z}{\sqrt{2\nu_t/\omega}} \quad (14)$$

Its asymptotic value above the boundary layer ($z \gg \delta$) is

$$-\rho(\overline{u\tilde{w}})_\delta = -\rho \frac{1}{4} k\delta (A\omega)^2 \quad (15)$$

which can be written in terms of the friction factor as

$$-\rho(\overline{u\tilde{w}})_\delta = \rho \frac{1}{4\sqrt{2}} k A^3 \omega^2 f_w \quad (16)$$

of Nielsen (1992). The wave friction factor may be determined from

$$f_w = \exp \left[5.5 \left(\frac{r}{A} \right)^{0.2} - 6.3 \right] \quad \text{for } r/A < 1 \quad (17)$$

as suggested by Nielsen (1992).

Estimation of $-\rho\overline{u\tilde{w}}$ in and above a turbulent boundary layer

The expression (13) was derived for wave boundary layers that are laminar or which are turbulent with constant eddy viscosity. For turbulent wave boundary layers with moderate relative roughness: $r/A < 0.06$ it is however necessary to adopt a different description, cf Nielsen 1992, p 47. At present we shall adopt the simple, boundary layer model of Nielsen (1985) by which the horizontal velocity under a decaying sine wave can be written as

$$\tilde{u}(z,t) = A\omega \left[\cosh kz - e^{-[1+i]\left(\frac{z}{z_1}\right)^p} \right] e^{i(\omega t - kz)} \quad (18)$$

Provided the boundary layer is thin: $|kz_1| \ll 1$. The wave decay is described by the imaginary part of the wave number $k = k_r + ik_i$. We note that the wave decay is not exactly exponential for a turbulent boundary layer, but we have approximately

$$k_i = \frac{1}{H} \frac{dH}{dx} \approx -H \frac{8\pi^2}{3gT_a^3 (c_{gr} + \langle \bar{u} \rangle) \sinh^3 kd} f_e \quad (19)$$

cf Nielsen (1992), p 78. T_a is the period seen by a fixed observer.

The boundary layer parameters z_1 and p may, for hydraulically rough (roughness r) conditions, be found from the following formulae from Nielsen (1985)

$$z_1 = 0.09 \sqrt{rA} \quad (20)$$

$$p = 0.59 \exp\left(0.59 \frac{1 - (A/38r)^{1.8}}{1 + (A/38r)^{1.8}}\right) \tag{21}$$

This model is likely to be satisfactory for all wave boundary layers in the relative roughness range which has so far been observed with beds of loose sand ($0.015 < r/A < 1$) as discussed by Nielsen (1992). For very rough beds, $p \rightarrow 1$, this model corresponds to constant eddy viscosity.

In order to find the wave Reynolds stress $-\rho \overline{u\tilde{w}}$ we first find the vertical velocity that corresponds to (18) from the continuity principle:

$$\tilde{w} = \int_0^z -\frac{\partial \tilde{u}}{\partial x} dz = A\omega e^{i(\omega t - kx)} [i \sinh k_z z - ik \int_0^z e^{-(1+i)\chi \frac{z}{z_1} p} dz] \tag{22}$$

where $\sinh k_z z \approx \sinh k_r z + i k_i z \cosh k_r z$ for $k_i z \ll 1$ so that

$$\tilde{w} \approx A\omega e^{i(\omega t - kx)} [-k_i z \cosh k_r z + i \sinh k_r z - ik \int_0^z e^{-(1+i)\chi \frac{z}{z_1} p} dz] \tag{23}$$

Similarly the expression (18) for the horizontal velocity can be simplified to

$$\tilde{u} \approx A\omega e^{i(\omega t - kx)} [\cosh k_r z + ik_i z \sinh k_r z - e^{-(1+i)\chi \frac{z}{z_1} p}] \tag{24}$$

Inside the boundary layer where $k_i z \ll k_r z \ll 1$ these expressions lead to an analogous (but very complicated) expression corresponding to (13). For the sake of brevity, we shall use (13) combined with (16) and with ζ replaced by $\xi = (z/z_1)^p$, i.e.

$$(\overline{u\tilde{w}})_{BL} \approx -\frac{1}{4\sqrt{2}} k_r A^3 \omega^2 f_w \cosh k_r z \left[1 - e^{-\xi} (2 \cos \xi - e^{-\xi} + 2\xi \sin \xi)\right] \tag{25}$$

where the subscript BL refers to this term being analogous to the boundary layer term considered by Longuet-Higgins (1956). The cosh factor only makes a difference far above the boundary layer where $\xi \gg 1$.

If we neglect the boundary layer terms (the last terms) in (22) and (23) we get the contribution due to wave decay:

$$(\overline{u\tilde{w}})_{DECAY} \approx -\frac{1}{2} (A\omega)^2 k_i z (\cosh^2 k_r z + \sinh^2 k_r z) = -\frac{1}{2} (A\omega)^2 k_i z \cosh 2k_r z \tag{26}$$

Figure 4 shows the two $\overline{u\tilde{w}}$ -contributions, evaluated for Klopman's (1994) tests.

Figure 4: Wave Reynolds stress contributions for $(h, T, H, r) = (0.5\text{m}, 1.4\text{s}, 0.12\text{m}, 0.0012\text{m})$. The units are $\text{m}^2/\text{s}^2 \times 10^{-5}$.

The eddy viscosity distribution

In order to find the \bar{u} -distribution from Equation (8) we must specify the eddy viscosity $\nu_c(z)$ felt by the current. We use the distribution suggested by Nielsen (1992) which consists of a parabolic/constant part based on the current friction velocity $\bar{u}_* = \sqrt{\tau_o / \rho}$ with a square toe added due to wave boundary layer mixing:

$$\nu_c(z) = \text{Max} \left\{ \begin{array}{l} 2\omega z_i^2 \\ 0.4\bar{u}_*z \left(1 - \frac{z}{D}\right) \text{ for } z < D/2, \\ 0.1\bar{u}_*D \text{ for } z > D/2 \end{array} \right\} \quad (27)$$

Discharge considerations

Calculation of the total discharge presents a problem because it must include the discharge which occurs above the wave trough where the velocities are not obtained by integration of Equation (8) as they are for the lower part of the flow. One estimate of the net flow between the wave trough and the crest can be obtained from linear wave theory namely

$$Q_{ic} = \frac{1}{8c} g H^2 \quad (28)$$

where c is the wave speed, see eg. Dean & Dalrymple (1991). It is however not obvious how this irrotational result can be combined with an integral over the lower flow domain ($z < D-H/2$) of the velocities obtained from Equation (8).

Identification	Q_{ic} [m ² /s] based on Eq (28)	Measured $D-H/2$ $\int_0^{\bar{u}} \bar{u} dz$ [m ² /s]	Measured total Q [m ² /s]	Total Q [m ² /s] based on Eq (29)

Table 1

We shall adopt the approach which is illustrated in Figure 5. That is, velocities below the wave trough are found from integration of Equation (8). Above the trough a parabolic velocity distribution corresponding to the flow rate given by Equation (28) is added to the velocity \bar{u}_* at the trough level. The total flow rate is then

$$Q = \int_0^{D-H/2} \bar{u} dz + \frac{gH^2}{8c} + \bar{u}_* H \quad (29)$$

Some comparison between this approach and measurements is afforded by Table 1. There is obviously some scope for improvement but the message from this limited data set is not very clear.

The surface slope

The surface slope $d\bar{\eta}/dx$, albeit very small influences the current distribution and hence the net flow rate per unit width Q . Hence, it is not possible to achieve agreement with experiments if the surface slope is assumed to be zero. Not even for a “no current situation”.

In practical applications it is some times Q which is specified while $d\bar{\eta}/dx$ is not. In such cases the model is easiest applied by trial and error. That is,

1. A reasonable value of $d\bar{\eta}/dx$ is guessed
2. Q is found by integrating Equation (8) and applying (29) to find Q .
3. An improved value of $d\bar{\eta}/dx$ is adopted.

The “necessary” surface slopes to match the usual wave flume conditions with horizontal beds are usually inside the range $\pm 5 \times 10^{-5}$. They are thus hardly measureable.

Comparison with experiments

A comparison of the model above with the “monochromatic waves, no current” experiment of Klopman (1994) is shown in Figure 5.

Figure 5: Model comparison with Klopman's data, Monochromatic waves, $D=0.5\text{m}$, $T=1.4\text{s}$, $H=0.12\text{m}$, $Q=0\text{m}^2/\text{s}$. The flume bed was covered with a single layer of 2mm sand giving a Nikuradse roughness of $r=1.2\text{mm}$. In order to achieve zero nett flow with the model, a surface slope of 0.0000017 must be assumed.

Figure 5 shows some discrepancy between the model and the measurements below $z = 6\text{mm}$. Part of this might be corrected by making adjustments to the eddy viscosity distribution in this area. However, the existing detailed data sets: van Doorn & Godefroy (1978), van Doorn (1981), Swan (1990) and Klopman (1994) show quite some variation. In particular, the negative velocities measured by Klopman at $z < 1\text{mm}$ are not paralleled by the other experiments. At any rate, comparison in very great detail is not warranted at levels smaller than the roughness height between this model, which is horizontally uniform, and measurements which, at this level, will depend upon the horizontal position of the probe. Measurements may show horizontal variation both on the scale of individual roughness elements and on the scale of the wave length if some reflection and/or circulation cells occur in the flume.

While the agreement between the model and experiments with weak currents is good as shown by Figure 5, adjustments are necessary in order to model stronger currents. In general the data show a stronger deviation from the logarithmic profile than the model predicts. See Figure 6.

Figure 6: Comparison between the model and the “monochromatic waves, following current” experiment of Klopman (1994). $D=0.5\text{m}$, $T=1.4\text{s}$, $H=0.12\text{m}$, $Q=0.08\text{m}^2/\text{s}$, $r=1.2\text{mm}$. Surface slope -0.00000145 .

Figure 6 shows a clear discrepancy between the model described above and Klopman’s “following current” experiment. The reason is believed to be that this rather strong current ($\langle \bar{u} \rangle = 0.92A\omega$) changes the wave motion and hence $\bar{u}\bar{w}$ in the upper part of the flow. An indication of this change can also be found the direct $\bar{u}\bar{w}$ -measurements of Supharatid et al (1992).

Figure 7 shows an improved model performance obtained by enhancing the wave Reynolds stress component $(\overline{\tilde{u}\tilde{w}})_{BL}$ (Equation 25) by the empirical factor

$$C_{WR} = 1 + 100 \frac{\overline{u_*} z}{A\omega D} \tag{30}$$

while $(\overline{\tilde{u}\tilde{w}})_{DECAY}$ is kept unchanged.

This is a purely empirical adjustment but it is thought to mimic changes to $\overline{\tilde{u}\tilde{w}}$ in the upper part of the flow due to extra vorticity of the wave motion caused by interaction with the strong current. There is little reason to believe that $\overline{\tilde{u}\tilde{w}}$ is changed appreciably inside the wave boundary layer by the current, cf the data Supharatid et al (1992) and Nielsen (1985, 1992). It is noted, however, that the same empirical adjustment would also improve the agreement with the zero-net-flow-data in Figure 5.

Figure 7: Comparison of the model with empirically enhanced wave Reynolds stress to the same data as in Figure 6. Surface slope -0.000021. The curve on the left shows the enhance distribution of $\overline{\tilde{u}\tilde{w}}$ given by Equations (25), (26) and (30).

Discussion

The magnitude of the eddy viscosity and its capacity to transfer vorticity upwards from the bed influences the nature of the solution as discussed by Longuet-Higgins (1953). If the eddy viscosity is small, the \overline{u} -profile would be strongly influenced by the end conditions through horizontal advection. In that case it would not be determined from the local force balance which leads to Equation (8). However Equation (35) leads to eddy viscosities which are very much larger than the laminar viscosity even in the “no current situations” corresponding to Figure 1a and Figure 4. Thus, in Klopman’s “no current” experiment Equation (9) gives a bed shear stress of

0.015N/m^2 corresponding to an eddy viscosity at mid depth of $0.00039\text{m}^2/\text{s}$, about four hundred times the laminar viscosity. This is probably the reason why “no current” experiments quite consistently show \bar{u} -profiles like to ones in Figure 1a and Figure 5 even though they may have different end conditions.

In other words, it appears that under conditions like those of van Doorn (1981) and Klopman (1994) and even the smooth bed experiments of van Doorn & Godefroy (1978) (D, T, H) = (0.3m, 2s, 0.12m) the eddy viscosity is strong enough that the net flow is governed by the local conditions as expressed by Equation (8). The experimental conditions of Swan (1990), smooth bed and (D, T, H) = (0.369m, 0.893s, 0.06m) are probably close to the limit although he did show (his Figure 5a) a \bar{u} -profile which is qualitatively similar to those observed under more vigorous flow conditions by van Doorn & Godefroy (1978), van Doorn (1981) and by Klopman (1994).

These observations seem to justify the use of Equation (8) as the basis of modelling currents in the presence of waves under field conditions and in most laboratory situations.

The present version of the model is open to a number of refinements. First of all with respect to the treatment of the flow above the wave trough. Secondly, the enhancement of the wave Reynolds stress in the presence of a stronger current should be investigated theoretically.

Application of the model above model to surf zone conditions may require adjustments in three areas:

1. An additional term due to bottom slope may need to be added to $\overline{u\tilde{w}}$,
2. A different expression for the flow above the wave trough, e.g. a roller model may be needed. The eddy viscosity must be enhanced in the upper part of the flow. Guidance in these respects may be found in the measurements of Nadaoka & Kondoh (1982) and Cox et al (1995).

The strength of the present model compared with previous ones is that a detailed description is achieved at the bottom at the same time as a reasonable overall water balance. This is of course necessary in order to model natural situations with movable beds.

Abstract

A recently developed Coherent Acoustic Sediment Probe (CASP) was deployed from an instrumented sled during the Duck94 nearshore experiment at Duck, North Carolina, in October 1994. The CASP measured acoustic backscatter profiles and three component velocity vectors in an $O(1\text{ cm}^3)$ volume 25cm in front of the downward-looking instrument package. The CASP was remotely positioned to selected heights to form profiles of velocity and sediment concentration through the bottom boundary layer. A vertical stack of 8, two-axis electromagnetic current meters extended the horizontal measurements to the surface. A co-located scanning pencil-beam sonar and tilt sensors were used to map the small-scale morphology across a 1m by 4m area centered on the CASP measurements, quantifying the local roughness and slope elements down to 4cm scales under low acoustic clutter conditions. It is shown that the stress measured near the bed in a gravity oriented vertical reference system is associated with both the turbulent Reynolds' stresses and a wave stress due the vertical velocity induced by the horizontal wave velocity acting on the sloping bottom being correlated with the horizontal velocity. The wave stress is largest at the bed and decreases towards the surface and can be larger than the turbulent Reynolds' stresses.

DUCK94 Experiment

The data presented herein were obtained during the comprehensive nearshore DUCK94 experiment conducted in October 1994 at the U. S. Army Corps of Engineers Field Research Facility (FRF), Duck, North Carolina. The FRF beach usually is a two-bar system composed of a dynamic inner bar (30-120 m offshore) and a secondary bar of lower amplitude (300-400 m offshore). The mean foreshore slope of the beach is approximately 0.08 (1:12) and the mean slope offshore of the bars is approximately 0.006 (1:170) (Lippmann et al., 1993). Sediments have a wide range of coarse sediment size on the beach and foreshore and fine, well sorted sand within the trough and seaward (mean grain diameter ~ 0.2 mm) (Stauble, 1992). The mean tidal range is approximately 1 m.

Boundary layer stress and velocity profile measurements from 11 October have been chosen to show the structure of the bottom boundary layer under strong wave forcing conditions. Storm waves with significant wave heights of 2m approaching at 16° (in 8m depth) produced

mean longshore currents of 1 ms^{-1} in the surf zone. The resulting bottom boundary layer was composed of both the steady longshore flow and $O(1 \text{ ms}^{-1})$ magnitude cross shore oscillatory flow due to the incoming waves.

Wave, velocity and sediment flux data were acquired using an instrumented sled. A Coherent Acoustic Sediment Probe (CASP) was mounted on a moveable boom (with elevation controlled from shore) deployed from the sled. The CASP measured acoustic backscatter profiles and three-component velocity vectors in an $O(1 \text{ cm}^3)$ volume 25cm in front of the downward-looking instrument package, as it was remotely positioned to selected heights to form profiles of velocity and sediment concentration through the bottom boundary layer. A co-located scanning pencil-beam sonar and tilt sensors were used to map the small-scale morphology across a 1 m by 4 m area centered on the CASP measurements, quantifying the local roughness and slope elements down to 4cm scales under low acoustic clutter conditions

Additional instrumentation on the sled included a vertical stack of eight Marsh-McBirney two-component electromagnetic current meters mounted on a 2.5 m mast to measure vertical profiles of longshore and cross-shore currents. The sled was oriented with the vertical stack of current meters placed on the up-current side to prevent the sled structure from contaminating flow measurements. Surface elevations were measured using an array of five pressure sensors configured in a 3 m square with sensors at the corners and one at the center. For data collection, the sled was towed by the CRAB to its furthest position offshore, dependent upon wave conditions, for the first data run. The sled was tethered to the shore with a chain. A forklift on the beach pulled the sled shoreward approximately 10 to 30 m for each subsequent run. Data were acquired at each location for approximately one hour at four to eight locations. Data were digitized on the sled and transmitted to shore via an armored fibre optic cable married to the chain tether.

Additionally, directional wave spectra were acquired using a linear array of 10 pressure sensors in 8 m depth offshore of the survey area. A fixed current meter in the trough at line 820 m was used to measure longshore currents continuously.

Vertical profiles of the mean longshore currents at various cross-shore location superposed on the bottom profile measured on 11 October are shown in Figure 1. The longshore currents were relatively strong on this day with mean currents exceeding 1 m/s . The bottom profile is barred. The small-scale morphology is near planar on the seaward side and atop the bar and on the foreshore, with well-developed mega-ripples within the trough.

Theory and Analysis

Linear wave theory over a horizontal bed predicts that the horizontal and vertical wave induced velocities are in quadrature, and therefore do not contribute to the Reynolds' stresses. However, for a sloping bottom in a gravity oriented vertical reference system, a vertical velocity is induced at the bed by the horizontal velocity acting on the sloping bottom

$$w = u \tan\beta \quad (1)$$

where u, w are the horizontal and vertical velocities and $\tan B$ is the bottom slope. The vertical

Figure 1. Measured longshore current vertical profiles (*) at various cross-shore locations compared with logarithmic profile (solid line) superposed on the bottom profile.

velocity near the bed will be in-phase with the horizontal velocity, resulting in a contribution to the co-spectrum, $\langle uw \rangle$, which is proportional to the Reynolds' stress. The total stress is composed of an induced wave stress plus the stress due to the friction velocity defined as

$$\frac{\tau}{\rho} = u_{*T}^2 = \langle \bar{u}\bar{w} \rangle = u_{*Friction}^2 + u_{*Wave}^2 \quad (2)$$

It is hypothesized that the appropriate coordinates to measure the Reynold's stresses near the bed are oriented normal to the bottom. However, the bed has a broad range of scales in the near shore (Thornton, et al 1997) ranging from the general bottom profile with horizontal scales $O(10m)$ to mega-ripples and ripples with horizontal scales $O(1m)$. A question then arises as to what is the corresponding scale over which to measure the bottom slope? Instead of trying to measure the appropriate bottom slope, we will use hydrodynamic measures to establish the coordinate system. Hydrodynamically, the velocity normal to the bed goes to zero at the bed. Therefore, the bottom slope in (1) is determined three different ways by minimizing the measured near-bed quantities of covariance between horizontal and vertical velocity, $\langle uw \rangle$, mean vertical velocity, \bar{w} , and vertical velocity variance, $\langle w^2 \rangle$.

Results and Conclusions

Direct estimates of the Reynolds stress components $\langle uw, vw \rangle$ and mean velocity $\langle U, V \rangle$ were formed at each measurement height with averaging times between 4 and 10 minutes. As a vertical profile of these quantities is formed over approximately 1 hour, measurement stations were selected where the mean currents and wave conditions were relatively constant during this time. Profiles of (U, V) vectors, orbital displacement standard deviations in the x, y directions, the friction velocity vector (u^*, v^*) , and the friction velocity magnitude for station 1 (see Figure 1) are shown in Figure 2. The instrument coordinate velocity vector time series was rotated into a vertically orientated coordinate system to a precision of $\pm 0.2^\circ$ before the mean velocity and stress estimates were made. Therefore the true vertical (rather than bed normal) stresses are shown here. Height above the bed was determined to ± 1.6 cm by using the acoustic backscatter profiles. The velocity coordinate system in these plots is $v+$ offshore and $u+$ toward the south, and $w+$ upwards. At both sites, the U/V profiles, which span the lower 0.5m of the bottom boundary layer, show strong offshore and long-shore mean currents decaying toward the bed. The upper CASP-measured mean velocities matched the em-current meter profiles, which extend to the surface (not shown). In the absence of an oscillatory flow component, the stress vectors would be expected to be aligned with the mean current direction within the inner "wall" boundary layer established by the mean flow. However, the mean vertical stress vector has a strong cross-shore wave stress component, increasing toward the bed, which rotates the stress vectors toward the offshore direction (Figure 2). This cross-shore stress is attributed to the wave stress component arising from the shoaling waves interacting with the bottom slope, producing a linearly decreasing wave stress toward the surface (Rivero and Arcilla, 1995). The slight increase in stress in the first 20cm above the bed seen in most of the profiles is likely due to the rotational stress components of the wave boundary layer arising from the strong oscillatory flow and the local bed roughness elements.

An example of the co- and quadrature spectra measured in gravity oriented coordinates at an elevation of 27 cm above the bed is shown in Figure 3. In the gravity oriented vertical reference coordinates, there is a large contribution to both the co- and quadrature spectra (vw, uw) at the wind-wave band of frequencies (0.1 - 0.5 Hz). The co-spectrum is minimized by rotating the coordinates about the x, y axis in 0.1° increments (Figure 4). A definite minimum is found, indicating a mean cross-shore slope of 4.3° and an alongshore slope of 1.6° . The minimized cross-spectra are shown in Figure 5. The co-spectra are greatly reduced, whereas the quadrature spectra are virtually the same, indicating the co-spectral contributions are bottom slope induced, and should not be attributed to turbulent Reynold's stress contributions.

The mean and vertical velocities variance were similarly minimized and the corresponding calculated bottom slopes were essentially the same as calculated from the minimization of the co-spectra. Therefore, the coordinate rotations are based on the minimization of the co-spectra.

The friction velocities calculated at various elevations over the vertical before and after rotations of the coordinates and the cross-shore tilt calculated from the minimization of the co-spectra indicative of the bottom slope are shown for locations offshore the bar and within the trough (Figures 6 and 7). The measured cross-shore bottom slope (averaged over 5m) is also indicated. On the near planar, smooth slope on the seaward side of the bar the calculated slope from the co-spectral minimization corresponds to the bottom slope (averaged over 5m) as the bottom is approached; this indicates that the additional stress is associated with the sloping

bottom. However, within the trough where mega-ripples are prevalent, just the opposite effect is seen where the calculated slope from the minimization of the co-spectra and the bottom slope measure over 5m do not converge until almost 40cm off the bed. The total near bed shear velocities are large. After subtracting u^2_{wave} from the total shear velocity, the residual friction velocities are essential constant over the vertical. The detailed bottom profile at station 5 shows the bottom is composed of mega-ripples with heights of approximately 15cm and wave lengths of about 1m (Figure 7). The location of the CASP is at the vertical dotted line and unfortunately information right beneath the CASP is not available. The mean slope is indicated and it can be seen that is can be quite different that the local slope near the bed as indicated by the tilt values calculated in Figure 6.

Conclusions

The total near-bed friction velocity is viewed as the sum of the friction velocity associated with the turbulent Reynolds' stress and a wave friction velocity induced by the sloping bed. The friction velocity is calculated by minimizing the co-spectra to eliminate the contribution by the horizontal wave velocity acting on the bed to induce an in-phase vertical velocity which contributes to the co-spectrum. The horizontal scale of the bed slope which induces the near-bed vertical velocity due to the waves appears to be related to the distance from the bed. Where a multitude of scales exist very close to the bed, such as when mega-ripples are present, the local bed slope (horizontal scale < 1m) appears to dominate, whereas away from the bed the corresponding bed slope can be much larger. For a smooth, near-planar bed, all horizontal scales have essentially the same slope.

The wave-induced friction velocity is largest near the bed and decreases toward the surface, which agrees with the theoretical work of Rivero and Arcilla (1995). The wave-induced velocity near the bed can be much larger than the turbulent Reynolds' stresses.

Acknowledgments

This work was funded by the Office of Naval Research, Coastal Sciences Branch under contract N00114-95-AF-002. The authors wish to express their appreciation to all those who participated in DUCK94 experiment, particularly the staff of the U.S. Arm Field Research Facility under the direction of B. Birkemeier. In addition, special appreciation is expressed to R. Wyland and J. Stockel for their roles in the acquisition and analysis of the data.

CHAPTER 316

Studies on the Suspended Concentration in the Surf Zone

Ching-Her Hwang¹ Li-Hung Tsai² Po-Ching Lin² Chin-Chi Tsai³

Abstract

This study is to carry out the field measurements of the suspended concentration by using MTB-16K turbidity records in the surf zone of mild sloping beach (1/144). Then the vertical concentration distributions of the suspended sediment at different water depth d/L_0 and the longitudinal concentration distributions of the suspended sediment across the surf zone are analyzed and discussed respectively in this paper.

Introduction

In order to understand the phenomena of sediment transport in the near shore, it is necessary to investigate the problems of the sediment suspension mechanism induced by waves. Earlier there are many scholars and experts, such as Farichild (1959), Homa and Horikawa (1962), Noda (1967) etc., who had been studied this problems by using siphon, pumped sampler and suspend sampler respectively. In fact, it is difficult to obtain the exact records of suspended sediment variations. Lately there are other researchers such as Homa (1965), Sleath (1974, 1982), Wrigh (1982), Deigaard (1986), Makoto Ifuku (1988), Gotoh (1994), Nielson (1994), Ono (1994) and authors (1993-1995) etc. had also been studied this problems in the laboratory and in the field respectively. And this study is to carry out field measurement of the suspended concentration in the surf zone of mild sloping beach ($S=1/144$) located at the mid-west coast of Taiwan, R.O.C. under the sponsor of the National Science Council for the integrated research program "Coastal Space Utilities".

³ Assist, the Coastal Engineering Division, IHMT.

Field Measurement

Four sets of memory MTB-16K turbidity recorder which set up above the sea-bed 6.5cm, 22cm, 35cm and 76cm etc. near the low water level at the tidal zone are used to measure the vertical concentration distribution of the suspended sediment. Also there are three sets of memory MTB-16K turbidity recorder which set up at a distance of 50m each other and above the sea-bed 6.5cm are used to measure the longitudinal concentration distribution of the suspended sediment across the surf zone. The maximum tidal range is about 5m in this area, hence their concentration distributions of the suspended sediment at different water depth can be measured by the tidal variations. Concurrently a DNW-5M pressure sensor and a UCM 40 Type MKII were also set up respectively near the sea-bed around the low water level and a waverider was set up outside the surf zone to record the oceanography conditions. The schematic diagrams are shown as Fig. 1.

Figure 1 The schematic diagrams of parameters and memory MTB-16K recorders mounted on sea-bed

Field data of wave, water level and suspended concentration are recorded respectively every one hour interval by using the DNW-5M pressure sensor and the MTB-16K turbidity recorder from PM 7, 14 March, 1995 to AM 7, 16 March, 1995. The recorded periods of field data are continuous 10 minutes every times and data is adopted by one second interval.

Data Analysis and Discussions

3.1 The distributions of wave height across the surf zone

Figure 2 shows the parts of time histogram of the wave height and water level field measured data taken from the DNW-5M pressure sensor in the near shore on 14 March, 1995.

Figure 2 Time series of wave height and water level in the near shore

And the corresponding time series of wave height and wave period taken from the waverider at -20m water depth outside the surf zone are shown as Figure 3.

Figure 3 Time series of wave period and wave height at -20m water depth

Results indicate that the distributions of wave height are gradually decreasing from the largest $H_0=2.2\text{m}$ occurred at AM 6, 14 March to the smallest $H_0=0.20\text{m}$ occurred at AM 7, 16 March and its corresponding distributions of wave period are decreasing from 6~7 secs to 3~4 secs during wholly observing periods.

Figure 4 shows the relationship diagram between the local wave height H and its corresponding water depth d by analyzing the field measured data in the surf zone. Various legends such as “□” and “+” etc. represent the results in the flood or in the ebb. Results also indicate that the local wave height is linearly decreasing with water depth when the H/d value is equal to 0.4. If we convert this relationship with the form $H=r(d+H)$, then the empirical constant is $r \cong 0.3$. This means that the distribution of wave height can be expressed as the following empirical form in the surf zone.

$$H = r(d + H) \qquad S = \frac{1}{144} \qquad (1)$$

$$H_0 < 2.2m$$

Figure 4 The relationship diagram between wave height and water depth in the surf zone

3.2 The distributions of suspended concentration in the surf zone

3.2.1 The vertical distributions of suspended concentration

Parts of the time series of suspended concentration measured at various positions and its corresponding water level are shown as Figure 5 and Figure 6 respectively.

Figure 5 Time series of suspended concentration at various position

Figure 6 Time series of the water level and its corresponding suspended concentration

Results indicate that the tendency of suspended concentration is decreasing with increasing the water depth. And the higher water depth is, the discrepancy of suspended concentration measured at different height is smaller.

By using the concept of Figure 1 schematic diagram, the concentration distributions of the suspended sediment at different relative water depth d/L_0 can be measured by the tidal variations. Figure 7(a)~(d) shows the vertical distributions of suspended concentration at different relative water depth d/L_0 . The dots and solid line in the Figure 7 represent respectively the field measured data and a regressive curve in this study. Results indicate that the vertical distribution of suspended concentration is more uniform for the smaller relative water depth d/L_0 .

And results also show that the maximum suspended concentration mostly occurs at the bottom for different relative water depth under the same wave conditions. Figure 8(a)~(d) shows the dimensionless relationship between measured relative suspended concentration (C/C_{max}) and different relative water depth d/L_0 .

Then, we can summarize the analyzed results in different way to express the vertical distributions of suspended concentration under various relative water depth d/L_0 as shown in Figure 9.

Moreover, the relationship diagram between the vertical suspended concentration at any relative depth y/d and the relative water depth d/L_0 can be also shown as Figure 10(a)~(c).

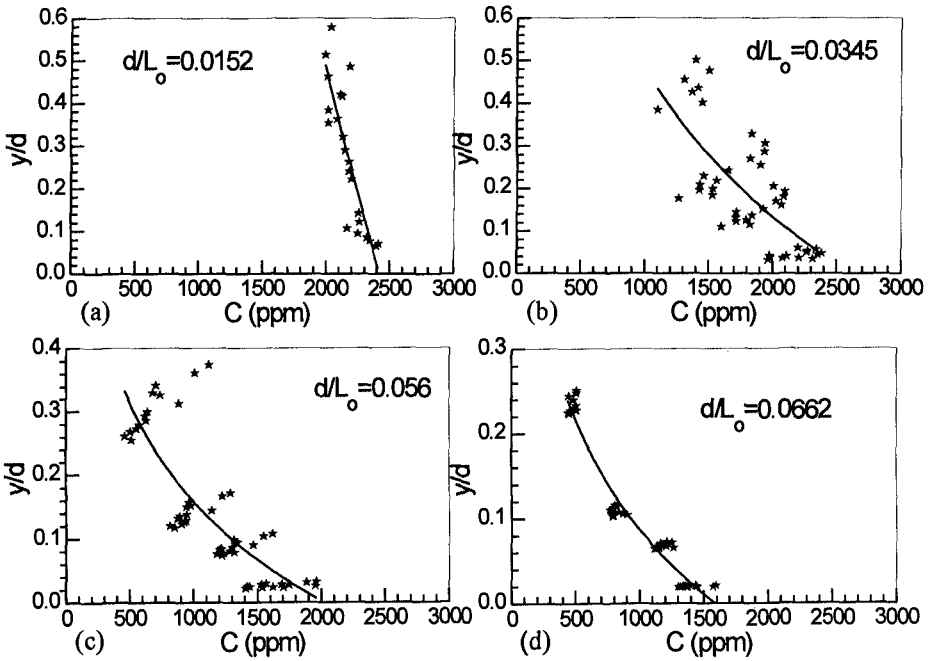

Figure 7 The vertical concentration distribution for the different relative water depth

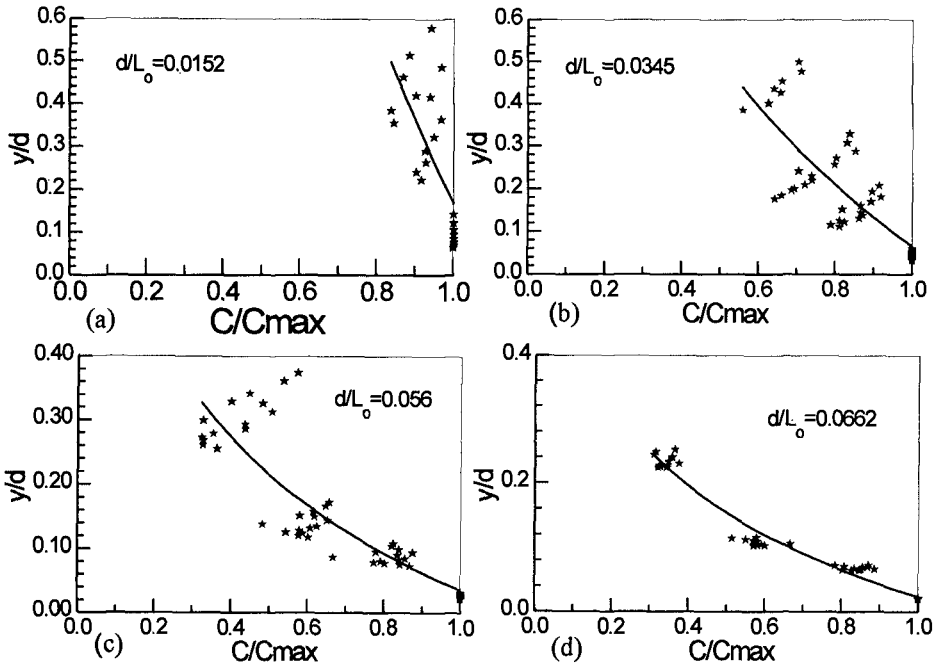

Figure 8 The vertical distribution of dimensionless suspended concentration

Figure 9 The vertical distributions of suspended concentration under the same wave condition

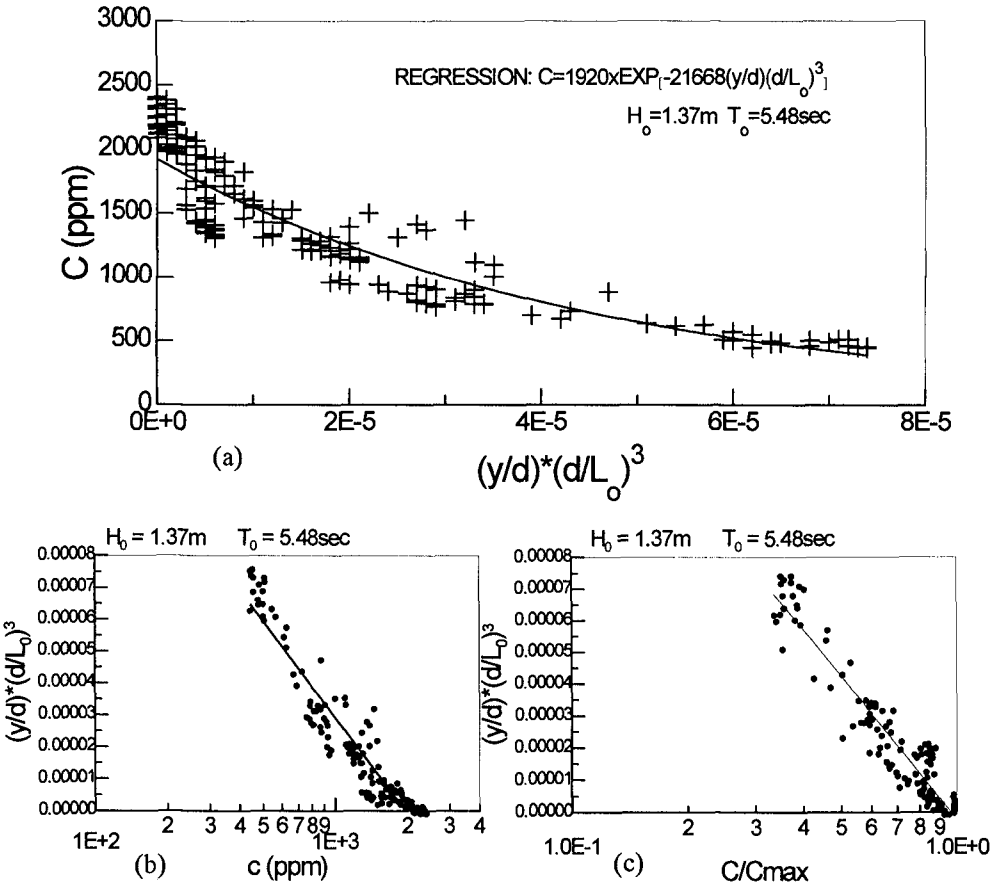

Figure 10 The relationship between suspended concentration C and $(y/d) \cdot (d/L_0)^3$

It means if the water depth d is given, then the suspended concentration at any depth y can be obtained by following regressive formuluss.

$$C = 1920 \cdot e^{-21668 \left(\frac{y}{d}\right) \cdot \left(\frac{d}{L_0}\right)^3} \tag{2}$$

where d : water depth
 y : height from the seabed
 C : suspended concentration, its unit is ppm

3.2.2 Suspended concentration near the seabed across the surf zone

Figure 11(a)~(d) shows the concentration distributions measured near the seabed across the surf zone under various wave steepness H_0/L_0 . The definitions of parameter X and X_b are shown as Figure 1. The width of the surf zone, X_b , is computed by wave theory here. In general, results indicate the maximum values of suspended concentration usually occur around the breaking point for the same wave condition.

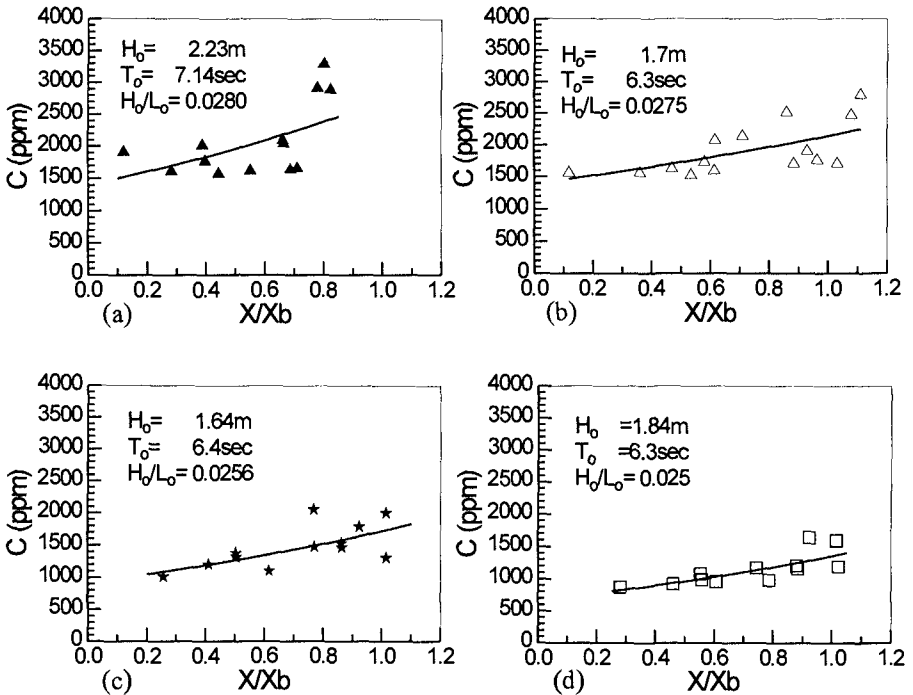

Figure 11 The distributions of concentration near the seabed across the surf zone

We can also summarize above results as Figure 12 under various wave steepness H_0/L_0 . It means that the suspended concentration near the seabed will be decreasing with decreasing the depth. But it will be increasing when the incident wave steepness H_0/L_0 is increasing for the same depth.

Figure 12 The concentration distributions near the seabed across the surf zone

Conclusions

Summarize above field data analysis and discussions, we can obtain some conclusions as following :

1. All measured field data can be provided as the quantitative basis of the numerical analysis in this study.
2. The local wave height H will be linearly decreasing onshore with depth d when the incoming wave is broken. Its relationship can be expressed as $H=r(d+H)$ when the beach is a mild slop $S=1/144$ and incident wave height H_0 is smaller than 2.2m, then the coefficient is $r \cong 0.3$.
3. The vertical distribution of the suspended concentration C can be computed by equation $C = 1920 \cdot e^{-21668 \left(\frac{y}{d}\right) \cdot \left(\frac{d}{L_0}\right)^3}$ if depth d is known.
4. The distributions of the suspended concentration across the surf zone are related with the incoming wave steepness H_0/L_0 . In general, its maximum value usually occurs around the breaking point.

CHAPTER 317

Suspended sediment mixing in the surf zone

José A. Jiménez, Francisco J. Rivero, Agustín Sánchez-Arcilla,
Vicente Gracia and Andrés Rodríguez¹

Abstract

The vertical distribution of suspended sediment in the surf zone is analysed by using field measurements. The analysis focuses in the description of the shape of the profile, *i.e.* mixing coefficient, and to do this, several approaches have been followed: pure diffusion, pure convection and combined diffusion-convection. The obtained results show a strong dependence of the sediment diffusion coefficient with the sediment grain size whereas the convective length scale presented a smaller grain-size influence.

Introduction

The vertical distribution of suspended sediment inside the surf zone may be generally considered as a combination of convective and diffusive processes. The distinction between both can be done in terms of mixing lengths, which in turn depend on the hydrodynamics acting on the sediment. According to Nielsen (1991, 1992), this can be mathematically described in a time averaged form by the convection-diffusion equation

$$w_f c + \varepsilon \frac{dc}{dz} - pF(z) = 0 \quad (1)$$

where w_f is the fall velocity of the sediment, c is the time averaged suspended sediment concentration, z is the elevation above the bottom, ε is the sediment diffusivity, p is the pick-up function and $F(z)$ is the convective entrainment function.

¹ Laboratori d'Enginyeria Marítima (LIM), Catalonia University of Technology (UPC), c/Gran Capitán s/n, 08034 Barcelona, Spain (jimenez@etseccpb.upc.es).

Equation (1) is generally truncated being the pure diffusive description the most common approach (see *e.g.* van de Graff and Roelvink, 1988 among others). In spite of this, the approach may be accurate enough to describe the suspended sediment distribution if sediment is characterised by a mean grain size (without considering the grain size distribution). However, when this distribution is taken into account, a dependence of diffusivity or mixed length with grain size can be often observed (see *e.g.* Nielsen, 1983, van de Graaf and Roelvink, 1988, van Rijn, 1993). Strictly speaking, although a slight variation of the diffusivity of a solid particle (the sediment) with respect to the one of the fluid should be expected (see *e.g.* van Rijn, 1984), large deviations between the sediment diffusivity and the fluid eddy viscosity should indicate that other mechanisms are affecting the sediment mixing.

In this work, the vertical suspended sediment distribution in the surf zone is analysed using field measurements. The analysis focuses on the shape of the distribution from the pure diffusive and/or convective approaches and, an attempt to use the combined diffusion-convection solution is also presented. This last point was introduced due to the observed dependence of the mixing coefficients with sediment characteristics.

Experimental data

The used data were acquired in a field campaign (DELTA' 93) carried out in the Trabucador Bar (Ebro delta, Spanish Mediterranean coast). The measured field data included bathymetry, waves outside and inside the surf zone, mean water levels across the surf zone, velocity field (both horizontal and vertical structure) by means of an instrumented sledge equipped with 6 electromagnetic currentmeters and a step wave gauge (see Rodriguez *et al.* 1995a for a full description of hydrodynamic measurements) and measurements of longshore suspended sediment transport across the surf zone.

Longshore suspended sediment transport were measured by means of portable sediment traps (hereinafter PST) similar to that described in Rosati and Kraus (1989). Each PST was composed by a vertical array of 5 to 6 traps, each one of the cube-type with a nozzle of 5.5x5.5 cm and with a streamer (collection bag) made with a mesh of 100 μm (Ortiz, 1995).

Measurements were taken in the inner part (inside the surf zone in all the cases) of a barred profile under wave conditions characterised by H_{rms} ranging between 0.4 and 0.6 m at 7.5 m depth and with peak periods, T_p , from 5 to 6 sec. Spilling breaking waves were representative of surf zone conditions during all the experiments, with induced longshore currents up to 0.7 m/s.

Figure 1 shows some measured vertical profiles of the longshore current, where it can be seen that for relative depths, $z/d \geq 0.1$, current velocity shows small changes in vertical, *i.e.* is nearly constant in vertical.

Longshore suspended sediment transport measurements were taken in three profiles across the surf zone, with 4 to 5 positions each. In each position, PST were operating during a time period of 2 to 5 min. After that time, PST are carried to shore and collected sand is stored in bags to be weighted and sieved at the laboratory.

Figure 1. Typical vertical profiles of longshore currents measured during the experiments.

Vertical distribution of suspended sediment concentration

In order to obtain the vertical distribution, the first working hypothesis was that because measurements were acquired inside the surf zone, where a well mixed water column can be assumed, a *constant in vertical* mixing coefficient was considered.

Figure 2 shows the vertical distribution of the vertical eddy viscosity obtained from time series of velocity measurements inside the surf zone (see Rodríguez *et al.* 1995 for further details in the calculation of diffusivity). It can be observed that for relative depths ≤ 0.6 the calculated diffusivity can be considered as constant in vertical, whereas in the upper part of the water column values increase, due to the generation of horizontal turbulent-momentum flux during breaking (Rodríguez *et al.* 1995).

This assumption of a constant in vertical diffusivity leads to an *exponential concentration distribution* (when a pure diffusive process is considered) given by

$$C(z) = C_0 e^{-w_f z / \epsilon}$$

where C_0 is the reference concentration at the bottom, w_f is the fall velocity of the sediment, z is the elevation above the bottom and ϵ diffusion coefficient.

Or in another form (assuming a pure convective process with an exponential function to describe convection, Nielsen, 992) as

$$C(z) = C_0 e^{-z/L}$$

where L is the mixing or length scale.

Figure 2. Vertical distribution of eddy viscosity obtained during the experiments.

When experimental profiles were fitted to a vertical distribution given by expressions (2) or (3), a good agreement was obtained. From 15 cases, covering three lines across the surf zone, the mean r^2 value of all the fits was 0.952, with a minimum r^2 value of 0.90 and a maximum of 0.995.

Figure 3 shows an example of the obtained normalised time averaged concentration profiles at different locations across the surf zone with the corresponding exponential fit for one of the monitored cross-shore profiles.

These results indicate that at least during the conditions prevailing during the field experiments, and for measurements taken inside the surf zone, the classical exponential profile describes well the time averaged concentration profiles. In this case, the averaging was done over a relatively long time period (from 20 to 50 waves) and because of this, these results cannot be considered in contradiction to those obtained by Mocke and Smith (1992) since the time scale of their analysis differs.

Cross-shore distribution of mixing coefficient

When the cross-shore distribution of the mixing coefficient was analysed, an increasing diffusivity from the shoreline towards the breaking point was observed for all the analysed cases (as expected). Fig. 4 shows the cross-shore distribution of the mixing length, L , for one of the control lines, where it can be clearly this increase in mixing towards the breakers where reaches the largest value.

Nielsen (1984) analysing the mixing length $-L-$ under non-breaking waves found that it was closely related to the bed ripple height. However, when the surf zone is considered a

different “physical entity” of L should be expected, since the mechanism inducing convection is clearly different.

Figure 3. Normalised time averaged concentration profiles at different location across the surf zone.

In this case, it was found that this length scale for convection was closely related to the local H_{rms} (see Figure 4). This fact can be used to validate the assumption of that, inside

the surf zone the sediment is picked-up from the bottom and put in suspension at an elevation above the bottom proportional to the wave height (Dean, 1973).

Thus, for the range of measured conditions and under spilling breakers, the local value of H_{rms} was found to be a good predictor of the magnitude of the convective length scale, L .

Figure 4. Cross-shore distribution of the mixing length L and H_{rms} .

When the cross-shore distribution of the mixing coefficient is put in terms of sediment diffusion coefficient, ϵ , the same pattern than before is observed (Fig. 5). This was due to that from equations (2) and (3) $L = \epsilon / w_f$, and no significant across-shore variations in sediment grain size was found.

Assuming that this sediment diffusion coefficient must be closely related to the fluid diffusion coefficient, their values should be equivalent to the vertical eddy viscosity for the fluid.

Fig. 5 shows the cross-shore distribution of the eddy viscosity for horizontal mixing using a k-model with production of turbulent energy according to Battjes (1975). It can be seen that both distributions (horizontal and vertical mixing) are qualitatively similar,

although the horizontal mixing coefficient is about two order of magnitude larger than the vertical one (see *e.g.* deVriend and Kitou, 1990). A detailed analysis of this discrepancy may be found in Svendsen and Putrevu (1994).

Figure 5. Cross-shore distribution of the sediment diffusion coefficient, ϵ , and calculated horizontal eddy viscosity v .

Effects of the grain size

Once the vertical suspended sediment distributions (assuming pure diffusion and convection) were analysed, the effects of the grain size on the sediment mixing was investigated. To do this, each sample was sieved into a series of fractions and, vertical distributions for each fraction were built. Once these classified vertical profiles were obtained, the same analysis than before was applied, *i.e.* fit to equations (2) and (3) to obtain the corresponding mixing coefficients for each fraction..

Figure 6 shows the obtained sediment diffusion coefficients, ϵ , for the same cases than the ones presented in Fig. 3 but considering different fractions. It can be clearly seen that diffusion coefficient is far from constant for the analysed range.

Focusing on the range of fractions characterised by a sediment fall velocity between 0.02 m/s and 0.06 m/s (out of this range some of the fractions were not statistically representative to build a “classified profile”), a linear relationship between the diffusion coefficient and the fall velocity was found: the larger the fall velocity is, the larger the coefficient will be. Similar results have been obtained for non-breaking waves by van de Graaf and Roelvink (1984) among others (see also Nielsen, 1992).

This result should indicate that for constant fluid diffusion coefficient, the sediment mixing will increase as coarser the sediment is. This discrepancy has been usually explained in terms of a greater influence of the centrifugal forces on the sediment particles with respect to the fluid in a turbulent flow. This would lead to an increase in the effective mixing length and diffusion rate for the sediment (see *e.g.* van Rijn, 1984).

However, although a small change in diffusivity between solid particles and fluid can be expected, the variations shown in figure 6 seems too high to assume that they are due to the above mentioned effect.

Figure 6. Variation of the diffusion coefficient ϵ_s vs fall velocity of the sediment for different locations across the surf zone. Grey rectangle indicates the range of fall velocities considered in the fit.

In fact, if the variations in diffusivity are measured as

$$\Delta\epsilon = \frac{\epsilon_{(w=0.06)} - \epsilon_{(w=0.02)}}{\epsilon_{(total\ sample)}} 100 \quad (4)$$

a mean value of 138% is obtained (considering the four locations across the surf zone).

From figure 6, it seems that the diffusivity dependence with grain size increases from shoreline (pst-9) towards the breaker point (pst-12). Although this is true in absolute

terms, when this variation is measured in relative terms (e.g. according to eq. 4), they are almost uniform, i.e. it seems to be constant across the surf zone.

Thus, the observed variations in the diffusion coefficient for the sediment mixing due to variations in grain size, introduce an uncertainty about the validity of the pure diffusion model to describe the vertical distribution of suspended sediment inside the surf zone.

Applying the same analysis to the case of pure convection model, i.e. looking to the variations in L when the different fractions are considered, the results depicted in Figure 7 are obtained.

In this case, although a variation in L is also observed, the direction of such variation is opposite to the above described one. Thus, assuming a pure convective process, as coarser the sediment is, smaller the mixing length will be. In other words, for coarser sediments, the mixing will be smaller.

This can be explained assuming that sediment response to convective process induced by wave breaking will be influenced by the sediment "weight". For heavier sediments (coarser), the theoretical distance from the bottom where they will be put in suspension (entrainment level) will be shortened as coarser the sediment is.

Figure 7. Variation of the length scale, L , vs fall velocity of the sediment for different locations across the surf zone. Grey rectangle indicates the range of fall velocities considered in the fit and grid lines represent largest value of L for each location (equal to the local depth).

Measuring the variations in the convective length scale, L , according to the equation 4, a mean value of 10% is obtained. The relative variations across the surf zone are also constant as it was for the previous case.

The main difference between the variations for diffusive and convective mixing lengths is that the former presented a larger variation than the convective one. In other words, the use of equation (3) to describe the vertical distribution of suspended sediment in the surf zone (assuming a pure convective process) is more "stable" in function of the sediment grain size than the use of a diffusive process. In spite of this, a small variation in the length scale was also found.

If the dominance of the process controlling the vertical distribution is measured in terms of its "stability", the convection process should be dominant under the monitored conditions.

Combined diffusion-convection process

Additionally to the above mentioned effect (variation in mixing coefficients for varying grain sizes), when the profiles for the different fractions were analysed, a change in the shape of the profile was also found. Thus, slight convex upward profiles were found to describe the fine fractions, whereas the coarser ones showed a slight concave upward shape. This change in shape was also explained by Nielsen (1992) as an indication of the presence of a combined diffusion-convection process controlling the sediment suspension.

In order to make a first attempt to describe the obtained suspended sediment profiles by using the combined diffusion-convection approach, a full solution of equation (1) was used.

In this attempt, a constant in vertical diffusion coefficient and a convective function given by an exponential law was selected (see *e.g.* Nielsen, 1992). Although this solution has not to be the best one, it was selected due to its simplicity, although presently other combined solutions are being analysed.

The integration of equation (1) with the selected description of diffusion-convection process leads to (Nielsen, 1992)

$$C = C_0 \left\{ \frac{1}{1 - \frac{\epsilon}{w_f L}} e^{-z/L} + \left(1 - \frac{1}{1 - \frac{\epsilon}{wL}}\right) e^{-wz/\epsilon} \right\} \quad (5)$$

By using the equation (5), the profiles for the different fractions presented in figure 8 were obtained. The main problem to apply this approach is that both diffusion coefficient as well as convective length scale has to be estimated. In this case, it was firstly selected the value of the diffusion coefficient by using the one corresponding to the finest fraction, and afterwards, the convective length was selected by fitting the predicted distribution to the measured profiles. In all the cases, the fitted values of convective length were in a range of 30%-40% of the obtained using a pure convective model.

Figure 8. Use of the combined diffusion-convection approach (according to equation 5) to describe the vertical distribution of the different sediment fractions across the surf zone.

Conclusions

For the analysed conditions, several conclusions can be obtained.

- ◆ During the measured conditions, the simple *exponential profile* describes well the time-averaged vertical distribution of suspended sediment in the surf zone.
- ◆ The *length* scale, L , of the distribution can be well represented by the local value of H_{rms} inside the surf zone.
- ◆ The eddy viscosity ν_t for horizontal mixing (obtained using a K-model with production of turbulent energy according to Battjes (1975)) shows a *cross-shore distribution similar* to the vertical mixing coefficient obtained from sediment data, ϵ_s . Obtained values of ν_t are two orders of magnitude higher than ϵ_s .

- ◆ For the analysed field data, the mixing coefficient ϵ_s depends on sediment characteristics, i.e. w_f . In the range of $w_f = 0.02-0.06$ m/s, a linear relationship between ϵ_s and w_f was found. Larger the fall velocity is, larger the diffusion will be.
- ◆ Assuming that the vertical distribution can be described by the length scale, L , a linear dependency with w_f was also found.
- ◆ The magnitude of the measured variation of ϵ_s with w_f was one order of magnitude larger than the obtained for L .
- ◆ These last two conclusions lead to argue the validity of the pure diffusion model to be used in the surf zone.

A first attempt to improve the description of the vertical distribution of suspended sediment considering the different grain has been done. To do this, the approach of Nielsen (1991, 1992) was followed by using a combined solution including diffusion and convection. First results are promising although further works have to be done, specially in the description of the “convective” function.

The generalisation of the obtained conclusions should require additional field data under different energetic conditions. This additional “field effort” is being carried out in the framework of an EU funded Research Project.

CHAPTER 318

Sand Suspension Events and Intermittence of Turbulence in the Surf Zone.

R.D. Kos'yan¹, H. Kunz², S.Yu. Kuznetsov³, N.V. Pykhov³, M.V. Krylenko¹

Abstract

The results of the joint field experiment Norderney-94 demonstrates the excellent coincide of fluctuations of suspended sand concentration and kinetic turbulent energy in the nearbottom region of the surf zone. Turbulent fluctuations were separated from the wave induced fluctuations as a part of the motions that are incoherent to the free surface elevation. The time and spatial scales of macroturbulent vortexes had been estimated and discussed.

Introduction

For the prediction of sediment transport in the breaking zone it is necessary to know the distribution of the suspended sediment concentration, of the water velocity and of the cross-correlation between them in the whole frequency spectrum of irregular waves. The analysis of modern approaches to the solutions of this problem published in literature and discussed at the international conferences during the last years (Coastal Dynamics 94, Barcelona/Spain, 1994; 24th Coastal Engineering Conference, Kobe/Japan, 1994; Coastal Dynamics 95, Gdynia/Poland, 1995; MAST 2 - Overall Meeting, Gdynia/Poland, 1995) shows that the most perspective ones are the models based on Boussinesq and Serra equations that afford to adapt these parameters to the time scales of approaching waves and k- ϵ models. But the latter models today allow only to assess mean-time profiles of the suspended sediment concentration in the breaking zone. The possibility to use k- ϵ model for the calculation of the suspended sand fluctuations in time is restricted by the absence of precise descriptions of the physical mechanisms of sediment

suspension above the bottom, it's distribution in the water column within the breaking zone and by the absence of quantitative correlation between the suspended sediment concentration and parameters of the turbulence for field conditions.

From the physical point of view the presence of instantaneous water flows from the bottom with a velocity that exceeds the sand particle settling velocity is a necessary condition for the occurrence of sediment suspension. In the wave breaking zone such water motions are forced, most probably, by macroturbulent vortexes. Two basic mechanisms of such vortexes formation are possible:

1. Vortexes formation near the water surface under the crests of the breaking waves and its penetration to the bottom. Such a mechanism was observed in laboratory experiments with monochromatic waves above a hard and a movable bottom (Nadaoka, Kondoh, 1989; Zhang et al., 1994). By these experiments it was determined that vortexes were formed as well with horizontal axis as with inclined vertical axis depending on the wave parameters, on the type of their breaking and on the bottom slope. When reaching the bottom, such vortexes, like a tornado, can capture sand from the bottom and suspend it in the flow. The dominant action of this turbulence for sediment suspension is verified by Sato et al. (1990) in a wave flume.

2. Vortexes formation in the bottom boundary layer due to the shear instability of water flow above a plane rough bottom. In this case an explosive character of the generation of turbulent energy and formation of coherent vortexes takes place. Those vortexes are forced from the bottom to the water column. The possibility of realization of such a mechanism has been shown in laboratory experiments (Hino et al., 1983), and its responsibility for the sand suspension is indirectly confirmed in the papers of Foster et al. (1994) and of Pykhov et al. (1995).

The reality of the existence of the first mechanism under field conditions is confirmed by some (not numerous for the present) measurements of the macroturbulence in the surf zone (George et al., 1990; Rodriguez et al., 1995). The results of this research only give a possibility to assess a time-mean value of the turbulent energy, the integral length scale, the turbulent viscosity. But they do not afford to trace the temporal variability of these parameters, which is necessary for the analysis of time fluctuations of the suspended sediment concentration. In spite of the fact that the hypothesis about sediment suspension by such vortexes is shared by the majority of investigators, till now there is no confirmation by direct field measurements.

The aim of our paper based on the data of field measurements is to confirm the existence of turbulent mechanisms of sand suspending by the determination of the scales of fluctuations of turbulent kinetic energy and suspended sand concentration and by ascertaining dependencies between these fluctuations.

Experiment

Field experiment was carried out on a beach section of Norderney Island, North Sea in October 1994 (Fig. 1).

A joint German-Russian team of scientists carried out multipurpose survey at an especially equipped testing site, which is located on the north-western side of the island. In this paper the results of measurements in one point (10 centimeters and more above the bottom) are presented and discussed (Fig. 2). The suspended sand concentration, the free surface elevation and the two horizontal components of water velocity were measured synchronously by optical turbidimeter, pressure gauge and two-component electromagnetic current meter at sampling rate of 18.2 Hz over 20 minutes.

The turbidimeter measures the light beam attenuation at a distance of 6 centimeters that then is recalculated into the suspended sand concentration (Kos'yan et al., 1994). Two-component electromagnetic current meter and pressure sensors (Type NSW) had been used for measuring. Their linear calibration characteristics are in the band of frequency from 0 to 20 Hz. The diameter of the measuring head of the currentmeter is 6 centimeters.

The bed consists of sand with a mean diameter of approximately 0.2 mm. The tidal range of about 2.4 m afforded to produce the measurements at a depth range from 0.5 to 2.5 m. The measurements were carried out in the inner and middle parts of the surf zone under the wind wave and swell conditions. The 25 series of

Figure 1. Site of the field experiment.

Figure 2. Bottom profile and point of measurements.

recording were obtained during the whole experiment.

Separation of turbulence

We consider the turbulence as a part of water particle fluctuations, which is incoherent to the elevations of the free surface. Spectral and mutual spectral analysis of fluid velocities and free surface elevations show the turbulent fluctuations of the cross- and the long-shore velocities at the frequencies $f > 0.8$ Hz. This is conformed by the absence of the coherence between cross-shore velocity ($u(t)$) and free surface elevations ($H(t)$) at the frequencies $f > 0.8$ Hz and by the change the velocity spectra ($S_u(f)$) gradient from $\sim f^{-4}$ to $\sim f^{-2}$ at $f = 0.8$ Hz (Fig. 3). Turbulent components of the cross-shore $u_t(t)$ and long-shore $v_t(t)$

Figure 3. Determination of boundary frequency between waves and turbulence. $f_b=0.8$ Hz. Record 5a. $H_S=1.03$ m, $T_P=8.7$ s, $\bar{h}=1.53$ m, Sp.

Figure 4. Example of single suspending event. Record 6a. $H_S=1.07$ m, $T_P=8.7$ s, $\bar{h}=1.53$ m, Sp.

velocities were obtained by digital filtering.

Examples of events

Analyses of the records show a rapid appearance and disappearance of suspended sand events, which are well coincided with the appearance and disappearance of turbulent fluctuations of the cross- and long-shore velocities.

A typical example for a single suspending event is given by Figure 4. Recorded are wind waves with a significant height $H_S=1.07$ m, mean period $T_P=8.7$ s, breaking by spilling at the depth $\bar{h}=2.36$ m. $H(t)$ is the free surface elevation, $u(t)$ and $u'(t)$ are the cross-shore velocity and its turbulent component, $v(t)$ and $v'(t)$

are the long-shore velocity and its turbulent component, $C(t)$ is the suspended sand concentration. The splash of turbulent velocity fluctuations and the splash of concentration between 697 to 700 s may be explained by horizontal advection of turbulent vortexes with trapped sand at the sensor array.

Figure 5 shows the two consecutive events of sand suspending for a more intensive wave regime ($H_s=0.90$ m, $T_p=8.7$ s, $\bar{h}=1.62$ m, breaking type is between spilling and plunging). The change of the amplitude of the turbulent fluctuation coincides well in time with the splash of concentration.

Figure 6 demonstrates the intermittence of turbulence and the corresponded events of sand

Figure 6. 8-minute fragment of suspending events. Record 7f. $H_s=0.90$ m, $T_p=8.7$ s, $\bar{h}=1.62$ m. Sp-Pl.

Figure 5. Example of two consecutive events of sand suspending. Record 7f. $H_s=0.90$ m, $T_p=8.7$ s, $\bar{h}=1.62$ m. Sp-Pl.

suspending events during the 500 s for the same record as shown on Figure 5. The fluctuation of turbulent kinetic energy ($E(t)$) coincides well with the fluctuation of suspended sand concentration. Turbulent kinetic energy was calculated as the sum of the squared turbulent velocity components: $E(t) = u'^2(t) + v'^2(t)$

Time scales of the turbulence

The upper parts of Figure 7 show the typical spectra describing the concentration fluctuations $S_C(f)$ and the kinetic turbulent energy variations $S_E(f)$ as function of frequency. Both spectra coincide with increasing frequency. The concentration spectrum has a feebly marked peak at the main wave frequency. Turbulent energy

spectrum is decreasing monotonously with increasing frequency except the peak at the frequency of 1.6 Hz, which is called forth by the method of the turbulence selection, i.e. by the filtering with a boundary frequency of 0.8 Hz, and therefore it has no physical sense (when squaring $(E(t) = u'^2(t) + v'^2(t))$ the frequencies are doubled).

The lower left part of Figure 7 displays the squared coherence function $G_{CE}(f)$. Significant values of the coherence G_{CE} at the frequencies $f < 0.05$ Hz afford to say, that the low frequency suspended sand fluctuations are determined by the bursts of the turbulent velocity fluctuations.

The lower right part of Figure 7 shows for low-frequencies ($f < 0.05$ Hz) the relation between the related components of concentration (C_{low}) and of kinetic turbulent energy (E_{low}). It demonstrates that the deviations from the linear connection are not caused by the nonlinearity, but by random reasons.

Let us consider the regularities of turbulent fluctuations within one suspension event.

Figure 8 presents the chronograms of turbulent components of velocities and their hodograf for a single suspending event, which was demonstrated at Fig. 4. The hodograf shows, how that the end of the vector of turbulent velocity component runs two full circles during one second. This may correspond to the passing of a series of four vortexes, as principally shown in the lower right part of Figure 8. Neighboring vortexes must rotate in opposite directions.

Figure 7. Connection between suspended sand concentration and turbulent energy. Record 5a. $H_S=1.07$ m, $T_p=8.7$ s, $\bar{h}=2.33$ m. Sp.

An assumption about the passing of a series of several consecutive vortices is confirmed by results of laboratory investigations presented at the conference Coastal Dynamics'94 by Zang et al. who presented the nomogram of the type and number of turbulent vortices that are formed in the moments of wave breaking depending on Reynolds number and breaker-type index given by Galvin. The nomogram shows that all our recorded wave regimes occurred in the region of formation of triple oblique vortices.

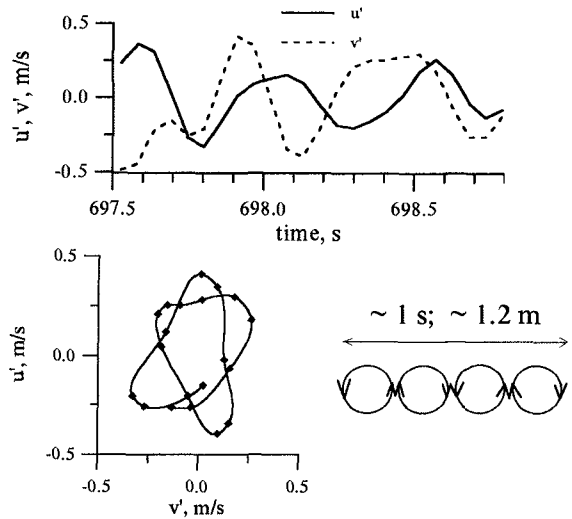

Figure 8. Time scales of turbulent vortices.

Spatial scales of turbulence

To assess spatial scales of turbulence the chronograms of the turbulent velocity fluctuations were recalculated into series of fluctuations along trajectories of the vortex movement according to Taylor's hypothesis "about frozen turbulence". Wave components ($f < 0.8$ Hz) were used as carrier velocities. The obtained series of spatial distribution of turbulent velocity fluctuations are presented as stick diagrams, an example is presented on Figure 9. The zero point of the spatial coordinate has been fixed arbitrarily.

The obtained stick diagrams show that turbulent vortices are grouped in large structures. The passing of these vortex-structures across the point of

Figure 9. Example of stick-diagram. Record 5a.

measurements coincides with the sand suspending events. The spatial boundaries of such structures were determined visually by using the velocity value of 0.1 m/s as a boundary between the vortex structure and the background turbulence. The length of such structures was varied from 1 to 10 m. Linear scales of vortices in the recorded structures varied from 0.3 to 1.5 m and there were the vortices of different size in one structure. There were also the structures of different size in one series of measurements. Since we had only one velocity gauge in operation, we could not determine whether the central or the outline part of turbulent vortex had been recorded. It was a reason of definite incoherence between wave flow dimensions and vortex size. But if we will consider only the largest vortices in the structures, such correlation becomes obvious.

The dependency between the largest vortex size in a series and a water depth is presented in Figure 10. It demonstrates how the diameter of vortex increases with depth. This dependency confirms the classic idea about a proportionality between sizes of vortices and flow.

To improve the accuracy of the assessment for the turbulent vortex size the next series of experiments will operate several gauges simultaneously, which were be placed at a distance about one meter.

Figure 10. Spatial scales of vortices.

Conclusions

Our results demonstrate that suspension events in the middle and inner parts of a surf zone are determined by macro-turbulent vortices and that the intermittence of turbulence determines the low-frequency fluctuations of suspended sand concentration. In our future investigations we will investigate the connections between intermittence of turbulence and wave parameters and the correlation between parameters of turbulence and the suspended sand concentration.

CHAPTER 319

MECHANISMS OF BEACH GROUND WATER AND SWASH INTERACTION

Andrew J. Baird¹, Travis E. Mason², and Diane P. Horn³

ABSTRACT

Previous studies of swash-ground water interactions have given prominence to infiltration of swash and backwash into unsaturated sand as the principal mechanism explaining sedimentation patterns in the inter-tidal zone. Here we consider the role of fluidisation in explaining such sedimentation patterns. It appears that fluidisation due to general ground water outflow from a beach is insufficient to induce fluidisation of surface sand. We propose a different mechanism for explaining fluidisation whereby very small amounts of swash infiltration into the seepage face cause rapid increases in pore water pressure below the beach surface. During the backwash, pressure unloading on the surface causes rapid ground water outflow from the surface sediment. The rate of this outflow is shown, using a simple model, to be sufficient to induce fluidisation. We also consider a model of general beach ground water behaviour and conclude that it can be satisfactorily used to provide boundary conditions for smaller scale models of fluidisation under swash.

1) INTRODUCTION

Grant (1946, 1948) was among the first to suggest a link between beach ground water behaviour and swash zone sediment transport. He proposed that a “dry” beach (one with a low water table, which he equated with unsaturated conditions below the beach surface) allows swash to infiltrate. The reduction in swash depth due to infiltration reduces swash velocity allowing sediment deposition. Therefore, a dry beach promotes accretion. Conversely, on a “wet” beach (one in which the water table is at or near the beach surface) the swash and backwash retain their depth because infiltration is limited. Backwash flows may be augmented by ground water outflow from the beach. Grant (1948) further suggested that the seepage force due to ground water outflow may

¹ Lecturer, Dept. of Geography, University of Sheffield, Sheffield S10 2TN, UK.

³ Lecturer, Dept. of Geography, Birkbeck College, University of London, London W1P 2LL, UK.

cause fluidisation of the sediment at the beach surface and enhance entrainment and sediment transport by backwash.

Infiltration

The logic of Grant's conceptual model has led many researchers to concentrate on the effects of infiltration losses on beach accretion and erosion (e.g. Emery and Foster, 1948; Emery and Gale, 1951; Isaacs and Bascom, 1949; Longuet-Higgins and Parkin, 1962; Duncan, 1964; Strahler, 1966; Harrison 1969,1972; Waddell, 1976; Chappell et al., 1979; Heathershaw, et al. 1981; Lanyon et al., 1982; Carter and Orford, 1993; and Turner 1993). Most of these authors have suggested that infiltration losses during swash provide the main mechanism by which beach accretion occurs above the still water level. However, despite the early suggestion of the importance of infiltration in the swash zone, few attempts have been made to model swash and backwash infiltration. Packwood (1983) developed a numerical model predicting runup due to a single bore incident on an initially dry beach. His justification for the development of this model was based on the assumption that infiltration is the mechanism that controls sediment transport on the beach face. Packwood (1983) argued that, as an incoming tide rises above the water table, the runup advances over dry sand and a proportion of the water mass is lost into the beach. Packwood's results showed that for fine sand (with a porosity, n , of 0.3, and a hydraulic conductivity, K , of 0.01 cm s^{-1}), very little water percolates into the beach. Packwood (1983) found that runup on fine sand and on an impermeable roughened slope are almost the same. In contrast, for medium sand ($n = 0.3$, $K = 0.1 \text{ cm s}^{-1}$), although the maximum runup is reduced very little, the backwash is significantly reduced in depth. This thin backwash layer drains rapidly into the sand, which will have a significant effect on the bed shear stress and the ability of the flow to transport sediment. Packwood (1983) concluded that the effect of a porous bed is seen much more in the backwash than in the swash. However, he did not consider the effect of a water table nearer to the beach surface on the infiltration process.

Fluidisation

In his 1948 paper Grant appears to suggest that the mechanism for fluidisation of sand grains on the beach surface is due to general ground water outflow from the beach associated with a high water table. A number of researchers have considered this effect but none have found convincing evidence of its importance in sand transport. For example, Oh and Dean (1994) used laboratory experiments and numerical modelling to investigate the influence of the beach water table on profile change and concluded that the effect of the upward flow on sediment transport appeared to be small compared with the effects of a steep slope. It seems likely that ground water outflow from a beach in response to a falling tide alone is insufficient to induce fluidisation, since hydraulic gradients under the beach surface will tend to be relatively small. It is proposed here that fluidisation is only generally possible in the presence of swash and that it occurs over relatively short timescales. As a swash flow advances over the saturated beach surface, there will be a relatively rapid increase in pore water pressures

below the beach surface. When under swash flow, the beach sediment behaves like a confined aquifer. The sediment is saturated and movement of water into the beach is extremely limited, since changes in porosity due to expansion and contraction of the mineral 'skeleton' will be minimal. However, because of this limited potential for infiltration, water pressures will propagate rapidly through the sediment. The characteristic time of propagation of any diffusion process is given by

$$t = \frac{x^2}{D} \quad (1)$$

where x is distance (L) and D is the diffusivity ($L^2 T^{-1}$), given by the ratio of hydraulic conductivity, K (LT^{-1}), to specific storage, s (L^{-1}). In a sand in the unconfined case, the specific storage multiplied by depth is called the specific yield and typically has values of between 0.1 and 0.3 per unit depth. In the confined case, which is effectively the case for sand under a swash lens, the specific storage is much lower and a value of the order of 0.002 is more realistic. The hydraulic conductivity of beach sands can be expected to be in the range 0.01 to 0.5 $cm s^{-1}$ (Packwood and Peregrine, 1980). For all of the values in this range, the small value of specific storage will give relatively large values of D and small times of propagation, so that the pressure acting on the sand surface under advancing swash will propagate at least into the surface layers of the beach sediment. As the swash retreats there will be a release of pressure on the beach, giving large hydraulic gradients acting vertically upwards immediately below the surface. The resultant seepage force associated with rapid ground water outflow could be sufficient to induce fluidisation of the sand grains at the beach surface. This may occur during the latter stages of backwash and will provide readily entrainable material that can be carried seaward by the backwash flow. To our knowledge this mechanism has not been previously identified and no attempt has been made at modelling it. Later in this paper, we consider in detail how the propagation of pressure through the beach sediment can be modelled. However, whether infiltration into unsaturated or saturated sand is being considered, a first stage in any modelling exercise is the accurate prediction of the position of the seepage face together with predictions of more general ground water flows and pore water pressures within the beach, since these will act as boundary and initial conditions for infiltration and pressure propagation models. Below we consider how the general ground water behaviour of a beach can be modelled.

2) MODELLING BEACH GROUND WATER BEHAVIOUR

Theory

Recently, we have developed a model capable of predicting water table elevations in, and the extent of the seepage face on, sandy beaches. The model, called **GRIST** (**G**round water **I**nteraction with **S**wash and **T**ides), has been developed as a modular package and is described in Baird and Horn (1996) and Baird et al. (in review). Two approaches, both based on Darcy's Law and the continuity equation, have been used for modelling water table behaviour in response to tidal forcing in sandy beaches in the

GRIST package. The first approach uses the one-dimensional form of the Boussinesq equation given by

$$\frac{\partial h}{\partial t} = \frac{K}{s} \frac{\partial}{\partial x} \left(h \frac{\partial h}{\partial x} \right) \quad (2)$$

where h is the elevation of the water table (L), t is time (T), K is the hydraulic conductivity of the beach sediment (LT^{-1}), s is the specific yield or drainable porosity (dimensionless), and x is horizontal distance (L). The main assumption in using this equation is that ground water flow in a shallow aquifer can be described using the Dupuit-Forchheimer (D-F) approximation. D-F theory states that in a system of shallow gravity flow to a shallow sink when the flow is approximately horizontal, the lines of equal hydraulic head or potential are vertical, and the gradient of hydraulic head is given by the slope of the water table. Using D-F theory, two-dimensional flow to a sink can be approximated as one-dimensional flow, and the resulting differential equation (equation (2)) is more readily solved. In beaches which are underlain by relatively impermeable solid rock or clay deposits it is likely that D-F theory will provide adequate descriptions of ground water flow. The second approach used in the **GRIST** model considers the beach as a two-dimensional flow system in which the water table is a free surface or flow line. The advantage of the second approach is that it can be used to predict radial flow towards the seepage face if such an approach is necessary; for example, in cases where the flow field in the beach suddenly narrows forcing water to the surface.

Both equations have been solved in the **GRIST** package using standard finite-difference methods and are described in detail in Baird et al. (in review). In the 1D model, a block-centred finite-difference scheme is used and tide-water table decoupling is assumed to occur if

$$h_{i,t} + \left(\frac{(Q_i - Q_{i+1})\Delta t}{s_i} \right) > e_i \quad (3)$$

where Q_i is the rate of ground water discharge ($L^3 T^{-1}$) (in a seaward direction) into cell i during Δt (from cell $i-1$), Q_{i+1} is the rate of discharge out of cell i during Δt , and e is the cell height (L). Further details of the model can be found in Baird and Horn (1996).

Field testing of the 1D model

The predictions of the 1D version of the model have been tested against field measurements which are described in detail in Baird et al. (in review). The field measurements were made on a microtidal beach at Canford Cliffs, Poole, Dorset, England. Canford Cliffs beach is a groyned beach and is backed by a sea wall. It has a mean slope of 3.2° ($\tan \beta = 0.056$) on the upper foreshore and a mean slope of 1.5° ($\tan \beta = 0.026$) on the lower foreshore. The tidal range at Canford Cliffs varies between 0.2 and 1.8 m on neap and spring tides respectively. The field measurements which are reported here were taken between the 21st and 28th October 1995 in a period leading from a neap to a spring tide, with a tidal range varying from 0.9 to 1.7

m. The significant wave height (H_s) varied from 0.35 to 0.76 m, while H_{rms} (root mean square wave height) varied between 0.25 and 0.53 m. Zero-crossing period varied between 5.2 and 6 s, and the peak spectral period varied between 5.6 and 9.8 s.

Water table elevations were measured with pressure transducers in ten screened wells placed at distances of 1.9, 3.8, 5.8, 7.8, 9.3, 10.8, 13.1, 15.6, 18.7, and 21.7 m seawards from the sea wall. Wave and tidal frequencies and amplitudes were measured with a seabed-mounted pressure transducer located at the low water mark. All instruments were logged using a PC at the top of the beach and were calibrated before and after the deployment. Beach profiles and instrument locations were measured using a total station. Sediment samples were collected at 0.5 m intervals along a cross-shore transect from the surface of the beach and at a depth of 20 cm for estimation of particle size parameters. Twelve sediment cores were also collected along the cross-shore transect for laboratory determinations of K using a constant head permeameter.

Results

The mean grain diameter of the surface sediments was approximately 0.24 mm (2.06 ϕ), the mean sorting was 0.44 ϕ and the mean skewness was -0.71. Results from 20 cm depth were very similar with a mean grain diameter of 0.22 mm (2.17 ϕ), a mean sorting of 0.36 ϕ and a mean skewness of -0.64. The mean K of the sediment cores was 0.225 cm s⁻¹, with a range from 0.036 to 1.179 cm s⁻¹, and a coefficient of variation of 143 per cent which is typical for this parameter.

The 1D model was run for Canford Cliffs using 40 computational cells with a width of 1 m. Measured values of tidal elevation were used in the simulation. The inland boundary was a no-flow condition at the sea wall. The bottom boundary was a no-flow condition given by the position of an impermeable barrier located 50 cm below Ordnance Datum. The seaward cell was assumed to be permanently saturated; that is, the water table was assumed to be always at the cell surface. A value of K/s of 0.75 cm s⁻¹ was used in the model simulation. This value was calculated using the arithmetic mean of the permeameter measurements of K (0.225 cm s⁻¹) and an assumed value of s of 0.3.

The predictions of the 1D model are shown for each of the wells in Baird et al (in review). Here we show only two examples of the model's predictions, for wells 6 and 10 (9.3 and 1.9 m seaward of the seawall, respectively). In both cases the remarkably good agreement between modelled and observed water table elevations can be seen. The agreement was similarly good for all ten wells. Thus the model was able to predict with some accuracy water table rise and fall at different positions in the beach, giving a good representation of changes in the shore-normal water table profile over time. For most of the wells the model very accurately describes the lag and asymmetry of water table response. The predictions of lag and asymmetry are less good for wells 8 to 10, with the model predicting a later and steeper rise than was observed. The earlier rise of the observed water table may be due to setup and runup above the shoreline causing a greater flow of water into the beach than would occur due to tidal rise alone (see below). This point is discussed in more detail in Baird et al. (in review). It is also possible that the K of the sediment at the back of the beach was lower than that more seaward, giving greater lags than predicted by the model which uses a single value of

K. However, such a pattern of variation in *K* was not evident from the hydraulic conductivity data although it is recognised that surface sand samples may not be representative of sand at depth.

Figure 1. Measured and modelled water table elevations at well 6 (9.3 m seaward of sea wall). Open squares - observed; medium solid line - simulated; thick solid line - observed tide. Elevations given above a datum which represents the position of the impermeable barrier below the beach surface. Time is from 20.00 GMT on 22nd October 1995.

Figure 2. Measured and modelled water table elevations at well 10 (1.9 m seaward of sea wall). Open squares - observed; medium solid line - simulated; thick solid line - observed tide. Elevations given above a datum which represents the position of the impermeable barrier below the beach surface. Time is from 20.00 GMT on 22nd October 1995.

The agreement between observed and simulated water tables is better before high water at 40000 s than after. This is probably due to the fact that wave heights and swash excursions were greater after this time. The wave record shows that through the period of measurement H_s increased from 0.35 to 0.76 m. Setup and swash excursion

can be expected to give higher water tables than would be expected due to the tide alone and this is indeed the case with the observed water tables, with levels in well 6 in particular rising above high tide levels (Figure 1). A water table elevation above the high tide elevation is only possible if an additional source of water, such as rainfall, is entering the beach, or if setup and runup raise the mean water surface causing greater rates of flow into the beach. Greater setup due to the larger wave heights at high tide will increase the elevation of the shoreline. This, in turn, will give rise to greater amounts of seepage into the beach than would occur if the free surface on the beach face were at the tide level. Runup will increase water table levels via vertical infiltration and downward movement of water through the unsaturated zone. No rainfall was recorded during the measurement period reported here, so the source of additional water is most likely to be setup and runup. It is also possible that the increased departure between modelled and observed is due to accumulated error in model predictions since a small error in water table predictions will feed into later predictions. However, error propagation will tend to be cumulative whereas the figures clearly show that the discrepancy between observed and predicted occurs more as a step change during the second high water. Thus setup and runup are the more likely explanation for most of the discrepancy between observed and predicted.

The model based on equation (2) provides a good description of water table dynamics in response to tidal forcing although an allowance should be made in future versions of the model for the effects of setup. We suggest, therefore, that the model can be used to provide satisfactory boundary conditions for swash infiltration and pressure propagation models.

3) THE POSITION OF THE WATER TABLE RELATIVE TO THE BEACH SURFACE

Figure 3 shows the measured position of the water table relative to the sand surface for two positions of the tide, low water at 22800 s and high water at 40000 s. At low water the water table intersected the beach face at a distance of about 32 m from the sea wall (the tide was below the level of the beach shown on the diagram) and tended to approach the beach face at a tangent as suggested by Bear (1972). The water table in wells 1 and 2 fell little during the period between low water and subsequent immersion by the rising tide. Thus during the advance of the tide over the seepage face and later across the zone between 18 and 32 m from the sea wall, where the water table remained close to the beach surface, there would have been little opportunity for significant swash infiltration. Any infiltration that did occur is unlikely to have had an effect on swash and backwash dynamics during these conditions because the beach would have behaved like the impermeable case analysed by Packwood (1983). The water table at high water shows a pronounced landward slope and a superelevation of the water table in wells 6 and 7. This superelevation can be attributed to setup and runup as discussed above, and indicates that infiltration into this part of the beach may have the potential to affect swash and backwash hydraulics in the way described by Packwood (1983) for a permeable beach.

It would appear from the above reasoning that swash and backwash infiltration are only likely to be important in affecting swash/backwash hydraulics on a beach such as

Canford Cliffs during the latter part of the rising tide when some swash and backwash move over an unsaturated beach. However, it is important to stress that even small amounts of swash infiltration into the seepage face followed by rapid ground water outflow could induce fluidisation on middle and lower parts of the beach, and that the interaction between beach ground water behaviour and sediment dynamics may be more subtle than suggested by existing swash/backwash infiltration models such as that of Packwood (1983).

Figure 3. Measured water table elevations along the shore-normal profile at low water after an elapsed time of 22800 s (closed squares), and high water at 40000 s (closed circles).

4) MODELLING FLUIDISATION UNDER SWASH

It was noted earlier that when a swash runs over a saturated beach there will be a relatively rapid increase in pore pressure below the beach surface, and that the pressure release associated with backwash could induce fluidisation of the beach surface. The equation governing water movement through an isotropic and homogeneous saturated beach sediment is

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{\partial^2 h}{\partial z^2} = \frac{s}{K} \frac{\partial h}{\partial t} \quad (4)$$

where here h is now the hydraulic head (L), and s is the specific storage (L^{-1}). For most purposes this equation can be simplified to its two-dimensional form.

Figure 4. Finite difference grid for the simulation of pressure propagation into a sand bed under swash. ① and ③ are boundaries where the head is given. ② is a no-flow boundary.

The requirements of a two-dimensional model of ground water flow, and therefore pressure propagation, through beach sediment under advancing swash and retreating backwash are shown in Figure 4. The diagram shows a finite-difference, mesh-centred grid representing the body of sand beneath and landward of swash. For the upper boundary condition the model requires a time series of swash depths for that part of the beach face which becomes inundated. It is assumed that the pressure acting on the beach surface at the base of the swash is equivalent to the swash depth; that is, the pressure is hydrostatic. It is this hydrostatic pressure that provides an upper boundary condition to the model. The lower part of the model is assumed to be a no-flow boundary (von Neuman condition) which can be simulated using a set of fictitious nodes shown by open circles. The boundary condition $\partial h/\partial z = 0$ translates in finite-difference form to $h_{i, j-1} = h_{i, j+1}$ assuming an indexing notation whereby j represents row number (z axis - positive upwards) and i column number (x axis - positive to the right of the diagram). The impermeable barrier is given by j so that $j-1$ represents the fictitious nodes. The inland boundary condition is a prescribed head condition (Dirichlet condition) which can be provided either from field measurements or, as noted above, from a larger scale beach ground water model such as **GRIST**. In Figure 4 it is shown as the column of nodes below the exit point. The position of the exit point can also be provided from measurements or modelling. The seaward boundary condition is given by prescribed heads at the nodes. This distribution of heads can be assumed to be hydrostatic and equal to wave height at this point. The initial condition for the internal nodes can be estimated from field measurements or can be assumed to be a hydrostatic distribution of hydraulic heads.

Figure 4 represents an ideal solution to the problem of fluidisation under swash and backwash. In the absence of detailed information on the two-dimensional structure of swash, which we are currently measuring using capacitance probes and video techniques, we consider below the effect of water loading and unloading on a one-dimensional column of saturated sand. A simple explicit finite-difference method was used to solve the one-dimensional form of equation (4). The solution is given by

$$\frac{h_{j+1}^n - 2h_j^n + h_{j-1}^n}{(\Delta z)^2} = \frac{s}{K} \left(\frac{h_j^{n+1} - h_j^n}{\Delta t} \right) \tag{5}$$

where the superscript n refers to time.

Five cases of inundation were considered in the model simulations. In all model runs the initial distribution of hydraulic heads below the surface was assumed to be hydrostatic. Nodes were spaced 2 cm apart and the total column length was 60 cm. The base of the column was a no-flow boundary. The cases were:

Case 1. Step increase in pressure on the upper boundary equivalent to a water depth of 10 cm followed by a step return to a condition of no excess pressure on the surface. The pressure loading lasts for 3 seconds and the simulation lasts for 6 s. $K = 0.1 \text{ cm s}^{-1}$; $s = 0.002 \text{ cm}^{-1}$.

Case 2. As for Case 1 except that $s = 0.004 \text{ cm}^{-1}$.

Case 3. Step increase in pressure on the upper boundary equivalent to a water depth of 5 cm followed by a step return to a condition of no excess pressure. The pressure loading lasts for 3 seconds and the simulation lasts for 6 s. $K = 0.025 \text{ cm s}^{-1}$; $s = 0.002 \text{ cm}^{-1}$.

Case 4. For a more realistic loading and unloading of water on the upper boundary we used Hughes' (1992) measurements of swash on beaches in Sydney, Australia (case 'a' from Figure 7a of Hughes, 1992). The actual swash depths were approximated using a ramp addition lasting for 2 s and a ramp loss of water lasting for 6.5 s, with a maximum water depth of 20 cm and a total period of inundation of 8.5 s. $K = 0.05 \text{ cm s}^{-1}$, $s = 0.002 \text{ cm}^{-1}$.

Case 5. As for Case 4 but with $K=0.02 \text{ cm s}^{-1}$.

Figure 5. Variations in v/K over time for Case 1 (see text for details).

Figure 6. Variations in v/K over time for Case 2 (see text for details).

Figure 7. Variations in v/K over time for Case 3 (see text for details).

Figure 8. Variations in v/K over time for Case 4 (see text for details). Note the change in axes scales.

Figure 9. Variations in v/K over time for Case 5 (see text for details).

Cases 1 to 5 are illustrated in Figures 5 to 9, respectively. In each figure, v/K is plotted against time, where v is the specific discharge (cm s^{-1}) through the sand. v/K is equivalent to the hydraulic gradient. Two time series are shown. That with the open squares represents the hydraulic gradient acting between the node 2 cm below the surface and the node representing the beach surface. The closed circles represent the hydraulic gradient between the nodes 4 and 2 cm below the surface. A positive gradient indicates flow downwards into the sand, a negative gradient upward flow. The values of K and s used in Cases 1 to 5 are all within the range of what might be expected for fine to medium sand (see Packwood and Peregrine 1980).

Packwood and Peregrine (1980) noted that for most sands and fine gravels, fluidisation occurs when $v/K < -0.7$ (using the sign convention above). (See also Bear, 1972, pp. 184-189). Fluidisation occurs when the effective stress becomes zero. It should also be noted that downward seepage has the effect of increasing the effective stress and increasing the stability of the sediment. Cases 1 to 3 show that there is an initially large hydraulic gradient associated with the addition of water to the sand surface which declines in an approximately exponential fashion with time. After the removal of the ponded water there is a sudden reversal in the direction of the hydraulic gradient. In all three cases fluidisation can be expected to occur since v/K is less than -0.7 . The period of potential fluidisation lasts for approximately 0.4 to 0.6 s. It is interesting to note that large values of v/K are only present in the uppermost layer of sand.

Under real swash, step loading and unloading is unlikely to occur, with the addition and removal of water being more gradual. As noted above, we used the measurements made by Hughes (1992) as a first approximation to loading and unloading under real swash. In Case 4 fluidisation is not predicted by the model. However, a reduction in the ratio of K/s , as shown in Figure 9 (Case 5), does give predicted fluidisation for approximately the last second of the backwash. Much more information is needed on swash and backwash velocities and shear stresses on the bed to understand the implications of this for sediment movement in the swash zone. However, the simple model is revealing in that it suggests that fluidisation of the bed occurs before the beach surface is exposed so that the entrainment and seaward transport of sediment in the

latter stages of backwash is enhanced. This is consistent with qualitative observations of backwash by Hughes (1992) who, with other workers, notes that as the swash lens thins during backwash it develops into a slurry of fluid and sediment. The one-dimensional model is obviously an over-simplification of pressure propagation through a sand bed under swash, as is the assumption of a single swash passing over the bed in which the initial condition is a hydrostatic distribution of hydraulic head. However, the model does suggest a mechanism for fluidisation in the swash zone apparently not previously considered by other workers, and one that may exert a greater control on sediment movement in the swash zone than infiltration of swash into the unsaturated part of the beach. It is important to stress that, although the mechanism described here involves infiltration into the sand bed, the amount of water lost from swash and backwash is negligible since the specific storage of saturated sand is so low. Thus it appears that infiltration *sensu* Grant (that is, infiltration into unsaturated sand above the water table) is not needed for ground water to have a significant impact on swash sediment dynamics. The mechanism of fluidisation given here is certainly worthy of further investigation, and to elucidate the processes involved we are engaged in measurements of swash/backwash flows and pressure propagation in both the laboratory and the field site at Canford Cliffs. Results from these studies will be reported in due course.

ACKNOWLEDGEMENTS

Most of the funding for this research came from the United Kingdom Natural Environment Research Council (Grant number GR9/01726). The remainder of the funding was from grants from Birkbeck College, University of London, and the University of Sheffield awarded to Horn and Baird respectively. We would like to thank Mike Wilkin, Paul Bentley, Peter Riley, John Cross, Steve Pearce, Matthew Foote, Simon Gaffney, Richard Kelly, Mark Lee, Chris Turner, Jill Ulmanis, and Steve Wallbridge for their help and advice. Finally, we would like to thank Poole Borough Council who kindly allowed us to use the Surf Lifesaving Club building at Canford Cliffs for housing logging equipment.

CHAPTER 320

The equations for integral and mean flow properties in the swash zone

M. Brocchini [†] and D.H. Peregrine [‡]

Abstract

The swash zone is the area of a beach where the waves move the instantaneous shoreline back and forth. This zone is modelled using the nonlinear shallow-water equations (NLSWE) as equations of motion, as is appropriate for gently sloping beaches. Integrated swash zone boundary conditions are derived for wave resolving models: their use gives considerable numerical advantages. Wave-averaged and swash-zone integrated boundary conditions have also been derived. They include numerous terms for which closures are to be found.

Equations and an analytic swash zone solution

In this section we introduce the basic equations used to describe the flow dynamics near the shore. We choose the still water level to be $z = 0$, and define

$$d(x, t) = h(x) + \eta(x, t) \quad (1)$$

where d is the total water depth, $z = -h(x)$ is the seabed, $z = \eta$ is the position of the free surface (see figure 1).

For a plane beach with $h(x) = \alpha x$ the inviscid equations are

$$\begin{aligned} d_{t^*}^* + (d^* u^*)_{x^*} + (d^* v^*)_{y^*} &= 0 \\ u_{t^*}^* + u^* u_{x^*}^* + v^* u_{y^*}^* + g d_{x^*}^* &= -g\alpha \\ v_{t^*}^* + u^* v_{x^*}^* + v^* v_{y^*}^* + g d_{y^*}^* &= 0. \end{aligned} \quad (2)$$

They can be put in a simple dimensionless form with no explicit dependence on the beach slope α (Meyer & Taylor 1972).

The dimensionless variables which eliminate the beach slope α from the equations are:

$$d = \frac{d^*}{\alpha l_0}, \quad u = \frac{u^*}{u_0}, \quad v = \frac{v^*}{u_0}, \quad u_0 = (g l_0 \alpha)^{1/2} \quad (3)$$

$$x = \frac{x^*}{l_0}, \quad y = \frac{y^*}{l_0}, \quad t = \frac{t^*}{t_0}, \quad t_0 = \left(\frac{l_0}{g\alpha} \right)^{1/2} \quad (4)$$

[‡]Professor of Applied Mathematics, School of Mathematics, University of Bristol, (*D.H.Peregrine@bristol.ac.uk*)

Figure 1: Flow definition in the vicinity of the swash zone.

where l_0 is a reference length which can be specified according to the particular problem under investigation. The equations become:

$$\begin{aligned} d_t + (du)_x + (dv)_y &= 0 \\ u_t + uu_x + vv_y + d_x &= -1 \\ v_t + uv_x + vv_y + d_y &= 0. \end{aligned} \quad (5)$$

For simplicity, friction terms are not included in this analysis and in most of the numerical modelling. Even at laboratory scale they are of secondary importance if beach slope is not too small. Watson et al. (1994) give a quantitative estimate of their importance. On the other hand, the energy dissipation of bores is included in the modelling as discontinuities in the solution.

Equations (5) can be further simplified by approximating for regular waves incident at small angle θ to the beach normal (Ryrie, 1983). We introduce a pseudotime t' and a small parameter ϵ such that:

$$t' = t - \epsilon y \quad (6)$$

gives the only y dependence. It implies that the wave pattern is moving along the shore with phase velocity of $1/\epsilon$. For example, this can occur for a regular train of waves incident towards the shore at a small angle θ to the shore normal, with an alongshore velocity $c/\sin\theta$.

For a weakly three-dimensional flow the following scaling:

$$y' = \epsilon y, \quad v' = v/\epsilon, \quad (7)$$

on substitution into the NLSWE (5), neglecting $\mathcal{O}(\epsilon^2)$ terms and dropping primes, gives the equations:

$$\begin{aligned} d_t + (du)_x &= 0 \\ u_t + uu_x + d_x &= -1 \\ v_t + uv_x - d_t &= 0. \end{aligned} \quad (8)$$

The last of the above set of hyperbolic equations is now decoupled from the first two. The v component of the velocity does not appear in the first two equations of (8) ('onshore problem') and a solution for the third equation ('longshore problem') is found once d and u are known. Characteristic directions in the (x, t) plane for the system (8) are given for the onshore and longshore problem respectively by:

$$\frac{dx}{dt} = u \pm c \quad \text{and} \quad \frac{dx}{dt} = u. \quad (9)$$

Equations (8) can be expressed in characteristic form:

$$\alpha_t + (u + c)\alpha_x = 0, \quad \beta_t + (u - c)\beta_x = 0, \quad \gamma_t + u\gamma_x = 0 \quad (10)$$

where the Riemann invariants are defined as follows:

$$\alpha = 2c + u + t, \quad \beta = 2c - u - t, \quad \gamma = v - \frac{1}{2}u^2 - d - x. \quad (11)$$

Carrier & Greenspan (1958) used a hodograph transformation (velocities are used as coordinates) in solving the onshore problem:

$$\lambda = \alpha - \beta = 2(u + t), \quad \sigma = \alpha + \beta = 4c, \quad u(\sigma, \lambda) = \phi_\sigma / \sigma. \quad (12)$$

The characteristic coordinates (σ, λ) are particularly effective for the moving shoreline since the $\sigma = 0$ contour maps the moving shoreline: $d = c = 0$. We note that σ is a space-like coordinate and λ is a time-like coordinate (e.g. see figure 2(d)). Combining the equations for the onshore problem gives a linear equation in ϕ :

$$(\sigma\phi_\sigma)_\sigma - \sigma\phi_{\lambda\lambda} = 0. \quad (13)$$

The simplest periodic solution is that of Carrier and Greenspan (1958):

$$\eta(\sigma, \lambda) = \frac{1}{4}\phi_\lambda - \frac{1}{2}u^2, \quad x(\sigma, \lambda) = \frac{1}{4}\phi_\lambda - \frac{1}{16}\sigma^2 - \frac{1}{2}u^2, \quad t(\sigma, \lambda) = \frac{1}{2}\lambda - u \quad (14)$$

where

$$\phi(\sigma, \lambda) = AJ_0(\sigma) \sin(\lambda), \quad (15)$$

J_0 is the Bessel function of the first kind. Not all the solutions can be transferred back to the (x, t) plane. This occurs for $A > 1$, i.e. when the Jacobian of the transformation vanishes.

Since the equation for the longshore problem is decoupled we can formally integrate this equation (10c):

$$\gamma_t + u\gamma_x = v_\lambda x_\sigma - v_\sigma x_\lambda + u(v_\sigma t_\lambda - v_\lambda t_\sigma) - (\eta_\lambda x_\sigma - \eta_\sigma x_\lambda) = 0. \quad (16)$$

After some algebra the equation can be rearranged to give a solution valid for any ϕ :

$$v = \frac{1}{4}\phi_\lambda + \text{const.} \quad (17)$$

and setting $\text{const.} = 0$ we get

$$v = \frac{1}{4}AJ_0(\sigma) \cos \lambda. \quad (18)$$

Details on some complicated multi-modal solutions are given in Brocchini & Peregrine (1996).

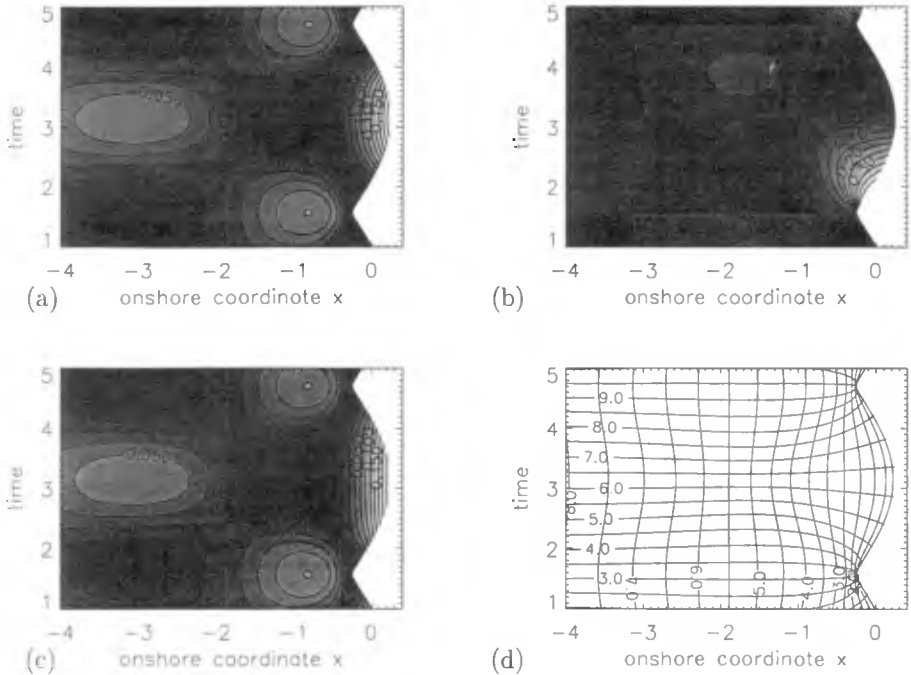

Figure 2: Contour lines for the dimensionless Carrier & Greenspan (1958) solution: (a) the free surface elevation η , (b) the onshore velocity u and (c) the longshore velocity, v , of the weakly three dimensional solution, for the case $A = 1$. Note that the dimensional longshore velocity is a factor ϵ smaller than the dimensionless quantity. (d) shows the (σ, λ) coordinates in the (x, t) plane. Lines of constant λ run from left to right whilst lines of constant σ run from top to bottom.

Contour plots of the free surface elevation and velocity components help visualise the behaviour of the solution, see figure 2. For all the flow properties shown in figure 2 there is a structured pattern of cells. Cells are confined by isolines of zero surface displacement. They also have different sizes and shapes. For all variables the largest values are reached within the most onshore cell. The particular characteristic of the contour structure for u is that it has an antisymmetric cellular pattern within the period. We can therefore state *a priori* that its mean value over a wave period is zero at each $x = const.$ position. This is not true for both the free surface elevation and the longshore velocity. They have similar cell patterns and for both of them, time averaging over a wave period results in a non-zero contribution.

Time averaging of flow properties is rather involved for the Carrier & Greenspan solution because of difficulties in relating (x, t) and (σ, λ) . Let

$$\langle G(x, t) \rangle = \frac{1}{T} \int_T G(x, t) dt = \frac{1}{T} \lim_{t \rightarrow T} H(x, t) \tag{19}$$

be the time average of $G(x, t) = g(\sigma, \lambda)$ where

$$H(x, t) = \int_0^t G(x, s) ds. \quad (20)$$

To evaluate this type of average which is based on time integration on curves of $x = \text{const}$ we solve the following partial differential equation along the curves $x = \text{const}$ in the (σ, λ) plane:

$$\frac{\partial H}{\partial t} = G(x, t) = g(\sigma, \lambda). \quad (21)$$

But for constant x we have

$$\frac{dH}{d\lambda} = \frac{\partial H}{\partial t} \left(\frac{\partial t}{\partial \sigma} \frac{d\sigma}{d\lambda} + \frac{\partial t}{\partial \lambda} \right). \quad (22)$$

Finally a set of two o.d.e.s for $\langle G(x, t) \rangle$ and σ is obtained:

$$\begin{aligned} \frac{d\langle G(x, t) \rangle}{d\lambda} &= \frac{1}{T} \lim_{t \rightarrow T} g(\sigma, \lambda) \left[\frac{\partial t}{\partial \lambda} \left(-\frac{\partial x}{\partial \lambda} / \frac{\partial x}{\partial \sigma} \right) + \frac{\partial t}{\partial \sigma} \right] \\ \frac{d\sigma}{d\lambda} &= -\frac{\partial x}{\partial \lambda} / \frac{\partial x}{\partial \sigma}. \end{aligned} \quad (23)$$

The first equation is the total derivative of $\langle G(x, t) \rangle$ in terms of $G(x, t)$ while the second states that we are integrating along curves where $x = \text{const}$. This method is used to compute the time average of velocities and mass fluxes.

Figure 3: (a) Mean longshore velocity in the swash zone and (b) mean longshore mass flux inside and near to the swash zone for $A = 1$, $A = 0.5$ and $A = 0.1$.

A mean drift is associated with the swash zone width while the average is identically zero outside the swash zone (see figure 3(a)). This closely resembles what happens for the Stokes' drift for 2-D water waves where a mass flux is associated with the motion of the free surface, with zero mass flux below the trough level, and hence is expected. However a more interesting result relates to the mean longshore mass flux (see figure 3(b)). Correlation between solution for the total water depth and the longshore velocity is such that the mean longshore mass flux is non-zero for a wide range of the solution domain.

A more detailed analysis on swash zone mean flow properties is given in Brocchini & Peregrine (1995; 1996).

The model equations for integrated flow properties

In order to average flow properties in the swash zone and to deal with the moving free surface we investigate a model with a boundary chosen at the lower limit of the swash zone.

The swash zone limits are x_l, x_h , the seaward (lower) and shoreward (higher) limits of the swash zone respectively. The seaward boundary may for example be, the lowest limit x_l of the moving shoreline in a group of waves. Integral properties of the water shoreward of that point are considered.

We integrate the basic flow equations across the swash zone. In the following we adopt Einstein's summation convention and use Greek suffices for the two dimensional horizontal flow properties. The general set of equations (5) and the related energy equation are put in conservation form:

$$\begin{aligned}
 d_t + (ud)_x + (vd)_y &= 0 \\
 (ud)_t + \left(u^2d + \frac{1}{2}d^2\right)_x + (uvd)_y + d + \tau_1 &= 0 \\
 (vd)_t + (uvd)_x + \left(v^2d + \frac{1}{2}d^2\right)_y + \tau_2 &= 0 \\
 \frac{1}{2} \left[d(u^2 + v^2) + d^2 \right]_t + \left(\frac{1}{2}u^3d + \frac{1}{2}v^2ud + ud^2 \right)_x \\
 + \left(\frac{1}{2}v^3d + \frac{1}{2}u^2vd + vd^2 \right)_y + u(d + \tau_1) + v\tau_2 &= 0.
 \end{aligned} \tag{24}$$

where a dimensionless bed friction $\tau = (\tau_1, \tau_2)$ is included.

We also assume the wave motion as occurring at a 'fast time scale' t while the swash zone boundaries x_h (run-up) and x_l (run-down) are supposed to vary (if varying in time) on a 'slow time scale' T such as $t = \epsilon T$. We do not use this notation since the separation of the two scales is generally quite clear. Equations (24) are integrated over the swash zone width, with constant x_l , to give:

$$\begin{aligned}
 \frac{\partial V}{\partial t} &= \int_{x_l}^{x_h} d_t dx = Q_1(t)|_{x_l} - \frac{\partial P_2}{\partial y} \\
 \frac{\partial P_1}{\partial t} &= \int_{x_l}^{x_h} (ud)_t dx = S_{11}(t)|_{x_l} - V(t) - \frac{\partial M_{12}}{\partial y} - \Upsilon_1(t) \\
 \frac{\partial P_2}{\partial t} &= \int_{x_l}^{x_h} (vd)_t dx = S_{12}(t)|_{x_l} - \frac{\partial M_{22}}{\partial y} - \Upsilon_2(t) \\
 \frac{\partial E}{\partial t} &= \int_{x_l}^{x_h} \left[\frac{1}{2}(u^2 + v^2)d + d^2 \right]_t dx \\
 &= F(t)Q_1(t)|_{x_l} - P_1(t) - \frac{\partial}{\partial y} \int_{x_l}^{x_h} FQ_2 dx - \Gamma(t).
 \end{aligned} \tag{25}$$

This introduces a number of new flow properties and flow properties integrated over the swash zone. These are listed in table 1 where $\mathbf{u} = (u_1, u_2)$ is the horizontal velocity vector.

The set of equations (25) for the fully three-dimensional motion can be reduced by Ryrie's approximation to a simpler set of equations valid for weakly three-dimensional motion. Second order terms are neglected after the formal substitution (7) is made. Then, at the leading order the set of equations (25)

Name	Explicit expression	Flow property
Q_μ	$u_\mu d$	Local mass flow
$S_{\mu\nu}$	$u_\mu u_\nu d + \delta_{\mu\nu} \frac{1}{2} d^2$	Local momentum flux tensor
F	$\frac{1}{2} \mathbf{u}^2 + d$	Local energy density
V	$\int_{x_1}^{x_h} d \, dx$	Volume of water in swash zone
P_μ	$\int_{x_1}^{x_h} Q_\mu \, dx$	Momentum of water in swash zone
$M_{\mu\nu}$	$\int_{x_1}^{x_h} S_{\mu\nu} \, dx$	Integrated momentum flux tensor
E	$\int_{x_1}^{x_h} (\frac{1}{2} \mathbf{u}^2 d + d^2) \, dx$	Energy of water in swash zone
Υ_μ	$\int_{x_1}^{x_h} \tau_\mu \, dx$	Friction force in swash zone
Γ	$\int_{x_1}^{x_h} u_\mu \tau_\mu \, dx$	Work done by friction in swash zone

Table 1: Definition of the flow properties adopted in equations (25).

becomes:

$$\begin{aligned}
 \frac{\partial V}{\partial t} &= \int_{x_1}^{x_h} d_t \, dx = Q_1(t)|_{x_1} \\
 \frac{\partial P_1}{\partial t} &= \int_{x_1}^{x_h} (ud)_t \, dx = S_{11}(t)|_{x_1} - V(t) - \Upsilon_1(t) \\
 \frac{\partial P_2}{\partial t} &= \int_{x_1}^{x_h} (vd)_t \, dx = S_{12}(t)|_{x_1} + \frac{\partial M_{22}}{\partial t} - \Upsilon_2(t) \\
 \frac{\partial \bar{E}}{\partial t} &= \int_{x_1}^{x_h} (\frac{1}{2} u^2 d + d^2)_t \, dx = \bar{F}(t)Q_1(t)|_{x_1} - P_1(t) - \bar{\Gamma}(t).
 \end{aligned} \tag{26}$$

Table 2 lists definitions which, because of the approximation, differ from those of table 1. We distinguish newly defined flow properties by using overbars in equations (26) and table 2.

Name	Explicit expression	Flow property
\bar{F}	$\frac{1}{2} u_1^2 + d$	Local energy density
\bar{E}	$\int_{x_1}^{x_h} \frac{1}{2} (u_1^2 d + d^2) \, dx$	Energy of water in swash zone
$\bar{\Gamma}$	$\int_{x_1}^{x_h} u_1 \tau_1 \, dx$	Work done by friction in swash zone

Table 2: Definition of some flow properties adopted in equations (26).

In the idealized case of no dissipation ($\Upsilon_1 = \Upsilon_2 = \bar{\Gamma} = 0$) the set of partial differential equations (26) is such that it can be recursively solved for the integral

flow properties in the swash zone (i.e. V , P_1 , P_2 and \bar{E}) once the local flow properties Q_1 , S_{11} , S_{12} and \bar{F} are known at the seaward boundary of the swash zone. The result of the equation for the water volume only depends on the known variable Q_1 . Once this equation is solved for V the result can be substituted into the second equation and so on.

We believe that equations (25) can be used as swash zone boundary conditions for wave resolving models. Use of integrated swash zone properties gives considerable numerical advantage, since adequate modelling of the details of the swash zone flows requires small time steps.

The swash zone boundary conditions for wave-averaged models

A natural extension to averaging the swash zone is to seek appropriate boundary conditions at the seaward swash zone limit for wave-averaged models of the incident motions (both long and short period motions). This requires definition of the contributions to the motion of the boundary $x = x_l$ from both long-period motions (e.g. low frequency waves, currents, etc..) and averaged short-period motions. The problem here is that there is no definitive model for the waves approaching the swash zone, especially for the most usual case where waves are already breaking. The following discussion develops swash-zone boundary conditions by assuming that appropriate short-wave properties are known.

To obtain dynamic equations for wave-averaged flow properties we start with the equations of motion and divide the basic flow properties u , v and d into long-period motions and the short-period wave contributions:

$$u = \langle u \rangle + \tilde{u}, \quad v = \langle v \rangle + \tilde{v}, \quad d = \langle d \rangle + \tilde{d}, \quad \langle \tilde{u} \rangle = \langle \tilde{v} \rangle = \langle \tilde{d} \rangle = 0. \quad (27)$$

Contributions to $\langle u \rangle$, $\langle v \rangle$ and $\langle d \rangle$ come from all motions whose typical time scale is significantly longer than the typical short-wave period. These can be for example either bound long waves associated with the set-down occurring under a group of short-period waves or free long waves caused by a time-varying break-point or any sort of current. On the other hand pure short-period contributions appear as correlations of wave-type terms (e.g. $\langle \tilde{u}\tilde{d} \rangle$, $\langle \tilde{u}\tilde{v} \rangle$, etc..).

By substituting in the shallow water equations (24) in this way for each flow variable and by phase averaging we obtain a set of equations for the long-period flow properties $\langle u \rangle$, $\langle v \rangle$ and $\langle d \rangle$:

$$\frac{\partial \langle d \rangle}{\partial t} + \frac{\partial}{\partial y} [\langle u \rangle \langle d \rangle + \langle \tilde{Q}_1 \rangle] + \frac{\partial}{\partial y} [\langle v \rangle \langle d \rangle + \langle \tilde{Q}_2 \rangle] = 0 \quad (28)$$

$$\frac{\partial}{\partial t} [\langle u \rangle \langle d \rangle + \langle \tilde{Q}_1 \rangle] + \frac{\partial}{\partial y} [\langle d \rangle (\langle u \rangle^2 + \langle \tilde{u}^2 \rangle + \frac{1}{2} \langle d \rangle) + 2 \langle u \rangle \langle \tilde{Q}_1 \rangle + \langle \tilde{S}_{11} \rangle] \quad (29)$$

$$+ \frac{\partial}{\partial y} [\langle d \rangle (\langle u \rangle \langle v \rangle + \langle \tilde{u}\tilde{v} \rangle) + \langle u \rangle \langle \tilde{Q}_2 \rangle + \langle v \rangle \langle \tilde{Q}_1 \rangle + \langle \tilde{S}_{12} \rangle] + \langle d \rangle = 0$$

$$\frac{\partial}{\partial t} [\langle v \rangle \langle d \rangle + \langle \tilde{Q}_2 \rangle] + \frac{\partial}{\partial y} [\langle d \rangle (\langle v \rangle^2 + \langle \tilde{v}^2 \rangle + \frac{1}{2} \langle d \rangle) + 2 \langle v \rangle \langle \tilde{Q}_2 \rangle + \langle \tilde{S}_{22} \rangle] \quad (30)$$

$$+ \frac{\partial}{\partial y} [\langle d \rangle (\langle u \rangle \langle v \rangle + \langle \tilde{u}\tilde{v} \rangle) + \langle v \rangle \langle \tilde{Q}_1 \rangle + \langle u \rangle \langle \tilde{Q}_2 \rangle + \langle \tilde{S}_{12} \rangle] = 0$$

where $\langle \tilde{Q}_\mu \rangle = \langle \tilde{u}_\mu \tilde{d} \rangle$ is the mass flow due to wave motion while the contribution of the momentum flux due to wave motion is given by the radiation stress term $\langle \tilde{S}_{\mu\nu} \rangle$.

The above set can be also written in matrix form in order to clarify the forcing action of the short-period contributions. The set of equations can, thus, be rewritten as:

$$AU_t + BU_x + CU_y + DU = \mathcal{E} \quad (31)$$

where

$$U = \begin{bmatrix} \langle d \rangle \\ \langle u \rangle \\ \langle v \rangle \end{bmatrix} \quad \text{and} \quad \mathcal{E} = - \begin{bmatrix} \langle \tilde{Q}_1 \rangle_x + \langle \tilde{Q}_2 \rangle_y \\ \langle \tilde{Q}_1 \rangle_t + \langle \tilde{S}_{11} \rangle_x + \langle \tilde{S}_{12} \rangle_y + \langle d \rangle \\ \langle \tilde{Q}_2 \rangle_t + \langle \tilde{S}_{12} \rangle_x + \langle \tilde{S}_{22} \rangle_y \end{bmatrix} \quad (32)$$

are respectively the column vector of the unknown variables and the purely short-wave forcing.

This set of equations is not 'closed' unless a particular wave theory for the short-period wave field is adopted to compute terms like the mass flow and the radiation stress. For instance, it is common practice to use linear wave theory while dissipation effects induced by wave-breaking are parameterized in the solution.

However linear wave theory is not a good representation for the wave field near the shore. The Carrier & Greenspan (1958) solutions and their extension described above can be more appropriate. To help crystallise ideas we note that one approach to this problem would be to extend the Carrier & Greenspan solution to $A > 1$ by computing the surf and swash zone behaviour for waves which have incoming Riemann invariants as for the Carrier & Greenspan solution with $A > 1$. The reflection, mass flow, radiation stress and the averaged swash zone properties, V , P and E could be tabulated as functions of the short-wave parameters. We assume that if a suitable model is found for the short-wave motion this can be described in terms of only an amplitude A a frequency ω and a wave number \mathbf{k} once the mean depth and mean flow velocity are given.

Figure 4: Schematic of: (a) the 'physical' (x, z) plane and (b) the 'characteristic' (x, t) plane for the rigid wall problem.

In order to obtain suitable boundary conditions for wave-averaged models we need to clarify what sort of information is available and what are the unknowns. To achieve this we first use a simple model of a moving boundary that is a rigid wall moving at velocity $U(t)\mathbf{i}$ which varies on a sufficiently slow time scale that its acceleration is unimportant (see figure 4). The flow is one dimensional and the medium is assumed uniform so that A, ω and \mathbf{k} do not depend on (x, t) .

A simple exercise of bookkeeping shows what are known and unknown parameters for both long and short wave motions (see table 3 and figure 4).

Natural boundary conditions for this flow are:

$$\langle d \rangle|_{x_{wall}} = const, \quad \frac{dx_{wall}}{dt} = \langle u \rangle = U(t) \quad (33)$$

Consequently it is possible to explicitly compute the long-period motion variable β (i.e. the outgoing Riemann invariant) from the known incoming variable α

$$\alpha = 2\langle c \rangle + \langle u \rangle, \quad \beta = 2\langle c \rangle - \langle u \rangle, \quad \implies \quad \beta = \alpha - 2U. \quad (34)$$

The incoming waves of amplitude A_{in} , wavenumber \mathbf{k}_{in} frequency ω_{in} may be perfectly reflected at the wall, but to determine the outgoing values of A , \mathbf{k} and ω the local behaviour at the moving wall must be considered.

In a frame of reference moving with the wall, the waves have an unchanging intrinsic frequency σ which is readily found from the Doppler shift:

$$\omega_{in} = \sigma + U\mathbf{i} \cdot \mathbf{k}_{in}. \quad (35)$$

If the waves are perfectly reflected then the outward propagating wave has $A_{out} = A_{in}$ and $\mathbf{k}_{out} = -(\mathbf{k}_{in} \cdot \mathbf{i})\mathbf{i} + (\mathbf{k}_{in} \cdot \mathbf{j})\mathbf{j}$ giving:

$$\omega_{out} = \sigma + U\mathbf{i} \cdot \mathbf{k}_{out} = \sigma - U\mathbf{i} \cdot \mathbf{k}_{in} = \omega_{in} - 2U\mathbf{i} \cdot \mathbf{k}_{in}. \quad (36)$$

	Long-period	Short-period
Known	$\alpha = \alpha(\langle u \rangle, \langle d \rangle), \quad \langle d \rangle _{x_l}$	$A_{in}, \quad \omega_{in}, \quad \mathbf{k}_{in}$
Unknown	$\beta = \beta(\langle u \rangle, \langle d \rangle), \quad x_l(t)$	$A_{out}, \quad \omega_{out}, \quad \mathbf{k}_{out}$

Table 3: Known and unknown flow variables for the rigid wall problem.

In comparing the moving swash zone boundary with the above simple boundary, we note that it is necessary to model the swash zone boundary as a 'leaky wall' such that fluxes of mass and momentum are allowed across $x = x_{wall}$ which for the 'leaky' case may be identified with $x = x_l$. We also note that:

1. sufficient information must be available to determine the motion of the swash zone boundary, $x_l(t)$, as well as to determine β ;
2. as above, a local wave model is needed to determine the properties of the outgoing wave, if any.

We concentrate on the first of these, and look at integration of swash-zone equations similar to (25), or (26), to provide the necessary information. It is clear that in addition to the kinematic type of boundary conditions that occur on the rigid wall (equations 33) a third condition is necessary for the longshore flow in the swash zone.

There is now an important choice to be made: how much of the swash motion, if any, should be assigned to the long time scales? Consideration of the moving

rigid wall example leads us to consider all motion relative to the point $x = x_l(y, t)$ to be short wave motion and $x_l(y, t)$ to be 'driven' by the long-period motions. As a result, we consider all the quantities defined in tables 1 and 2 to be defined with velocities relative to x_l and also to be considered as known once incident short-wave parameters A_{in} , k_{in} and σ are known.

Inside the swash zone most the short-wave quantities averaged over the short wave motion, such as $\langle V \rangle$, $\langle P \rangle$ etc., are to be determined from a short-wave model of the swash. There are exceptions for the longshore current quantities P_2 , M_{p2} which are not entirely dependent on the local waves. When a bore, or flow which was near a bore, enters the swash zone it makes a large contribution to the longshore velocity, which often may only respond to bed friction on the longer time scale, e.g. see Ryrie (1983). This means that a decomposition of long-wave and short-wave contributions is also necessary within the swash zone.

We achieve this decomposition by assuming that swash motion is almost entirely assigned to short-wave contributions and that the only long-wave contribution, other than the motion of x_l , comes from parameterising the longshore drift due to wave-breaking by a longshore current velocity $W = W(y, t)$. In similar fashion to equation (27), which applies outside the swash zone, we separate short-wave from long-wave contribution for the flow properties inside the swash zone:

$$d = \hat{d}, \quad u = \frac{\partial x_l}{\partial t} + \hat{u}, \quad v = W + \hat{v}, \quad (37)$$

where a short-wave property inside the swash zone is defined as \hat{G} rather than \tilde{G} which pertains to short-wave contributions outside the swash zone. This decomposition permits the integrated terms depending on the longshore velocity to be divided between long and short waves:

$$\langle P_2 \rangle = \langle W \hat{V} \rangle + \langle \hat{P}_2 \rangle, \quad (38)$$

$$\langle M_{12} \rangle = \langle W \hat{P}_1 \rangle + \langle \hat{M}_{12} \rangle + \frac{\partial x_l}{\partial t} (\langle W \hat{V} \rangle + \langle \hat{P}_2 \rangle), \quad (39)$$

$$\langle M_{22} \rangle = \langle W^2 \hat{V} \rangle + 2 \langle W \hat{P}_2 \rangle + \langle \hat{M}_{22} \rangle. \quad (40)$$

All the integral properties which are to be considered as short-wave terms have a hat symbol. In principle it is possible to choose a different short-wave solution for the two regions separated by $x = x_l$ also on many sandy beaches there is a strong difference in the character of the bed in the swash zone compared with the bed just outside the swash zone.

In order to avoid greater complexity, the longshore variation of x_l has been assumed to be negligible in the above derivation. This is essentially a geometrical matter, and the above boundary conditions can be interpreted as being applicable when the x direction is normal to the mean lowest boundary of the swash.

To obtain explicit expression of the first boundary condition we consider the flow of mass into the swash zone relative to $x = x_l$. Average of equation (25) is:

$$\frac{\partial \langle V \rangle}{\partial t} + \frac{\partial \langle P_2 \rangle}{\partial y} = \langle Q_1 \rangle|_{x_l} \quad (41)$$

where now the right hand side contains the relative flow velocity ($u - \partial x_l / \partial t$). The left hand side is also rewritten in terms of the local variables inside the

swash zone and then after using (38) for $\langle P_2 \rangle$, after integration across the swash zone width and averaging over the short waves we obtain

$$\frac{\partial \langle \hat{V} \rangle}{\partial t} + \frac{\partial \langle W \hat{V} \rangle}{\partial y} + \frac{\partial \langle \hat{P}_2 \rangle}{\partial y} = \left\langle \left(u - \frac{\partial x_l}{\partial t} \right) d \right\rangle = \langle u \rangle \langle d \rangle + \langle \tilde{u} \tilde{d} \rangle - \frac{\partial x_l}{\partial t} \langle d \rangle. \quad (42)$$

The first term on the left hand side of this equation is the rate of change of the total volume of water in the swash zone; the second and third terms are the change in volume due to the lateral variation of longshore currents respectively associated with the longshore velocity inside the swash zone W and with the wave contribution $\langle \hat{P}_2 \rangle$. The right hand side of (42) is the increase of water in the swash zone through its lower boundary. The right hand side of (42) is evaluated at $x = x_l$ using outer variables.

A similar derivation for the average balance of onshore momentum in the swash zone gives

$$\begin{aligned} & \frac{\partial}{\partial t} \left[\langle \hat{P}_1 \rangle + \frac{\partial x_l}{\partial t} \langle \hat{V} \rangle \right] + \frac{\partial \langle W \hat{P}_1 \rangle}{\partial y} + \frac{\partial \langle \hat{M}_{12} \rangle}{\partial y} \\ & + \frac{\partial x_l}{\partial t} \left[\frac{\partial \langle W \hat{V} \rangle}{\partial y} + \frac{\partial \langle \hat{P}_2 \rangle}{\partial y} \right] + g\alpha \langle \hat{V} \rangle + \langle \Upsilon_1 \rangle = \left\langle \left(u - \frac{\partial x_l}{\partial t} \right)^2 d + \frac{1}{2} g d^2 \right\rangle = \quad (43) \\ & \left(\langle u \rangle - \frac{\partial x_l}{\partial t} \right)^2 \langle d \rangle + \frac{1}{2} g \langle d \rangle^2 + 2 \langle \tilde{u} \tilde{d} \rangle \left(\langle u \rangle - \frac{\partial x_l}{\partial t} \right) + \langle \tilde{u}^2 \rangle \langle d \rangle + \langle \tilde{u} \tilde{d} \rangle + \frac{1}{2} g \langle \tilde{d}^2 \rangle. \end{aligned}$$

In this equation dimensional expressions have been inserted to clarify the origin of terms. The first two terms on the left hand side are the rate of change of the mean momentum in the swash zone. The group of terms with y derivatives are the contribution from longshore velocity gradients which include both long period contributions (terms with W) and short period contributions (terms with $\langle \hat{P}_2 \rangle$ and $\langle \hat{M}_{12} \rangle$). The following terms are the action of gravity and friction on the water in the swash zone. The right hand side is the momentum transfer into the swash zone at $x = x_l$ where the mean flow velocity relative to the swash zone limit appears in both long and short period terms. Finally pure short period contributions appear. Conservation of longshore momentum similarly yields

$$\begin{aligned} & \frac{\partial \langle W \hat{V} \rangle}{\partial t} + \frac{\partial \langle \hat{P}_2 \rangle}{\partial t} + \frac{\partial \langle W^2 \hat{V} \rangle}{\partial y} + 2 \frac{\partial \langle W \hat{P}_2 \rangle}{\partial y} + \frac{\partial \langle \hat{M}_{22} \rangle}{\partial y} + \langle \Upsilon_2 \rangle = \left\langle \left(u - \frac{\partial x_l}{\partial t} \right) v d \right\rangle = \quad (44) \\ & \left(\langle u \rangle - \frac{\partial x_l}{\partial t} \right) \langle v \rangle \langle d \rangle + \langle \tilde{u} \tilde{v} \rangle \langle d \rangle + \langle \tilde{u} \tilde{d} \rangle \langle v \rangle + \langle \tilde{u} \tilde{v} \rangle \langle d \rangle + \langle \tilde{u} \tilde{d} \rangle \langle v \rangle + \langle \tilde{v} \tilde{d} \rangle \left(\langle u \rangle - \frac{\partial x_l}{\partial t} \right) + \langle \tilde{u} \tilde{v} \tilde{d} \rangle. \end{aligned}$$

The above three equations are boundary conditions for the long wave motion and x_l if the short wave properties on each side of $x = x_l$ have 'known' models. Whereas in the rigid wall model only the two boundary conditions are required, now we also need to evaluate the changes in W . In addition, the short-wave models may be chosen to permit the reflection of short waves. Note, the short-wave swash model must be used relative to $x = x_l$, hence the motion of x_l is seen as the long period contribution to the swash zone. A delicate matter concerning the different wave models needed on each side of x_l also needs attention.

The short-wave contribution

In this section we briefly analyse the relevance of the short-wave contributions with particular emphasis on those appearing in the equations (42), (43) and (44) which are used to define the boundary conditions at the lower limit of the swash zone. Computation of the contributions has been performed by integrating the analytical solution for $A \leq 1$ and by integrating the fully numerical solution when wave-breaking occurs, i.e. for $A > 1$.

For waves that break momentum and energy are transferred from the short-waves to the longshore currents hence terms depending on the longshore drift velocity W are to be taken into account as major contributions to the swash zone motions in equations (42), (43) and (44) (see figure 5). Note that the curves have been obtained by joining discrete points which represent the results of single computations. This explains the lack of smoothness in some of the curves.

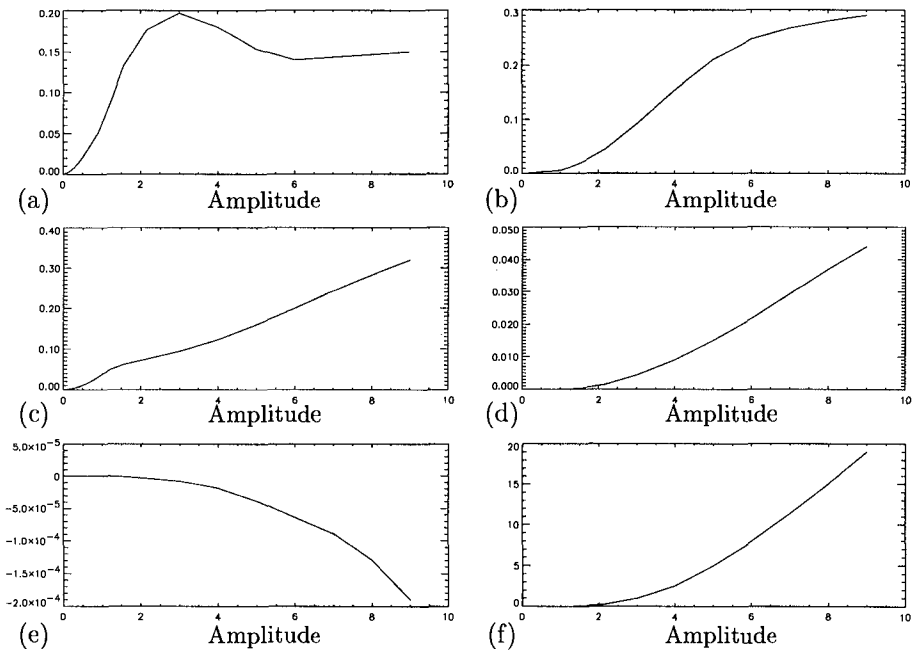

Figure 5: Short-wave contribution at the boundary x_l and inside the swash zone. From top left to bottom right they are the short-wave correlations (a) $\langle \hat{u}^2 \rangle$, (b) $\langle \hat{d}^2 \rangle$ the integral properties (c) $\langle \hat{V} \rangle$, and the rate of change of the three global integral properties (d) $\langle P_2 \rangle$, (e) $\langle M_{12} \rangle$ and (f) $\langle M_{22} \rangle$. Note that for $A \leq 1$ numerical integration of the analytical solution is shown while for $A > 1$ fully numerical solution of the NLSWE is represented.

The input of longshore momentum from the bores is balanced by bed friction but this is generally on the longer time scale. Although bores die out when they meet the shoreline and cause run-up, the water that forms the swash has acquired longshore momentum from the bore before it enters the swash zone. A

fully detailed consideration of this case also awaits further study; here we present the rate of change in time of the quantities $\langle \hat{V} \rangle$, $\langle \hat{P}_2 \rangle$ and $\langle \hat{M}_{22} \rangle$.

The figure presented here indicates that not all the terms that are introduced into the boundary conditions (42, 43 and 44) are necessary. Inspection of figure (5) reveals that the largest term to be retained in case of wave breaking is the rate of change of $\langle \hat{M}_{22} \rangle$. This is not surprising as $\langle \hat{M}_{22} \rangle$ is the only integral term proportional to W^2 (see equations 38) and hence it is more heavily influenced by the longshore drift induced by wave breaking. We can further comment that the non-diagonal contribution $\partial \langle \hat{M}_{12} \rangle / \partial t$ seems to be negligible in this particular case in which we have used $x_l = \text{const}$. However, in view of equation (39), here reported for ease of inspection,

$$\langle M_{12} \rangle = \langle W \hat{P}_1 \rangle + \langle \hat{M}_{12} \rangle + \frac{\partial x_l}{\partial t} (\langle W \hat{V} \rangle + \langle \hat{P}_2 \rangle) \quad (45)$$

we believe that this term may give larger contribution for a time-varying x_l as the rate of change of the boundary position explicitly contributes to this term.

Further investigation should help to clarify both which are the most significant terms when considered in the context of the equations and what are the effects of friction terms.

CHAPTER 321

Wave Overwash of Subaerial Dunes

Yukiko Tega ¹ and Nobuhisa Kobayashi, M. ASCE ²

Abstract

Small-scale experimental results consisting of 72 runs for minor to major dune overwash are analyzed to improve existing dune erosion models that do not account for wave overwash processes explicitly. The measured cross-shore sediment transport rate is found to vary approximately linearly from the measured rate somewhat below the still water level, which is affected by the overwash intensity, to the overwash rate over the dune crest. The measured overwash sand concentration for the sand with its median diameter of 0.38 mm used in this experiment was in the range of 0.02 to 0.06. The time-dependent one-dimensional numerical model for the overtopping flow combined with two sediment transport formulas indicates that the overwash sand concentration may be on the order of 0.04 except for very fine or coarse sands.

Introduction

The quantitative understanding of wave overwash of dunes is essential for predicting dune erosion as well as coastal flooding hazards during storms. Existing dune erosion models generally assume that the net sediment transport rate may be extrapolated linearly from the value slightly below the still water level (SWL) to zero at the upper limit of wave runup estimated empirically. This linear extrapolation may be necessary for lack of a simple swash model and appears to be a reasonable first approximation for the case of no overwash.

A simple empirical method for predicting the onshore sand transport rate associated with wave overwash of subaerial dunes is presented herein by expanding the experimental study by Hancock and Kobayashi (1994). The experiment was limited to subaerial dunes, while experiments on submerged dunes were conducted by Steetzel and Visser (1992). Kobayashi et al. (1996) showed that the measured reflection coefficient and overtopping rates could be predicted using the empirical formulas developed for coastal structures and adjusted for dunes. This paper examines the cross-shore sand transport on dunes.

Experiment

Fig.1 shows the setup of the dune overwash experiment conducted in a wave tank that was 30 m long, 2.44 m wide, and 1.5 m high. The experiment was

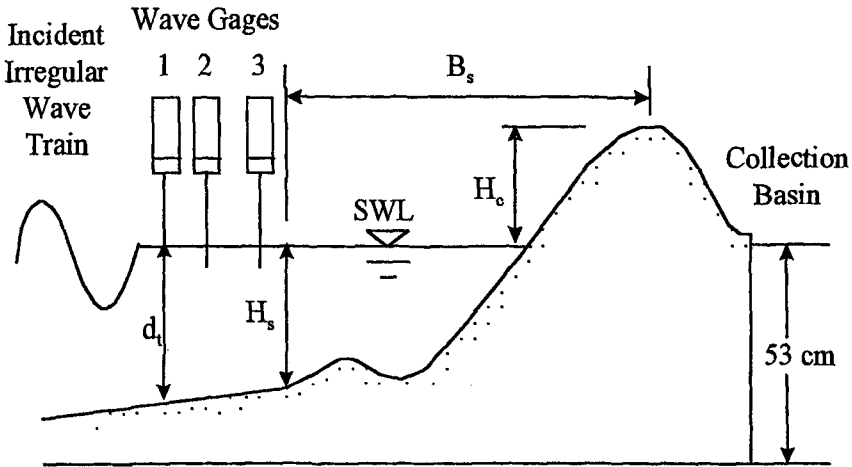

Figure 1: Experimental Setup.

conducted in a 61 cm wide channel by constructing a divider wall to reduce the effects of re-reflection from the wave paddle used to generate irregular waves. The well-sorted sand with a median diameter of 0.38 mm was placed in front of a 53 cm high basin used to collect both overtopped water and overwashed sand. The measured specific gravity, porosity and fall velocity of the sand were 2.66, 0.41 and 5.29 cm/s, respectively. Three wave gages placed immediately seaward of the breaker zone were used to separate the incident and reflected waves at wave gage 1 for each run (Kobayashi and Raichle 1994). The duration of each run was 325 s and the sampling rate for the three gages was 20 Hz.

Seven tests, referred to as tests A to G hereafter, were conducted for minor to major overwash. The dune crest was initially located at approximately 12 cm above SWL and at a horizontal distance of 40 cm from the basin wall. Each test consisted of a series of runs to examine the changes of the overtopping rate per unit width, Q , and the overwash rate per unit width, Q_s , as the beach and dune profile evolved. The overtopping and overwash rates per unit width, Q and Q_s , for each run were obtained by dividing the volumes of water and sand, respectively, collected in the basin by the run duration 325 s and the channel width 61 cm. The value of Q_s is based on the sediment volume only without any void. The test was terminated just before the collection basin wall would become exposed to direct wave action. Beach and dune profiles were measured along three lines using an ultrasound profiler at the beginning and end of each test and after runs of noticeable profile changes. The average profile of the measured three profiles was used to find the dune crest height H_c above SWL, the location where the depth below SWL equals to the significant wave height H_s measured at wave gage 1, and the horizontal distance B_s from the dune crest to this location as shown in Fig. 1. The equivalent uniform slope for wave overtopping, m_o , is assumed to be given by $m_o = (H_c + H_s)/B_s$. The measured values of m_o were interpolated to obtain the value of m_o in the middle of each run.

Table 1 lists the number of runs in each test and the ranges of the incident wave characteristics at wave gage 1, the dune crest height H_c , the equivalent slope m_o , the overtopping rate Q and the overwash rate Q_s for the seven tests. The water depth d_t below SWL at wave gage 1 for each test was constant where the bottom change at wave gage 1 was negligible. The spectral peak period T_p was

F	24	43.2	1.4	12.0-12.3	7.9-11.3	0.31-0.47	0.007-0.026	0.09-0.16
G	9	43.2	2.0	12.0-12.4	7.8-11.1	2.89-4.38	0.10-0.16	0.11-0.16

also constant for each test and $T_p = 1.2 - 2.0$ s for the seven tests. The significant wave height, H_s , based on a zero upcrossing method varied little during each test and among the seven tests because the TMA spectra with the spectral significant wave height $H_{m0} = 12.5$ cm and $T_p = 1.2 - 2.0$ s at the wave paddle were used to generate the incident irregular waves. On the other hand, the dune crest height H_c and the equivalent slopes m_o decreased with the increase of run number as the beach and the dune profile evolved. The data from tests A to E consisting of 39 runs were presented by Hancock and Kobayashi (1994). These tests corresponded to high dunes with large storm surge. Two additional tests, F and G, consisting of 33 runs were conducted by placing more sand in front of the initial dune profile used in tests A to E to reduce the water depth at the toe of the dune.

Data Analyses

First, the measured overwash rate Q_o is related to the measured overtopping rate Q in the form

$$Q_o = C_s Q \quad (1)$$

where C_s is the average volumetric sediment concentration in the overwash. The dimensional values of Q_o and Q are plotted in Fig. 2 to show that these values were from the small scale experiment. Fig. 2 shows that the 72 data points fall within the narrow range of $C_s = 0.02 - 0.06$ and that the empirical formula (1) with $C_s \approx 0.04$ may be used to estimate Q_o for Q predicted separately. The subsequent sections will examine whether the assumption of constant C_s holds for field conditions and other sands.

To predict the overtopping rate Q for normally incident breaking waves on dunes, Kobayashi et al. (1996) adjusted the empirical formula for

wave overtopping on coastal structures proposed by Van der Meer and Janssen (1995). The toe of a coastal structure was assumed to correspond to the location of wave gage 1 immediately seaward of the breaker zone. The equivalent uniform slope m_o was assumed to represent the overall slope effect on wave overtopping of dunes. The adjusted formula was shown to yield the agreement between the measured and empirical values of Q almost within the 95 % confidence limits of the original formula based on about 500 data points. Fig. 3 shows the measured overwash rate Q_o as a function of the empirical overtopping rate Q_e based on the adjusted formula by Kobayashi et al. (1996). The formula (1) with Q replaced by Q_e is still reasonable. However, most of the values of C_s are in the range of $C_s = 0.01 - 0.04$ with a typical value of $C_s = 0.02$. These values of C_s are smaller than those of C_s based on Q by a factor of about two. This is because the adjust formula for Q_e tends to overpredict the overtopping rates for the tests with larger

Figure 2: Measured Overwash Rate Q_s vs. Measured Overtopping Rate Q .

Figure 3: Measured Overwash Rate Q_s vs. Empirical Overtopping Rate Q_e .

overtopping rates. The accurate prediction of Q_s using (1) requires the accurate predictions of C_s and Q . Unfortunately, only the order of magnitude of Q , even for coastal structures, can be predicted at present. Consequently, the present study aims at the prediction of C_s within a factor of about two.

In order to predict the beach and dune profile evolution, the cross-shore variation of the net sediment transport rate is required. The net cross-shore sediment transport rate q_s was calculated using the continuity equation of sediment and the measured profiles starting from the seaward location of no profile change as described by Hancock and Kobayashi (1994). The value of q_s at the landward

Figure 4: Schematic Representation of Cross-Shore Sediment Transport Rate q_s over Dune

boundary should correspond to the net sediment transport rate into the collection basin but was not exactly the same as the average overwash rate for the same duration calculated from the collected sand because of small profile measurement errors. As a result, the normalized results are presented as explained in the following.

Figure 5: Normalized Cross-Shore Sediment Transport Rate, q_s/q_{s1} , as a Function of $-x/x_1$ with $x = 0$ at Edge of Collection Basin.

The measured cross-shore sediment transport rate q_s is taken to be positive onshore as shown in Fig. 4 where $x =$ cross-shore coordinate taken to be positive seaward with $x = 0$ at the edge of the collection basin. The dune crest is located at $x = x_1$. The seaward limit of this analysis may be taken at the location x_2 where the water depth below SWL equals $H_s/3$ because this depth of $H_s/3$ is larger than the typical smallest depth adopted by existing cross-shore sediment transport models in the surf zone. The values of q_s at $x = x_1$ and x_2 are denoted by q_{s1} and q_{s2} , respectively. The locations of x_1 and x_2 varied somewhat between the two profiles measured consecutively. The first of the two profiles was used to find x_1 and x_2 . The average value of H_s during the runs between the two profile measurements was used for the depth $H_s/3$ for x_2 . The results presented in the

following are not sensitive to the details of the data analysis.

The normalized cross-shore sediment transport rate, q_s/q_{s1} , is plotted in Fig. 5 as a function of $-x/x_1$ in the range $0 < x < x_2$ for all the cross-shore variations of the onshore sand transport rate based on the consecutive profile measurements. Fig. 5 shows that the value of q_s landward of the dune crest is almost constant and may be approximated by the overwash rate Q_s , which is based on the sand volume collected in the basin for each run and should be more accurate than q_s . Furthermore, q_s increases approximately linearly from q_{s2} at $x = x_2$ somewhat below SWL to q_{s1} at the dune crest. Consequently, the cross-shore variation of q_s required for the prediction of the dune profile evolution using the continuity equation for sediment may be represented by $Q_s \simeq q_{s1}$ and q_{s2} where Q_s may be estimated using (1).

Existing dune erosion models estimate the cross-shore sediment transport rate slightly below SWL without regard to wave overwash. To examine the effect of overwash on q_s below SWL, the values of q_{s2}/q_{s1} are plotted as a function of the overtopping rate Q and the overwash rate Q_s in Fig. 6. Since $q_{s1} > 0$ in this experiment, the positive and negative values of q_{s2}/q_{s1} imply the onshore and offshore sediment transport at $x = x_2$ below SWL, respectively. Fig. 6 indicates that the net sediment transport somewhat below SWL in this experiment was offshore for small Q and Q_s but tended to become onshore with the increase of Q and Q_s . This implies that the estimation of q_{s2} will need to account for wave overtopping and overwash.

Figure 6: Normalized Sediment Transport Rate q_{s2}/q_{s1} , Somewhat below SWL as a Function of Overtopping Rate Q (top) and Overwash Rate Q_s (bottom)

Numerical Modeling

To elucidate the overwash processes and extrapolate the small-scale experimental results presented above, use is made of the time-dependent one-dimensional numerical model RBREAK2 (Kobayashi and Poff 1994). RBREAK2 was shown

to predict the overtopping rates for revetments in surf zones within about 40 % errors (Kobayashi and Raichle 1994). Two sediment transport formulas are combined with RBREAK2 to predict the net sediment transport rate q_s .

The empirical formula proposed by Trowbridge and Young (1989) for unbroken water waves under sheet flow conditions may be used to express q_s in the form

$$\frac{q_s}{wd} = \frac{A\overline{|u|u}}{g(s-1)d} \quad (2)$$

in which w = fall velocity of the sand particle; g = gravitational acceleration; d = median diameter d_{50} where d is used for brevity; s = specific gravity of the sand; u = instantaneous depth-averaged velocity computed by RBREAK2 ; and A = empirical parameter. The overbar in (2) denotes the time-averaging for the duration of each run. The formula (2) with $A \simeq 0.25$ was employed successfully to predict the onshore sand transport outside the surf zone at the CERC Field Research Facility.

On the other hand, Ribberink and Al-Salem (1994) developed a sediment transport formula using large oscillating water tunnel data. This formula expresses q_s as

$$\frac{q_s}{wd} = af^{1.5} \frac{\overline{u^3}}{w^3} \quad (3)$$

where a = empirical parameter; and f = Jonsson's wave friction factor. The formula with $a = \sqrt{2}$ was shown to yield good agreement with their water tunnel data.

Table 2: Measured and Computed Overtopping Rates for 10 Runs

Test	f	T_p (s)	H_s (cm) (cm)	Measured Q (cm^2/s)	Computed Q_c (cm^2/s)
B6	0.014	1.4	12.36	0.93	0.38
B9	0.014	1.4	12.28	1.08	1.09
B9	0.012	1.4	12.28	1.08	1.06
B9	0.010	1.4	12.28	1.08	0.90
D5	0.012	1.8	12.30	4.63	1.98
D5	0.010	1.8	12.30	4.63	2.19
D7	0.012	1.8	12.29	4.46	1.78
D7	0.010	1.8	12.29	4.46	1.97
E1	0.010	2.0	12.49	6.33	2.16
E2	0.010	2.0	12.67	8.40	3.12
E3	0.010	2.0	12.71	8.38	13.07
G1	0.010	2.0	12.42	2.89	0.12
G2	0.010	2.0	12.34	4.26	0.23
G3	0.010	2.0	12.05	4.38	1.48

The formulas (2) and (3) developed for the sand transport due to prototype large-scale unbroken waves may be applied to the sand transport due to broken waves overtopping on dunes if the empirical parameters A and a are adjusted.

Computations were made for 10 representative runs using the measured profile and incident wave train at wave gage1 as input to RBREAK2 . Table 2 summarizes the computed runs where f = friction factor specified in the computation;

T_p = spectral peak period of the incident waves; H_s = incident significant wave height; Q = measured overtopping rate; and Q_c = computed overtopping rate which is the time-averaged volume flux per unit width at the edge of the collection basin during each run. The friction factor f for the overtopping flow is expected to be different from Jonsson's friction factor. The value of $f \approx 0.01$ is a reasonable estimate from the previous calibration for wave overtopping of revetments performed by Kobayashi and Raichle (1994). RBREAK2 with $f = 0.01 - 0.014$ predicts the order of magnitude of the overtopping rates. For tests E and G, where the overall beach and dune slope was gentler for test G as may be inferred from the range of m_o listed in Table 1, the computed overtopping rates were varied much more than the measured rates for the different profiles of tests E and G and as the profile evolved in each test. This apparent sensitivity of RBREAK2 to the beach and dune profile is not certain for lack of measurements on the depth and velocity of the overtopping flow in this experiment.

The cross-shore variation of the net sediment transport rate q_s is also computed using (2) and (3) where RBREAK2 predicts the temporal and cross-shore variations of the depth-averaged velocity u during each run. The computed cross-shore variation of q_s in the region between the dune crest and the edge of the collection basin is essentially constant and consistent with the measured variation shown in Fig. 5. However, the computed values of q_s seaward of the dune crest vary too rapidly in comparison to these shown in Fig. 5. The assumption of the instantaneous response of sand particles to the depth-averaged velocity u made in (2) and (3) may not be valid seaward of the dune crest. The following analysis is limited to the computed results at the edge of the collection basin which are representative of the computed results landward of the dune crest.

The computed time series of the normalized water depth, $h_* = h/H_s$, where H_s = incident significant wave height for each run, and the normalized depth-averaged velocity, $u_* = u/\sqrt{gH_s}$, are stored at the sampling rate of 20 Hz during each run lasting 325 s. In order to find a relationship between h_* and u_* , the stored values of h_* and u_* for the 10 runs listed in Table 2 are plotted in the form

Figure 7: Computed Normalized Velocity, u_* , and Square Root Depth, h_* , of Overwash Flow for 10 Runs

of u_* v.s. $\sqrt{h_*}$ in Fig. 7. RBREAK2 assumes that the overtopping flow at the landward boundary of the computation domain is critical ($u = \sqrt{gh}$ and hence $u_* = \sqrt{h_*}$) or supercritical ($u > \sqrt{gh}$ and hence $u_* > \sqrt{h_*}$). The scattered points in Fig. 7 may be represented crudely by the simple relationship, $u_* \simeq 2\sqrt{h_*}$. This relationship corresponds to that between the bore speed and flow depth on a barrier island measuring using video techniques by Holland et al. (1991) if the celerity and fluid velocity of the bore are assumed to be the same.

The simple relationship of $u_* = 2\sqrt{h_*}$ may describe the overall trend of the overtopping flow but is not accurate enough to predict the instantaneous relationship between u_* and h_* . As an example, Fig. 8 shows the computed time series of u_* and $2\sqrt{h_*}$ for run B9 where $t_* = t/T_p$ is the normalized time with $t_* = 0$ at the beginning of each run. The relationship of $u_* = 2\sqrt{h_*}$ tends to underpredict the peaks of u_* and overpredict the receding segments of u_* .

Figure 8: Computed Time Series of u_* and $2\sqrt{h_*}$ for Run B9

Figure 9: Computed Normalized Velocity Moment $|u_*|u_*$ as a Function of Computed Normalized Overtopping Rate Q_* .

Figure 10: Computed Normalized Velocity Moment u_*^3 as a Function of Computed Normalized Overtopping Rate Q_* .

In order to explain the approximate linear relationship between Q_s and Q expressed by (1) using the formulas (2) and (3), the computed time-averaged values of $\overline{|u_*|u_*}$ and $\overline{u_*^3}$ for each of the runs listed in Table 2 are plotted as a function of the computed normalized overtopping rate, $Q_* = \overline{h_*}u_*$, in Figs. 9 and 10, respectively. The dimensional overtopping rate Q is given by $Q = H_s\sqrt{gH_s}Q_*$. In Fig. 9, $\overline{|u_*|u_*}/Q_* = 7.3 - 18.8$ and the linear regression coefficient is about 8.

In Fig. 10, $\overline{u_*^3}/Q_* = 3.8 - 5.3$ and the relationship of $\overline{u_*^3} = 4Q_*$ based on the assumption of $u_* = 2\sqrt{h_*}$ yields very good agreement. These relationships together with (2) and (3) are used to express the overwash sand concentration C_s in (1) in terms of the sand and wave characteristics.

Overwash Sand Concentration

The overwash rate Q_s is estimated as the values of q_s in (2) and (3) at the edge of the collection basin. Substitution of (1) into (2) and (3) yields the following expressions of C_s :

$$C_s = Av_* \frac{\overline{|u_*|u_*}}{Q_*} \quad ; \quad w_* = \frac{w}{(s-1)\sqrt{gH_s}} \tag{4}$$

and

$$C_s = af^{1.5}d_* \frac{\overline{u_*^3}}{Q_*} \quad ; \quad d_* = \frac{gd}{w^2} \tag{5}$$

where w_* and d_* are the normalized fall velocity and diameter respectively. To calibrate the empirical coefficients A and a in (4) and (5), the measured concentration C_s is plotted as a function of $w_*\overline{|u_*|u_*}/Q_*$ and $f^{1.5}d_*\overline{u_*^3}/Q_*$ in Figs. 11 and 12, respectively, for the computed runs listed in Table 2. Fig. 11 indicates $A \approx 0.1$ in (4) instead of $A \approx 0.25$ calibrated by Trowbridge and Young (1989).

Figure 11: Measured Sand Concentration C_s Compared with Formula (4) with $A = 0.1$

Figure 12: Measured Sand Concentration C_s Compared with Formula (5) with $a = 5$

Fig. 12 suggests $a \approx 5$ instead of $a \approx \sqrt{2}$ obtained by Ribberink and Al-Salem (1994). These order-of-magnitude agreements are encouraging in light of the scale differences (small-scale experiment v.s. field or large-scale experiment) and the different wave conditions (breaking wave overwash of dunes v.s. unbroken waves on essentially horizontal bottoms.). Figs. 11 and 12 also reveal the difficulty in predicting the relatively small variation of C_s .

The formula (4) with $A \approx 0.1$ together with $\overline{u_* u_*} / Q_* \approx 8$ in Fig.9 may be simplified as

$$C_s = Bw_* \tag{6}$$

where B = empirical parameter on the order of 0.8. Furthermore, the formula (5) with $a \approx 5$ and $f \approx 0.01$ along with $\overline{u_*^3} / Q_* \approx 4$ in Fig. 10 may simply be rewritten as

$$C_s = bd_* \tag{7}$$

where b = empirical parameter on the order of 0.02.

For the seven tests consisting of 72 runs listed in Table 1, $d = 0.38$ mm, $w = 5.29$ cm/s, $s = 2.66$ and $H_s \approx 12$ cm. As a result, $w_* \approx 0.03$ and $d_* \approx 1.33$ for this experiment. For the narrow range of the measured values of C_s for the 72 runs, $B = 0.63 - 2.22$ with its mean being 0.8 and $b = 0.014 - 0.049$ with its mean being 0.025. The formulas (6) and (7) are no better than the linear regression between Q_s and Q shown in Fig.2 since w_* is essentially constant and d_* is constant in this experiment. However, (6) and (7) may be applied to estimate C_s for other sands.

The variation of the overwash sand concentration C_s with respect to its median diameter d estimated using (6) with $B = 0.8$ as well as (7) with $b = 0.025$ are shown in Figs. 13 and 14, respectively, where the specific gravity of the sand is assumed to be $s = 2.6$ and its fall velocity w is taken to be equal to that of the spherical particle falling in quiet water whose kinematic viscosity is $\nu = 0.01 \text{ cm}^2/\text{s}$. In Fig.13, use is made of $H_s = 0.1, 1$ and 5 m because w_*

Figure 13: Variation of Sand Concentration C_s with Median Diameter d Estimated by $C_s = 0.8w_*$.

defined in (4) depends on the incident significant wave height H_s . Contrary to our expectation, Fig. 13 suggests the increase of C_s as d is increased and H_s is decreased. This indicates the limitation of the formula (2) proposed by Trowbridge and Young (1989) who stated that their formula might be limited to quartz sand whose diameter should not be too different from 0.2 mm. On the other hand, Fig. 14 indicates the increase of C_s with the decrease of d as expected. The formula (3) proposed by Ribberink and Al-Salem (1994) was compared with the data with $d = 0.2 - 1.8$ mm. The rapid increase of C_s with the decrease of d in the range $d < 0.2$ mm in Fig. 14 appears to be unrealistic in view of the physical upper limit of $C_s \simeq 0.6$. The range of $C_s = 0.018 - 0.065$ for the 72 runs in comparison to the variation of $C_s = 0.025d_s$ for $d = 0.2 - 1.0$ mm in Fig. 14 implies that it will be difficult to detect the effect of d on C_s unless very fine or coarse sands are employed in experiments.

Figure 14: Variation of Sand Concentration C_s with Median Diameter d Estimated by $C_s = 0.025d_s$.

Conclusion

This small-scale experiment on wave overwash of subaerial sand dunes indicates that the net cross-shore sediment transport rate q_s varies approximately linearly from $q_s = q_{s2}$ somewhat below SWL, to $q_s = q_{s1}$ at the dune crest which is approximately the same as the overwash rate Q_s measured at a short distance landward of the dune crest. The transport rate q_{s2} is affected by the overtopping rate Q and may not be assumed to be the same as that for the case of no overtopping. The overwash rate Q_s may be estimated using the simple relationship of $Q_s = C_s Q$ with $C_s \simeq 0.04$ for the median sand diameter $d = 0.38$ mm but the accuracy of this relationship is limited mostly by the accuracy of the empirical formula for Q which predicts only the order of magnitude of Q . In order to extrapolated these small-scale experimental results, the numerical model RBREAK2 for

the overtopping flow is combined with two empirical formulas for C_s . The computed results suggest that C_s is on the order of 0.04 except for very fine or coarse sands. This finding is useful for future experiments.

CHAPTER 322

PRESSURE GRADIENTS WITHIN SEDIMENT BEDS.

Thomas. E. Baldock¹ and Patrick Holmes²

ABSTRACT

A new technique for measuring dynamic pressures and pressure gradients within sediments is developed. The pressure is measured with a series of small diameter steel probes connected to pressure transducers via semi-rigid tubing. The dynamic response of the system was evaluated and found to be satisfactory for typical laboratory wave frequencies. Comparisons with measurements of the pressure gradients obtained from conventional transducers show good agreement. The present technique is demonstrated with pressure measurements at the toe of breakwaters and across the surf zone of model beaches.

1) INTRODUCTION

Pressure gradients induced within sediment beds by surface gravity waves may have a significant influence on the transport of sediment and the stability of coastal structures. The pressure gradients may either be steady or transient. For example, the wave induced set-up of the water level at the shoreline will produce a steady flow within a beach (Longuet-Higgins, 1983). This may be increased by the percolation of swash through the upper part of the beach. Alternatively, transient pressure gradients may locally reduce the effective strength of the sediment, possibly temporarily fluidising the bed material (e.g Madsen, 1974; Yamamoto, 1978). This may lead to higher rates of sediment transport and reduce the stability of structures within the surf zone.

However, considerable uncertainty remains as to the effects of pressure gradients on sediment transport rates and previous work has provided conflicting

results (Martin, 1970, Oldenzien and Brink, 1974). Loveless (1994) suggested that vertical wave induced pressure gradients were particularly important during toe scour and Conley and Inman (1992) suggested that bed ventilation could be an important aspect in scale modelling. Seepage within the beach may also be an important feature in both long term beach morphology (Turner, 1995) and short term (storm duration) beach evolution. This effect is highlighted by the performance of coastal drainage systems (e.g Vesterby, 1996; Sato et al, 1994). Nevertheless, the mechanism by which the watertable influences the beach dynamics is not immediately apparent. Sato et al (1994) suggest that the drain reduces offshore flows such as the undertow, in addition to increasing percolation into the upper beach, while Vesterby (1996) suggests that an increase in the beach stability and a reduction in wave induced liquefaction are the dominant factors. However, numerical calculations by Oh and Dean (1994) indicated that the pressure gradients induced by changes in the watertable within a beach were generally far too small to influence sediment stability.

Therefore, although the pressures within sediments have been measured by a number of authors (e.g. Sleath, 1970; Yamamoto et al, 1978), measurements of the pressure gradients will enhance the understanding of both sediment transport mechanisms and beach dynamics. The present study addresses this point and outlines the development of a flexible non-intrusive measurement technique. The method allows the pressure gradients at any position within the fluid or sediment bed to be determined quickly and easily, with minimum disturbance of the local flow field. The technique may also be used close to or under structures such as breakwaters, where it may be difficult to obtain results from conventional pressure transducers.

2) MEASUREMENT TECHNIQUE

Conventional pressure transducers have a number of disadvantages when attempting to measure pressure gradients. Firstly, they are relatively large and therefore when mounted close together may significantly disturb the local flow field. Secondly, a large number of transducers are needed to measure the pressure gradients at a number of points without repeatedly disturbing a sediment bed. Finally, the measurement position must be chosen *a priori* and cannot be changed readily. This is a significant drawback when measuring the pressure gradients within model beaches which evolve over time. For example, in order to measure the pressure gradients over either a bar, or at the toe of a beach, it would first be necessary to run a model test to predetermine the measurement positions.

The aim of the present study is to overcome these limitations and develop a measurement method that is as flexible as possible. The technique has been developed from a method used previously to investigate static pressures within

model sand embankments. However, the method has not previously been used to measure either dynamic pressures or pressure gradients. The underlying principle is similar to that proposed by Nielsen et al (1994) and has also been used in medicine to measure blood and lumbar pressures (Kumar et al, 1993).

The pressures within the fluid or sediment are measured by means of a series of 2mm ID steel probes. Each probe is connected to a 0.1 Bar pressure transducer via a three way ball valve and short length of 3mm ID semi-rigid nylon tubing (figure 1). Air may be flushed from the tubing and probe by opening the valve to a small header reservoir mounted above the transducer/valve system. The pressure variation is transmitted into each probe through 12 0.4mm diameter holes drilled into the tip. In order to measure the pressure gradients, five probes are arranged in an array such that both the vertical and horizontal pressure gradients are obtained at a single point. The probes may be moved vertically within the bed by means of a traverse mechanism, with minimal disturbance of the sediment. The probe holder, pressure transducers and header tank are mounted on a carriage running on rails above the flume, which allows the probes to be positioned at any position within the sediment bed.

Figure 1. Pressure measurement system.

The static pressure recorded by the probes is the elevation head between the pressure transducers and the mean or still water level. This is generally negative and a variable offset was therefore added to the pressure transducer amplifiers. The “mean pressure” may therefore be set to zero, allowing amplification to be used

when sampling the dynamic pressure. This increases the accuracy of the measurements, since the amplitude of the dynamic pressure may be considerably smaller than the static pressure in many practical circumstances. Note that moving the probes vertically does not change the recorded static pressure and that the probes do not measure a velocity head.

3) EVALUATION / CALIBRATION

For the purpose of measuring mean or steady pressure gradients the probe technique requires no calibration. However, for the purpose of measuring dynamic pressure gradients the dynamic response of the measurement system requires evaluation. The dynamic response depends on the length of the probe and tubing, the geometry of the valve/transducer connection and the speed of the pressure pulse. In order to achieve a satisfactory dynamic response the natural frequency of the system must be as high as possible. If it is assumed that the system behaves as a quarter length resonator (Nielsen et al, 1993) then the natural frequency, f_o , is given by

$$f_o = c / 4L \quad (1)$$

where c is the speed of the pressure pulse and L the length of the probe and tubing. L is consequently kept as small as possible (<1m), while the speed of the pulse should be maximised. The pressure pulse is a one-dimensional wave, whose speed is dependent on the fluid density, ρ , the compressibility of the fluid, C , and the distensibility of the tubing, D (Lighthill, 1978).

$$c = \frac{1}{\sqrt{(\rho(C + D))}} \quad (2)$$

The distensibility of the tubing is given by

$$D = 2a / tE \quad (3)$$

where a is the tube radius, t is the wall thickness and E is the Young's modulus of the tube material ($O \sim 10^9$ N/m²). In the present instance D is of order 10^{-9} m²/N and the compressibility of pure water is approximately $5 \cdot 10^{-10}$ m²/N, giving $c \approx 800$ m/s. However, the presence of small air bubbles within the tube will increase the compressibility of the water significantly. For example, an air content of 0.4% will give a compressibility of $5 \cdot 10^{-8}$ m²/N. Hence, from (2), a few small air bubbles ($O \sim 1$ mm) are sufficient to reduce c to about 150 m/s. This results in a natural frequency of about 35 Hz, far higher than the wave frequencies used in typical laboratory studies (0.5-2 Hz). In order to confirm the estimates above, the speed of

a pressure pulse along a 10m length of tubing was calculated by correlation of this signal with that obtained from a conventional transducer. In this instance the lag along the tube was found to be of order 0.06s, giving a value for c of 150m/s (figure 2). The lag along a 1m length of probe and tubing is therefore less than 0.01s. The difference in lag between probes is inconsequential for the purposes of calculating the pressure gradients (figure 3), although in this figure the ± 0.02 s lag on two of the probes indicates the wave speed.

Figure 2. Correlation of the pressure signal from two probes with that from a conventional transducer. $L=10$ m.

Figure 3. Correlation between the five probes arranged in the measuring array and a conventionally mounted pressure transducer. $L=1$ m.

Regular waves

With a natural frequency of 35Hz, probe/transducer system was expected to have a linear frequency response function and a gain close to 1 over the required

range of wave frequencies. However, some damping is to be expected due to energy losses. In regular wave tests the gain function was evaluated by comparing the amplitude of the signal recorded through the probe/transducer system with that obtained from a conventional transducer. Figure 4 shows the measured response functions for a range of frequencies. In each case the response function is very similar, although some difference is observed in the absolute gain values. This is probably due to slight variations in the concentration of air bubbles in each probe. Therefore, when regular waves are used, each probe is individually calibrated at the beginning of the test session. After calibration, the pressure signal recorded by each probe is very close to that recorded by a conventional pressure transducer (figure 5).

Figure 4. Gain functions measured for each probe/transducer system. $L=1\text{m}$.

Figure 5. Comparison of the dynamic pressure recorded by two probes with that recorded by conventionally mounted pressure transducers. — Transducers, --- probes.

In order to obtain the pressure gradients, the pressure signals from each probe were first low pass filtered at 5Hz and then the gradients calculated with a simple finite difference scheme. The best results were obtained with a probe spacing of 0.06m in the horizontal direction and 0.02m in the vertical direction. The reduced vertical spacing was necessary to obtain the pressure gradients close to the surface of the sediment bed. A comparison of the dynamic horizontal pressure gradient calculated from probe measurements with that from equally spaced conventional transducers clearly shows good agreement (figure 6). Finally, it was necessary to check the performance of the system with all five probes operating and, in particular, to ensure that the phase relationship between the pressure and pressure gradient was accurately reproduced. Figure 7 shows that this was indeed the case.

Figure 6. Comparison of the dynamic horizontal pressure gradient.
 — Transducers, --- Probes.

Figure 7. Pressure and pressure gradients within a sand bed.
 — Pressure, --- Horizontal, — · — Vertical.

Random waves

Two approaches are possible when using the present method to measure the pressure variation induced by random waves. The first is simply to calibrate each probe over the appropriate frequency range using regular waves. However, best results are obtained by calibrating the probes at the outset of a model test by using a random wave series and a spectral method. In this instance the pressure signal recorded by each probe is Fourier transformed and compared to the Fourier transform of a pressure signal recorded by a conventional transducer. An impulse response function may then be calculated for each probe and applied to all subsequent measurements. This approach gives gain functions very similar to those for regular waves shown above. Applying the appropriate impulse response function during subsequent tests then results in close agreement between the dynamic pressure obtained from the probe system and that obtained from a conventional transducer.

4) RESULTS / APPLICATIONS

The flexibility of the present technique has considerable advantages for a wide range of pressure measurements. For example, the minimal flow resistance of the probes makes it possible to measure the pressure and pressure gradients at any point within a fluid flow. This is not possible with conventional transducers, which must generally be mounted flush with a surface in order to minimise turbulence effects. A second advantage of the present method is that data may be obtained at a large number of positions within a sediment bed with a minimum number of pressure transducers. This is because the small diameter of each probe allows the probes to be moved vertically within the sediment with virtually no disturbance of the bed material. The variation in the dynamic pressure over the vertical is therefore easily obtained. For example, figure 8 shows measurements of the maximum dynamic pressure within a sand bed and an anthracite bed under regular waves. Data could be collected at a large number of points with only one pressure transducer and gave good agreement with the solution of Sleath (1970).

Pressure gradients

Figures 9 and 10 show the horizontal and vertical pressure gradients at the face of a vertical breakwater and at the toe of a sloping breakwater respectively. The face of the vertical breakwater is an antinode, and therefore the horizontal pressure gradient is small, while the vertical pressure gradient increases rapidly close to the surface of the sediment bed. The sharp discontinuity in the vertical pressure gradient expected at the fluid/sediment interface is also clearly visible, although the finite spacing of the probe tips is apparent. Nevertheless, data of this sort would be difficult to obtain with conventional transducers. The toe of the

sloping breakwater lies between a node and antinode and therefore, in this instance, the horizontal and vertical pressure gradients are of similar magnitude at the sediment surface. However, the present measurement technique is sufficiently accurate to detect the change in the rate of decay of the horizontal pressure gradient at the fluid/sediment interface. This change occurs because the variation in the horizontal pressure gradient within the fluid approaches zero at the interface, while the rate of decay within the bed is proportional to the thickness of the sediment bed (e.g. Sleath, 1970).

Figure 8. Dynamic pressure within a sand bed and an anthracite bed. □□□□ Sand, $T=0.7s$, ——— Sleath (1970), ◇◇◇◇ Anthracite, $T=0.5s$, — · · — Sleath (1970).

Figure 9. Horizontal and vertical pressure gradients at the face of a vertical porous breakwater. □□□□ Horizontal, ◇◇◇◇ Vertical.

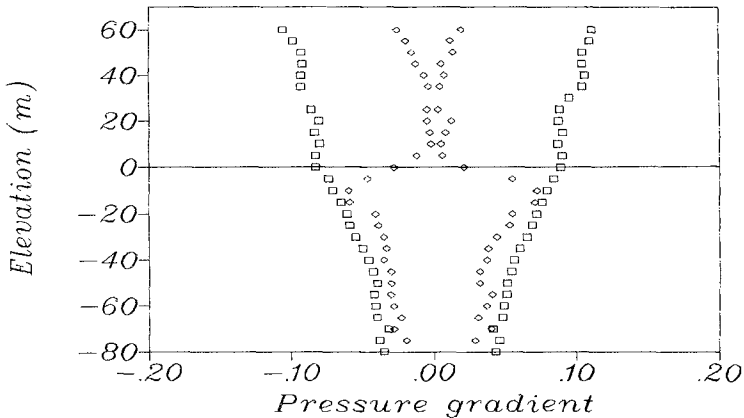

Figure 10. Horizontal and vertical pressure gradients at the toe of a sloping porous breakwater. □□□□ Horizontal, ◇◇◇◇ Vertical.

The pressure gradients within laboratory scale sediment beaches were also investigated with the present measurement technique. The first case considered a coarse sediment beach with a median grain size of 1.5mm and a thickness of 0.1m. Regular waves with a height of 0.1m and wave period of 1.5s were used. Waves were run until the initially plane beach reached a stable shape and the pressure gradients just below the bed surface were then measured at a number of locations across the surf zone. Measurements of this kind would be very difficult to obtain using conventional transducers, which would have to be positioned before the beach attained an equilibrium profile.

Figure 11 shows the mean horizontal pressure gradient increasing across the surf zone due to wave induced set-up and swash zone percolation, reaching a maximum of about 0.1 at the still water level. The vertical pressure gradient has a similar magnitude at this point and is again positive. The flow within the beach is therefore downward and seaward. The vertical pressure gradient reaches a minimum in the middle of the surf zone and, consequently, the flow is out of the beach. However, the mean pressure gradients appear too small to significantly influence the stability of the beach sediment, in general agreement with the numerical calculations of Oh and Dean (1994).

In a second experiment the maximum dynamic pressure gradients were measured across a barred laboratory scale beach. In this instance the beach consisted of sediment with a median grain diameter of 0.5mm and was again 0.1m thick. Regular waves were again run until a stable beach formed and the pressure gradients were measured 20mm below the bed surface in the region of the bar. The data show that both the horizontal and vertical pressure gradients reach a

maximum just seaward of the bar and then decrease rapidly after wave breaking (figure 12).

Figure 11. Mean horizontal and vertical pressure gradients within a laboratory scale sand beach. — Water depth, —□—, horizontal, — ·◇· — vertical.

The maximum horizontal gradient does not reach the value required for liquefaction of a sand bed (Madsen, 1974), but is nearly twice that required to initiate the failure of an anthracite bed. The negative horizontal pressure gradient is much larger than the positive gradient, indicating steep wave fronts, while the reverse is the case for the vertical pressure gradients, indicating steep crests and flatter wave troughs (figure 13).

Figure 12. Maximum horizontal dynamic pressure gradient across a laboratory scale sand beach. — Water depth, —□—, negative, — ·◇· — positive.

Figure 13. Maximum vertical dynamic pressure gradient across a laboratory scale sand beach.

— Water depth, —□—, negative, —◇—, positive.

CONCLUSIONS

The development of a new technique for measuring the pressure gradients within sediments is presented. The pressure gradients are measured using a series of small diameter steel probes connected to pressure transducers with semi-rigid flexible tubing. This allows the pressure gradients to be determined quickly and easily with minimal disturbance of the sediment. For the purpose of measuring mean pressure gradients the method requires no calibration. The dynamic response of the system was evaluated using both regular and irregular waves and was found to be satisfactory for typical laboratory wave frequencies. A comparison of the pressure gradients obtained by the present technique with those measured using conventional pressure transducers showed good agreement. Measurements of the mean and dynamic pressure gradients within laboratory scale sand beaches have demonstrated the advantages of the system. The measurement technique has already proved useful for investigating the role of pressure gradients in sediment transport mechanics (Baldock and Holmes, 1996) and will aid investigations into the flow pattern within laboratory scale beaches.

CHAPTER 323

Analysis of Mud Mass Transport under Waves Using an Empirical Rheological Model

Qin Jiang¹ and Akira Watanabe²

Abstract

This study is focused on deepening our insight into rheological properties of soft mud under oscillatory forces, on quantifying their effects on the interaction between water waves and mud bed, and especially on the resultant mud mass transport. On the basis of a large number of experiments, an empirical rheological model and formulas for model parameters are proposed. In addition, a simple analytical model for evaluating the temporal change in mud water content ratio under waves is derived. Using these two models, a vertical 2-D numerical model is developed to predict the wave-induced bed mud motion and the resultant mud mass transport velocity. Comparisons between the calculations and measurements are presented.

1. Introduction

Mass transport in a soft mud layer is one of the noteworthy phenomena in a mud bed. Studies on it are of practical importance for both siltation and environmental problems in muddy coasts and estuarine areas.

Variety of theories and models have been proposed to describe the wave-mud interaction and relevant phenomena. The theoretical analysis was initiated by Gade (1958), who assumed that the soft mud would behave as a highly viscous fluid and developed an analytical model for the surface wave attenuation in shallow waters. On the same assumption, Dalrymple and Liu (1978) presented a linear theory for water waves propagating in a two-layer viscous fluid system. Instead of viscous fluid assumption, elastic models were proposed by Mallard and Dalrymple (1977) and Dawson (1978), poro-elastic models by Yamamoto

¹Research Engineer, Penta-Ocean Institute of Technology, 1534-1, Yonku-cho, Nishinasunomachi, Nasu-gun, Tochigi, 329-27, Japan

²Professor, Department of Civil Engineering, University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo, 113, Japan

et al. (1983, 1987) and Yamamoto and Takahashi (1984), visco-elastic models by Hsiao and Shemdin (1980), Macpherson (1980) and Maa and Mehta (1988, 1990), as well as a Bingham fluid model by Mei and Liu (1987). Recent studies include visco-elasto-plastic models by An *et al.* (1991) and Shibayama and Nguyen (1993).

A primary difference among the above models is in the assumptions of rheological properties of mud. Due to the complexity of the mud properties, it is difficult to judge which of them is most applicable to the wave-mud interaction problems under a certain condition. In addition, many of these models have been proposed either without enough experimental proofs or on the basis of experiments with unidirectional rotary viscometers in which the mud motion is considerably different from the real situation in coastal waters.

On the other hand, Hyunh *et al.* (1990) developed a dynamic rotary shear meter and studied the rheological behaviors of mud under various patterns of loading. Their experiments showed that there existed complicated relationships between the shear stress and shear strain or shear rate when the soft mud was subjected to cyclic loading. Following them, Shen *et al.* (1993) conducted similar experiments and proposed empirical models for the rheological properties and for the mud-wave interaction. However, their experiments only under limited conditions are not sufficient to understand and model the general features of mud behaviors under dynamic wave action.

The present study aims at gaining further understanding on the rheological properties of soft mud under the action of oscillatory forces and the interaction between water waves and a mud bed. An empirical rheological model of soft mud under oscillatory loading will be proposed on the basis of large numbers of measurements. Moreover, a simple analytical model for change in the water content ratio under wave action is derived in order to evaluate its effects on the rheological behaviors and on the motion of bed mud. By incorporating the proposed rheological model as well as the water content ratio model with the linearized Navier-Stokes equations, a vertical 2-D numerical model is constituted for simulating wave-mud interaction and the bed mud motion. Finally, calculated mud mass transport velocities and wave height changes are compared with those measured.

2. Rheological Properties of mud

2.1 Experiments and results

In order to clarify the rheological properties of soft mud under waves, laboratory experiments were conducted for more than 800 runs by using a dynamic rotary shear viscometer that can generate oscillatory forcing like waves (See Hyunh, 1991, for details of the setup). Instead of real seabed mud, pure kaolinite mixed with tap water was used for the test. This is because it has rheological properties similar to and less complicated than those of natural mud in actual coastal areas.

A wide range of conditions was covered in the test, in which the water content

ratio was changed from 120% to 300%, the period of cyclic loading was from 1s to 10s, and its angular amplitude was from 0.5° to 28° . With a series of combinations of the motion of the viscometer and the water content ratio, the measurements were made to examine influences of the angular amplitude and period of the oscillatory shear forces as well as the water content ratio on the rheological behaviors of the mud.

Figures 1 (a) and 1 (b) are the experimental results showing the effects of the angular amplitude A of cyclic forcing, which were obtained under the fixed period T and water content ratio W . Examples indicating the effects of the cyclic loading period and water content ratio are given in Figs. 2 (a) through 3 (b).

Fig. 1 (a) Shear stress vs. shear strain (effects of the angular amplitude).

Fig. 1 (b) Shear stress vs. shear rate (effects of the angular amplitude).

From these figures, it can be concluded that under the oscillatory action of external forces, the soft mud is characterized by very complicated visco-elasto-plastic properties. The shear stress of the mud is a function of both the shear strain and shear rate with strong nonlinearity featured by remarkable hysteresis in their relationships. In addition, the mud properties are significantly influenced by the water content ratio as well as by the period and amplitude of cyclic loading.

2.2 Constitution equation

On the basis of the above experimental results, a constitution equation of the soft mud is constructed for describing its rheological properties under cyclic loading.

Figures 4 (a) through 4 (g) illustrate a basic concept for constructing the constitution equation. Among these figures, Fig. 4 (a) stands for the hysteresis loop of the shear stress τ versus the shear rate $\dot{\gamma}$. It is obvious that this loop can be separated into two parts, namely, a backbone curve shown in Fig. 4 (b) and a

Fig. 2 (a) Shear stress vs. shear strain (effects of the cyclic load period).

Fig. 2 (b) Shear stress vs. shear rate (effects of the cyclic load period).

Fig. 3 (a) Shear stress vs. shear strain (effects of the water content).

Fig. 3 (b) Shear stress vs. shear rate (effects of the water content).

compensatory curve in Fig. 4 (c). On the other hand, regarding the relationship between the shear stress τ and the shear strain ε shown in Fig. 4 (d), the curves in Fig. 4 (e) and Fig. 4 (f) correspond to Fig. 4 (b) and Fig. 4 (c), respectively, because of the 90° phase lag between the shear strain and shear rate. Namely, combining Fig. 4 (e) and Fig. 4 (f), we obtain Fig. 4 (d) that represents the hysteresis loop of the shear stress versus the shear strain, and Fig. 4 (f) gives the backbone curve for the loop in Fig. 4 (d).

Fig. 4 Definition sketch for the constitution equation.

The concept mentioned above suggests us that if these two backbone curves of the hysteresis loops, Fig. 4 (b) and Fig. 4 (f), are properly determined, the shear stress in mud under waves can be easily obtained through their linear superposition. The constitution equation for the soft mud under the cyclic loading or wave action is thereby written as

$$\tau = \frac{G_0 \varepsilon}{1 - \alpha |\varepsilon|} + \frac{\mu_0 \gamma}{1 + \beta |\gamma|} \quad (1)$$

in which G_0 is the initial shear modulus at $\varepsilon = 0$, μ_0 is the initial viscosity at $\gamma = 0$, and α and β are coefficients determining the shapes of the backbone curves. The applicability of the above proposed model is strongly dependent on these four model parameters. With regression analyses, empirical formulas for them are obtained as follows:

$$\begin{aligned}
 \alpha &= \{1.0 - (0.8 - 5.0 \times 10^{-3} \cdot T) \\
 &\quad \cdot \exp(-[0.75 \cdot \tanh(T/4)] \cdot \varepsilon_{\max})\} / \varepsilon_{\max} \\
 \beta &= (0.45 + 0.11 \cdot T + 0.015 \cdot T^2) \\
 &\quad \cdot \varepsilon_{\max}^{(1.05 - 1.42 \cdot T^{0.2})} \\
 G_0 &= (5.6 \times 10^5 \cdot W^{-2.8}) \\
 &\quad \cdot \{[-7.26 - 560 \cdot (1.0 + \tanh(-0.58 \cdot T))] \\
 &\quad + [81.70 + 707 \cdot (1.0 + \tanh(-0.47 \cdot T))] \\
 &\quad \cdot \alpha^{1.71/[1 + 9.87 \exp(-0.87 \cdot T)]}\} \\
 \mu_0 &= (5.6 \times 10^5 \cdot W^{-2.8}) \cdot \{37.5 \cdot (1.31^T)\} \\
 &\quad \cdot \ln[24.7 \exp(-0.31 \cdot T \cdot \beta + 1.0)]
 \end{aligned}
 \tag{2}$$

where $T(s)$ is the period of the cyclic loading, ε_{\max} ($0.5 \leq \varepsilon_{\max} \leq 4.0$) is the shear strain amplitude, and $W(\%)$ is the water content ratio of the mud. (Here, for convenience, the angular amplitude of cyclic shear load was replaced by the amplitude of shear strain).

Equations (1) and (2) form a thorough rheological model for the soft mud. Their validity was well confirmed both qualitatively and quantitatively through trial hindcasting of experimental data. Examples of the calculated results are shown in Figs. 5, which corresponds to the measurements shown in Fig. 1 in the previous section.

Fig. 5 (a) Shear stress vs. shear strain (effects of the angular amplitude).

Fig. 5 (b) Shear stress vs. shear rate (effects of the angular amplitude).

3. Water Content Changes in Bed Mud under Waves

The water content ratio is an important factor affecting the rheological properties of the mud. Recent studies revealed that the dynamic change in the water content ratio takes place in a mud bed as a result of wave action. The results of experiments by Shen *et al.* (1993) showed that both the mud self-weight and water waves play significant roles in the variations of water content ratio in mud layers. As compared with the solo consolidation under the self-weight, the wave action causes further complicated change in the water content ratio, including the densification in deeper lower layers of the mud bed and liquefaction or swelling in the near-surface layers. On the basis of these experimental results, a simple analytical model is developed for evaluating the temporal change in water content ratio in bottom mud layers under waves.

3.1 Mechanism of Mud Densification and Liquefaction

Figure 6 illustrates an idealized state of stresses in a mud bed under waves. With consideration for the different effects of wave-induced stresses in mud layers, wave action on a mud bed can be classified into two components which are called "pumping" and "shaking". The pumping means the process of compression and expansion in a mud bed due to the dynamic wave pressure, while shaking refers to the tangential action by the oscillatory bottom shear stresses and the gradient of dynamic pressure in the wave propagation direction.

Fig. 6 Idealized stress state in mud bed under waves.

The downward transmission of the pumping and shaking action through the overlying water results in complicated processes in mud layers such as the oscillatory motion of the bed mud, the erosion or settlement of mud particles, and the change of the mud bed structure. Therefore, the water content changes in a

mud bed is regarded as the combined results of the pumping and shaking due to waves.

(a) Densification by the Pumping Action of Waves

It is said and often assumed that the effective stress in the underwater deposits remains unchanged even if the water level varies. However, it is not always true under wave action. According to Zen *et al.* (1993), the excess pore pressure and effective stress will be induced whenever the water surface elevation changes so quickly that the associated water pressure on the interface cannot be entirely transmitted into the deposits as the pore pressure. From this fact, the densification of the mud layers can be regarded as the result of the pumping action due to waves.

In this way the pumping action of waves may generally cause oscillatory change of the normal stress in a mud bed. As a result, the excess pore pressure and effective stresses may vary oscillatorily, and the bed mud is thus forced to condense and expand alternatively responding to the up-and-down motion of the water surface. During every wave period, a process of dewatering or densification may occur since the volume compression rate of the mud is bigger than its expansion rate. The cyclic pumping action of waves will thus induce the densification of the bed mud.

(b) Liquefaction Due to the Shaking Action of Waves

A well-known fact as for noncohesive sediment is that shear loading causes the increase in gross sediment volume, which is called dilatancy. In fact, dilatancy is a general soil property both for noncohesive and for cohesive sediments. Therefore, like the liquefaction of noncohesive sediment, the increase of water content ratio in near-surface mud layers can be reasonably interpreted as the dilatancy effect under the cyclic wave action.

This phenomenon can also be regarded as a result of the exchange of water and mud particles. Parchure and Mehta, *et al.* (1985) has found that the erosion of cohesive sediment occurs if the shear force exerted on mud beds is large enough and it takes place much more easily under the cyclic action of waves. This is because the contacts between mud particles are weakened and the shear strength of the mud decreases under the action of external forces in particular under that of oscillatory forces like waves. Thus the mud particles are entrained into the water part and the water particles enter into the new-born pores where the mud particles lodged, resulting in the increase of the water content ratio in near-surface mud layers with the growth of erosion in the mud bed.

3.2 Water Content Change Model

On the basis of the above discussions, the water content change in a mud bed under wave action e_{s+w} can be divided into three parts, which are the consolidation by the self-weight e_{cs} as well as the densification e_{dw} and liquefaction e_{lw} due to waves. Accordingly, an analytical one-dimensional model is developed for

evaluating the vertical distribution of water content ratio in mud layers by the linear superposition of the three parts.

Since the mud densification is similar to the soil consolidation and the liquefaction can be treated as its reversal process, all of these processes can be expressed by the conventional consolidation equation.

A general equation for the consolidation of soft mud was given by Gibson *et al.* (1967) as

$$\frac{\partial e}{\partial t} - \frac{\partial e}{\partial z} \left[\frac{k}{\rho_f (1+e)} \frac{d\sigma'}{de} \frac{\partial e}{\partial z} \right] + (\rho_s - \rho_f) \frac{d}{de} \left[\frac{k}{\rho_f (1+e)} \right] \frac{\partial e}{\partial z} = 0 \quad (3)$$

in which e is the void ratio of mud, k is the permeability coefficient, σ' is the effective stress, ρ_f and ρ_s are the densities of the water and mud, and z is the vertical coordinate measured from the rigid bottom elevation. Its linearized form can be written as

$$\frac{\partial e}{\partial t} = C_v \frac{\partial^2 e}{\partial z^2} \quad \text{for } 0 \leq z \leq z_0 \quad \text{and} \quad t \geq 0 \quad (4)$$

where $C_v (= k / [\rho_f (1+e)] (d\sigma'/de))$ is the coefficient of consolidation, t denotes the time, z_0 is the thickness of mud layer at $t = 0$.

For the consolidation due to the self-weight and densification caused by the pumping action of waves, the initial and boundary conditions are given as follows.

- 1) Assuming that the distribution of void ratio e_0 at $t = 0$ is uniform, the initial condition is

$$e(z, 0) = e_0 = \text{const.} \quad (5)$$

- 2) On the mud bed surface, the void ratio remains constant because the effective stress is zero, i.e.,

$$e(z_0, t) = e_0 \quad (6)$$

- 3) At the rigid bottom underlying the mud, the impervious boundary condition is

$$\left(\frac{\partial e}{\partial z} \right)_{z=0} = \beta \quad (7)$$

where β is a constant depending on the void ratio distribution at the ultimate state of consolidation by the self-weight and densification due to waves, and is expressed as

$$\beta = \frac{(\rho_s - \rho_f)}{\lambda} + \frac{p_0}{z_0 \lambda} \quad (8)$$

After simple manipulation, the solution of Eq. (4) for the void ratio is obtained as

$$e(z, t) = e_0 - \frac{\beta}{z_0} \left[1 - \frac{z}{z_0} - 2 \sum_{n=0}^{\infty} \frac{\cos \frac{m\pi z}{z_0}}{m^2 \pi^2} \exp \left(-m^2 \pi^2 \frac{C_v t}{z_0^2} \right) \right] \quad (9)$$

where $m = 2n + 1/2$, $\lambda = d\sigma'/de$, and p_0 is the amplitude of wave induced bottom pressure.

Regarding the fact that the volume change of pore water in a mud bed compensates that of the mud eroded from the bed, the swelling of mud by the shaking action of waves can be derived as

$$\Delta e(z, t) = \Delta e_s \left\{ -\frac{z}{z_0} - \frac{2}{\pi} \sum_{n=1}^{\infty} \left[\frac{\sin \frac{n\pi z}{z_0}}{z_0} \exp \left(\left(\frac{n\pi z_0}{z_0} \right)^2 C_i t \right) \right] \right\} \tag{10}$$

where Δe_s is the change of void ratio on the mud surface expressed as in the above equations, $C_i (= k_i/[\rho_f(1 + e)](d\sigma'/de))$ is the coefficient of expansion, N is the number of discretized points in the mud bed layers, and Δz is the grid length in the z direction. The volume of mud particles entrained from the mud bed, V_E , can be estimated by using an empirical formulas for the erosion rate E of mud particles (Parture and Mehta, 1985) as follows:

$$V_E = \sum_{k=1}^K \left(\frac{E\Delta t}{\gamma_s} \right) = \sum_{k=1}^K \left\{ \frac{E_0\Delta t}{\gamma_s} \exp \left[\alpha (\tau_b - \tau_c)^{0.5} \right] \right\} \tag{11}$$

where Δt is time interval, γ_s is the unit weight of the mud, E_0 is the floc erosion rate ($g/cm^2/s$), α is a model constant, τ_b is the wave-induced shear stress on the mud bed, and τ_c is the shear strength of the mud.

From Eqs. (9) and (10), the change in water content ratio W in the mud bed can be calculated from,

$$W(z, t) = e(z, t) \frac{\gamma_s}{S} \tag{12}$$

in which S is the saturation degree of the mud.

The validity of the above model is examined through comparisons of the computations with the measurements by Shen *et al.* (1993). Figure 7 shows comparisons between the calculations and measurements for the temporal change in water content ratio distributions under the conditions listed in Table 1. A good agreement is seen through the overall depth for each time step except for little discrepancy near the rigid bottom, where accurate measurement is generally difficult. Hence it is concluded that if values of the model parameters are properly determined for a mud material of interest, this model can be used to evaluate the temporal change in water content ratio distributions under waves with an acceptable accuracy.

Table 1 Computation conditions.

W_0 (%)	$k/[\rho_f(1 + e)]$ (m^4/kgs)	$k_i/[\rho_f(1 + e)]$ (m^4/kgs)	$\lambda = d\sigma'/de$ (kg/m^2)	T (s)	H_0 (cm)

4. Numerical Model of Mud Motion

4.1 Model Equations

A vertical two-dimensional numerical model for the interaction between waves and a mud bed is developed by incorporating the proposed rheological model and the water content ratio model with the Navier-Stokes equations.

On the assumption that the convective acceleration is not significant, the linearized momentum equations and the continuity equation for the incompressible soft mud layer under waves are

$$\rho_m \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} + \frac{\partial \tau_{zx}}{\partial z} \tag{13}$$

$$\rho_m \frac{\partial w}{\partial t} = -\frac{\partial p}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} \tag{14}$$

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \tag{15}$$

in which p is the dynamic pressure, u and w are the velocity components in the horizontal x and vertical z directions, ρ_m the mud density, and τ_{xz} and τ_{zx} are the shear stresses which can be obtained by the proposed rheological model Eqs. (1) and (2).

Equations (13) through (15) give a closed set of governing equations for u , w and p . With the non-slip condition ($u_n = w_n = 0$) at the fixed bottom under the mud layers, the zero shear stresses ($\tau_{xz0} = \tau_{zx0} = 0$) and pressure continuity conditions on the mud surface, and the periodic lateral boundary conditions, this

equation system can be solved numerically, for instance, by using the SIMPLEC algorithm.

The coefficient of wave damping along the wave propagating direction, D_H , can be estimated as

$$D_H = -\frac{1}{H} \frac{dH}{dx} = \frac{1}{2EC_g L} \int_x^{x+L} \int_0^d \tau \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) dz dx \quad (16)$$

The mass transport velocity of mud, U , is given as the summation of the Stokes drift U_S and the mean Eulerian velocity U_E , which are

$$U_S = \overline{\frac{\partial u}{\partial x} \int_0^t u dt'} + \overline{\frac{\partial u}{\partial z} \int_0^t w dt'} \quad (17)$$

$$\mu' \frac{\partial^2 U_E}{\partial z^2} = \overline{\frac{\partial \rho_m u^2}{\partial x}} + \overline{\frac{\partial \rho_m u w}{\partial z}} \quad (18)$$

where μ' is the mean viscosity averaged over one wave period,

$$\mu' = \frac{1}{T} \int_t^{t+T} \frac{\partial \tau}{\partial z} dt = \frac{1}{T} \int_t^{t+T} \frac{\mu_0}{(1 + \beta |\gamma|)^2} dt \quad (19)$$

4.2 Comparisons with Results of Experiment

In order to verify the above-described numerical model, results of calculations are compared with those of experiments by Sakakiyama and Bijker (1989). Figures 8 and 9 give examples of the comparisons with respect to the wave height distribution and the vertical profile of mud mass transport velocity. Agreement is very good for the mass transport velocity distribution, while the wave damping is slightly underestimated by the present model.

To examine the effect of water content ratio on the motion of bed mud, the change of the mud mass transport velocity in response to the temporal change in water content ratio is evaluated as an example. Figure 10 is the predicted mass transport velocity that corresponds to the evolution of water content ratio shown in Fig. 11. It can be seen in these figures that the temporal change in the water content ratio naturally has effect on the mud mass transport but it is not very significant as far as under the conditions in this example.

5. Conclusions

The soft mud is characterized by the very complicated visco-elasto-plastic properties in response to the cyclic action of external forces. In addition, the mud properties are significantly influenced by the water content ratio as well as the period and amplitude of cyclic loading. The proposed empirical rheological model can be regarded more general than most of previous ones, although the formulas for the model parameters may not be directly applicable to actual coastal mud. The temporal change in the mud water content ratio under waves has also been studied and formulated as a simple analytical model. By incorporating these

Fig. 8 Comparison between calculated and measured wave damping.

Fig. 9 Calculated and measured mud mass transport velocity.

Fig. 10 Temporal changes of mud water content ratio under waves.

Fig. 11 Evolution of mud mass transport velocity under waves.

models with the Navier-Stokes equations, a vertical two-dimensional numerical model has been constituted to simulate the interaction of waves and mud. It has been verified that the proposed models can reproduce satisfactorily the rheological properties of mud, the temporal change in the water content ratio as well as the mud mass transport velocity under waves.

Acknowledgment

The authors would like to thank Prof. Masahiko Isobe, Department of Civil Engineering, University of Tokyo, for his valuable discussions throughout this study.

CHAPTER 324

COUNTERMEASURES AGAINST WIND-BLOWN SAND ON BEACHES

--- A short summary of the present state-of-the-arts and introduction of new methods ---

Shintaro Hotta*
and
Kiyoshi Horikawa**

Abstract

Characteristics and functionings of prevention works for wind-blown sand are briefly reviewed and discussed. Then, guidelines for their use are given. In addition, new prevention works, including trench, movable porous sand fence, and large-scale sand ripples, are proposed according to the result of recent research.

I. Introduction

One of the important problems in beach stabilization is how to control wind-blown sand. Typical problems concerning blown sand are preservation and promotion of the growth of dunes, prevention of channels, inlet and river mouth closure, protection of residential and cultivated land from contamination by sand, and so on. Many kinds of works for preventing blown sand have been employed all over the world. However, no general criteria or technical standards for the use of prevention works exist at present. Therefore, the main objectives of this study are to summarize the operational characteristics of prevention works for wind-blown sand and to provide specific guidelines for their use.

Attempts are made (1) to systematize and classify prevention works for wind-blown sand according to their functioning, and (2) to evaluate conventional prevention works. In addition, (3) new prevention works are proposed according to studies recently carried out.

II. Functioning and Classification of Prevention Works for Wind-Blown Sand

Prevention works for wind-blown sand might have the following two functions: one is to restrain and stop the generation of blown sand, and the other is to trap the blown sand at the upwind side and to store the blown sand at a given location so that it is not transported further downwind. Hereafter, in short for later convenience, the former function will be known as a restrain function and the latter

* Shintaro Hotta, Dr., Prof. of Dept. of Construction Engrg. Nihon University, Narashino-dai 7-24-1, Funabashi, Chiba Pref., 274, Japan.

** Kiyoshi Horikawa, Dr., Prof. Emeritus of the University of Tokyo and President of Saitama University, Shimo-Okubo, Urawa, Saitama Pref., 255, Japan

function as a trap and fixation function. If a prevention work has a perfect restrain function and can fully stop the generation of blown sand, the work does not need the trap and fixation function. However, it is usually difficult to perfectly stop the generation of blown sand by using a certain prevention work which has the restrain function. It may be expensive or it may prevent an effective use of the beach if we intend to completely stop the generation of blown sand. In such cases, it may be recommendable from an engineering point of view to employ a prevention work which has the trap and fixation function at the downwind site while it may permit the generation of blown sand by decreasing the restrain function, which could be done through changing the kind of prevention work used or downsizing the scale of the prevention work.

The restrain function can be provided by the following methods. One method is to increase the resistance force to the wind which acts on the sand surface and sets sand grains on the surface into motion as blown sand. Another method is to decrease the wind speed that acts near the sand surface to a level so that the sand grains can not begin to move. Examples of methods for increasing the resistance force of the sand surface are spraying water (fresh or salt) or coagulant on the surface and replacement of surface sand. To decrease the wind speed (or the shear stress) that acts on the sand surface, methods to be considered are placing fences, planting shrubs or trees, and covering by grass, nets or mats in order to shut off the wind from direct action on the sand surface.

Two cases are considered for the trap and fixation function. The first case is the forced trap and fixation function that traps coercively blown sand in the air without changing of the basic motion of the sand grains and brings them to rest. The second case involves trapping or bringing to rest the blown sand grains by means of decreasing the wind speed. Cases that catch blown sand grains with streamer-type traps or adhere blown sand grains to a plate coated by an adhesive are considered as cases where the forced trap and fixation function acts. However, it is not possible to trap and store a large amounts of sand by these methods. Thus, these methods can not be employed for engineering use. Another case is where blown sand grains strike a fence stretched by a net with a small mesh and with a high porosity, where the porosity is defined as the ratio of open space area to total projected area, drop and come to rest at the foot of the fence. In this case, we may think of the fence as having the forced trap and fixation function because the fence does not disturb the wind flow and the motion of the sand grains in the air significantly. Such a fence can be applicable for engineering use since the fence can be constructed easily. A trench (which will be described in Section IV) several meters wide and deeper than 1 m can trap almost all blown sand (nearly 100 % of the total amount) without disturbing the wind field (Horikawa *et al.*, 1984). The trench stops coercively the motion of sand grains in the surface creep and saltation at the upwind tip of the trench. Therefore, we may regard the trench as having the forced trap and fixation function. However, inside the trench the wind speed becomes low and sand grains dropped into the trench come to rest. Thus, the trench also has the function of trapping sand by reducing the wind speed.

Prevention works which have the trapping function by reducing the wind speed are fences, foredunes (artificial embankments), planting shrubs, conservation forests for wind-blown sand, artificial large-scale sand ripples, and movable porous fences.

An attempt to systematize and classify the prevention works according to their functioning is given in Fig. 1. In Fig. 1, the prevention works involving trenches, artificial large-scale sand ripples, and movable porous fences are those proposed by the present authors for future use, and they are described in more detail in Section IV.

The prevention works normally employed have both the functions of restrain and of trap and fixation, although some prevention works only have either the function of restrain or trap and fixation. Therefore, the fundamental rule for employment of prevention works is to use more than one type of works, considering the conditions for the generation of blown sand and the general purpose of the works, aiming for the works to perform both functions as effectively as possible.

Functioning and Classification of Prevention Works for Wind-Blown Sand

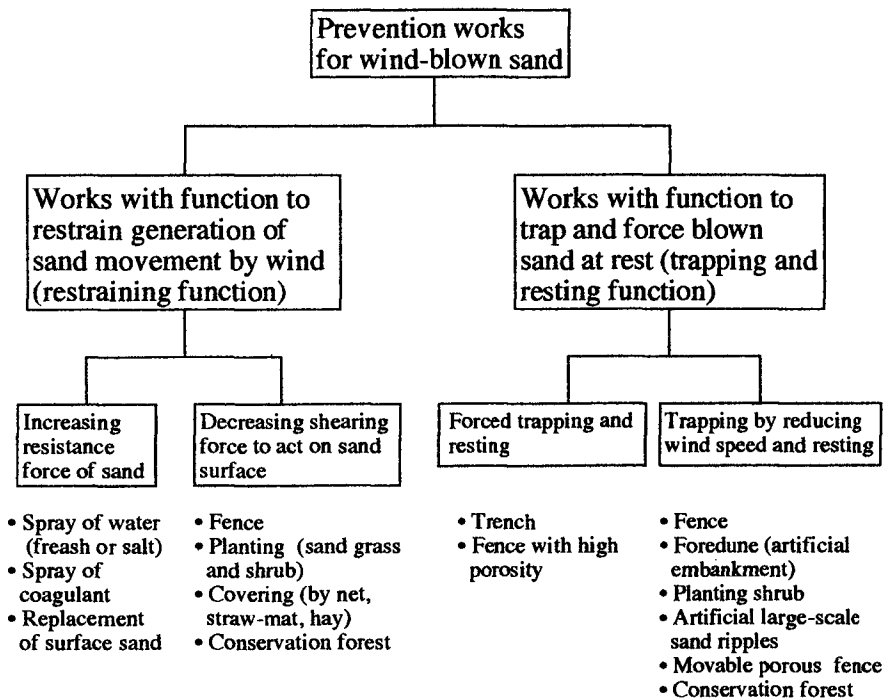

Fig. 1 Functioning and classification of prevention works for wind-blown sand.

III. A Brief Summary of Operational Characteristics and Guidelines for Use of Prevention Works

The prevention works commonly employed worldwide are sand fences, foredunes (including artificial embankment quickly constructed by earthmoving machines), vegetation (planting sand grass or shrubs), and coastal conservation forests. The characteristics and guidelines for practical use of these prevention works are briefly summarized in the following sections.

III.1 Sand Fence

The sand fence is the most commonly employed prevention work throughout the world. Many types of sand fences of varying shape and materials have been designed and employed adapting to the local conditions. The characteristics and guidelines for practical use of sand fences are relatively well understood. Hotta, Kraus and Horikawa (1987) made a critical review of the literature about single row sand fences. They summarized its characteristics and gave guidelines for practical use.

In the guidelines they gave it is recommended to use fence with material of wooden plate, fern, reed, brush, and bamboo which rapidly decompose, expecting that the sand fence will be left in the accumulated sand after the fence is buried. However, if the sand fence is used as a collecting device to interrupt the blown sand intruding into residential area or cultivated land, and if it is planned to remove the accumulated sand for long-term use, it is recommended to use long-life fabrics or metal as the fence material.

For multi-row sand fences, Hotta, Kraus, and Horikawa (1991) also gave a review that concerned the forming of foredunes. Studies regarding multi-row sand fences are limited and many of these studies are not explaining the functioning well. Hotta *et al.* (1992) found important facts about two-row sand fences by means of a wind-tunnel study. The experiment showed that the fence placed downwind would not function to collect blown sand until the fence placed upwind was buried and lost its collecting ability when two-row fences were placed at intervals shorter than $10H$, where H is the height of the fence. This means that two-row fences have no advantage when it comes to collecting blown sand. However, experiments carried out by Manohar and Braun (1970) showed that multi-row sand fences were effective when the wind was strong. Further studies are needed to understand the characteristics of multi-row sand fences and this should be done in the near future.

III.2 Foredune (artificial embankment)

In order to control blown sand, formation of a dune by means of repeated employment of sand fences has been carried out for a long time. The dune formed is usually called a foredune. However, at present formation of a dune is often carried out quickly by using earthmoving machines, and vegetation work is used on the dune surface. A dune formed artificially by construction machines is normally called an artificial embankment.

It is often assumed that the function of a foredune or artificial embankment is almost the same as a non-permeable solid fence. But, the dune has a certain crown width and slopes on both the upwind and downwind sides. Thus, the foredune

probably has a somewhat different function from the non-permeable fence. Figure 2 shows a schematic illustration of the wind flow field and sand accumulation characteristics around an artificial embankment. The wind speed profile begins to distort at a location A affected by the existing embankment. A domain where the wind speed is reduced is formed at the foot of the embankment (around a location B). However, at the upper part of the front slope, the wind will accelerate and the wind speed at the front shoulder of embankment C becomes around 1.2 - 1.8 times of that if no embankment exists. A large circulation cell is formed downwind of the embankment. The wind profile will recover at a location F because of energy supplied from the upper layer. A foredune can catch and store a large amount of blown sand in the wind-reduced domain at the foot, if the foredune is sufficiently high. However, sand is transported beyond the foredune when the wind-reduced domain is filled up by the trapped sand and the storage capacity is lost.

Fig. 2 Schematic illustration of the flow field around an embankment.

There is also a possibility that sand is transported beyond the foredune when the surface of the front slope is bare or paved with some hard material. This can be explained by considering the sand grain motion. A large portion of the sand is transported in a mode of saltation. The sand grains which fall on the hard slope surface can rebound easily and continue the saltation motion. During their stay in the air, sand grains in saltation are accelerated by the wind, and the possibility for the motion to continue increases. Then, sand grains may eventually reach to the top of the foredune. When the surface of the front slope is vegetated by grass or shrubs, the vegetated surface can stop the motion of sand grains and store the grains in the space of the vegetation body. The foredune (or artificial embankment) can control the blown sand as long as the foredune does not lose its storage capacity at the foot and the vegetation on the front slope surface is not buried. Studies concerned with the function of the foredune or embankment for controlling blown sand are limited. Figure 3 shows an example of equi-ratio curves of wind speed reduction in front of an embankment from an experiment by Hotta and Horikawa (1990a). Figure 4 shows the sand accumulation process in front of an embankment under the wind condition corresponding to Fig. 3 (Hotta and Horikawa, 1990b). Note that the scales in the vertical and horizontal directions are not the same in Figs. 3 and 4 and that the figures are distorted.

Fig. 3 Equi-ratios curves of wind speed reduction in front of an embankment. (After Hotta and Horikawa, 1990a)

Fig. 4 The sand accumulation process in front of an embankment. (After Hotta and Horikawa, 1990b)

III.3 Vegetation Work

Vegetation is one of the most popular prevention works for controlling blown sand and it has been employed all over the world from early times. Vegetation work has both restrain and trap and fixation functions. Plants (sand grass and shrubs) that cover the sand surface can restrain the generation of blown sand by preventing the wind from acting directly on the surface, and can also trap and fix the blown sand with decreasing wind speed. We can expect a considerable storage capacity for shrubs but not so much for sand grass. The fundamental property required for plants employed in vegetation work is that the rate of growth must be bigger than that of sand accumulation. We can no longer expect any ability for controlling blown sand when plants are buried. There are many previous examples of vegetation works used in the field. The works sometimes succeeded but they occasionally

failed. The circumstances surrounding plant growth involve many factors such as weather condition, bed material, and character of plants. No guidelines for engineering use exist at present. The most suitable plants for selection may be the ones that grow at the site under consideration.

III.4 Coastal Conservation Forest

On many beaches a coastal conservation forest is often planted for several purposes. One of the most important purposes of a conservation forest is to control the wind-blown sand. We can regard the conservation forest as an aggregate of porous fences. Therefore, the function of a conservation forest is almost the same as a porous fence. However, the domain where the wind is reduced is much larger for a conservation forest than for porous fence, since the trees composing the conservation forest are considerably higher than a porous fence, and the forest has a certain width. The boundary towards the beach-end at the seaside edge of the forest is a battle field where the trees fight back against the penetration of blown sand. Therefore, to keep the primary function that a conservation forest should control blown sand, the trees planted at the seaside boundary must grow up above the thickness of the accumulating sand layer occurring during strong winds. Growth of trees is usually slow and trees at the seaside boundary are always exposed to the risk of withering due to the attack of the strong wind, blown sand, and salt transported from the sea. Therefore, it is not wise to only use conservation forests for controlling blown sand. In general, sand fences or a foredune will be placed to prevent the withering of the trees. Then, we may as well consider that a conservation forest provides protection in emergency situations.

Trap and fixation function of a conservation forest depends on the height of the trees, planting distance, kind of tree, and width of forest. To control blown sand satisfactorily, a width of the forest of more than 100 m is required.

III.5 Other Prevention Works

It is a technique commonly employed to spray water on the ground surface to reduce the dust generation when the surface becomes dry and dusty during windy days. Spraying water increases the resistance force against the wind, and suppresses the generation of blown sand, or decreases the amount of sand transported. However, in our review, we could not find any examples where spraying water was employed for controlling wind-blown sand, although we found an example where fresh water was sprayed or showered by sprinkler or portable shower vehicles for washing down salt adhered to leaves of pine trees growing in a conservation forest. Taking care of conservation forests by showering fresh water will be reported in detail by the same authors in the near future. We could not find any examples where coagulant was sprayed for controlling wind-blown sand, although we found several examples of spraying coagulant containing fertilizer for promoting vegetation work. We suppose that usage of coagulant will not be recommended because it may contaminate beach sand and obstruct a comfortable use of the beach.

Covering work by net, hay, straw-mat, and others have often been employed to restrain wind erosion of the ground surface. However, it is difficult to cover a large area of the ground surface, such as the beach, and it is also expected to be costly. We can not ignore that there is an engineering possibility to cover a whole beach surface by a kind of plastic net for effectively controlling blown sand. But, the

problem has not been studied fully yet. Employment of covering work should be limited to small areas.

IV. New Prevention Works

Based on previous studies carried out by the present authors, we would like to propose the following three new prevention works: trench, movable porous fence, and artificial large-scale sand ripples. These three type of works will be discussed in the following sections.

IV.1 Trench

The idea of a trench in prevention work for wind-blown sand is based on long-term experience and results from our previous studies. Iwagaki(1950) studied the phenomenon of blown sand by using diffusion theory. He predicted that (i) the flying distance of a sand grain in saltation motion was rather short, and that (ii) over 97 % of the sand grains in saltation fell within a range of 5 m from the end of the sand bed when the bed abruptly disappeared like at the shoreline. As a verification of his predictions he pointed out that cultivated land in a sandy beach of Tottori Prefecture where it is facing Japan Sea, was protected from the blown sand by excavating a stream upwind, letting sand grains fall into the stream, and returning the sand to the sea. Considering these results, Horikawa *et al.* (1994) tried to measure the sand transport rate by using a trench which was 1 m deep and several meters wide in the field. The measurements showed that the trench trapped almost 100 % of blown sand transported. Hotta and Horikawa (1993) measured the flying distance of sand grains in saltation using a large wind tunnel. They found that the flying distance for an amount of over 95 % of the blown sand was smaller than 1 m. Using the same technique as Hotta and Horikawa, Shiozawa *et al.* (1993) measured the flying distance of blown sand at a real beach. They found the same result as Hotta and Horikawa (1993). Therefore, the present authors concluded that the trench could be employed as a prevention work for wind-blown sand and propose to use a trench practically in the field. However, it is not clear how many meters of trench width that are suitable. Horikawa *et al.* (1996) carried out a wind tunnel experiment and a numerical experiment to determine the flow field in an open cavity. They found that a width of about 5 or 6 meters would be acceptable when the trench is dug deeper than 1 m. An example of how to use a trench for control of blown sand can be seen in Fig. 7.

IV.2 Movable Porous Fence

This method is based on a simple idea. It is an attempt to erect or place a temporary fence, which is not large and can be movable, on the beach sand surface where the blown sand is generated during the windy season. After the windy season has passed, the fence should be removed to a storage for usage the next windy season. When a strong wind blows, blown sand will be generated even though the sand surface is wet (Hotta *et al.*, 1984). The problem with blown sand is usually most serious when the wind blows from the offshore to the inland. Therefore, the fence should be placed near the inland side of the shoreline where the blown sand is generated, although we have to consider the risk that the fence may be attacked by the runup waves during stormy sea conditions. Figure 5 shows a sketch of a test manufacture of a fence.

Fig. 5 A test manufacture of a movable porous fence.

IV.3 Artificial Large Scale Sand Ripples

This type of works is based on the same idea as the trench; that is, the flying distance of a sand grain in motion is not so long as described in Section IV.1. The work is simple, and the purpose is only to form giant ripples 2 or 3 m high and several meters long, as shown in Fig. 6, on the beach surface by using earthmoving machines such as power shovels or backhoes. The blown sand generated from the crest part of the giant ripple falls into the following trough part downwind. The sand is not transported beyond the next crest until the trough fills up. The blown sand will be generated on the whole beach surface and the sand will be transported into the inland when the trough is buried. We must form the ripples again as soon as the trough is buried. This type of works means that the blown sand generated from a small area is caught in a short distance downwind and brought back to the original place.

Fig. 6 A schematic illustration of artificial large scale sand ripples.

IV Systematical Use of Prevention Works

Figure 7 shows an example of the systematical use of conventional and new prevention works for wind-blown sand. Movable porous fences are placed on the part of the beach neighboring the shoreline where the blown sand is generated. When fences are buried to more than about two-third of their height, the fences must be pulled up. Then, the fences will recover their restrain and trap and fixation functions. A trench traps the blown sand which pass through the fence field. A fence erected at the downwind tip of the trench with a low fence porosity has a tendency to accumulate sand in front of the fence (Hotta and Horikawa, 1990b). Therefore, we can expect that over 90 % of the amount of the total blown sand can be trapped as far as where the fence is erected at the downwind tip of the trench.

We may remove the sand stored in the trench by using earthmoving machines as a power shovels or backhoes. But, we can also remove sand by using sea water, as described in Fig. 7. The sea water is withdrawn from outside the breaker point, flushing the water in the trench, and draining away the sand at the shoreline. Instead of using seawater, we can also use water from the landside, if enough water is available.

A small amount of blown sand in suspension can be transported beyond the fence. Prevention works arranged behind the trench must control the sand that pass. In the wind field around an embankment, a wind-reduced domain is formed at the foot of the embankment. The domain has a possibility to store the blown sand. Shrubs and grass on the slope of an embankment weaken the wind, and catch and store the blown sand.

The crown of the embankment may be used as a bicycle road or walking road. At the seaside shoulder of the embankment the wind accelerates. To moderate the wind, placement of a fence with a median porosity is recommended. The fence height should be lower than 1 m to maintain a good view.

At the landside shoulder of the crown, placement of a relatively high fence is recommended to reduce the wind and to protect the inland. A low porosity fence is recommended for the upper part of this fence.

V. Concluding Remarks

The characteristics of prevention works for wind-blown sand have mainly been studied in the field of agricultural engineering, forestry, geomorphology and coastal engineering. Studies have been carried out both in the wind tunnel and in the field. The results obtained were qualitative and quantitative evaluations of the effectiveness of the prevention works are scarce. The phenomenon is so complicated that theoretical analysis will be difficult. To evaluate the effectiveness of prevention works quantitatively, systematical and well controlled wind tunnel studies or field studies are needed, although numerical experiment based on the detailed description of the fluid dynamics in computers can assist our understanding.

Fig. 7 An example of systematical use of conventional and new prevention works.

CHAPTER 325

Sea breeze Effects on Nearshore Coastal Processes

Charitha Pattiaratchi¹ and Gerhard Masselink²

Abstract

The sea breeze, created by the diurnal solar heating and cooling cycle, is a well known meteorological phenomenon and occurs globally on a regular basis with varying intensity. The impact of the sea breeze system on nearshore coastal processes and sediment budget has received very little attention. In this paper, field data collected from two micro-tidal coastal regions: south-western Australia and Sri Lanka, are presented to illustrate the importance of the sea breeze system in these regions. It is shown that the rapidly changing wave climate, generated by the sea breeze, increases the cross-shore and longshore currents and sediment suspension on the beach. This results in an increase of the longshore sediment flux by up to a factor of 100. The effects of the sea breeze may be present up to 10 hours after the cessation of the sea breeze. The sea breeze system plays a major role in the coastal sediment budget in these regions.

Introduction

On micro-tidal wave dominated beaches, morphological change is primarily induced by variations in the incident wave climate. These variations are usually ascribed to the passage of storms. A neglected source of change to the wave field is the diurnal sea breeze, generated by the differential solar heating of the land and ocean, which could be obscured by the presence of high-wave energy levels or tidal effects. The sea breeze is a dominant feature along tropical and subtropical coastlines and occur along two thirds of the earth's coastlines (Abbs and Physick, 1992; Simpson, 1994). In these areas wind waves generated by the local sea breeze can contribute significantly to the temporal variation in the incident wave climate. In this paper, field studies undertaken in south-western Australia and Sri Lanka are presented to demonstrate the importance of the sea breeze system on the nearshore region and, in particular, the coastal sediment budget.

Data presented in this paper were collected during three field experiments. Two of these experiments were undertaken at City Beach, Western Australia (Figure 1) on 23 January 1992 and 3-9 March 1994. The third experiment was conducted in Ambakandawila, located to the south of Chilaw along the west coast of Sri Lanka (Figure 2). Both sites are located on a relatively straight, north-south oriented shoreline far from any engineering structures and are micro-tidal (tidal range < 0.7 m at spring tides). However, in Western Australia, the tide is diurnal whilst in Sri Lanka the tide is semi-diurnal. The swell waves approach the beach from the south-west at both sites but the direction of the wind (sea breeze) waves differ due to the different direction of the sea breeze. In Western Australia, the sea breeze blows parallel to coastline from the south (an explanation for this effect is given in Pattiaratchi et al., 1997) and thus the sea breeze generated waves approach the beach with a crest of angle 70° (from south-south-west). In Sri Lanka, the sea breeze (in January) blows from north-west and the

sea breeze generated waves also approach from the same quadrant. The occurrence of sea breezes in both of these regions is well known to local residents and fisherman in these regions. In Western Australia, the sea breeze is called the 'Fremantle Doctor' due to cooling effect of the breeze during the summer. In Sri Lanka (in the Chilaw region), the sea breeze is termed Kode by the fisherman.

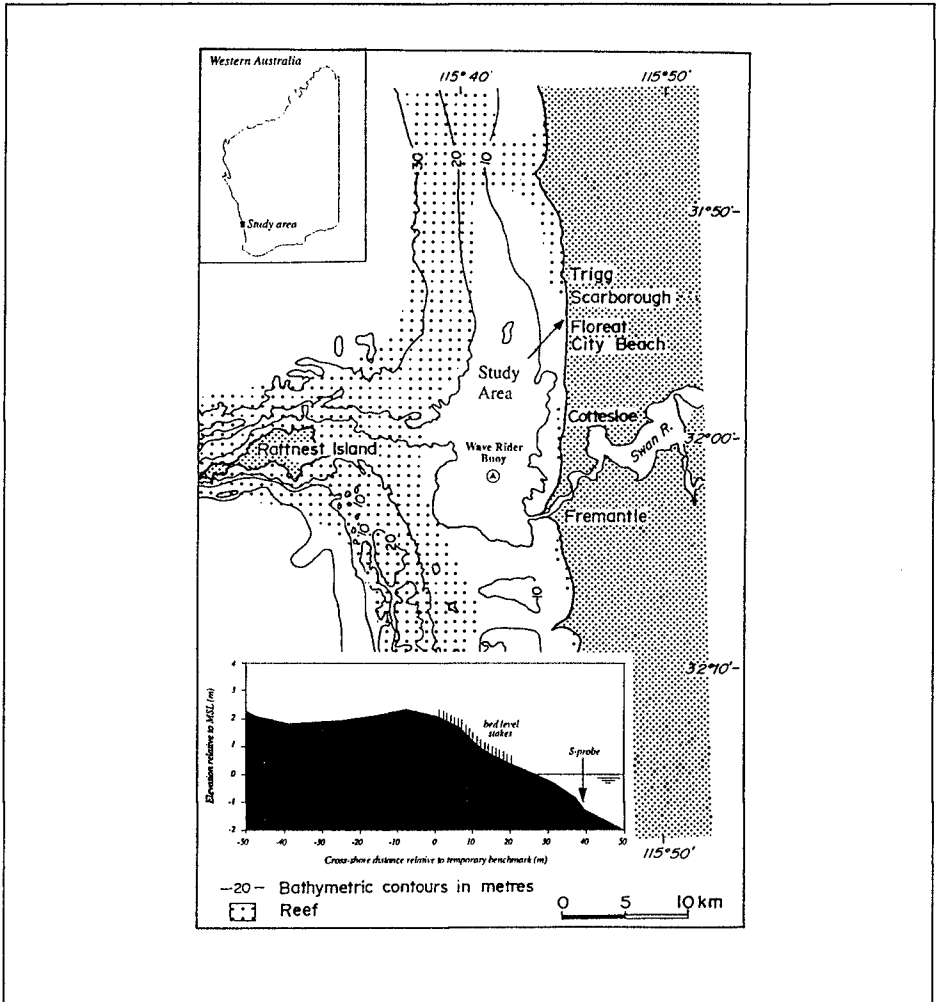

Figure 1 - Location of City Beach, Western Australia

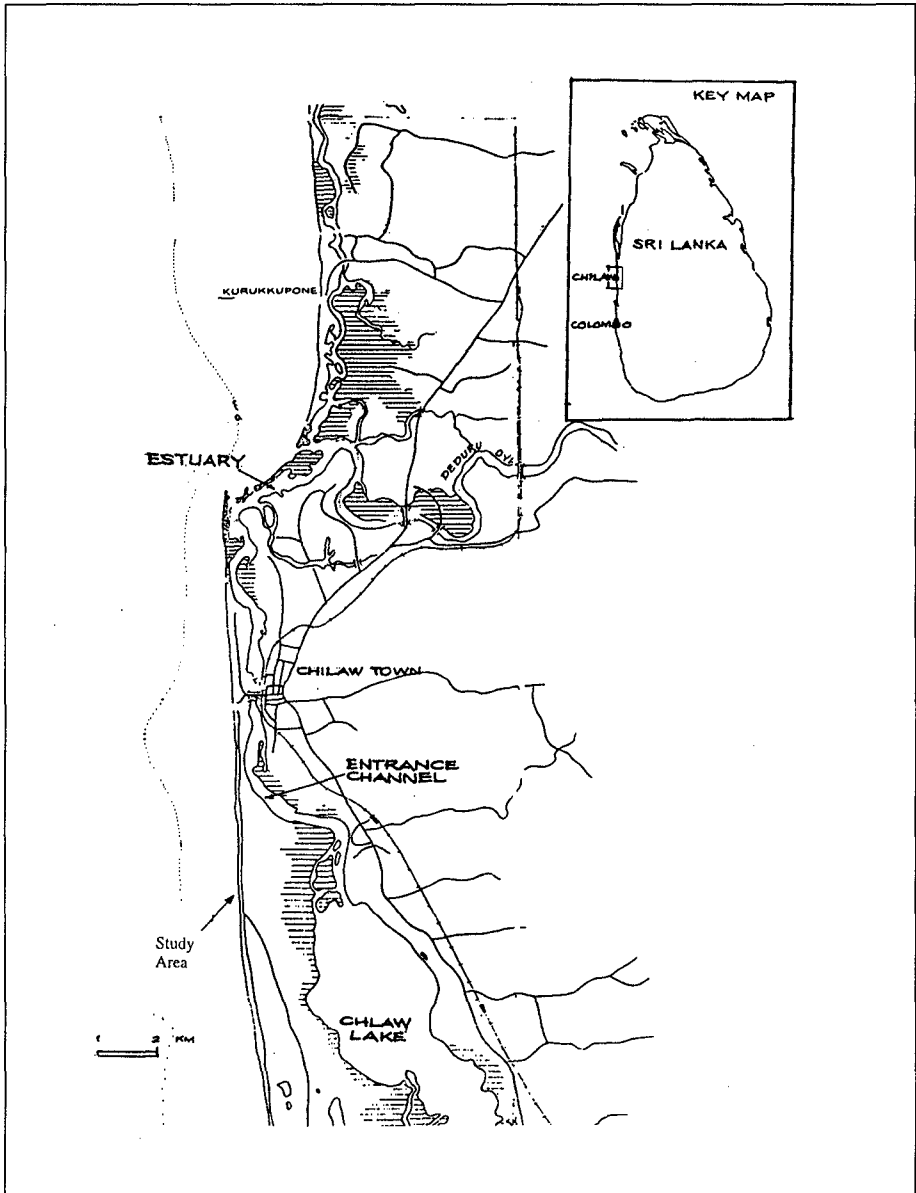

Figure 2 - Location of Ambakandawila, Sri Lanka

Although the sea breeze is a global phenomenon, it's intensity, which depends primarily on the land-ocean temperature gradients, varies geographically. The field data presented in this paper were collected under

sea breeze speeds between 7 and 12 ms^{-1} . To allow comparison with other regions, the following maximum speeds, recorded during the sea breeze, have been reported: 14 ms^{-1} in Barcelona, Spain (Redano et al., 1991); 10 ms^{-1} in Greek waters (Prezerakos, 1986; Balopoulos et al., 1986); 9 ms^{-1} near Kingston, Jamaica (Huntley et al., 1988); 8 ms^{-1} in Tokyo (Yoshikado and Kondo, 1989); 7 ms^{-1} in Monterey, California (Banta, 1995); and, 5 ms^{-1} in Santa Rosa Island, Florida (Sonu et al., 1973).

Methodology

The data presented in this paper were all collected using the 'S-probe', an instrument package, developed at the Centre for Water Research, University of Western Australia. It consists of a Digiquartz pressure sensor, a Neil Brown ACM2 acoustic current meter and three optical backscatterance sensors. The pressure sensor was mounted 0.35 m from the sea bed, whereas the two-dimensional, horizontal current velocity was recorded 0.2 m above the bed. The optical backscatterance (OBS) sensors measured the suspended sediment concentration (SSC) at 0.025 m, 0.125 m and 0.275 m from the bed. The data were transferred via a cable connected to a shore-based computer and logged at a sampling rate of either 5 Hz (exp. 1) or 2 Hz (expts. 2 and 3). The S-probe was deployed in the surf zone at each of the study sites. Calibration of the OBS sensors was conducted with sand samples collected at the survey site, using the methods and apparatus similar to that described by Ludwig and Hanes (1990). Analysis of the water surface elevation, current velocity and suspended sediment concentration records were carried out on time series of 2048 points (approximately 7 or 17 minutes). Although additional data (e.g. offshore wave climate, beach ground water levels, instantaneous shoreline, beach morphology changes etc), have been collected at each of these sites only data collected by the S-probe is presented here. More comprehensive account of the data sets from City Beach may be found in Pattiaratchi et al. (1997),

Masselink and Pattiaratchi, (1997), Masselink et al., (1997).

Data obtained from City Beach on 23 January 1992 (expt 1) is limited to four hours after the onset of the sea breeze. After this time, the S-probe could no longer be maintained in an upright position due to the extremely energetic surf zone conditions. However, continuous data over 3 sea breeze cycles are available from the subsequent survey from City Beach, 3-9 March 1995 (expt 2) and over two days from Ambakandawila, Sri Lanka, 18-20 January 1996 (expt 3).

Results

Experiment 1: City Beach, WA - 23 January 1992

Time series of wind speed and direction obtained on this day indicate a typical sea breeze cycle characterized by weak offshore winds in the morning and early afternoon, and a strong sea breeze starting at 1445 hours which continued into the evening (Figure 3). Wind speeds associated with the sea breeze exceeded 10 ms^{-1} and occur frequently in the summer months in this region. The direction of the sea breeze was consistently from the south and hence the sea breeze was blowing parallel to the shoreline, a feature of the sea breeze system in this region (Pattiaratchi et al., 1997).

Changes in wind speed and direction are reflected in the incident wave field, nearshore currents and suspended sediment concentrations (Figure 3). Prior to the sea breeze, small-amplitude swell ($H_S=0.4 \text{ m}$) with zero-upcrossing periods (T_Z) of 7-8 s were present. Mean cross-shore (offshore) and longshore (northerly) currents were less than 0.05 ms^{-1} and 0.1 ms^{-1} , respectively whilst the mean SCC at a distance of 0.275 m above the bed was about 1 gl^{-1} . Sediment was only re-suspended during the passage of large waves in wave groups. The onset of the sea breeze induced an almost instantaneous change in the nearshore hydrodynamics. The wave height increased ($H_S=0.7 \text{ m}$), the wave period decreased and assumed a constant value ($T_Z=4 \text{ s}$) within

one hour of the start of the sea breeze. Offshore-directed cross-shore currents in the surf zone rapidly increased in strength to a maximum of 0.16 ms^{-1} and the northerly longshore current progressively increased and exceeded 1 ms^{-1} . Sand was continuously re-suspended by the waves and the amount of SSC in the water column (at 0.275 m) increased seven-fold to 7 gl^{-1} . The surf zone averaged northward longshore suspended sediment transport rate increased from approximately 1 kg s^{-1} before the start of the sea breeze to $100\text{--}200 \text{ kg s}^{-1}$ during the sea breeze, an increase by a factor of 100 (Figure 3).

Experiment 2: City Beach, WA - 4-6 March 1995

The results from this experiment are essentially the same as that for experiment 1. However, due to weaker sea breezes (max 7 ms^{-1}), the hydrodynamic changes induced by the sea breeze were less extreme. Continuous measurements of three successive sea breeze cycles were made and these enabled the investigation of the recovery period of the wave conditions after the cessation of the sea breeze. Prior to the sea breezes, offshore winds prevailed with speeds of $2\text{--}3 \text{ ms}^{-1}$. All three sea breezes persisted for approximately 7 hours and a relatively constant wind speed of $5\text{--}7 \text{ ms}^{-1}$ was maintained. After the onset of the sea breeze, immediate changes occurred to the incoming wave field with a decrease in T_z from 10 to 5 s and an increase in the longshore current velocity to $0.15\text{--}0.2 \text{ ms}^{-1}$. Around 2045 hrs each day, the sea breezes stopped. The wind direction gradually shifted back to the east and the wind speed decreased to $< 4 \text{ ms}^{-1}$. T_z increased and the longshore current velocity decreased immediately after the sea breeze had subsided. Around 0600 hrs on the following day, nine hours after the end of the sea breeze, the wave period and the longshore current velocity had reached pre-breeze levels.

Energy spectra of the cross-shore current were computed to construct a three-dimensional time-frequency plot to illustrate the change in spectral signature over the second sea breeze cycle (Figure 4). The cross-shore current data were used, rather than the

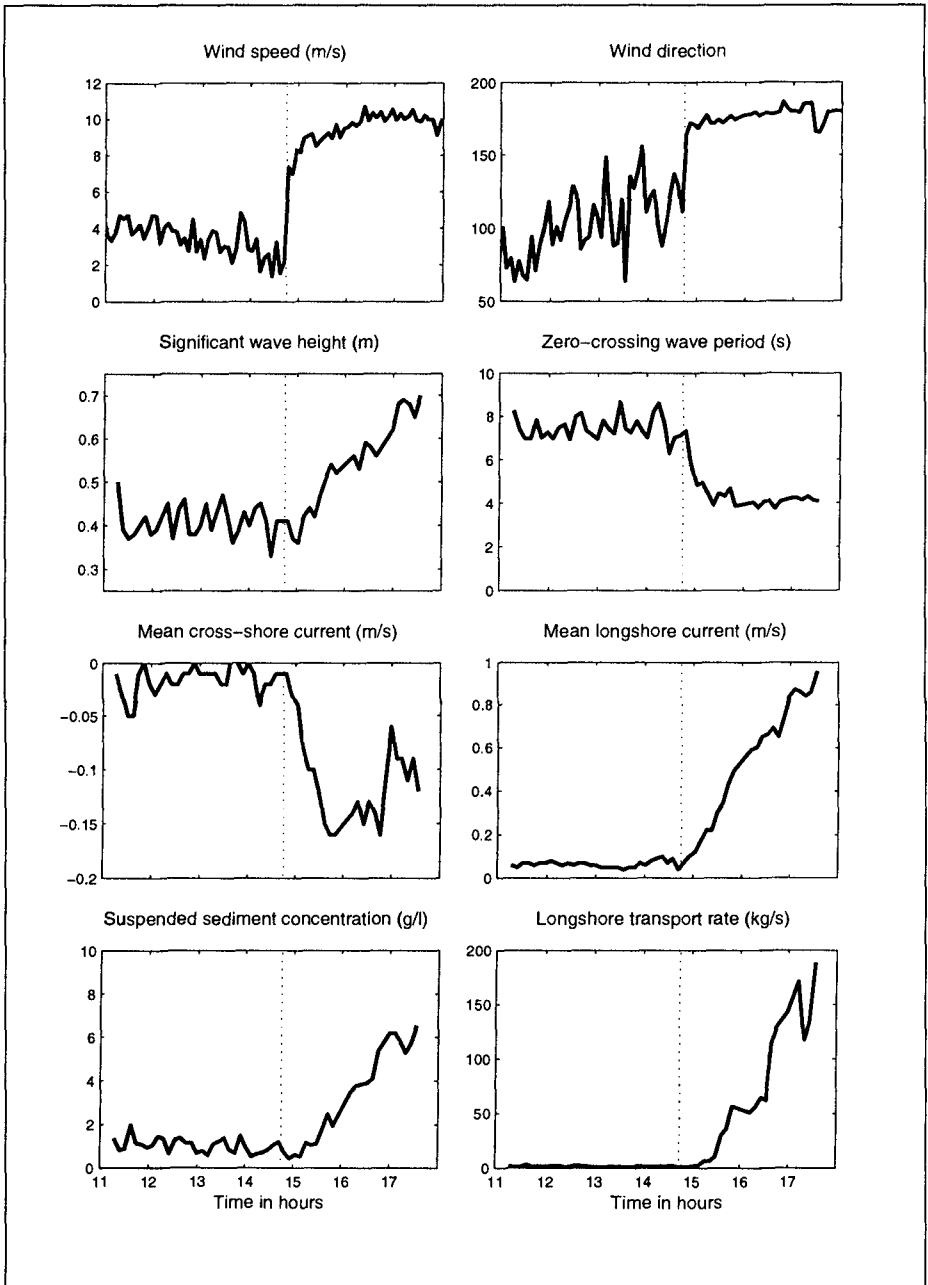

Figure 3 - Time series results for Experiment 1. The vertical dashed line indicates the start of sea breeze.

water surface elevation because they show more clearly the short-period wave energy caused by the sea breeze (frequency > 0.15 Hz). The long-period background swell is present in the time-frequency plot in the form of a linear ridge at frequency 0.07-0.1 Hz. The peak period associated with the swell energy was 12 s and remained relatively constant. After the onset of the sea breeze, wind wave energy begins to emerge at the high-frequency end of the spectra, indicating peak wave periods of 2.5 s. During the sea breeze, the frequency associated with the wind waves decreased progressively, forming a curved ridge in the frequency-time plot. At the end of the sea breeze (2100 hrs), the wind wave energy was concentrated around a frequency of 0.25 Hz, indicating a peak period of 4 s. After the sea breeze had subsided, the wind wave energy gradually decreased, but remained significant. The frequency associated with the wind wave energy decreased to 0.15 Hz, merging with the swell energy. Fifteen hours after the cessation of the sea breeze (1200 hrs 08/03/93), there was still some wave energy present which was generated by the sea breeze in the nearshore zone. This implies that the effect of the sea breeze on the nearshore hydrodynamics may be felt continuously during the sea breeze season (summer).

Figure 4- Time frequency plot of cross-shore currents

Experiment 3: Ambakandawila, Sri Lanka - 18-20 January 1996

Data collected from this experiment has not been thoroughly analysed and only a preliminary description is given here. On 18th January 1996, the sea breeze started at 1415 hours and 30 minutes later reached a maximum speed of $10-12 \text{ ms}^{-1}$. Continuous wind data is unavailable at present and the wind speeds quoted here were obtained using a hand-held anemometer on the beach. Coincident with the increase in wind speed, the longshore current increased from 0.05 to 0.75 ms^{-1} and then decreased just before midnight (Figure 5). The cross-shore currents (max = 0.23 ms^{-1}) and SSC (max = 3.8 gl^{-1}) indicated a similar trend (Figure 5). Pre-sea breeze values were reached prior to midnight. The exact time of the sea breeze cessation is unknown at present.

On the following day (19th) the sea breeze started earlier, at 1215 and continued blowing at $6-7 \text{ ms}^{-1}$ throughout the afternoon. Here, although the sea breeze was weaker than the previous day, the recorded maximum values are higher (Figure 5): the longshore current max. is 0.80 ms^{-1} ; max cross shore current 0.35 ms^{-1} ; and, max. SSC 4 gl^{-1} . As per previous day, all values had returned to pre-sea breeze levels before midnight. On both days, the longshore suspended sediment flux (southward) increased by a factor of 60 during the sea breeze.

Discussion

This paper summarizes the results of three field experiments aimed at investigating the impact of sea breeze activity on nearshore processes. The findings are similar to those of Sonu et al. (1973), to date the only other study into sea breeze effects. In summary, the sea breeze results in: (1) an increase of the wave height; (2) a decrease in the wave period; (3) an intensification of the nearshore currents; and, (4) an increase in suspended sediment levels and suspended sediment transport. In Western Australia, due to the predominantly longshore component of the sea breeze,

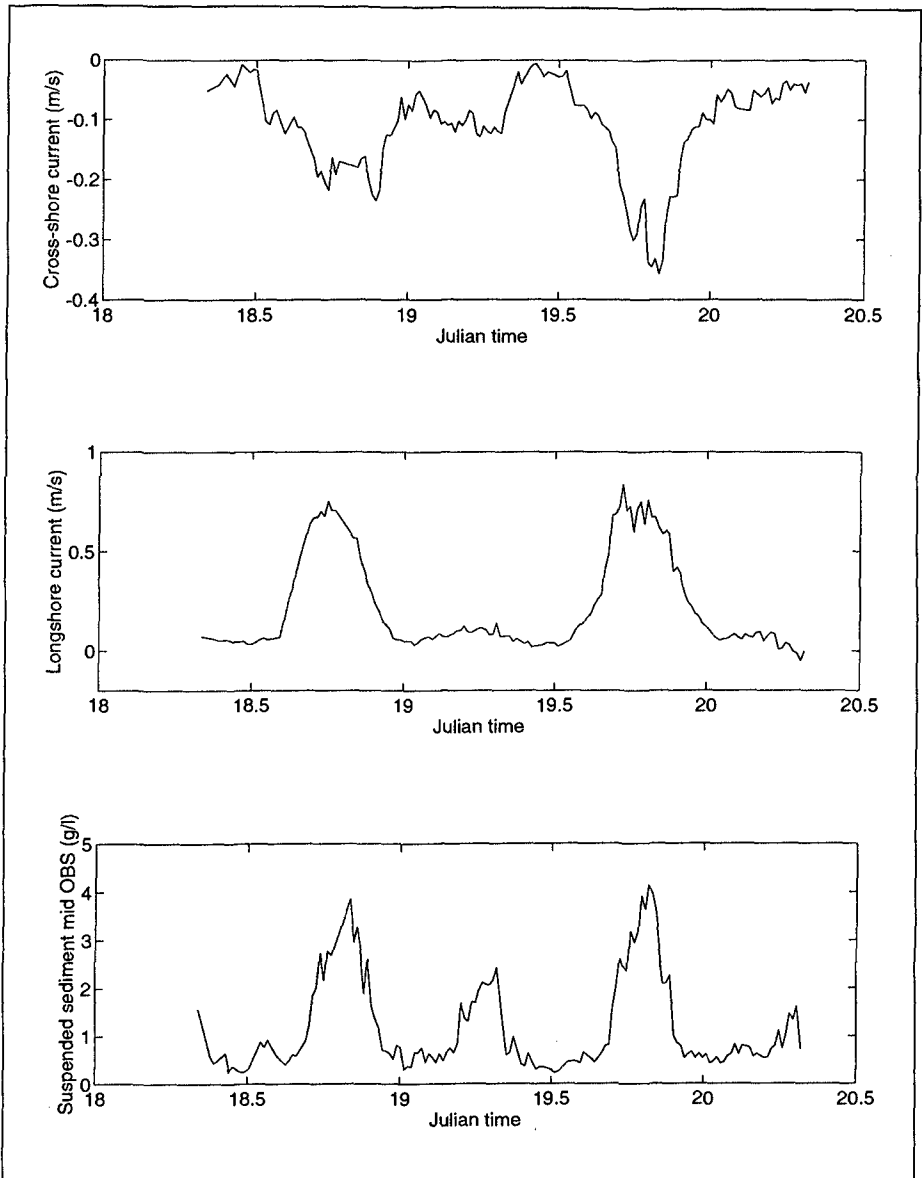

Figure 5 - Time series of cross-shore and longshore currents and SSC from Ambakandawila, Sri Lanka.

the nearshore hydrodynamics are affected long after the sea breeze has ceased to blow. Sonu et al. (1973)

refer to this as the "afterglow effect". Preliminary data from Sri Lanka, shown here, indicate that the impact of the sea breeze did not persist after midnight although visual observations of wave direction on the following morning indicated waves approaching from the direction of the sea breeze. Both the strength and consistency of the sea breeze, and the afterglow effect contribute to the important role that the sea breeze plays on the nearshore processes in both regions.

The sea breeze induces a diurnal cycle of beach change by causing erosion of the upper part of beach and/or planation of beach cusp morphology (Masselink et al., 1997). These changes are reversible in that the beach is usually restored to its pre-breeze state after the cessation of the sea breeze Pattiaratchi et al. (1997). On the larger temporal and spatial scale, the dramatic increase in the longshore sediment transport caused by the sea breeze is important. Masselink and Pattiaratchi (1997) and Pattiaratchi et al. (1997) estimate that along the stable Perth Metropolitan coastline, the annual longshore transport driven by the sea breeze is approximately 100,000 m³. This estimate of longshore transport due to the sea breeze compared favourably with estimates of sediment accumulation at the southern side of Trigg Island (Perth) at the end of the summer. During the winter, the predominant north-westerly storms transport this sand southwards thus completing the seasonal sediment budget. Hence, it is clear that the sea breeze plays a dominant role in the sediment budget of the coastline around Perth.

Similarly, the sea breeze plays an important role in the annual longshore sediment budget along the west coast of Sri Lanka. During the south-west monsoon (May to September), the longshore sediment transport is predominantly northward. The occurrence of the sea breezes during the north-east monsoon period (October to February) would transport some of this sediment southward as shown by the results obtained from this study. Hence, also in this region, the sea breeze plays a dominant role in the annual sediment budget.

Conclusions

Field data presented from two different micro-tidal areas have shown the importance of the sea breeze system on nearshore processes. The sea breeze system induces a diurnal change in the incident wind wave climate (wave height and period) resulting in large increases to longshore and cross velocities and suspended sediment concentrations. The longshore suspended sediment flux can increase by a factor of 100 or more during the sea breeze which is very important in terms of annual sediment budgets.

Acknowledgments

A large number of individuals assisted in the data collection at the West Australian (WA) site and we would particularly like thank Dr Bruce Hegge for his efforts. Funding for the WA experiments was provided by an Individual Research grant awarded by the Division of Engineering and Computer Science at the University of Western Australia (UWA) to CP. Funding for the development of the S-probe was provided by UWA and the Centre for Environmental Fluid Dynamics. The Perth City Council is acknowledged for granting access to the field site. Funding for the field experiments at Ambakandawila (Sri Lanka) was provided by the Ministry of Fisheries and Aquatic Resources (Sri Lanka) as part of the ADB Chilaw Anchorage project to Lanka Hydraulic Institute and the Centre for Water Research. This paper has Centre for Water Research reference ED1243 CP.

CHAPTER 326

WIND BLOWN SAND AT CASTROVILLE, CALIFORNIA

Douglas J. Sherman¹, Bernard O. Bauer², Paul A. Gares³, Derek W.T. Jackson⁴

ABSTRACT

This paper reports the results of a study designed to evaluate the performance of a set of aeolian transport models, including moisture content corrections, as tested against field measurements. Empirical data were obtained during experiments conducted near Castroville, California, in January, 1993. The comparisons show that the Lettau and Lettau (1977) transport model, coupled with the Belly (1964) moisture correction model, produces estimates most closely approximating measured rates. Nevertheless, the advantages of this approach relative to using an "uncorrected" Bagnold model are small.

INTRODUCTION

Aeolian sand transport is an important component of the sediment budget of many coastal environments. Blowing sand may represent a hazard (Sherman and Nordstrom, 1994) or a resource, especially with regard to dune building and habitat creation (Carter, 1988). For these reasons, it is important to model the aeolian system in a manner consistent with the needs of coastal engineers and resource managers. From a geomorphological perspective, an understanding of the nature of aeolian systems yields insight into fundamental aspects of sediment transport and resulting

landform change. Determining which model constitutes the most accurate and physically-meaningful approach to aeolian flux prediction is, therefore, a critical challenge.

A number of models have been developed for the purpose of predicting aeolian sand transport rates (see summary by Namikas and Sherman, in press). Those of most practical interest are based on a common set of assumptions: the wind is steady, uniform, and blowing across an unobstructed, horizontal surface of clean, dry, homogeneous sand. These conditions describe the most basic transport systems that one can posit. Models developed from these assumptions have been discussed extensively elsewhere (e.g., Anderson et al. 1991; McEwan and Willetts 1994; Lancaster 1995), and their derivations are not reviewed here. We note, however, that the idealized conditions they describe are seldom, if ever, appropriate to coastal environments. Complicating effects of sediment moisture content and surface slope, in particular, may exert considerable control on the behavior of the transport system.

Previous field experiments aimed at matching observed and predicted transport rates have usually found poor correspondence. Some successes have been reported in cases where empirical constants have been adjusted to improve the model's performance. Because such adjustments are usually site specific, they are of relatively diminished utility when little is known about the transport environment or where field work is impractical. Indeed, if we are always forced to perform field experiments to calibrate the equations, the practical value of modeling is severely constrained. The purpose of this paper is to report the predictive performances of several transport models, in light of field data and in consideration of slope effects and adjustments for moisture content. The objective is to test the models as they appear in the literature and as they might be employed in an engineering or management context.

MODEL DESCRIPTION

Several previous efforts at comparing observed and predicted transport rates have been reviewed recently by Sherman et al. (in press). Typically, these have omitted slope and/or moisture effects, have used liberally the empirical constants in the models, or have been predicated on potentially flawed experimental designs. The Sherman et al. study suggests that, of the five models tested, the best statistical explanation (of the order of 20%) was afforded by the Bagnold (1936) and Zingg (1953) models. These two equations are essentially the same, varying only in the selection of the constant. Their conclusions point to the necessity for similar comparative studies using high quality data sets from other environments.

In the present study, we test the transport models of Bagnold (1936), Kawamura (1951), and Lettau and Lettau (1977). They were selected in conformity with the findings of Sherman et al. (in press) and because they are commonly used in coastal applications. We also considered the moisture-content correction equations

of Belly (1964), Hotta et al. (1984), and Kawata and Tsuchiya (1976). For all tests, we assumed a sediment density, ρ_s , of 2650 kg m^{-3} , an air density, ρ , of 1.23 kg m^{-3} , and a gravity constant, g , of 9.8 ms^{-2} . Sediment flux, q , is in $\text{kg m}^{-1} \text{ s}^{-1}$. A brief description of the models follows.

One of the most frequently used models to predict transport rates is that of Bagnold (1936) who suggested that:

$$q = C \sqrt{\frac{d}{D}} \frac{\rho}{g} u_*^3 \quad (1)$$

where C is a surface-sediment-dependent constant ranging in value from 1.5 to 3.5 ($C = 1.8$ for typical dune sands and this value is used here), d is mean grain diameter, D is a reference grain diameter of 0.25 mm, and u_* is shear velocity.

Kawamura (1951) proposed a model that includes an explicit threshold shear-velocity term, u_{*t} .

$$q = C \frac{\rho}{g} (u_* - u_{*t}) (u_* + u_{*t})^2 \quad (2)$$

In this expression, $C = 2.78$, and we adopt this value even though Horikawa et al. (1984) suggest that $C = 1.0$ might be better.

Lettau and Lettau (1977) proposed an expression with some of the attributes of both previous models:

$$q = C \sqrt{\frac{d}{D}} \frac{\rho}{g} (u_* - u_{*t}) u_*^2 \quad (3)$$

where C in this case has a value of 4.2.

The Kawamura (1951) and Lettau and Lettau (1977) models require the threshold shear velocity to be estimated according to local sediment size characteristics. Bagnold (1936) suggested a Shields-type relation for u_{*t} of the following form:

$$u_{*t} = A \sqrt{gd \left(\frac{\rho_s - \rho}{\rho} \right)} \quad (4)$$

where A is a constant (assumed to be 0.085 during saltation).

When moisture is present in the interstices of surface sands, the resulting surface tension acts as a cohesive force. The shear velocity required to entrain sediments must therefore increase (e.g., review by Namikas and Sherman 1995). We considered three models developed to account for increased threshold shear velocity as a result of moisture content, u_{*tw} .

Belly (1964) proposed an empirical model based upon his wind tunnel experiments:

$$u_{*tw} = u_{*t} (1.8 + 0.6 \log_{10} w) \quad (5)$$

where w is percent moisture content by weight. This model applies to conditions where w does not exceed 4%.

Kawata and Tsuchiya (1976, described in Hotta et al., 1984) developed a model based upon direct consideration of the surface-tension-force distribution between particles:

$$U_{*tw} = U_{*t} \sqrt{1+B} \quad (6)$$

where

$$B = \frac{2\sqrt{6}}{5} \sqrt{\alpha_1 \alpha_2} \sqrt{n_o} \sqrt{\frac{\rho_s}{\rho_w}} \frac{T \sqrt{w} \cos \xi}{(\rho_s - \rho) g d} \quad (7)$$

and α_1 , α_2 are constants, n_o is the number of grain contact points, ρ_w is density of water, ξ is the water/grain contact angle, and T is the surface tension of water.

Hotta et al., (1984) proposed a wind-tunnel-derived empirical relationship for moisture effects:

$$U_{*tw} = U_{*t} + 7.5w \quad (8)$$

The prescribed applicability range for this model is 2% to 8% moisture content and sediment sizes between 0.2 mm and 0.8 mm.

In order to obtain the information necessary to evaluate the above models against prototype conditions, measurements or derivations of the following parameters are required: shear velocity, surface slope, mean grain size, transport rate, and moisture content. In order to attribute differences between observed and predicted transport rates to model performance, substantial care must be taken in experimental design. A field study was designed with the aim of obtaining suitable data.

STUDY SITE

Field experiments were conducted at a site along the coast of Monterey Bay, approximately mid-way between Santa Cruz and Monterey, near the town of Castroville. The site is exposed to open-ocean winds and waves from the southwest to northwest, and aeolian activity is therefore common. Instruments were deployed on the upper, flat portion of a well-developed, high-tide berm (Figure 1) fronting a small foredune system that is essentially continuous from the mouth of the Salinas River (to the south of the site) to Moss Landing (to the north). The upper foreshore is relatively steep and often cusped, and it descends to a much flatter low-tide terrace merging, seaward, with bar topography that is periodically punctuated with rip channels. Morphodynamically, the system falls into the reflective regime during high tide and the dissipative regime during low tide stages. Spring high tides are often associated with foredune scarping and the deposition of flotsam (mostly kelp and woody debris) on the berm flat. Additional details of this site are described in Bauer et al. (1990) and Bauer (1991).

Figure 1: Castroville study site with instrument array.

EXPERIMENTAL DESIGN

Field experiments were conducted over a 30-day period in January, 1993. Only the January 13 data are presented here because this day had the longest duration of continuous sand transport during the study period. Further, winds were blowing

nearly parallel to the shore so that it is reasonable to assume that local equilibria between the velocity profiles and the saltation system existed—that is, conditions were as close to ideal as one might expect for a beach environment. This eliminates complications arising from potential fetch effects (e.g. Nordstrom and Jackson 1992), or from internal-boundary-layer development (e.g. Bauer et al. 1996). Measurements began at 05:45 (PST), and continued for about the next five hours. A total of five data runs were completed, each with three to five u_* - q pairings.

Five sampling locations were established across the berm at 5 m intervals (Figure 2). Gill-type, three cup anemometers were hardwired to a PC-based data acquisition system. All sample runs were of 15 minute duration, with sampling at 1 Hz. Tower 1, near the toe of the foredune, had anemometers at elevations of 0.25, 0.5, 1.0, 2.0, 3.0, and 4.0 m above the sand surface. Towers 2, 3, and 4 had anemometers at 0.2, 0.6, 1.2, and 1.8 m. Tower 5 had anemometers at 0.15, 0.3, 0.6, 1.2, 1.8, and 2.4 m. The lowest Tower 5 anemometer was disabled during this experiment. Wind vanes were installed at the tops of Towers 1 and 5. A set of cylindrical sand traps was deployed adjacent to each tower. Moisture samples were taken at Towers 1 and 3 throughout the experiment, and at Tower 5 only near the end of the data collection, by taking scrapings from the upper 3-5 mm of the sand surface. Topographical slope was measured by rod and level survey.

Figure 2: Instrument configuration on January 13, 1993.

Shear Velocity estimates were obtained through analysis of vertical wind-speed profiles. Linear regression was used to obtain “best fit” profile slopes, s , following the methodology described in Bauer et al. (1992). Assuming that the law of the wall applies, estimates of u_* were made using the relationship $u_* = \kappa s$, where κ is von

Karman's constant. To increase the statistical confidence of the u_* estimates, we restricted our analysis to instances where the R^2 associated with the best fit line was greater than 0.98.

Grain Size statistics were estimated using sand samples taken from the sediment traps. Samples were washed, dried, and sieved at 0.25ϕ intervals, and the data were processed according to the method of moments.

Moisture Content was estimated on the basis of pore-water weight relative to dry weight of the sediment sample. Samples were weighed, oven dried, and reweighed in order to solve:

$$w = 100 \left(\frac{W_t - W_d}{W_d} \right) \quad (9)$$

where W_t is total sample weight and W_d is the dry weight of the sample.

Sediment Transport Rates were measured with cylindrical traps (Leatherman 1978; Rosen 1978). Traps were opened for 15-minute periods to correspond with wind sampling. Trapped sands were oven dried and weighed to obtain the transport rate data.

RESULTS AND MODEL EVALUATION

Grain size estimates were obtained from a total of 19 samples taken during the transport event. Grain-size statistics were surprisingly consistent over the entire measurement period with a mean 'd' of 0.12 mm and a standard deviation of 0.007 mm. **Moisture content** was also almost constant, with a mean 'w' for the data set of 6.9 % and a standard deviation of 0.7 %. **Surface slope** upwind of the instrument array was negligible, largely because the predominant wind fetch was oriented parallel to shore. Three shore-parallel lines were surveyed upwind of the instrument array, and they indicated a maximum relief of the berm flat of less than 0.3 m over a 50 m transect. Common slope-correction models indicate that such minor relief affects predicted transport rates by less than 1%. This value is much less than our confidence level for other measurements and estimates, and therefore, we did not investigate slope effects further. **Sediment transport rate** measurements were also obtained for 19 samples. In a recent field experiment, Greeley et al. (1996) found that the efficiency of the cylindrical traps is approximately 30%. Based on that finding, we adjusted our measured transport rates uniformly by 300%.

Our first evaluation was to test the three transport models without moisture (or slope) corrections. Comparison of observed and predicted rates are presented in Figure 3. It can be seen that the Kawamura model over predicts substantially, while the Bagnold and Lettau and Lettau models fit the observations relatively well. There is very little difference in the degree of statistical explanation associated with each

model. With the Bagnold model, $R^2 = 0.50$; for Kawamura, $R^2 = 0.48$; and for Lettau and Lettau, $R^2 = 0.50$. The main difference between the model performances are associated with the slopes and offsets of best-fit lines.

Figure 3: Comparison of observed and predicted transport rates without moisture content adjustments.

A second comparison incorporating moisture-content corrections was made. We evaluated the three moisture models described above (Equations 5 - 8) for their viability with the field data. In several instances, both the Hotta et al. and Kawata and Tsuchiya models yielded predictions of 'no transport' when our measurements clearly showed sediment movement. This peculiar situation arises when the threshold shear velocity predicted by these models on the basis of moisture content is greater than the observed shear velocities. We decided that this was one rational basis upon which the viability of the moisture models, vis-a-vis field data, could be distinguished. Since only the Belly (1964) model was immune to this problem, we used it with the transport equations. Note, however, that because there is no explicit threshold term in the Bagnold model (it is implicit in the parameterization of shear velocity), it was not considered appropriate to apply a moisture correction factor to his equation. Therefore, only the Kawamura and Lettau and Lettau models, with the Belly modification, were compared. Figure 4 shows that there is still considerable scatter in the relationship, with the main effect of accounting for moisture content being an overall reduction in predicted transport rate.

Figure 4: Comparison of observed and predicted transport rates using the Kawamura and Lettau and Lettau models with Belly's moisture model.

Linear regression was used to determine the statistical association between observed and predicted transport rates. On a log-log plot, R^2 for both models was 0.50. However, the Lettau and Lettau/Belly combination yielded predictions that were closer to a one-to-one correspondence with observations. This is best illustrated in Figure 5 using probability density plots (normalized frequency of occurrence) that compare smoothed distributions of ratios of predicted to observed values for both

Figure 5: Comparison of ratios of predicted to observed transport rates.

models. An ideal model would have a narrow, peaked distribution centered around one--indicative of a near-one-to-one match between model and prototype conditions. Figure 5 shows that the Lettau and Lettau model, including the moisture content correction, approaches this ideal distribution, whereas the Kawamura and Belly combination over predicts substantially. These distributions of pairwise ratios of observed to predicted transport rates, coupled with the regression analysis, may represent one of the least ambiguous tests of comparative model performances.

DISCUSSION

All statistical comparisons between predicted and measured transport rates show that the scatter around a linear regression fit is approximately the same, regardless of transport model and moisture-content correction (R^2 values range from 0.48 to 0.50). Presumably, this reflects the similarity of the underlying physical bases for the models, and the fact that the variability in sediment moisture content during our experiments was small enough that the Belly model essentially acted as a near-uniform offset in the predictions--that is, all predicted transport rates were approximately uniformly reduced in magnitude.

It is encouraging that, under the conditions reported here, approximately half of the statistical variability in the transport rates monitored can be explained by the models evaluated. The uncertainty regarding the other half of the variability can be ascribed to several sources. First, our estimates of shear velocity were based upon line fitting procedures that, by their very nature, incorporate some degree of statistical uncertainty. Although this uncertainty has been minimized by excluding all wind profiles where R^2 was less than 0.99, it is not totally eliminated (e.g. Bauer et al. 1992). Because errors in estimates of u_* are compounded in the transport models (because third powers of shear velocity are used), 10 % errors translate to about 30% errors in predicted transport rates.

Second, there is substantial uncertainty associated with the measurement of sediment flux using cylindrical-type traps. We implemented a first-order correction to our measurements based on the findings of Greeley et al. (1996), but this is a crude adjustment that forces us to presume that trap efficiency is constant for the range of transport rates. This remains a point of contention.

Third, we feel some degree of unease with the universality of the models themselves and their underlying assumptions concerning grain-size distributions (only mean values are used, and sorting effects are ignored) and the steadiness of the wind field (steady-state conditions are assumed). We are also unable to make substantive distinctions among the physical--theoretical foundations of the different approaches which might provide guidelines as to their applicability. Thus, we are left with statistical performance assessments only.

It is noteworthy that whereas the use of the Lettau and Lettau model with

Belly's moisture correction provides the best predictions of transport for the Castroville system, the results are only marginally better than those obtained using the simple Bagnold model. Figure 6 compares the probability density distributions for the two approaches--the models perform almost identically for this range of conditions. The over-predictions obtained using the Kawamura model may also reflect the use of $C = 2.78$, instead of the more conservative estimate of 1.0 recommended by Horikawa et al. (1984). The latter value brings the Kawamura results into much closer correspondence with the other models and with our observations.

Figure 6: Comparison of ratios of predicted to observed transport rates.

Our results also compare favorably with those of Sherman et al. (in press). In that study of across shore transport conditions, the best models (Bagnold and Zingg) explained only about 20% of the statistical variability found in the observations. The Kawamura and Lettau and Lettau models each accounted for about 15% of the variability in prototype transport rates.

CONCLUSIONS

Conclusions that arise from this study include:

1. Under conditions of relatively uniform slope, grain size, and sediment moisture content, either the Bagnold, Kawamura (with $C = 1.0$), or Lettau and Lettau models provide reasonable estimates of aeolian sand transport. The performance of the Lettau and Lettau model can be enhanced through its coupling with the Belly moisture

model. Any of these model combinations is able to explain about 50% of the variability in transport rates observed during this part of the Castroville experiments.

2. We believe that it is possible, with carefully designed field experiments, to obtain process data of a quality comparable to that obtained in the laboratory. Nevertheless, continued uncertainty regarding the performance of field instrumentation in general and sediment traps in particular confounds our ability to assess accurately aeolian processes across beaches. The inherent complexity of natural systems may never be captured completely.

ACKNOWLEDGMENTS

This project received financial support through a contract from the California Department of Boating and Waterways and a grant from the North Atlantic Treaty Organization. We are also grateful to Andy Smith and the Monterey Dunes Colony Association for pleasant accommodation, and to the California Department of Parks and Recreation for beach access. Able field assistance was provided by Kevin Parnell, John Wolcott, Deming He, Jianchun Yi, Jinkang Wang, James Tyner, and Steven Namikas.

CHAPTER 327

PIPELINE PROTECTION IN THE SURF ZONE

Gerrit J. Schiereck, Henri L. Fontijn¹

ABSTRACT

Stability relations for rock on a mild slope in breaking waves were investigated, both experimentally and theoretically. Assumptions were made for the influence of turbulence in breaking waves on the load exerted by the wave motion. It appears that with these assumptions, the mechanism is reasonably described in a qualitative way. For design purposes the method is not accurate enough. This is possibly due to the neglect of the (vertical) velocity field near the bottom in a breaking wave, giving an underestimation of the difference in stability in spilling or plunging breakers. The experimental results seem consistent and can be used provisionally for design purposes. An interesting point is that they also are in line with existing relations for stability on steep slopes.

ACKNOWLEDGEMENT

The authors thank prof.dr. Marcel Stive of Delft Hydraulics for his permission to use the wave model ENDEC. ACZ Marine Contractors is thanked for their initiative on the study on pipeline protection and the continuous interest in the progress.

1. INTRODUCTION

Pipelines on the sea bottom are usually protected in order to prevent damage by anchors or erosion. Where a pipeline crosses a beach, it often lays in a dredged trench, see Figure 1, and is covered with stones. For the design of such a protection, which can be seen as an armour layer on a mild slope, a provisional design rule was established, see Schiereck et al., 1994, based on theoretical considerations and experiments. For non-breaking waves on a mild slope, the

¹*Delft University of Technology, Faculty of Civil Engineering,
P.O. Box 5046, 2600 GA Delft, The Netherlands*

Figure 1 Outfall protection

result was reasonably satisfying. For the stability in breaking waves no theoretical concept was available and the number of experiments was not sufficient to give reliable results. In addition, new experiments were carried out, in which the slope, the stone density and the stone size were varied. Also, an attempt was made to derive a theoretical relationship for the stability of stones in breaking waves. The purpose of this attempt was twofold. First, experimental results that can be explained from theory are better understood, decreasing the danger of misusing empirical relations, while, vice versa, theories that can be verified by experiments get more practical value in hydraulic engineering. The second reason comes from didactics. Hydraulic engineering is still heavily based on empirical relations. Presenting all these relations without a link to the theory on fluid motion is considered a weak point in academical engineering education.

2. APPROACH

Experiments are indispensable to establish design rules in hydraulic engineering, so, laboratory tests are the basis of the research in this paper. But, as already stated in the introduction, the experimental results should be connected with the physical background of forces due to moving water. The creation of a link between the fluid motion and experimental results is tried with a simple, but complete description of the phenomena involved. The stability of stones on a slope is governed by the relation between load and strength. The strength is usually satisfactorily described with the effective weight and the friction of the stones. The load is much more complex. The moving water in a breaking wave will exert forces on a stone. Even in a breaking wave, the orbital velocities will play a role in the velocity field. Also, the breaking will cause turbulent eddies, with their own velocity field. The whole of orbital and turbulent velocity field is responsible for the loading on a stone. Another complicating factor is that waves in nature are irregular. Therefore, some statistical description of the waves is necessary.

In the computations the load will be composed of forces caused by the orbital motion, in combination with turbulent velocities due to breaking. For the stability, existing relations between the load and strength of a stone layer in an oscillating water motion will be used.

3. BASIC EQUATIONS

Orbital motion

The oscillatory flow near the bottom is approached with the linear wave theory:

$$\hat{u}_b = \omega a_b = \frac{\omega H}{2} \frac{1}{\sinh kh} \quad (1)$$

Turbulent velocities

For the turbulent velocities, an approach as given by Battjes, 1975 and Battjes, 1987 is used. Battjes coupled the rate of production of turbulence energy to the rate of dissipation of wave energy due to breaking:

$$q \approx (D_B / \rho_w)^{1/3} \quad (2)$$

in which q is the turbulent velocity scale ($q^2 = u_i u_i$). Figure 2 shows a comparison between measured and computed turbulent velocity scale. In this paper the expression for q , equation (2), will be used as a measure for the turbulent velocity.

Figure 2 Comparison of computed and measured turbulent velocity scale

The dissipation of wave energy is derived from the analogy between a bore and a breaking wave, see Battjes and Jansen, 1978:

$$D_B = \frac{1}{4} \frac{Q_B}{T_P} \rho_w g H_M^2 \quad (3)$$

in which Q_B is the fraction of the (irregular) waves that are broken, derived

from:

$$\frac{1 - Q_B}{\ln Q_B} = - \left(\frac{H_{RMS}}{H_M} \right)^2 \quad (4)$$

and where H_M is the maximum wave height, given by:

$$H_M = 0.88 * k^{-1} * \tanh(k h) \quad (5)$$

For more details, see Battjes & Janssen, 1978. Several models are available in which this concept is implemented, e.g. the 2-dimensional DUT model HISWA, see Holthuijsen et al, 1989. In this study the 1-dimensional model ENDEC (Delft Hydraulics, see Battjes & Stive, 1985) was used to compute the various wave parameters along the different slopes, since in this model the wave set-up is explicitly computed, which possibly could be important.

Wave height distribution

As a basis for the wave height distribution the Rayleigh distribution is taken. This distribution is also used in Battjes and Janssen, 1978. In shallow water, the wave height distribution deviates from the Rayleigh distribution. $H_{1\%}$ in shallow water, which plays an important role in the stability calculations, is given by, according to Stive, see CUR/CIRIA, 1991:

$$H_{1\% - shallow} = \frac{H_{1\% - Rayleigh}}{(1 + H_s/h)^{1/3}} \approx \frac{1.5 * H_s}{(1 + H_s/h)^{1/3}} \quad (6)$$

Load - strength relations

A simple relation to express the stability of stones in oscillating flow is based on experiments in an oscillating water tunnel by Rance and Warren, 1968 (see also Schiereck et al., 1994):

$$\frac{a_b}{T^2 \Delta g} = 0.025 \left[\frac{a_b}{d_{50}} \right]^{-\frac{2}{3}} \quad (7)$$

Another approach is given by Sleath, 1978. Analogous to the Shields approach in uniform flow, Sleath gives a relation between the shear stress (which is not necessarily the dominant load) and the stone weight, partly based on the experimental data by Rance & Warren (1968). The relation for stones reads:

$$\hat{\tau}_b = 0.056 \cdot (\rho_s - \rho_w) \cdot g \cdot d \quad (8)$$

d is the equivalent spherical diameter, in this paper approximated by d_{50} , the

median sieve diameter, which is easily available and differs only a few percent from the spherical diameter. The shear stress due to orbital velocities can be expressed by:

$$\hat{\tau}_b = \frac{1}{2} \cdot \rho_w \cdot f_w \cdot \hat{u}_b^2 \quad (9)$$

with f_w and \hat{u}_b depending on the wave height, H , and the period, T . The circumflex over a parameter denotes "amplitude of". Given a certain wave height, the longer the period is, the larger the orbital velocity at the bottom, \hat{u}_b . For f_w , the friction coefficient, the opposite holds: the shorter the period, the larger the friction coefficient. In CUR/CIRIA (1991) an expression by Swart is given, based on Jonsson (1966), where f_w is given as a function of the orbital stroke at the bottom, related to the bottom roughness:

$$f_w = \exp[-6 + 5.2 \left(\frac{a_b}{k_s}\right)^{-0.194}] \quad (f_{w \max} = 0.3) \quad (10)$$

Computations

The combination of orbital velocities, turbulent velocities, wave height distribution and load-strength relations into a design procedure can be done in various ways. In section 5, this is further elaborated.

4. EXPERIMENTS

Experiments were done in a wave tank (length 40 m, width 0.8 m, depth 0.9 m) at the Laboratory of Fluid Mechanics, Delft University of Technology (DUT), see Ye, 1996. The slope angles were 1:10 and 1:25. The mass densities of the stones were 2550 and 2850 kg/m³ while the nominal diameters, d_{n50} , varied between 1 and 1.5 cm. The width of the sieve curves of the stones (d_{85}/d_{15}) used in the experiments was about 1.5. 3 to 4 layers of stone were used, in order to ascertain a proper roughness between stones and slope. The difference with the geometry of a real pipeline cover, which has a filter layer under the top layer, is assumed to be negligible with respect to the stability of the top layer.

The stones were laid in coloured strips of 0.25 m (measured in the wave direction) over the full width of the flume. The total number of stones displaced after every test, n , divided by the number of stones in the width of the flume, was used as the total damage S :

$$S = n d_{n50} / w \quad (11)$$

in which w is the width of the flume. An arbitrary damage level of 2 was chosen for incipient motion.

Irregular waves were generated according to a JONSWAP-spectrum; the number of waves tested per spectrum was 2000. The wave heights and spectra were determined at the toe of the slope. The water depth at that location was 0.6 m.

Figure 3 shows the results of the experiments. The stability is expressed as $H_s/\Delta d$, in which H_s is the significant wave height at the toe of the slope. The stability is plotted against the breaker parameter, ξ , the slope angle relative to the wave steepness.

Figure 3 Experimental results

The general tendency is an increase in stability with decreasing ξ . This can partly be explained from the slope angle: the left-hand side of the figure represents the results for the slope 1:25 and the right-hand side those for 1:10. Within the results for each slope angle, there is also clearly an influence of the wave steepness: the larger the wave steepness, the larger the stability. This tendency has to do with the breaker characteristics and was previously found in other experiments, see e.g. Schiereck et al., 1994 and van der Meer, 1988. Within this general tendency, there is some influence of stone density and stone dimension. Whether this is a matter of accuracy or comes from physical reasons, remains to be seen.

5. COMPARISON OF COMPUTATIONS AND EXPERIMENTS

In order to compare the computational results, obtained with the approach described in section 2, with the experimental results, at first the wave parameters along the slope were computed with ENDEC, using the measured wave characteristics at the toe of the slope at the threshold of motion. From previous investigations (see Schiereck et al.,1994) it appeared that in irregular waves, the higher waves are responsible for the incipient motion, in particular the wave height that is exceeded by 1% of the waves. This wave height is computed with equation (6) for various locations along the slope. The orbital velocities at the bottom in these waves were computed with equation (1).

Rance & Warren

Figure 4 Comparison of experiments with computation according to Rance & Warren

The necessary stone diameter is first computed with the relation of Rance & Warren. With $\hat{u}_b = \omega \cdot a_b$, equation (7) is rewritten as:

$$d_{50} = \frac{2.56 * \hat{u}_b^{2.5}}{\sqrt{T_p} * (\Delta g)^{1.5}} \tag{12}$$

This equation is valid for a horizontal bottom. The diameter in this formula is

the median sieve diameter, d_{50} . In order to compare the computational results with the experiments, the nominal diameter (dn_{50}) is required, which is approximately $0.84 * d_{50}$. The turbulent velocity, from equation (2), is simply added to the orbital velocity from equation (1). Together with a correction for the influence of the slope angle on the stability, the equation finally becomes:

$$dn_{50} = \frac{0.84 * 2.56 * (\hat{u}_b + F * q)^{2.5}}{\sqrt{T_P} * (\Delta g)^{1.5}} * \frac{\sin \phi}{\sin(\phi - \alpha)} \quad (13)$$

in which F is a calibration factor and ϕ is the angle of repose of the stones, here taken as 45° . q , as defined in equation (2), is taken as the turbulent velocity.

With this equation the necessary diameter along the slope is computed. The maximum computed diameter is used, which is equivalent to the use of a total-damage concept in the experiments, regardless of the location of the damage. For comparison, the results of the experiments with $\rho_s = 2550 \text{ kg/m}^3$ and $dn_{50} = 1 \text{ cm}$ are being used. Figure 4 shows the results for $F = 1$ and $F = 2$. The influence of the slope angle, as seen in the experiments, is also found in the computations, but the influence of the wave steepness is not reproduced correctly.

Jonsson/Sleath

The relationship as found from the results of Rance & Warren (equation (7)), expresses the relation between the stroke of the orbital motion and the necessary diameter to prevent the incipient movement of the stones. This implicitly indicates the influence of the inertia of the orbital motion on the stone stability. The simple addition of a turbulent velocity to the orbital velocity, as done in equation (13),

attributes the same influence to the turbulent velocity, which is not logic.

Another approach is the following. Consider the forces on a grain in a flow field, see Figure 5. The shear force is exerted by the orbital movement, described with equations (9), (1) and (10). Equation (8) gives the relation between shear stress and stone size for incipient motion. This equation is now rewritten for the equilibrium of forces, where the turbulent velocity is assumed to generate a lift force, reducing the effective weight of the stone. In this way, the influence of turbulence is treated separately from the orbital motion with its specific relation for the friction factor, equation (10).

Figure 5 Flow forces on a grain

The equilibrium of forces then leads to the following proportionality:

$$\frac{1}{2} \rho_w f_w u_b^2 A_h \propto (\rho_s - \rho_w) g V - \frac{1}{2} \rho_w C_L A_h q^2 \quad (14)$$

in which A_h is a representative horizontal area, both for shear and lift. V is the volume of a stone and C_L the lift coefficient. Using equation (8), this leads to:

$$\frac{1}{2} \rho_w f_w u_b^2 = 0.056 (\rho_s - \rho_w) g d - \frac{1}{2} \rho_w C_L q^2 \quad (15)$$

giving finally:

$$dn_{50} = \frac{0.84 \frac{1}{2} (f_w \hat{u}_b^2 + F q^2)}{0.056 \Delta g} * \frac{\sin \phi}{\sin (\phi - \alpha)} \quad (16)$$

in which C_L is replaced by F , a calibration factor in which both the lift coefficient and the transfer from wave energy dissipation into turbulence is included.

Figure 6 Experimental results compared with computations according to Jonsson/Sleath

Figure 6 shows the results for $F = 0.1$ and $F = 0.5$. The agreement is somewhat better than with the relationship of Rance & Warren. The influence of

the slope angle is represented just as good as for the Rance & Warren relation, while the tendency of the influence of the wave steepness is qualitatively correct. The difference in stability between low and high values of ξ , however, for one value of the slope angle, is too small in the computations.

Variable friction factor in ENDEC

Until now, in ENDEC only one friction factor has been used, viz. 0.05, which is a relatively high value due to the rough bottom. Equation (10) leads to higher friction factors for steeper waves. Using different friction factors for different wave steepness, ($f_w = 0.05, 0.04, 0.03$ for $s = 0.05, 0.03, 0.01$, respectively) is justified, because of equation (10). For the calibration factor F in the computations 0.25 is used, being a value in between the two values of Figure 6.

Figure 7 Variable friction factor in ENDEC

The results are now a little bit better, see Figure 7. The models being used are very simple. Considering the fact that the values of the calibration factor F are realistic with respect to the lift coefficient, the description is quite reasonable in a qualitative way. From the point of view of design practice, however, the results are still far from perfect.

The same underestimation of the favourable effect of high wave steepness was found in non-breaking waves, see Schiereck et al., 1994. The explanation has probably to be found in the negelection of the vertical flow pattern in breaking waves. Figure 8 shows a plunging breaker in which a jet obliquely to the bottom occurs, while the jet is absent in a spilling wave. This jet may have an

unfavourable influence on the stone stability, which is not described in the models used here. This difference will only appear when using a 2-dimensional wave model for the wave motion on a slope. The agreement so far is encouraging enough to try to couple the experimental results to the water motion, using a better wave-velocity model.

Figure 8 Plunging jet

6. EVALUATION

Figure 9 Experimental results compared with van der Meer formula for plunging breakers

Figure 9 shows the experimental results discussed before. The investigations were done in the range $\xi = 0.1 - 1.0$. The figure also shows the relation for stone stability on relatively steep slopes as proposed by van der Meer, 1988. This relation was validated for values $\xi > 1$. The trend for both situations is the same, which encourages further research in this field. Together with a 2-dimensional model, describing the wave motion on a slope in more detail than the models used in this paper, it should be possible in the future to give a satisfactorily accurate description of stone stability in (breaking) waves on slopes. For the time being, the experimental results as presented in this paper can be used as a first approximation for stone stability on mild slopes.

7. CONCLUSIONS

- 1- The computational results give a description that follow the trends of experimental results reasonably well in a qualitative way, when including the following elements from the physical process of the stability of stones in breaking waves on a mild slope:
 - orbital movement (from linear wave theory, equation 1)
 - wave shear stress (according to Jonsson, equation 10 and using equation 9)
 - Rayleigh distribution (with shallow-water correction by Stive, equation 6)
 - wave breaking and energy dissipation (according to Battjes/Janssen, equations 3, 4 and 5)
 - turbulent velocities (according to Battjes, equation 2)
 - stone stability (according to Sleath, equation 8)
 - .
- 2- The computed relation between stone stability ($H_s/\Delta d$) and breaker parameter ($\xi = \tan\alpha\sqrt{H_s/L_0}$), is quantitatively insufficient. Probably the fact that the vertical velocities near the bottom in a plunging breaker were not taken into account, is the main reason for this. Other weak points are possibly the turbulence model used and the influence of turbulence on the stability of a single stone.
- 3- The experimental results seem consistent and are also in line with the (empirical) van der Meer relation for stability of stones on steep slopes. This resemblance can be used as a basis for future research on stone stability in breaking waves on slopes in general.
- 4- The experimental results in this paper can be used for the design of a protective rock layer on a mild slope.

CHAPTER 328

Modeling Tidal Circulation in Florida Bay

Y. Peter Sheng¹, Member ASCE, and Justin Davis²

Abstract

A preliminary modeling study on tidal circulation in Florida Bay has been conducted, based on a set of high resolution (20 meters x 20 meters) bathymetric data and a comprehensive set of water level data for Florida Bay obtained by the Everglades National Park in 1993 and 1994. Using the data and a 3-D curvilinear-grid model developed by Sheng (1989, 1994), we conducted preliminary model simulations of tidal, wind-driven and density-driven circulations in Florida Bay (Sheng et al. 1995). This paper presents some results of tidal simulation and comparison with tidal data. The results indicate that the 3-D model is capable of simulating many of the observed circulation features in Florida Bay, including tidal amplitude, tidal phase and residual circulation. Additional work is being conducted with the use of a very fine 50m grid and a robust wetting-and-drying scheme.

Introduction

Florida Bay is a shallow coastal water body located at the southern tip of Florida. It is adjacent to the western Florida Shelf and is separated from the deep Florida Strait by the Florida Keys. In the past few years, Florida Bay has undergone substantial changes in the form of major seagrass die-off and massive algal bloom. Due to the lack of understanding of the extremely complex ecosystem, it is unclear presently as to how Florida Bay can be restored (Johnson and Fennema 1989). One restoration plan, which is based on the assumption that reduced freshwater supply and increase in hypersalinity (salinity reaching up to 35-50 ppt) has caused the seagrass die-off and algal bloom (Figure 1), is to increase the inflow of freshwater into Florida Bay from its northeastern shore. In order to determine the soundness of this

¹Professor, Coastal & Oceanographic Eng. Dept., Univ. of Florida, 32611-6590, USA

²Graduate Assistant, Coastal & Oceanographic Eng. Dept., Univ. of Florida, USA

restoration plan, it is essential to have a quantitative understanding on the circulation and salinity transport in Florida Bay. This paper presents a preliminary study on tidal circulation in Florida Bay. In addition to a comparison between simulated and measured water levels in Florida Bay, we also examine the exchanges between Florida Bay and Florida Strait through the tidal channels along the Florida Keys.

Figure 1. Florida Bay Map with Areas of Massive Algal Bloom and Seagrass Die-off.

Field Data

As a first step, we reviewed a comprehensive set of data which includes the high resolution bathymetric data for Florida Bay and hydrodynamic and hydrographical data at numerous stations in Florida Bay during 1993 and 1994, both compiled by the National Park Service (Sheng et al. 1995). As shown in Figure 2, much of the eastern Florida Bay is less than 1 m deep. Figure 3 shows that mudbanks in Florida Bay actually divide the Bay into numerous lakes during low water. Field data collected in Florida Bay include water level, water temperature, conductivity, rainfall, and evaporation. Water level data were taken at the 27 stations shown in Figure 4. Using these water level data, Smith (1995a) obtained the co-amplitude chart and co-phase chart for the M_2 tide as shown in Figure 5. As can be seen from Figure 5, M_2 tide enters the Florida Bay from both West Florida Shelf and Florida Strait. Diurnal tides such as O_1 and K_1 constituents primarily enter into Florida Bay from West Florida Shelf. Some tide data are from the offshore waters to the south of Florida Keys (Smith 1995b). Wind data are available from 1-2 offshore CMAN stations only. Freshwater discharge data and current meter data are lacking. High evaporation rate often leads to hypersalinity of more than 50 ppt inside Florida Bay even during the wet season.

Using the data indicated above and a 3-D curvilinear-grid model developed by Sheng (1987, 1989, 1994), we conducted model simulations of tidal, wind-driven

and density-driven circulations in Florida Bay (Sheng et al. 1995). In this paper, we present some results of preliminary simulation of tidal circulation. model results.

Figure 4. A Map of Monitoring Stations in Florida Bay.

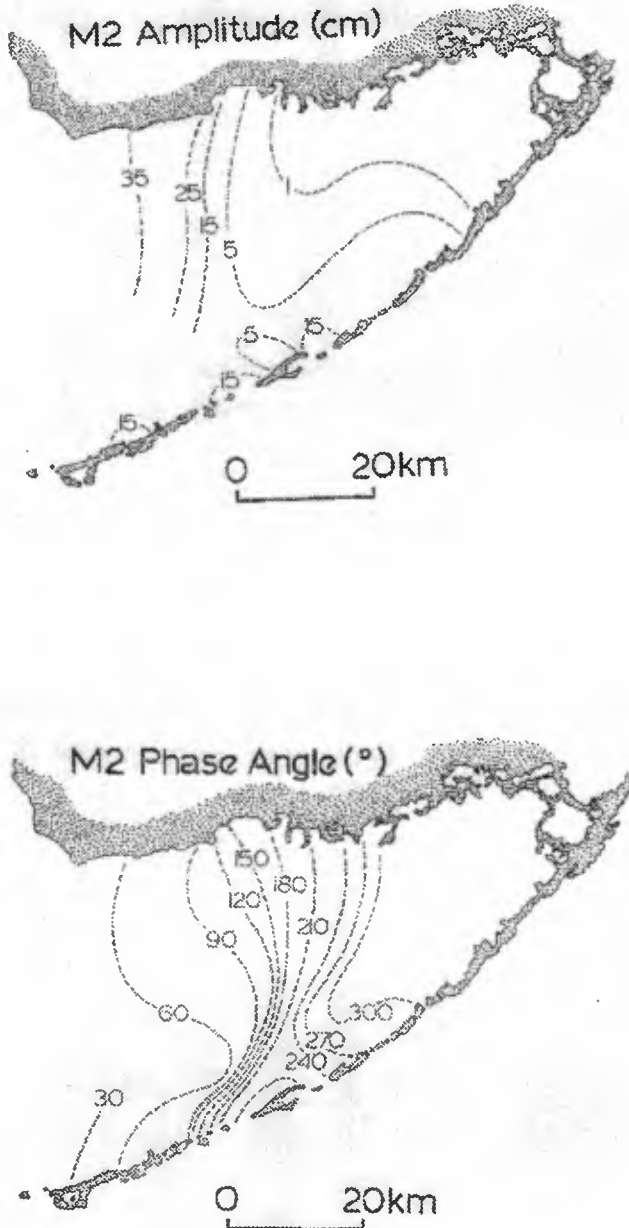

Figure 5. Co-Amplitude and Co-Phase Lines of M_2 Tide in Florida Bay.

Model and Grid

CH3D, the 3-D curvilinear-grid circulation model developed by Sheng (1989, 1994) is modified for application to Florida Bay. In the past few years, through numerous research projects (Chesapeake Bay, James River, Sarasota Bay, Lake Okeechobee, Indian River Lagoon, and Tampa Bay), we have significantly improved the model's features/capabilities for simulating stratified flow, effect of vegetation on circulation, ocean-estuary coupling, and wind-induced flow. The model solves for the three-dimensional equations of motion in terms of the water level and contravariant velocity components. The model solves the vertically-integrated equations of motions as well as the vertical structures of the flow field. Since the same time step is used for the solution of the external mode and the internal mode, the model solutions are consistent with each other and converge. A robust vertical turbulence model (Sheng and Villaret 1989) is used to represent the vertical turbulent mixing. The model allows the use of boundary-fitted grid which can accurately represent the complex shoreline in Florida Bay. In the vertical direction, the sigma grid is used. Sheng et al. (1995) used several boundary-fitted grids to resolve Florida Bay.

The grid shown in Figure 6 includes all the area covered in the detailed bathymetry map in Figure 3 plus the offshore area between the Florida Keys and the reef tract. A total of 98 by 75 grid points are contained in this grid. For 3-D simulations of tidal circulation, a total of 4 vertical cells are generally used.

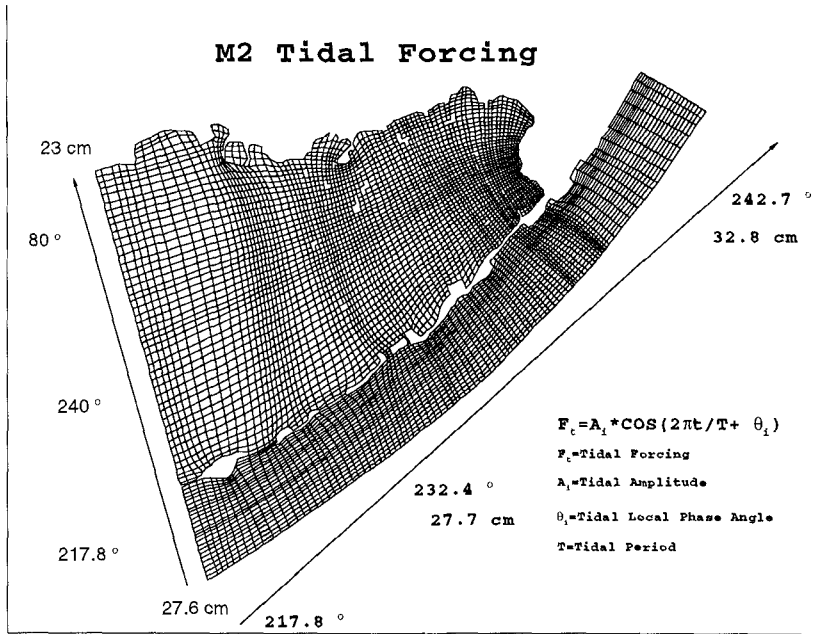

Figure 6. A model grid with 98x75 cells and open boundary conditions for M₂ tide in Florida Bay.

Simulation of Tidal Circulation

Using the horizontal numerical grid shown in Figure 6 and a vertical sigma-grid with 4 cells, we conducted simulations of tidal circulation in Florida Bay with CH3D (Sheng et al. 1995). The major objectives of tidal simulation is to examine the model's ability to simulate tide propagation and dissipation inside Florida Bay, and to examine the simulated residual flow inside the Florida Keys. For the first objective, detailed comparison between model results and data have been made (Sheng et al. 1995). For the second objective, model results can be compared qualitatively with preliminary flow measurement by Smith (1995b) which showed persistent southerly residual flow inside the Florida Keys.

To simulate the tidal dynamics in Florida Bay, it is essential to include part of the offshore water in the numerical grid as shown in Figure 6, since tides in Florida Bay are influenced by tides from the Gulf of Mexico and the Florida Strait. Tidal data along the reef tract were taken at Carysfort Reef, Alligator Reef, Tennessee Reef, Sombrero Key and Sand Key Light. These data were analyzed to produce the amplitudes and phases for various tidal harmonic constituents. Using these data and the tidal data inside Florida Bay, we produced the boundary conditions for the M_2 simulation as shown in Figure 6.

Using the open boundary conditions for M_2 tide described above, the 3-D model CH3D was run for 5 days. The result during the last tidal cycle was then analyzed to produce the maximum water level chart and a corresponding co-phase chart. The simulated maximum water level chart for M_2 tide in Florida Bay is shown in Figure 7. Amplitude in the extremely shallow eastern Florida Bay, where the depth is generally less than 50 cm, is on the order of 1-5 cm only.

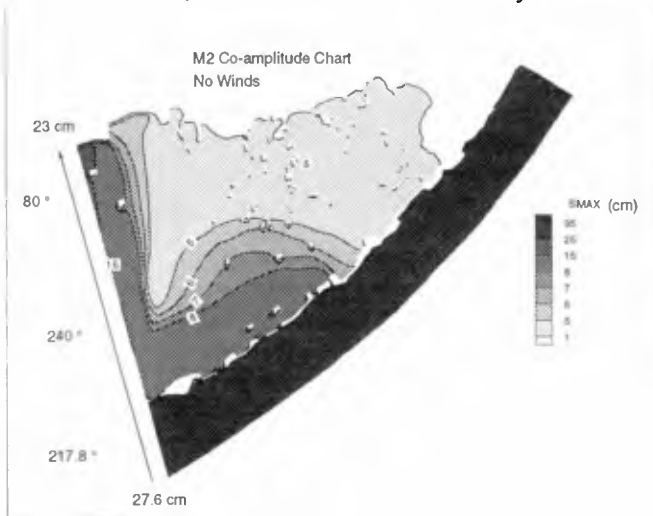

Figure 7. Co-amplitude chart of M_2 tide simulated by the 3-D model.

The results shown in Figure 7 compare favorably with the co-amplitude chart produced from data as shown in Figure 5. The simulated peak water level in the eastern Florida Bay is larger than the observed amplitude, suggesting insufficient tidal dissipation in the model. The simulated co-phase chart, which is presented in Sheng et al. (1995), showed that tides propagated further eastward. This is partly due to the fact that the complicated mudbanks, extremely shallow depths, and narrow Florida Keys in the eastern Florida Bay are not accurately represented in the 3-D model grid and bathymetry. The minimum horizontal grid spacing is approximately 100 meters while a spacing of 20 m may be necessary to represent the detailed bathymetry.

Other reasons for discrepancy between model results and data are that wind and wetting-and-drying were not included in the preliminary simulations. In the absence of wind, the residual (tidally-averaged) water level in the eastern Florida Bay is about 2 cm plus. By including a mild summer wind from the southeast, simulated maximum water level chart as shown in Figure 8 agrees better with the co-tidal chart based on data. In the presence of a summer wind, the residual water level in eastern Florida Bay became approximately -0.5 cm. A robust wetting-and-drying scheme has recently been implemented in CH3D. With the wetting-and-drying scheme and a fine grid (50m minimum grid spacing), we are able to produce much better results with 1 cm tidal amplitude in the eastern Florida Bay.

The tidally-residual vertically-averaged flow field as shown in Figure 9 exhibits significant southerly flow in the Florida Keys, in agreement with recent flow measurement by Smith (1995b). The southerly residual flow results from the higher residual water level in eastern Florida Bay.

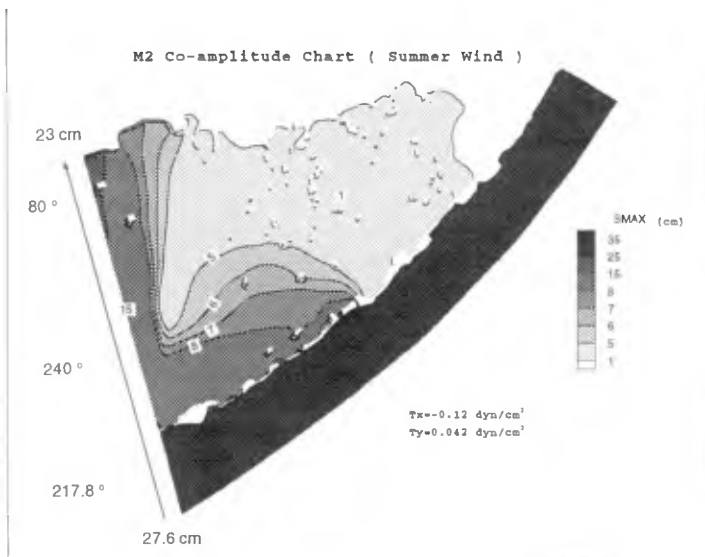

Figure 8. Co-amplitude chart of M_2 tide simulated by the new fine grid model with average summer wind condition.

Figure 9. Simulated tidal residual currents in Florida Bay with forcing by pure M_2 tide.

To examine the influence of tides from the southern open boundary, we made a model run with closed Florida Keys. As shown in Figure 10, the maximum water level compares poorly with that in the co-amplitude chart based on the 1-year data. These results also suggest that simulated results in Figure 8 exhibit stronger influence from the southern open boundary than that shown in the data. This could be improved by more accurate representation of the Florida Keys and more accurate open boundary conditions along the southern open boundary.

Figure 10. Simulated maximum water level of M_2 tide in Florida Bay with the Florida Keys closed.

Discussion

A curvilinear-grid 3-D circulation model developed by Sheng (1987, 1989, 1994) has been modified to simulate the tidal circulation in Florida Bay. Tide data collected at 27 stations inside Florida Bay during 1993 and 1994 plus offshore tide data during earlier time periods were analyzed in terms various diurnal (O_1 and K_1) and semi-diurnal (M_2) constituents. Using the tidal constituent data to construct open boundary conditions along the southern and western open boundaries, we conducted numerous model simulations with a number of numerical grids and various forcing conditions: first with tide only, then with tide and wind, and finally with tide, wind and salinity field (Sheng et al. 1995). Due to the dominance of M_2 tide from both the Gulf of Mexico and the Florida Strait, this paper focuses on the simulation of M_2 tide. The simulated maximum water level and co-phase chart compare reasonably well with the co-amplitude and co-phase charts produced from the 1-year tide data. Significant dissipation due to the mudbanks and extremely shallow water depths result in very small tidal amplitude on the order of 1-5 cm in the eastern Florida Bay. The residual (tidally-averaged) model results indicate that there is a setup in the eastern Florida Bay which causes southerly residual flow inside the channels along the Florida Keys, which has been found by recent flow measurement.

Additional model simulations of K_1 and O_1 tides and baroclinic circulation have been conducted by Sheng et al. (1995). Model results suggest that data gap in freshwater inflow and evaporation data prevents longterm (from 1 month to 1 year) simulation of Florida Bay circulation at the present time.

We have continued with the modeling effort. Recently, a robust wetting-and-drying scheme has been implemented in CH3D. A very fine grid, with a minimum grid spacing of 50m, has also been used in recent simulations. This grid gives much better representation of the mudbanks and the complex bathymetry. Using the very fine grid and the wetting-and-drying scheme, we are able to significantly improve the model results in the eastern Florida Bay. Maximum M_2 tidal amplitude in the eastern bay was reduced to 1 cm. Details of the wetting-and-drying scheme and the improved model simulations will be reported in two upcoming papers.

CHAPTER 329

RECENT DEVELOPMENTS IN COASTAL DEFENCE POLICY AND GUIDANCE IN ENGLAND

Reg Purnell¹

SUMMARY

In recent years we have seen fundamental changes in the way that coastal defences are planned and implemented. Engineers have recognised the overwhelming public desire to see the environment taken more into account when designing major infrastructure projects and our understanding of coastal processes has improved, allowing the design of coastal defences to become more scientifically based. As a result we have seen attention turn to adapting and supplementing natural coastal processes with the aim of adopting a coastal policy which is both more environmentally acceptable and sustainable in engineering terms.

In England, to reflect these engineering changes, to secure better value for money for our investment in coastal defence and offer a more sustainable approach in the longer term, the Ministry of Agriculture, Fisheries and Food, which has policy responsibility for flood and coastal defences, has invested significant sums of money into research. This has resulted in a better understanding of coastal processes and significant changes to national policy.

INTRODUCTION

As one would expect of a historical maritime nation, England has significant centres of population and economic wealth all around its coastline. The result is that over 5% of the population live in areas which are at risk of coastal flooding, perhaps not significant proportion in international terms. In addition there is an associated risk of coastal erosion which has seen the loss of a significant number of villages and large areas of land over the last few hundred years. The potential economic loss resulting from flooding or erosion is therefore significant in terms of its impact on the GDP. Recognising these risks the UK government spends some \$100m per annum on grant aiding capital improvement works in England to achieve its published overall policy aim which is “to reduce risks to people and the developed and natural environment from flooding and coastal erosion by encouraging the provision of technically, environmentally and economically sound and sustainable defence measures”.

INSTITUTIONAL ARRANGEMENTS

Whilst the Ministry of Agriculture, Fisheries and Food has overall policy responsibility for flood and coastal defences decisions on where and when defences will be provided are left to the local community. Responsibility for the provision of defences

¹Chief Engineer, Flood and Coastal Defence with Emergencies Division, Ministry of Agriculture, Fisheries and Food, Eastbury House, 30/34 Albert Embankment, London SE1 7TL, England.

against flooding are generally with the Environment Agency, which although a national body, makes such decisions on a regional basis with strong local input. Defences against coastal erosion are provided by Local Councils, some of whom also have additional powers with respect to provision of defences against coastal flooding. The boundaries of these bodies generally take no account of coastal processes being based on historical precedent and geography.

Historically these authorities have not generally cooperated in the provision of coastal defences tending to make their decisions on the basis of local needs and precedence.

STRATEGIC PLANNING

In the past defence measures were planned and implemented on a one-off site specific basis, not the most scientifically based approach. Indeed such site by site appraisal not only restricted engineering options but also ensured that not all costs and impacts were taken into account with the result that options were often limited to merely replacing on a like for like basis. This often perpetuated, previous sometimes, inappropriate solutions such as the replacement of hard reflective walls with more of the same. Improvements in the understanding of coastal processes clearly showed that by considering options over a wider area and a longer timescale more lateral thinking was possible, enabling the preparation of schemes that complemented natural processes rather than fighting against them. It was also felt that this more strategic approach would allow the Ministry to more easily meet its own policy objective.

As noted previously the boundaries of the authorities with primary responsibility for the delivery of coastal defences took no account of coastal processes. In addition these authorities had historically made decisions reflecting the needs and wishes of their own electorate and with little consultation with adjoining authorities. Therefore the first policy objective was to encourage these authorities to work together towards more strategic planning such that decisions taken on the basis of engineering knowledge could cross political boundaries. This was achieved by the establishment of voluntary Coastal Defence Groups, encouraged by MAFF, which took account of coastal process cells. To facilitate this a research study was commissioned from HR Wallingford to define logical boundaries of coastal process cells. Cells were defined as lengths of coastline within which the movement of coarse sediment is largely self-contained. Sub-cells within these were also defined on the basis of limited cross boundary influence due to coarse sediment transport.

Once formed these groups allowed authorities on adjoining lengths of coastline to meet and discuss similar problems and solutions and consider joint approaches to the gathering of data etc. Central government also encouraged collaboration between these groups by setting up the Coastal Defence Forum on which all groups in England and Wales are represented.

Central government then provided guidance and encouragement on the production of Shoreline Management Plans which aim to set out a strategy for coastal defences for a specified length of the coast taking account of the natural coastal processes and human and other environmental influences and needs.

The objective in developing these plans was to:

- improve understanding of the coastal processes operating within the sediment cells;
- predict the likely future evolution of the coast;
- identify all the assets within the area covered by the plan which are likely to be effected by coastal change;
- identify the need for regional or sites specific research investigations;

- facilitate consultation between those bodies with an interest in the coastline.

Once the plan was completed the authorities involved in its preparation would then have the means by which they could:

- assess a range of strategic coastal defence options and agree a preferred approach;
- outline future requirements for monitoring, management of data and research related to the shoreline;
- inform the strategic planning process and related coastal zone planning;
- identify opportunities for maintaining and enhancing the natural coastal environment taking account of any specific targets set by legislation or any locally set targets;
- set out arrangements for continued consultation within the group and other interested parties.

BEACH RECHARGE

The practice of recharging beaches as a form of coastal defence has been recognised worldwide for many years, although its use in England has been more limited than in many other countries in Europe. This is partly because of the greater difficulty of predicting beach behaviour due to the variability of beach material and partly because of the difficulty in gaining sufficient suitable material resulting in greatly increased costs.

Improved knowledge of coastal processes and an increasing public desire to take account of environmental effects when designing major infrastructure projects, increased pressure to use beach recharge as a form of coastal defence in England. Such forms of defence were also considered more sustainable in engineering terms. Initial research allowed improvements to modelling techniques which reduced the perceived financial risks and assisted in educating decision makers on the benefits of beach recharge. However, it was soon recognised that recharged beaches needed management if they were to provide a long term sustainable solution. Unfortunately such management works had not previously attracted Central government funding with the costs falling on the local community. Hence the possibility existed that the chosen solution might have more to do with the availability of funding than finding the right engineering solution.

The resulting policy change was to encourage authorities to produce long term beach management plans with the cost of implementing and monitoring for the first time attracting Central government grant. Thus the choice of solution could now more fully depend on science rather than the source of funds. As an additional benefit this change in policy allowed beach management on its own, without the benefit of an initial recharge, to be seen as an effective means of continuing coastal defences along parts of the coastline. With the possibility of Central government finance, operating authorities are now more willing to seek to understand the periodic movements of beach material and manage it for the benefit of improved coastal defences, thereby achieving better value for money and possibly reducing long term capital expenditure.

MANAGED SET-BACK

It was King Canute who first demonstrated to the English population the strength and power of the sea and the need for man to adapt to the wishes of Neptune rather than impose his will on nature. In the intervening years the lesson has been reinforced by the significant loss of land to the sea, recognising that it is not scientifically or economically sensible to protect all 4000 kilometres of our coastline. However, with the change to more naturally sustainable types of defence the option of doing nothing, or more importantly, allowing the

coastline to retreat had to be looked at in a different light. Whilst the retreating of defences did not require any major policy changes, since Mother Nature was doing that already, strategic planning now allowed more informed decisions and the opportunity for environmental enhancement. With improved long term planning it becomes possible to foresee the extent of likely retreat in future years thereby allowing landowners and developers to make more informed decisions but just as importantly the potential beneficial impact of such retreat on other areas of the coastline can be examined.

To compensate for the loss of valuable inter-tidal habitat resulting from coastal squeeze, and man's interference, government also took the opportunity of providing funds to recreate lost tidal wetlands in these setback areas. In areas where setback of the coastline is seen as a viable response mechanism and an opportunity for habitat creation exists, government can now offer payments to landowners for long term management to achieve environmental goals. Obviously merely setting back the coastline may not lead to environmental gain hence a research programme has commenced to determine suitable management regimes.

CARE OF THE ENVIRONMENT

There can be no doubt that flood and coastal defence measures can have a significant impact on the environment with the potential loss of important natural habitats. This is in addition to natural losses which may be exacerbated as a result of the coastline being unable to flexibly respond to natural changes due to man's intervention. These recent changes in coastal defence policy have made it possible to more easily establish the impact of our works on the natural environment and hence consider the possibility of mitigating measures. In addition it may also allow us in the future to understand and quantify some of the natural changes which may result in the loss of important wetland habitat thereby allowing the possibility of adjusting approaches in order to take mitigating measures to retain biodiversity.

FUTURE

As outlined in this paper cooperation between engineers and policymakers has in recent years allowed the scientific advances achieved by coastal engineers to result in consequential policy changes, however, these changes will not necessarily make life any easier for engineers. The move towards long term strategic planning of defences which encourages the maintenance of coastal processes will, without doubt, bring engineers' decisions under closer public scrutiny. Some of their recommendations may not be in accordance with the views of the local population, especially if these include realignment or even the abandonment of some existing defences. With longer term planning an increasing number of people will be involved in decisions affecting the coastline, hence engineers may have to seek consensus views from a wider range of people and interest groups.

The increasing move towards more environmentally friendly solutions to coastal problems will continue to result in change. Earlier in this paper I noted that beach recharge was not as widely used in England as elsewhere in Europe due largely to material supply problems. This is because the material suitable for recharging beaches is also sought by the construction industry. Many prefer to see the use of marine dredged material because of the perceived adverse environmental impact of extracting land based materials whilst the environmental impact of extraction from the sea bed is much less obvious to the general public. Unfortunately in many areas of the North Sea there is now insufficient coarse aggregate to satisfy the long term needs of both the construction industry and beach recharge. Therefore the next policy area that requires consideration is whether the use of marine

aggregate sources should be restricted to allow increased use for beach recharge or to leave it to market forces, as at present.

No matter what the decision on any future restrictions in the use of marine aggregate by the construction industry, demand will, at some time, exceed supply. Engineers' response to this possibility is to seek improvements in the predictive tools for long term sediment movement and developments in coastal morphology. An integrated research project is at present underway which should show some interesting results within a few years. In addition estuaries which are an important but little understood part of the sediment chain are a matter for current review.

The continued move towards more natural forms of defence brings forward questions of risk assessment since decisions are now dependent on a greater number of variables. This has been demonstrated in recent years by the unexpected failure of some soft forms of defence as a result of storm series that were not taken into account in the design process. Our response will be improved techniques in risk assessment leading perhaps to greater use of probabilistic design in coastal defences. An interesting perspective for policymakers.

The move towards strategic planning of coastal defences has resulted in a change of public awareness and perception of coastal engineering problems and as a result the public now takes a fuller part in the decision making process, even questioning the advice of engineers, especially when the "do nothing" option is the preferred choice. This move will, without doubt, bring other areas of coastal use into the decision making process leading to more integrated decisions, although implementation of coastal zone planning in its truest sense is, in my opinion, still some way off.

CONCLUSIONS

It is too early to claim complete success for the recent policy changes in this country, but I have no doubt that we are moving in the right direction and with a speed that has surprised many. Clearly the impact and improvements of recent years has been a lesson to us all and the need for engineers and policymakers to work together remains with us. However, if we are to make the best use of our improved scientific knowledge then it should not always be the policymakers responding to new engineering concepts, but engineers should themselves recognise the pressure on policymakers and be ready to respond with help and advice. Not only should changes in engineering techniques help drive policy but changes in policy need should also feed into engineering research.

CHAPTER 330

STRUCTURAL RESTORATION OF CORAL REEFS DAMAGED BY VESSEL GROUNDINGS

Kevin R. Bodge, Ph.D., P.E.¹

ABSTRACT

In 1995, a unique project was completed in which two coral reef sites in the Florida Keys were structurally restored after having sustained severe damage from the groundings of large vessels. The project, believed to be the world's first major structural restoration of a damaged reef (vs. in-kind mitigation using artificial reefs), demonstrated numerous innovative materials and marine construction techniques. Restoration focused upon the stabilization of coral rubble and large craters which resulted from the vessel groundings. The project's intent was to re-create a stable foundation which closely emulates the adjacent natural seabed and which would foster future recruitment of local biota. Work at one site included the mechanical transfer of coral rubble back into the craters, placement of limerock boulders atop the rubble, and back-filling the boulders' voids with carbonate sand. Work at the other site included excavation of coral rubble and the precision placement of 40 pre-cast reef-replicating armor units into the crater. The gaps between the units and along the crater's perimeter were filled with a specially-designed, non-separable underwater concrete -- into which coral rubble and soft corals were impressed. Design was complicated by the sites' proximity to environmentally sensitive coral beds and shallow depths (2.5 to 11 m). During construction, semi- real-time video images of the underwater work were relayed to the Engineer's office via the Internet to augment construction review. Construction was successfully completed per the engineering plans with no consequent environmental damage amidst a very active tropical storm season.

BACKGROUND

In two separate incidents in 1989, the 40-m *M/V Alec Owen Maitland* and the 142-m *M/V Elpis* went aground upon living coral reefs in the Key Largo National Marine Sanctuary in the Florida Keys, U.S.A. The two sites were within 6.8-km of one another, about 10.4 km offshore of northern Key Largo; and, about 74 km south-southwest of Government Cut at Miami Beach. The Maitland and Elpis sites, respectively, are located in the vicinity of N 25°11'58.776", W 80°13'34.421"; and N 25°8'54.088", W 80°15'9.20" (see Figure 1).

The impact and weight of the vessels upon the reef fractured the underlying coral substrate; and the ships' screws created deep craters in the coralline seabed. Large amounts of coral rubble were created from the fractures and ejected from the craters. Monetary damages were paid by the vessels' operators to the U.S. federal government under the auspices of the National Marine Sanctuaries Act

¹ Sr. Engr, Olsen Assoc., Inc., 4438 Herschel St., Jacksonville, FL 32210 USA; (904) 387-6114.

Figure 1:
Location Map

for the purposes of site rehabilitation. The author was retained by the U.S. National Oceanic and Atmospheric Administration (NOAA) to quantitatively assess the sites' structural damage, and to design and supervise engineering works to structurally restore the damaged reefs.

ENGINEERING ASSESSMENT

Site Survey and Conditions. A precision survey of the two damage sites was undertaken in July, 1994 using tightly-gridded fathometer transects and diver measurements involving triangulation and taut-wire cross-sections of the craters' geometry and rubble piles. A multi-beam fathometer (such as SEABAT) would have been ideally suited for the remote survey work, but was not yet commercially available at the time of the study.

Damage at the shallower Maitland site (-1.8 to -3.0 m, MLW) consisted primarily of a 370-m² crater, varying in relief from 0.1 to 1.0 m, relative to the ambient seabed. The crater was formed by the ships' screw when an attempt was made to free the vessel under her own power. Since its creation, the crater had partially infilled with rubble, but had also doubled in size from what was originally two separate holes. The expansion of the crater was due to wave- and current-induced erosion of its coralline perimeter -- a thin (< 1.5-m) semi-continuous crust overlaying 15-m of densely-packed gravelly-sand. The volume of the crater, measured below the ambient seabed grade, was about 115 m³. The seabed of the crater featured a matrix of sand and 7- to 20-cm diameter, loose coral rubble with scattered larger pieces measuring up to 50-cm.

Damage at the deeper Elpis site (about -11 m, MLW) primarily included two adjacent craters, measuring 69 m² and 163 m², likewise formed by the ships' screws as she tried to free herself. The

depth of the craters, below ambient grade, varied from 0.5 to 2.3 m. The volumes measured 127 m³ and 200 m³. The craters' seabed was composed of sand and coral rubble similar to that of the Maitland site, but featured numerous large coralline boulders of up to 1.8-m diameter. The sand fraction was carbonate, with $d_{50} = 0.6$ mm. Adjacent to the craters were three berms consisting entirely of relic *Acropora cervicornes* (elkhorn) coral rubble that had been initially ejected from the craters. This naturally branched rubble, primarily 10- to 25-cm long by 3-cm diameter, was interlocked but easily succumbed to dismantling by hand or jet probe. The berms' relief varied from 0.3 to 1.2 m with crest widths of 0.6 to 1.5 m, and totalled about 30 m³ in volume.

Scattered across a 0.5 by 1.5 km² area centered about the craters were over a dozen patches of fractured coral rubble. These patches, varying in size from 3-m diameter to 230 m², traced the inbound and outbound paths of the *Elpis* as her hull clipped and crushed higher-relief coral spurs. The weight of the vessel upon these spurs caused the coral to fracture deep below its surface. As a result, the surface rubble (about 10 to 20 cm) was loose and fairly easily dislodged by hand or jet probe. However, once exposed, the underlying coral could *also* be dislodged -- to an apparently limitless depth -- because of the dense cracks which permeated the substrate. By volume, the rubble measured about 15% at 18 cm, 30% at 13 cm, 20% at 9 cm, 25% at 5 cm, with the remaining 10% being sand. The total area of the rubble fields was estimated to be over 450 m².

Both sites, being at the seaward edge of the Florida Keys reef tract, were exposed to ocean waves. Annual average heights and periods were hindcast as about 1.0 m and 5.0 seconds. The largest waves, associated with tropical storms, were assumed to be depth-limited conditions, with nominal 2-m storm surge levels. Both sites featured daily tidal currents on the order of about 0.3 m/s. Hourly wind observations for an 8-year period were analyzed to discern those weeks for which the average hourly-sustained wind speeds were less than 5-, 10- and 15- knots. These data were later utilized to determine the statistically optimum window(s) during which on-site construction activities would be best undertaken. (In brief, the optimum window was found to be July 22 - August 18, with the most expansive window being June 17 - September 22.)

Conceptual Design Alternatives. A range of conceptual engineering alternatives was developed for the sites' structural restoration (Bodge and Creed, 1993). These were evaluated by the Sanctuary's Trustees (the National Oceanic and Atmospheric Administration (NOAA)) in terms of stability, construction feasibility, aesthetics, potential for biotic colonization, and probable cost (Sheehy, Bodge, and Finch, 1995).

The no-action alternative was ultimately not favored primarily because (1) there was little indication that the two sites' injuries were rapidly, naturally healing; (2) there was no indication that the shallower Maitland site's crater would cease its expansion; and (3) there was potential for additional injury by mechanical damage associated with the sites' mobile rubble. (That is, in storm conditions, rubble colonized by juvenile coral larvae would overturn and destroy the colonies and, perhaps, other established corals.) Other alternatives considered for the sites, but ultimately declined in favor of the preferred alternative (described below), included a continuous concrete cap, concrete-filled pillow mats, gabions, cable- and non-cable-stayed revetment mats, conventional boulder fills, and soil stabilization. Particularly at the shallower Maitland site, it was essential that the restoration structurally secure the crater's friable perimeter, and that the work physically fit into the shallow and irregular relief of the crater.

The selected alternative for the deeper *Elpis* site involved temporary relocation of the existing coralline boulders (i.e., those with existing biota), from the craters to the surrounding seabed. The coral rubble berms would then be mechanically relocated back into the craters from which the rubble was ejected. An armor layer of 1.2-m marine limerock boulders (totalling 400 tons) would be then placed atop the rubble. The voids were then to be partially filled with aragonite sand (approx: 60 m³). The temporarily relocated coralline boulders, originally salvaged from the crater, would be then replaced atop the imported boulders and sand fill. (See Figure 2.)

Figure 2: Typical section of Elpis site restoration.

The selected alternative for the shallow *Maitland* site (-2.5 m MLW) involved precision placement of 40 pre-cast "Reef Replicating Armor Units/Living Foundations" (RRAULF's) into the crater, and an underwater pour of specially-designed non-separable concrete (approx. 45 m³) intended to bind the fragile coral perimeter to the armor units and to fill the gaps between the units (Figure 3). The finished elevation of the work was designed to match that of the natural seabed (Figure 4). Steel bar, driven into the seabed, and limerock boulders were to be placed between the units and the crater's perimeter to help secure and dress the concrete, respectively (Figure 5). Limerock gravel and coral berms were to be used as termination forms for the concrete where necessary (Figure 6). As for the Elpis design, the overall stability of the work was designed for a 50-year storm event using stream function wave theory and considerations of drag, inertia, lift and frictional resistance. For stability, the minimum coefficient of friction between an independent armor unit and the seabed was computed as $\mu_f \geq 0.5$ (conservative $C_{Lift} = 0.73$) or $\mu_f \geq 0.38$ ($C_{Lift} = 0.4$).

Each of the 40 armor units featured a highly irregular surface of limerock boulders and exposed aggregate in order to emulate the ambient seabed (Figure 7). The units, each 8300 kg (dry weight), were formed in six different sizes to accommodate the irregular shape and depth of the crater. Steel reinforcement for each unit was designed as a perimeter box beam such that each could be cantilevered 50% in any direction -- in anticipation of the irregular seabed. A standard Portland cement mix was specified for the armor units.

Mix design and specifications for the underwater non-separable concrete were developed by Ben C. Gerwick, Inc. (BCG) of San Francisco, CA. The design mix is summarized in Table 1. Details of the mix design are available from the author, Bodge (1995), or BCG ((415) 398-8972).

IMPLEMENTATION

Permits. Environmental permits for the work were issued by the U. S. Army Corps of Engineers, pursuant to Section 10 of the Rivers and Harbors Act, and Section 103 of the Marine Protection, Research and Sanctuaries Act of 1972. (The latter was required because it was proposed that surplus rubble removed from the sites would be disposed of at an existing ocean disposal site offshore of Miami.) The NOAA Sanctuaries and Reserves Division (SRD) likewise issued a permit for operation within the marine sanctuary. The State of Florida (DEP) was contacted, but did not issue a permit because the activity was outside of State waters (i.e., 4.8-km limit from shore).

Contracting. In mid 1994, NOAA entered into a cooperative agreement with the U. S. Army Corps of Engineers, Jacksonville District, by which the Corps would solicit and manage the construction contract for the work.

Final construction plans and specifications for the work were prepared by the author for the Corps by December, 1994. Procurement was based upon a "best overall value" approach, whereby potential contractors concurrently submitted separate Technical Proposals and Cost Proposals. The former included the Contractor's response, by prescribed form, to specific questions regarding their corporate and personnel experience (among other factors), and their narrative proposals describing their probable technical approach to the work. The offerors' responses were ranked according to prescribed evaluation criteria, previously prepared for the Corps by the author. Cost was to be used only as a "tie-breaker" among the most technically-qualified offerors (which, ultimately, was not necessary). Five proposals were received. The work was awarded to Team Land Development, Inc. of Pompano Beach, FL, in March, 1995.

Construction. Project construction was initiated in April, 1995. The Maitland site's 40 armor units were cast in the Contractor's south Florida yard over a 30-day period using about a dozen wooden forms. The limerock boulders and gravel were locally quarried. The carbonate sand for the Elpis site was oolitic aragonite, imported from the Bahamas and stockpiled in Fort Pierce, FL.

On site, the Contractor utilized conventional shallow draft barge (12 m by 43 m with 1.1-m draft at 150-ton nominal payload), and 27-m tug (1.4 m draft) as the primary work platform. A 10-m pusher tug (0.8 m draft) was used to maneuver the work barge over the shallow Maitland site. At nightfall, the 8- to 12-man work crew bivouaced ashore, at Key Largo, via small workboats.

Table 1: Nominal mix design for underwater, non-separable marine concrete.

Cement	600 lbs./cu.yd.
Fly Ash (class F)	90 lbs./cu.yd.
Silica Fume	43 lbs./cu.yd.
Coarse Aggregate (3/8")	1105 c.y. (40%)
Fine Aggregate	1685 c.y. (60%)
Water	250 lbs/cu.yd.
HRWRA (Sikament 300)	1.3 gals./cu.yd.
AWA (Sikamix 100 SC)	0.6 to 0.9 gals./cu.yd.
Water/Cement Ratio	0.4 ± 0.01
Slump	10" (spec); 9" - 11" (typ.)
Unit Weight (typ.)	142 lb/cu.ft.
% Washout Loss	<1.5%
Initial Setting Time	60 minutes (approx.)
4-day Strength (typ.)	5425 lbs/in ²
28-day Strength (typ.)	6110 lbs/in ²

Virtually all aspects of the work were primarily accomplished or directed by one or two surface-air-supply divers. These divers' communications were audible to the crane operator on the barge deck.

A 3-point mooring was used at the Elpis site, with 120-degree separation at 120-m distance, each, from the work site. Each mooring consisted of a 61-cm, 1.3-cm steel plate anchored to the seabed via four 3-cm, 1.2-m long threaded rods located at the corners of the plate. The rods were anchored to the seabed by pre-drilling deep holes into the coral seabed, placing the rods therein, and grouting with pre-mixed hydraulic cement carried to the seafloor in a 10-cm PVC tube. The plate was secured to the rods by a lockwasher and nut. A padeye was welded to the center of each mooring plate. To each padeye was attached a 3-cm shackle and a buoyant (9-cm polypropylene) mooring line for the barge. Each of the four threaded rods at the corner of each mooring plate was load-tested to vertical pull-out resistance in excess of 66.8 N (15 kip). The barge moorings for the Maitland site consisted of three 61-cm dia. by 1.3-cm wall steel pipes driven approximately 6-m into the seabed by vibro-hammer. Here, the barge was moved offsite at night, during particularly low tides, or in advance of approaching squalls.

At the Elpis site, the rubble berm material was transferred into the craters using both a crane-operated grapple and diver-operated water jet. The latter was more successful, by far, than the former. The limerock armor boulders were placed individually by grapple. The fill sand was placed by a crane-supported, diver-operated 3.5-m³ hopper. Tidal currents carried some of the sand as much as 150-m downcurrent, and resulted in the upcurrent crater being filled with sand to a notably lesser degree than the downcurrent crater (see **Figures 8 and 9**, respectively). As seen in **Figure 9**, local fishes were attracted to the work within hours of its completion.

Attempts were made at the Elpis site to remove unconsolidated coral rubble using both a 15-cm suction dredge with deck-mounted pump and a 10-cm water lift discharging into metal baskets lowered to the seabed. Neither technique proved satisfactory for the work because the rubble was scattered and productivity was very poor. Larger rubble (>8 cm) frequently jammed the intake. [Subsequent rubble removal activities undertaken with suction dredging and water lifts at other grounding sites -- where the rubble was more spatially concentrated and completely unconsolidated (i.e., where the vessel grounding had occurred within the previous year) demonstrated far greater success than at the Elpis site.]

At the Maitland site, the Contractor preferred to use gravel fill to level the crater's seabed (in preparation for the units' placement) rather than excavation. This choice was primarily dictated by the cumbersome difficulty in excavating the dense rubble/sand matrix of the crater's coralline seabed. Excavation around the crater's perimeter, however, was nonetheless necessary to ensure that the upper surface of the perimeter armor units (thickness < 36 cm) would not extend above the adjacent, ambient seabed grade. Coral rubble excavated from within the crater was used to construct a berm around the crater to serve as an additional termination form for the underwater concrete, and to help blend the units' perimeter with the ambient seabed.

After precision placement of the 40 armor units (placed with 5-cm maximum allowable gap between units, and tighter tolerances for vertical differential), and placement of the perimeter boulders and coral/gravel berms, the underwater concrete was placed using a swing-tube pump with 5-cm hose, PVC nozzle, and diver-operable ball-valve. The concrete was batched aboard the barge using a portable ("junior") mixer.

Figure 8:

Photograph of upcurrent Elpis site crater immediately after restoration. Voids between the boulders provided extensive fish habitat and vertical facing for coral larvae recruitment, but resulted in an aesthetic that contrasted with the ambient seabed.

**Figure 9:**

Photograph of downcurrent Elpis site crater immediately after restoration. Voids between the boulders were more effectively filled with carbonate sand, resulting in an excellent aesthetic match with the ambient seabed.

Figure 10 (next page) is a photograph of the *M/V Maitland* hull aground upon the reef in 1989. **Figure 11** depicts one of the pre-cast armor units being lowered from the barge deck to the Maitland site seabed. **Figures 12 and 13** are typical photographs of the Maitland site restoration, taken about a week after the work was completed.

Site work was conducted between June 19 and July 12 at the Elpis site, and between July 13 and September 1, 1995, at the Maitland site. For about half of this time, however, no site work was undertaken because of relentlessly bad seas. In all, the 1995 season was the second worst on record in terms of Atlantic tropical storm activity. At one point in August, there were five tropical storms simultaneously lined-up across the Atlantic, moving toward the Florida peninsula.

Construction Review. Real-time construction review was conducted and coordinated by the Corps, with direct participation of NOAA/SRD personnel and the Design Engineer (Olsen Associates, Inc.). The unique and complex relationship between the project's many parties was facilitated, from the outset, by a 2-day *partnering* conference organized by the Corps prior to construction.

Figure 10:

Photograph of Maitland aground on the reef, 1989. The ship screw is seen resting amidst the coral rubble caused by the grounding.

**Figure 11:**

Photograph of one of the 40 pre-cast reef-replicating armor units being lowered to the seabed. The lifting eyes were unscrewed from the units' threaded inserts after installation.

**Figure 12:**

Photograph of the top surface of the Maitland site repair, taken several days after project completion. The ambient seabed is in the far background. A grouted joint between adjacent armor units is discernible below the fish, in the foreground.

Between site visits, the Engineer (author) was kept abreast of the work by viewing underwater images that had been video-taped by his on-site representative (Mr. Mark Schroeder, Continental Shelf Associates, Inc.). Selected videotape images were captured as a single frame by Mr. Schroeder, then transmitted from his boat via laptop computer, cellular phone, and E-mail to the author's Jacksonville office -- usually within 20- to 30-minutes of the original photography. On

several occasions, the Engineer's access to virtually real-time construction photos permitted timely, cost-saving corrections to the work; or, alerted the Engineer to situations that required an immediate trip to the site and/or instructions to the site-representative.

Environmental Monitoring. Turbidity was monitored using concepts of "exposure" by which "cumulative NTU-hours" were measured and tabulated. There was no observed environmental degradation resulting from the work -- despite the fact that the work was conducted in the midst of sensitive coral resources. Fishes, soft and hard corals have begun re-colonizing the sites (Harold Hudson, NOAA/SRD - personal communication).

Project Cost and Completion. The project's construction cost (bid) was U.S. \$1,047,000, with subsequent change orders resulting in a net additional cost of \$19,600. The total construction cost was about 10% less than the Engineer's estimate. Overall, the project was completed on-time, within budget, in accordance with the design intent, and with no apparent net adverse impact to the environment.

Figure 13:

Photograph of exposed side-face of Maitland restoration, where the repair was terminated adjacent to an existing sandy channel. The restoration is on the left, the ambient seabed is on the right.

CONCLUSION

To the author's knowledge, this experimental project represents the first large-scale, in-situ structural restoration of a coral reef damaged by mechanical impact. Innovative methods introduced, or resurrected, during this project included

- development of structurally sound seabed restoration with emphasis on aesthetic blending with the ambient environment;
- further application of new non-separable underwater marine concretes,

- contract award by the Corps using "best-overall-value" procurement,
- unique cooperation between multiple federal agencies and the private sector, and
- semi-real-time construction review using underwater-taped video images via the Internet among other items. The unfortunate, increasing frequency with which vessels ground upon coral resources -- and other environmentally sensitive seabed resources -- suggest that the lessons learned as part of this project will be of increasing utility to future restoration projects.

ACKNOWLEDGEMENT

The engineering assessment, design, and construction review work described herein were conducted in principal part by Olsen Associates, Inc. under subcontract to Industrial Economics Inc. (IEc), Cambridge, Massachusetts, as authorized by the U. S. Dept. of Commerce, National Oceanic and Atmospheric Administration (NOAA), Contract No. 52-DGNC-1-00007, under Task Order Nos. 50062 and 50089. The leadership of Dr. Dan Sheehy, of IEc, in this project is specifically noted. Initial site survey work was coordinated by Mr. Keith Spring of Continental Shelf Associates, Inc. (CSA), of Jupiter, Florida. The Engineer's on-site technical representative was Mr. Mark Schroeder, also of CSA. Hydrographic survey work was conducted by ARC Surveying & Mapping, Inc., of Jacksonville, FL. Mr. Chris Creed, of Olsen Associates, Inc., greatly assisted in the site survey, data analysis and preparation of the engineering assessment. The innovative internal structural design and specifications for the Maitland site armor units was principally created by Mr. Steve Klecka of SK Engineering, Inc., Jacksonville, FL. The highly successful concrete mix design and specifications were provided by Dr. Dale Berner of Ben C. Gerwick, Inc. (BCG), of San Francisco, California; and then field-reviewed by Mr. Patrick Durnal of BCG. Construction management was executed by the U. S. Army Corps of Engineers, Jacksonville District. Construction review for environmental protection was directed by Messrs. Harold Hudson, Bill Goodwin, and John Halas of the NOAA Sanctuaries and Reserves Division, Key Largo. The construction contractor was Team Land Development, Inc., Pompano Beach, Florida; Mr. Ron Coddington, President. For the contractor, Mr. Charles Calloway was the lead engineer. On behalf of the project's sponsor, NOAA, Mr. Tim Osborn (National Marine Fisheries/Restoration Center), Dr. Charles Wahle (Sanctuaries and Reserves Division), Ms. Darlene Finch (Damage Assessment Center), and Lt. John Tokar (contracting officer) each managed principal aspects of the project, each with great patience and faith.

CHAPTER 331

Dredging and Disposal within the Limits of a National Park

H. A. Manzenrieder and J. M. de Vries¹

Abstract

In coastal areas under tidal influence, recurrent dredging is an important part of the maintenance work to secure the nautical situation and the functionality of the harbors. In the past, the orientation of dredging activities was purely economic but since the early 80's, environmental concerns have rapidly increased and these concerns often define the limiting or determining factors that cover all parts of such operations in the marine region. At present, the sometimes quite different interests of engineering and ecological groups are becoming more gentle. Besides the natural learning effect from the changes in general, economic conditions are also an important factor.

This situation especially applies when maintenance dredging takes place within the limits of a national park where environmental concerns have the highest priority.

The scope of the engineering investigations was the estimation of the environmental capacity as a function of hydrology, sedimentation and biology leading to a specific management for dredging and disposal areas.

Introduction

Public awareness concerning the environment was highlighted at the United Nations Conference on the Environment in 1970. This triggered the development of legislation concerning the control of all kinds of waste. In Europe, a need for legal action ensued from the following international agreements, some of which were ratified by Germany:

- Oslo Convention of Feb. 15, 1972, with a supplement of June 12, 1991
- Helsinki Convention of April 9, 1972, with a supplement of June 6, 1992
- London Dumping Convention of Dec. 29, 1972
- Paris Convention of June 4, 1974

¹ Consulting Engineering Office Dr. Manzenrieder and Partner, Brookweg 29, 26127 Oldenburg, Germany

The guidelines for the disposal of dredged sediments are designed to assist contracting parties in the management of dredged sediments in a way that will prevent pollution of the marine environment. The relative importance of the dumping of dredged material within the containment arriving in the North Sea is estimated at approx. 1,600,000 t/y for nitrogen and approx. 10,000 t/y for lead (Neville-Jones 1994).

The guidelines and restrictions apply to the removal as well as the disposal of dredged sediments. A special question is hydraulic injection dredging and transport by the local current capacity.

When making an assessment in general, it will be necessary to consider the central factors as legal requirements, technical aspects, economic considerations, environmental aspects and more complicated subjective local knowledge and emotional aspects or estimations.

In fact, a very important stimulus for this investigation came from the observations of people who have been personally involved in local activities for a long time (even generations), e.g. the tourist guide.

In practice, environmental requirements are reflected in the individual permits which are only valid for a limited time (2-3 years). In Germany, such official permits actually specify the amount of dredging material (sand, mud), the dredging and dumping areas and the duration of dredging and disposal related to the season in the year (preference: winter) and the phase during the astronomic tidal cycle.

The need for investigation which is laid down by the valid guidelines is determined by the pollution load of the dredged material. Guide values r (mg/kg) are respectively defined for the individual heavy metals.

The guide value r results from concentration c related to the 20 μm fraction multiplied with an uncertainty factor α ($r = c \cdot \alpha$), at present $\alpha = 1.5$.

Within the maximum period of three years, the need for investigation is classified by three ranges of values ($c \leq r$, $r < c \leq 5 \cdot r$, $c > 5 \cdot r$).

In addition, permits can also define the need for and determine the scope of investigations on environmental effects as in this case.

Dredging in the National Park

The islands along the southern part of the German North Sea coast, which are predominately oriented to tourism, are located within the eco-system of the National Park's tidal mud flats and have been an important part of this young park, deserving special protection, since 1985.

Based on a mathematical model that gives a rough description of the current field (Dick 1992), the transport system under tidal effects is predominantly from West to East:

The protection status is to safeguard natural development and covers all activities in an area of approx. 2,400 km^2 with some exceptions within the framework of

coastal protection (dikes) and maintenance activities (dredging). In 1993, the National Park became part of the UNESCO-Program "Man and Biosphere" (MAB). This status was the reason for some interesting economical and engineering requirements e.g. when an expensive tunnel was build for a standard pipeline with a diameter of approx. 1 m (Europipe-Project) or the work to raise a dike was suspended during the operation.

Within this protectorate, the navigable channels to the harbors along the coast and the islands lie mainly in areas with continuous sedimentation, the transport processes of which are defined by a regular average tidal range of approx. 2.6 m, superimposed by random storm surges. The consequence of these conditions is the substantial necessity for quasi permanent dredging activities inside the National Park and subsequent dumping. Alternatives, such as disposal outside the protected area or use of the material for beach nourishment in the vicinity are discussed and carried out in part.

Within the National Park, annual dredging quantities of between 300,000 and 500,000 m³ arise from the maintenance of navigation channels. Small suction hopper dredges with a cargo hold capacity of 150 t (mud) to 300 t (sand) are used for dredging and disposal, the limiting factor of which is the allowable draught with a maximum of 3 m determined by the shallow depth of the flat tidal area. As a rule, disposal is carried out gradually over the whole disposal area to achieve an even as possible distribution at the bottom and in the space of the water.

In connection with intensive monitoring of all dredging activities within the National Park, the measures are based on complete modernization of the position finding system based on the highest GPS technics in combination with the continuous recording of basic data to objectively document dredging activity.

With these measures, the efficiency of maintenance dredging is to be increased on the one hand and on the other, complete evidence on the executed dredging and disposal processes are to be ensured.

Effects of Dredging and Disposal

Due to the fact that the main problems concentrate more and more on the disposal of dredged material, the following description will focus on this question. Dependent on material and area specific parameters, the introduction of dredged material into the water space may, as a result, have a variety of effects on the ecological boundary conditions (changes in the environment). This especially applies to the tidal mudflats.

In keeping with the knowledge we have today, an underlying, lasting and negative effect cannot be assumed a priori.

Area specific parameters such as e.g. current conditions, bottom material or sea conditions, are important boundary conditions for the transport and the dispersion behavior of the solid matter introduced into the natural tidal mud flat area by disposal.

The content of suspended solid matter is influenced by a number of parameters:

- Tide (current velocity, water level, turbulence, salinity)
- Meteorology (sea conditions, temperature,) and Climate (duration of ice covering)
- Topography (surrounding tidal mud flats, bottom material, artificial buildings)

In addition, there are chemical parameters such as e.g. oxygen or nutrient content which influence solid matter content, sedimentation behavior and turbidity conditions.

An urgent, independent problem is defining and selecting suitable parameters and characteristic quantities for describing or supplying evidence on the effects against a background of high, natural variance in tidal waters.

In the following, possible effects from the introduction of dredged material into the space of water and therefore the questions associated with it are presented for assessment:

- Local increase of solid matter content
 - Is there a correlation between solid matter content and turbidity?
 - Does a sandblasting effect occur at the bottom in the case of sandy material?
 - Can a natural turbidity or solid matter background be defined?
 - Are changes in light conditions to be evaluated vertically?
 - Is the influence on photosynthesis quantifiable?
 - Will the migration behavior of fish be influenced?
 - Will this reduce the recognition of danger (e.g. fishing nets)?
 - Are there accumulation effects?
- Reduction of oxygen content by introducing oxygen-depleting matter
 - Which material is considered oxygen-depleting?
 - Which depletion potential leads to a reduction in oxygen content?
 - How does the same depletion potential act under dynamic variability?

According to ESSINK (1993), the disposal of dredged material can, among other things, have the following ecological effects:

- Change of the nutrient balance

Example: Phosphate redissolution can have the effect of increasing the growth of phytoplankton (Sea grass can be negatively influenced when algae cover the surface).
- Inhibition of growth

Example: An inhibition of the growth of phytoplankton can occur through increased turbidity resulting in a reduced supply of food for zooplankton and

filtering bottom organisms. Turbidity interferes with the search for food of visual predators (flat fish, ocean swallows)

- Inhibition of respiration

Example: Increased content of suspended solids inhibit gill respiration of fish and invertebrates as well as food intake for zooplankton and filtering organisms (small crabs, mussels)

- Overtaxed adjustment

Increased sedimentation rates have the effect of smothering bottom animals. Sedentary Benthos species have less chance of survival as opposed to mobile species. Fundamental changes in the composition of sediment can increase the damaging effect on bottom fauna.

The processes that take place in the water space and at the bottom are interdependent and have superpositioning effects. Colonization at the bottom can, for example, lead to increased erosion resistance and therefore influence the suspension content (Manzenrieder 1983).

Relevant Publications

In the past years, several papers have been published on the problem of environmental effects caused by dredging and disposal of sedimentary material and International Conferences in particular have provided an opportunity for exchanging ideas and establishing relationships on a wide range, e.g.. DREDGING '94 by the ASCE in Orlando.

Some of the projects include the results of field studies and corresponding theoretical models. In Table 1, a partial list gives short information on selected studies based on the results of field programs covering typical engineering tools (sounding, sampling, sensor measurements, etc.) and an indication of extended results from natural science (Chemistry, Biology). The depth given indicates the depth at the dumping area.

The targets, size and executing institutions and - last not least - financial frame for such programs vary. In general, it can be stated first of all that every dredging and disposal area has its own behavior so that a direct transfer of results is not likely. Experience in engineering practice has often indicated that the respective research must be delegated to basic research and research with a direct reference, the latter of which often has narrow limitations on time and budget. Nevertheless, this is often the appropriate solution.

To answer basic questions concerning mud flats, a very large research program named "Ecosystem-Research" has been underway in Germany since 1989, the main phase expected to end in 1996. Beyond general statements, the results presented could not support the concrete questions formulated in the permits for maintenance dredging.

The various public interests in the results of such (expensive) investigations which include social and political components are often much greater than the knowledge that has been established on the processes. The contrary explanations for the appearance of large areas with a oxygen deficit in the upper mud flat surface, so called "black spots" after a strong winter, was the last remarkable example.

Procedure

The main target of our investigation was and is compliance with the requirements that are a part of the permit, currently valid for a period of 3 years. To achieve this, an investigation program was started in 1994 which is still being executed, the areas of operation being:

- sediments in the subtidal and intertidal flats
- water column
- macrozoobenthos

For a pilot project, disposal sites are selected, which differ in respect to their location within the hydrological units, the quantity of material being disposed as well as the type of disposed material.

In compliance with the concrete time and economic terms of reference and under the responsible coordination of engineering sciences, a pilot study was developed for the interdisciplinary questions, the structure with long-term measurements and detailed surveys was selected as follows:

- Meteorological and hydrological surveys
- Static and dynamic sedimentological surveys
- Biological surveys

To describe biological processes, macrozoobenthos were selected as an indicator group.

Long-term measurements gradually broaden our knowledge and are therefore a part of extended basic research. In view of the investigations listed for the disposal site area, these are primarily oriented to stabilizing the respective causal analysis:

- Analysis of the dredged material (grain distribution, pollutants)
- High resolution topographical surveys using state-of-the-art techniques
- A rough sedimentological and biological survey of the disposal sites
- Taking samples from monitoring stations in the subtidal and intertidal flats
- Sedimentological characterization of surface samples from the mudflats
- Assessment of macrobenthic fauna on the mudflats

The detailed investigations include a great number of individual measurements and are continuously coordinated to developments. Previous investigations have concentrated on the natural variation of turbidity and the change and extension during disposals as well as the changes in oxygen content during disposals.

Previous Results

Part 1: Dredged Material

All objective reflections on the effects of disposal arise from the potential load potential and therefore from the properties of the dredged material with following results:

- The results of laboratory measurements confirm pronounced material-dependent differences.
- As opposed to fine sand, silt (coastal marsh sediments) shows continuously higher depletion rates.
- Silt samples show an up to 45 times higher average depletion activity related to mass than fine sands.
- Depletion curves of the silt samples show a high initial depletion at the beginning which can exceed mean oxygen depletion by 10 times.
- Quantitative results of stabilized laboratory results cannot be directly confirmed by the natural measurements during disposal.
- In individual measurements during the disposal of coastal marsh sediments and sand, no changes in oxygen content beyond the fluctuation margin of measured values before disposal were determined in the space of water over a period of approx. one hour after disposal.
- Heavy metal concentrations determined in the grain size fraction $d < 20 \mu\text{m}$ all range below the defined limiting values in the guidelines used (Figure 1).
- On the basis of this assessment, the examined dredged material can be rated as non-polluted.
- At present, there is no uniform assessment concept for the evaluation of heavy metal content and organic pollutants in dredged material.
- In regard to the area-specific loads from sediments, there is a need for uniform recording of data as a basis for documentation and the evaluation of trends while isolating anthropogenic intervention

Part 2: Disposal Sites

Previously determined results of the engineering and natural science work fields will be presented in abbreviated form.

- Sediment composition and seasonal changes are different at every disposal site.
- Fine and medium grain sands dominate in the sublittoral, the highest variation being shown by the fine grain size fractions.

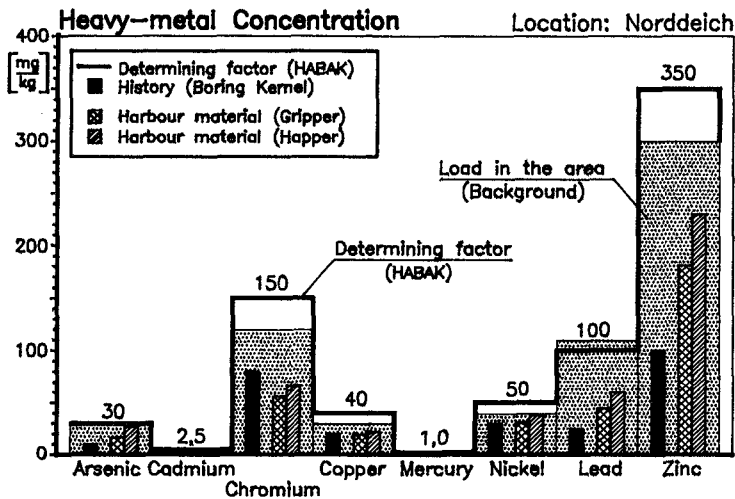

Figure 1. Heavy Metal Concentration and Determining Factors

- With mostly constant main sediment types, changes also occurred on the examined mudflat surfaces during the low-energy summer months in the fine grain areas.
- A sorting of grain size takes place within the immediate disposal site.
- The fine sediment part rises to the edges of a hydraulic/morphological unit (tidal mudflat watershed).

Part 3: Turbidity and Suspension

In order to determine the value range and variation of the natural suspended matter content in connection with current behavior, selective measurements were made over one tide respectively. These results form the basis for an evaluation of concentrated measuring results that were made during the disposal of sand and coastal marsh sediment. The results are characterized as follows:

- The suspension content measured fluctuated during a natural tide cycle (without disposal) in a wide range between 120 mg/l and 660 mg/l. The result over the whole tide was a mean suspension content of $c=225$ mg/l with the maximum values near the bottom.
- Drogues and continuous current measurements in the area of the examined disposal site support a current potential with the highest velocities close to the surface of up to 1.5 m/s at ebb current which, as a whole, dominates over the flood current.
- The measurements made immediately before disposal at lower current velocities comprised recorded values of 2.5 to 30 TE/F (turbidity unit related to Formazin) with respective suspension samples with solid matter contents of 50 to 200 mg/l.

- During disposals, stationary and dynamic measurements were made at a mean water depth of 15 m and in depth steps of 5 m and 10 m in the disposal site and adjacent lee area to survey the spreading cloud of turbidity.
- In Figure 2 a passage of the turbidity cloud during a disposal of sand (d_{50} ca. 0,15 mm) giving a current velocity and water level above the probe is presented. Distance to the input point was approx. 200 m. It was observed that the disposal "trail" clearly stands out against the background values of turbidity. Just a few minutes after input, turbidity values at the selected measuring position rise to approx. 100 TE/F. The mean basic turbidity of approx. 15 TE/F is significantly exceeded over a period of approx. 11 minutes with up to 150 TE/F. After that, the level returns to the level before disposal. At a mean current velocity of 40 cm/s, an extension in the length of the turbidity cloud to approx. 270 m results which corresponds to doubling.
- After the disposal of coastal marsh sediment, the maximum level in the turbidity cloud over a range of 3,000 m was reduced to a third of the measured maximum value.
- The oxygen content within the detected turbidity cloud consistently ranged within the measured natural fluctuation margin.

Figure 2. Turbidity Cloud during Dumping passing in the central Lee Side

The newest version of a modern self-sufficient instrument, a so called sand-surface-meter (Manzenrieder 1995) was placed during the disposal of sand and mud direct under the hopper dredger. The real-time history of the stationary measurements is concentrated on Figure 3.

During the observation the disposal of sand is predominant indicated by a stepwise change in the bottom position. The dominant effect of mud disposal is the transient

formation of a cloud with very low particle movement. The stability of the mud clouds was detected between 2 and 6 hours during the measurements.

In-situ measurement during disposal (20.-22.06.1995)

(Below hopper dredger, depth at disposal site: -8 m below chart datum)

Figure 3. Direct Measurements under a Hopper Dredger during Disposal

Part 4: Benthos Investigations

In the subtidal flats, quantitative samples were taken using van Veen grab sampler supplemented by trawl net catches from a research dredge which were to give a qualitative overview of the epibenthic animal species.

In the intertidal flats, surface samples up to 30 cm in depth were taken respectively. A presentation of the complicated types of analysis and the different extensive groups of results will not be dealt with in this paper.

Assessment (Example)

Since the natural measurements carried out and the model approaches that are available do not form a stable basis for a closed solid matter balance, continuous current and suspension measurements were carried out for a rough model of solid matter loads.

For a defined cross-section in the middle of the disposal site, corresponding suspension loads of 5,800 to 7,700 t per tide phase result for suspension contents of 150 to 200 mg/l. Independent analyses on local bed loads carried by currents show that with an order of magnitude of approx. 10 % of the suspension load, this is a clearly smaller part of the total solid matter load. In Figure 4 the increase of the above presented (natural) suspension transport caused by the input of two dredged material disposals with a quantity of 300 t each is presented for the cross-section of the disposal site. In this case, the first disposal is assumed at approx. 2 hours after the turn of the tide and the second disposal 2 hours before. Under the assumptions made here, both disposals lead to an increase in the quantity of solid matter

transported in suspension during the course of a tide of approx. 10%. This value lies within the documented natural fluctuation margin for the location.

Figure 4. Increase of the natural suspension transport due to 2 disposals (example)

The conditions presented are based as an estimate on assumptions stabilized by measured data and describe the order of magnitude of the solid matter transported. Greater knowledge about natural variation as a result of seasonal fluctuations or meteorological influences as well as secured data concerning the transport of sediment and suspended solids and their distribution for individual tide phases separately are needed for a secured, quantitative assessment of the effect of dredged material disposal. For this, a corresponding picture of current and transport must be described for the area.

Disposal Site Management

Because of the great number of influencing factors that are to be taken into consideration when managing dredged material, especially in shallow water areas, individual disposal site management is to be connected with corresponding ecological requirements. Here, the qualitative and quantitative assessment of specific boundary conditions provides an opportunity to combine the relevant economic and ecological interests into solutions capable of reaching a consensus. Sufficient knowledge on the load potential in connection with the tolerance potential forms the basis for such disposal site management.

The load potential (stress factors) comprises all effective area and material specific effects concentrated in disposal.

The tolerance potential (ecological elasticity) describes the available reaction options of the water ecology and especially the bottom of the body of water under natural and/or anthropogenic loads.

A sensitivity classification as a basis for making decisions which defines limit criteria by stabilized guide parameters and therefore contains e.g. statements on allowable sedimentation dynamics (height, duration) should be the goal for selecting main areas for disposal or disposal sites.

When defining possible disposal sites, the question of whether selective or gradual disposal presents the more economical and ecological solution in the course of a year and for different energy input must be answered.

All of the known or the yet to be determined area and material specific parameters supply a contribution to the effect processes which define the eco-system.

Tolerance potential >> Load potential → Mostly uninfluenced environment

No prolonged change or damage to water ecology and little utilization of loading capacity

Tolerance potential > Load potential → Stable environment

No long-term change or damage to water ecology to be expected for high utilization of loading capacity

Tolerance potential = Load potential → Unstable environment

Unstable limit state of water ecology is reached by full utilization of loading capacity

Tolerance potential < Load potential → Destabilized environment

Prolonged changes or damage to water ecology occur when loading capacity is exceeded

Tolerance potential << Load potential → Changed environment

Comprehensive changes or damage to water ecology by clearly exceeding loading capacity

In the following, an evaluation matrix for the individual monitoring stations has been compiled for a disposal site within the National Park (example).

Based on a measuring program carried out over a period of several years in the area of the disposal site, short-termed, local changes could be quantitatively determined.

Long-term changes or damage to the environment which can be directly attributed to the disposals could not be documented in the dynamic ocean area so far.

A valid assessment of the project dream - "stable environment" - was undertaken according to the presented assessment scheme for the evaluation of intervention in the eco-system which forms the basis for the pending decision of the responsible permit authorities.

Parameter	Retake stations in/around the disposal area in relation to LW												
	above (mudflats)											below	
Bottom Sediments	-	-	/	-	-	/	/	-	/	/	+	/	n

Turbidity	n	n	n	n	n	n	n	n	n	n	n	+	+
Suspension	n	n	n	n	n	n	n	n	n	n	n	+	+

Values in relation to the natural variation: +:above,/ :boundary,-:below,n:not determined

When objectively viewing the (required) state of knowledge on the manifold influencing factors (cluster), it can be determined that there are considerable deficits. Therefore, qualitative natural observations and quantitative natural measurements will still supply the central contributions.

Conclusion

The quantity of the actual dredged material in the National Park is relatively small in relation to the average annual amount in Germany of 35 million m³. By complying with the defined requirements, the unit price for dredging in the National Park - up to US \$ 13 - has nearly doubled in the past few years. When compared internationally, for example with the United States which has an annual average of 230 million m³, the relation of costs for 1995 is approx. 10:1 (Hales 1995).

The type and nature of the sediment is often different from that in the harbors (mud) and the connecting navigable channel (sand). This is important for dredging and the area influenced by disposal. The strategy and collected results were used as input for characterizing the environmental behavior of each region as a part of a morphological and hydrological unit. To do this, the natural background needed to be described in its seasonal variation, also with regard to the effect of single, extremely energetic storm periods. The assessment will resume on the central question concerning the following relation between the natural tolerance potential and the additional artificial load potential due to dredging and disposal with the simple effects for the concerned environment:

Tolerance potential > Load potential = Stable environment

Tolerance potential ~ Load potential = Unstable environment

Tolerance potential < Load potential = Destabilized environment

Experience from such investigations with an ecological orientation show that not only the formulated requirements and limit values but also the relevant investigations are to be objectively adjusted to the respective questions. In this connection, the results from natural measurements are of central importance with increasing duration of observation.

In this process, the engineering sciences with their optimizing work methodology must actively shape these projects in a major way, also searching for overlapping areas in other sciences as they proceed.

CHAPTER 332

Storm-Derived Bar/Sill Dynamics in a Dredged Channel

Sean O'Neil, Student Member ASCE,¹ Keith W. Bedford, Member ASCE,² and David P. Podber, Student Member ASCE³

Abstract

The development of sediment bars and sills due to storm-induced flow events in a dredged Great Lakes tributary is studied. The hydrodynamics associated with long-waves from the lake, create flow reversals at the river mouth, and storm runoff produces large sediment loads delivered to the lake. A laterally-averaged numerical model, including a turbulence closure sub-model, is used to simulate the hydrodynamics. A simple sediment settling, resuspension and transport model is coupled to the hydrodynamic model. Model runs are made for flow and temperature conditions which would be typical of the region during the spring season. Runs are made with and without the sediment settling velocity term, which effectively represents the modeling of two grain sizes; clay particles which have extremely small settling velocities and tend to floc together producing neutrally buoyant particles, and silt sizes which have finite settling velocities.

Introduction

Harbor dredging is the necessary result of long term, persistent deposition of watershed-derived sediments. Periodic redredging is required to ameliorate the occurrence of sills and bars which form as a result of the interaction of wave climate, channel geometry, tributary flow and littoral drift. As opposed to the persistent and predictable tidal forcing on coastal harbors, the harbors on the Great Lakes are moderated by random, long-wave effects derived from storms. The storm surges and resulting seiches, coupled with a high sediment influx from watershed runoff, often

¹Graduate Research Associate, ²Professor and Chair, ³Graduate Research Associate. Department of Civil and Environmental Engineering and Geodetic Science, The Ohio State University, 470 Hitchcock Hall, 2070 Neil Avenue, Columbus, OH 43210-1275, USA. email: sean@superior.eng.ohio-state.edu

conspire to yield a two-sill bottom configuration which motivates maintenance dredging.

As part of a study designed to investigate the impacts of dredging operations, the physical processes responsible for the formation of sills and/or bars is explored by the use of detailed numerical models. The models developed as part of this study will also be used to enhance the tributaries portion of Great Lakes Forecasting System (e.g., Bedford and Schwab, 1994) which currently produces nowcasts four times daily and 24-hour daily forecasts of the state (water levels, wave heights, temperature, currents, etc.) of Lake Erie. This contribution details some of the results of the sill dynamics modeling and analysis for conditions marked by flow reversals and stratified flow.

Study Site

Toledo Harbor, on the Maumee River, is the third busiest port in the Great Lakes shipping arena. The site of the model investigation, shown in Figure 1, extends along

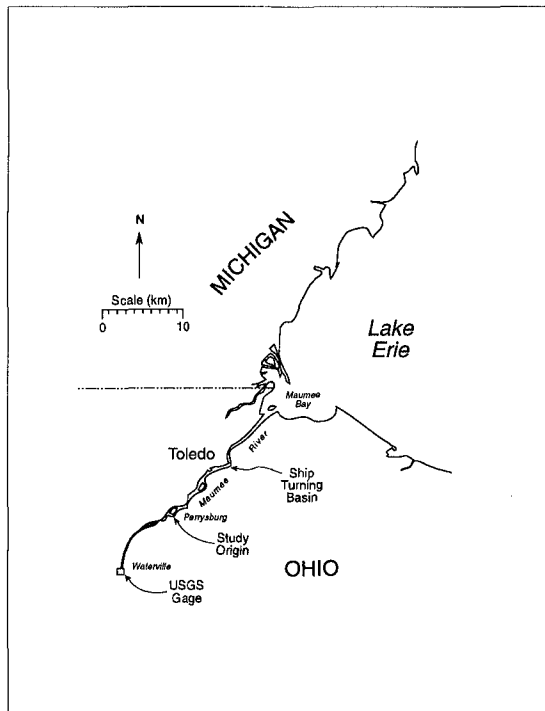

Figure 1: The Maumee River region.

the river, through the Maumee Bay, along a dredged navigation channel. The Maumee River delivers the single largest tributary-derived sediment load to Lake Erie, con-

tributing 44% of the total annual load (Kemp *et al.*, 1976). This high load occurs because 85% of the watershed land use is for agriculture. The extreme shallowness of Maumee Bay, with an average depth 1.5 m (5 ft), and the Western Basin of Lake Erie, average depth 7.6 m (25 ft), necessitates the maintenance of the 152 m (500 ft) wide, 8.5 m (28 ft) deep navigation channel. The dredged portion of the model domain extends from a ship turning basin 9 km upstream in the river, to approximately 6 km into the bay. Figure 2 shows a profile of the modeled portion of the river and navigation channel including the double-silled bathymetric configuration near the mouth of the river.

Figure 2: Schematic of model domain profile.

Physical Setting

The physical setting within the Maumee River, Bay and Western Basin of Lake Erie displays all of the features which might be found in a typical marine estuarine system, excluding of course tidal regularity. Storm events in the Lake Erie region occur with a frequency of 5-7 days during the spring and fall, with durations of 1-2 days. The corresponding increase of river flow rate and stage attain values that are significant fractions of the ambient levels.

A typical storm track during these seasons will follow the major axis, west to east, of Lake Erie, producing a significant storm surge at the eastern end of the lake. The storm surge will decay into a lakewide seiche with frequently observed 14.4, 9.1, 5.9 and 4.2 hour longitudinal modes. The seiche typically produces water elevation changes of more than 1 m, which is a significant fraction of the average water depth at Toledo Harbor. After the storm event, the decaying seiche may take 3-4 days to completely disappear. The narrow and deep dredged channel results in a "pipelining" of the excess flow due to runoff into the lake. The oscillations combined with the seasonal variations in water density gradients, here due to temperature differences

between river and lake water, result in a system which behaves like a typical estuary during storms, and like a river during calm conditions. Flow reversals are frequently noted as are internal waves and oscillations.

Numerical Models

The numerical methods and schemes employed for this set of model runs have all been well documented and used by several researchers under a variety of conditions, therefore only a brief outline will be given as to how the model couplings occur. The one-dimensional, hyperbolic de St. Venant equations are solved to determine the river stage and discharge from Waterville, OH to the river mouth at Lake Erie, in this case using the upstream discharge at Waterville and the downstream stage at the lake, as boundary conditions. In turn, the values of discharge and stage are used as the boundary conditions for the two-dimensional hydrodynamic model, which is based on the laterally-averaged, hydrostatic, Navier-Stokes equations. The use of this type of model allows the vertical structure of the flow field to be captured without the expense of a fully three-dimensional model. The use of the model is justified by the fact of the narrow, deep dredged channel. The two-dimensional model is used only from the ship turning basin (see Figure 2) to the lake and uses specified temperature and velocity boundary conditions at the upstream, downstream and bottom. A turbulent closure submodel, the Mellor-Yamada level 2.5 scheme (e.g., Blumberg and Mellor, 1987), is employed to calculate the time-varying vertical eddy viscosities and diffusivities. At the water surface, the flux of velocity and heat are nil, and at the bottom a drag-law based on the square of the horizontal velocity just above the bottom, allows for a shear stress or no-slip condition.

The sediment transport component of the model solves the advection-diffusion equation for suspended sediment concentration using an upwind advection scheme, a size specific constant settling velocity term, and source/sink terms for the erosion and deposition of sediment. The erosion and deposition terms are parameterized using the model of Sheng and Lick (1979), where the deposition of sediment is proportional to the sediment concentration and erosion is proportional to an excess shear stress as compared to the shear stress for sediment resuspension. Boundary conditions are specified to be no sediment flux through the water surface, a well mixed upstream condition giving a constant input sediment concentration, and lake-like concentration and temperature profiles imposed downstream. Empirical parameters in the erosion and deposition terms are based on previous studies performed in the Western Basin of Lake Erie and reported in Sheng and Lick (1979).

Conditions and Assumptions

The specific imposed conditions and assumptions which are applied for the spring season case study are outlined. The boundary conditions at the two ends of the model would normally come from data, or possibly, the output from other models. For the

spring storm conditions of interest, a typical steady river inflow was applied upstream, the magnitude of $141.6 \text{ m}^3/\text{s}$ (5000 cfs) was determined from flow hydrographs obtained during the spring months (Pinsak and Meyer, 1976). To approximate the effect of the lake seiche after a storm, a downstream sinusoidal water elevation with an amplitude of 0.61 m (2 ft) and a period of 14 hours, was applied for four complete cycles. Given the short term nature of the simulation, the bottom was assumed to be fixed, so that the sills were not moving or changing shape. This is justified by the fact that (with the exception of the spring snow melt discharge) the bottom probably doesn't evolve much under the influence of a single storm event, but does over the course of a season or longer.

The river temperature was assumed to be a constant upstream value of 12°C and the lake was assumed to have a temperature of 7°C , typical for spring (Shindel *et al.*, 1993). The upstream sediment concentration was assumed to be $1 \text{ kg}/\text{m}^3$, and downstream a constant concentration profile, with maximum concentration near the bottom of $1 \text{ kg}/\text{m}^3$, imposed if the flow reversed and lake water traveled upstream. However, the form of the profile was found not to affect results in trials with different profile shapes. Model runs were performed for single sediment grain sizes, and two cases were examined. The Stokes' settling velocities were determined to be $1 \times 10^{-5} \text{ m}/\text{s}$ and 0 for the two cases of silt (median diameter 0.004 to 0.06 mm) and clay particles (median diameter $< 0.004 \text{ mm}$).

Results

Analyses examine the impacts of flow reversals introduced by seiches versus regular downchannel river flow during inter-event periods. The following plots depict the water velocity field in the dredged channel as well as the suspended sediment concentration contours. These results were determined at several points within a single seiche cycle, where the cycle fractions are defined as in Figure 3. For brevity, not all of the cycle points designated in Figure 3 will be shown. Depicted in the figures is the third of four complete cycles run due to the fact that the fourth cycle of a run is generally not very different from the third.

The velocity fields shown in Figures 4-7 show that moderate seiche amplitudes are sufficiently strong enough to cause flow reversals in the river, even for riverine flow rates as high as $141 \text{ m}^3/\text{sec}$ (see also Podber and Bedford, 1993). The upstream sill proximity is consistent with its origination from simple channel deposition of sediments introduced upstream, and the downstream sill is located at the furthest up-channel extent of the 14-hr seiche mode excursion distance. During spring conditions a stable gyre is present above the downstream sill and positioned such that horizontal velocities are zero directly above the peak of the downstream sill, as shown in Figures 5 through 7. As the cycle progresses, the gyre appears to move up and then back down in the water column, but maintaining its position above the downstream sill. This may be an extremely important agent in sill formation and migration. Note also that at all times in the cycle the stratification of the water is maintained, where

Figure 3: Definitions within a seiche cycle.

the warmer river water flows over the colder lake water. During the fall the inverse situation occurs.

In comparing the suspended sediment contours, it can be seen in all cases that there is a greater mass of the silt sized sediment within the water column than the neutrally buoyant particles. This is seen by fact that the larger valued contours are closer to the bottom and the lake side of the modeled domain. This is most likely due to the fact that neutrally buoyant particles enter the modeled region from the upstream direction, but they can only pass out through the downstream end of the model domain. For the case of the settling silt particles, some portion of the total mass of particles will be settling towards the bottom, and though the flow reversal will bring less sediment-dense water into the river, the settling sediment will tend to push the contours down and closer together. Also note that the extent of the upstream excursion of the intruding lake water has the effect of pushing the neutrally buoyant particles back to the upstream sill, whereas the maximum upstream extent of the silt particles is the downstream sill, which occurs at maximum flood.

Acknowledgements

This research was supported in part by the Coastal Ocean Program of NOAA. The Ohio Supercomputer Center provided computing resources under OSC Grant No. PAS891-1. The support is very much appreciated. This is a contribution from the Great Lakes Forecasting System.

CHAPTER 333

Bivalve Habitat Based on Sediment-Transport Mechanics

Hitoshi Gotoh¹ and Tetsuo Sakai², M. ASCE

Abstract

After a storm, thousands of dead bivalves washed upon a beach are sometimes observed. Bivalves are important not only as the marine products but also as the index of the quality of coastal environment. Hence, the field observations of the distribution of bivalves in a coastal zone; and the laboratory experiments on the characteristics of the behavior of bivalves have been performed.

An interesting result is found by Yamashita and Matsuoka (1994) in a laboratory experiment on the burrowing process of bivalves under eroding condition due to the oscillatory flow: even when the descending velocity of a sand surface is sufficiently smaller than the burrowing velocity of bivalves, some bivalves cannot stay in the sand layer and are picked-up by oscillatory flow.

In this study, the physical background of their results are considered from a viewpoint of sediment transport mechanics. Two important aspects are investigated: the one is the stochastic aspect of the burrowing process of bivalves; and the other is the reverse grading phenomena observed in motion of mixed-size grains.

Introduction

Thousands of dead bivalves washed upon beach after a storm have been sometimes observed in the coastal region around Japan. Most of the former field observations and laboratory experiments (Watanabe, 1982; Higano and Yasunaga, 1988; Yamashita and Matsuoka, 1994; and Kuwahara and Higano, 1994) have been performed because

¹ Lecturer, Department of Civil Engineering., Kyoto University
Yoshida Honmachi, Sakyo-ku, Kyoto, 606, Japan

² Professor, Department of Civil Engineering., Kyoto University

of the importance of bivalves as fishery products. Bivalves, or creatures living in sandy beach, are also important as the index of coastal environment.

There are many irregular factors in a moving process of bivalves such as fluctuation of bottom velocity, descending velocity of sand surface due to scoring, size of bivalves, activity, or moving ability, of bivalves and so on. To take these irregularities into consideration, the moving process of bivalves should be treated as a stochastic process.

The other important aspect in the moving process of bivalves is the mode of sediment motion around bivalves. In general, sediment is transported in various modes; bed load, suspended load over sand ripples and sheetflow. Especially, during storm, or under the action of high-shear force, sheetflow should be a dominant transport mode. In the sediment transport in sheetflow regime, the particle/particle interaction, or the momentum transport due to interparticle collision is a mechanism governing the flow structure. To understand the behavior of bivalves in a sediment layer moving in sheetflow regime is an important subject to clarify the mechanism of bivalves-upward motion in a sand layer.

Two important aspects mentioned above are treated in this study based on the numerical model such as the stochastic model for simulating the probabilistic characteristics of bivalve's behavior and the granular material model for the simulation of sediment/sediment and sediment/bivalves interactions.

Laboratory experiment by Yamashita & Matsuoka

Yamashita and Matsuoka (1994) found out very interesting characteristics of bivalves in their laboratory experiment. They performed the experiment on the burrowing process of infant bivalves, or *Spisula sachalinensis*, maximum length of which is more than 5 mm and less than 20 mm, under the oscillatory flow generated by U-tube type oscillating water tunnel. They investigated the probability of the occurrence of the bivalves picked-out-of sand layer under the various values of the ratio of the descending velocity of sand surface, or v_e , to the burrowing velocity of bivalves, or v_s . Figure 1 shows the one of the results of their study on the relation between the probability of the occurrence of the bivalves picked-out-of sand layer and the velocity ratio v_e/v_s .

When the descending velocity of sand surface due to the erosion is larger than the one-thirds of the burrowing velocity of bivalves, namely in the region where the ratio $v_e/v_s \geq 0.3$, whole of the bivalves in a sand layer are picked-out-of sand. In their experiment, the burrowing velocity of bivalves are measured in a still sand layer. To understand the physics of this phenomena, the behavior of bivalves in a streamwise-moving sand layer should be investigated.

In the region $0.1 \leq v_e/v_s < 0.3$, some bivalves are picked-out and others are staying

Figure 1. Occurrence of the bivalves picked-out
(Data from Yamashita and Matsuoka, 1994)

in a sand. This means the importance of stochastic consideration of the motion of bivalves to express the probabilistic aspects of the moving process of bivalves.

Stochastic consideration of burrowing process of bivalves

procedures of stochastic calculation

The following assumptions, some of which are based on the previous experiments conducted by Higano, Kimoto and Yasunaga (1993) and Yamashita and Matsuoka (1994), are introduced in this calculation.

(1) The shell length of bivalve $l_s=8$ mm. (2) The bivalve burrows in a sand layer keeping shell-length axis parallel to the vertical direction. (3) Initially, the top edge of bivalve coincide with the surface of sand layer, as schematically shown in Fig. 2.

(4) Bivalve begins to burrow in a sand layer when its top is exposed due to the scouring. The threshold of exposed length at the beginning of bivalve's burrowing is treated as the probabilistic variables based on the experiment by Higano et al (1993). (5) Bivalve rests in sand layer when the clearance between its top edge and the surface of a sand layer is equal to the half of shell length as shown in Fig. 2. The burrowing and the resting are iterated alternately. (6) Bivalve is defined to be picked out of sand layer when the 80% of the shell length are exposed in water as shown in Fig. 2. (7) The cycle of calculation begins at the moment when the condition (5) is satisfied. If the condition (6) has not been satisfied for 2200 s from the beginning, the calculation is terminated. This situation is defined as the survival of bivalves. (8) As it is mentioned above, bivalve is repeating the burrowing process and resting process, the average of the repeating period of which is equal to 2.2 s, according to Yamashita and

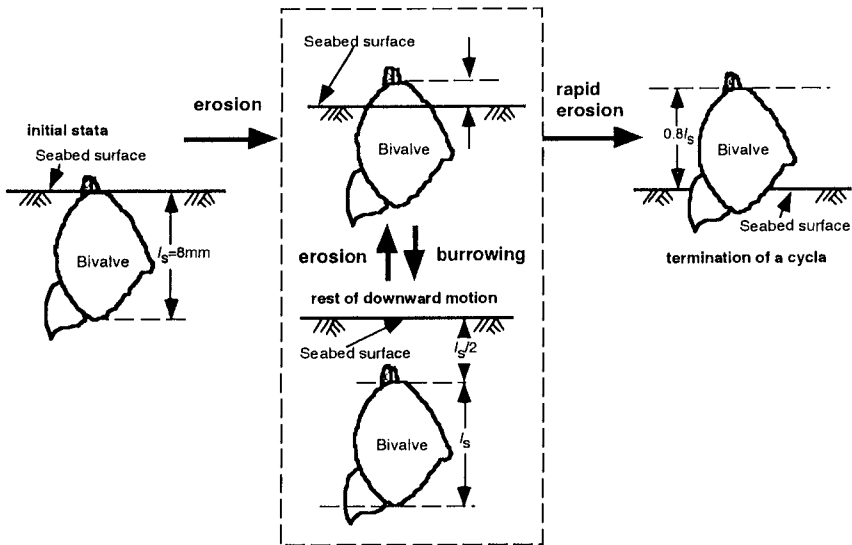

Figure 2. Definition of parameters in bivalves

Matsuoka (1994). They also investigated the distribution of burrowing velocity of bivalves. In this calculation, the burrowing velocity of bivalves changes at every 2.2 s based on the Monte Carlo Method, namely by generating the random numbers following the distribution of the burrowing velocity experimentally investigated. (9) The descending velocity of the surface of sand layer is treated as a probabilistic variables following the normal distribution, the standard deviation of which is equal to one-third of averaged descending velocity, or $\sigma = v_e/3$.

results of the stochastic calculation

Figure 3 shows one of the calculated results of the one-cycle of the burrowing process of bivalves under the condition of $v_e/v_s=1.0$. In this figure, the time series of the existing height of bivalves, elevation of sand-layer surface and the thickness of sand layer above the top of bivalves, or δ , are shown. In this case, the thickness δ is decreasing rapidly during $0.0 \leq tv_s/l_s \leq 1.0$, and on the verge of the picking-out of bivalves. After $tv_s/l_s=1.0$, the thickness δ increases again. In this case, the bivalve survives through one cycle of calculation. If the decreasing velocity of the thickness δ during $0.0 \leq tv_s/l_s \leq 1.0$ is a little more rapidly, this bivalve is picked-out-of sand layer. The survival of bivalve is strongly depends on the accidental-drastic change of the surface elevation of sand layer.

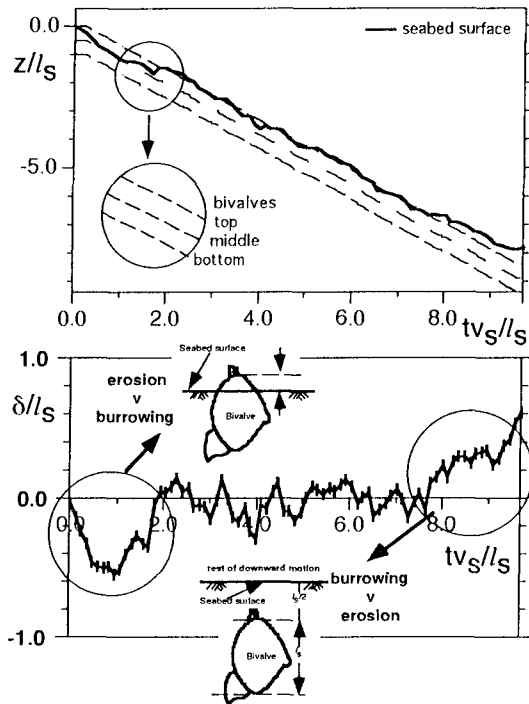

Figure 3. Burrowing process of bivalve

The probability of the survival of bivalves, or P_m , is calculated by continuing the cycle of calculation for m -times with assessing the occurrence of the bivalves picked-out-of a sand layer. Fig. 4 shows the existing probability of bivalves after 100 cycle of calculation, or P_{100} , against the ratio of the descending velocity of sand-bed surface to the burrowing velocity of bivalve, $v_e/v_s (= \alpha)$. Two cases of the calculation are shown in this figure. The one is the calculation in which the probabilistic characteristics of bivalves are only considered; and the other is the calculation in which both of the probabilistic characteristics of bivalves and that of sand-bed surface are considered. The transition range of the probability of the survival of bivalves experimentally investigated by Yamashita and Matsuoka is also shown in this figure.

The transition range of the experiment is $0.1 \leq \alpha \leq 0.3$, while the calculation, in which the probabilistic characteristics of bivalves is only considered, shows the drastic transition around $\alpha=0.9$. The calculation, in which both of the behavior of bivalves and the motion of sand-bed surface are treated as the probabilistic variables, predicts the transition range in $0.6 \leq \alpha \leq 0.75$. But even if the probabilistic characteristics of

Figure 4. Survival probability of bivalve

sand-bed-surface elevation is considered, the threshold of the emergence of bivalves picked-out-of sand layer are overestimated.

Although the stochastic calculation reproduces the existence of the transition region in the probability of the bivalve's survival against the change of velocity ratio v_e/v_s , the threshold of the bivalve's survival is not reproduced well at least quantitatively. This fact suggests the existence of other mechanism, which promotes the picking-out-of bivalves.

Behavior of bivalves in sheetflow layer

reverse grading as the mechanism of upward vertical motion of bivalves

Boulders are frequently observed to be concentrated at the near-surface region of the front part of debris flow. This phenomenon, namely the existence of the boulders above other grains and gravel, is called reverse grading.

Interparticle collision is the governing mechanism both of debris flow and sediment transport in sheetflow regime. Therefore the same kind of phenomena as the reverse grading of debris flow can be thought to be a mechanism to promote the bivalves to be picked-out-of sand layer. In this study, the behavior of bivalves is traced numerically in the moving sediment particles in sheetflow regime by the distinct element method (=DEM).

distinct element method

Sakai and Gotoh (1995) performed the numerical simulation of the motion of sheared sediment-particle layer based on the distinct element method. In this study,

their simulation is applied to simulate the interactive behavior between bivalve and sediment particles around bivalve by regarding the bivalve as a large and light particle.

governing equations of sediment particles

Sediment particles are modeled by the rigid cylinders with uniform diameter d ; and the bivalve is modeled by the rigid cylinder with diameter D . At inter-cylinder and cylinder-bivalve contacting point, the spring and dashpot systems are introduced, and the equations of motion of cylinder and bivalve are solved by an explicit method.

Equations of motion of the i -th particle or bivalve in the vertically two-dimensional coordinate are as follows:

$$\frac{\pi\sigma_i d_i^2}{4} \frac{d^2 x_i}{dt^2} = \sum_j \left\{ -f_n(t) \cos \alpha_{ij} + f_s(t) \sin \alpha_{ij} \right\}_j + F_{0i} \quad (1)$$

$$\frac{\pi\sigma_i d_i^2}{4} \frac{d^2 y_i}{dt^2} = \sum_j \left\{ -f_n(t) \sin \alpha_{ij} + f_s(t) \cos \alpha_{ij} \right\}_j - \frac{\pi(\sigma_i - \rho) d_i^2 g}{4} \quad (2)$$

$$\frac{\pi\sigma_i d_i^3}{16} \frac{d^2 \phi_i}{dt^2} = \sum_j f_s(t)_j \quad (3)$$

in which f_n, f_s =the forces acting between the i -th and j -th particles; α_{ij} =contacting angle between the i -th and j -th particles; F_{0i} =shear force acting on the i -th particle; σ_i =density of particle; and d_i =diameter of particle; and g =gravitational acceleration. The subscript "n", "s" mean normal and tangential components, respectively.

calculation of interparticle-acting force

Figure 5 shows the schematics of the interaction between two contacting particles. Between two contacting particles, springs and dashpots are introduced to describe the dynamic interparticle relation. The acting force between the i -th and j -th particles in normal and tangential direction, f_n and f_s , can be written as follows:

$$f_n(t) = e_n(t) + d_n(t) \quad ; \quad f_s(t) = e_s(t) + d_s(t) \quad (4)$$

$$e_n(t) = \min \{ e_n(t - \Delta t) + k_n \cdot \Delta \xi_n, e_{n\max} \} \quad ; \quad d_n(t) = \eta_n \cdot \frac{d\Delta \xi_n}{dt} \quad (5)$$

$$e_s(t) = \min \{ e_s(t - \Delta t) + k_s \cdot \Delta \xi_s, e_{s\max} \} \quad ; \quad d_s(t) = \eta_s \cdot \frac{d\Delta \xi_s}{dt} \quad (6)$$

in which e_n, e_s =forces working on springs; d_n, d_s =forces working on dashpots; $\Delta \xi_n, \Delta \xi_s$ =displacement of particle during the time Δt (Δt =time step of the calculation); k_n, k_s =spring constants; and η_n, η_s =damping coefficients. In this simulation, particles

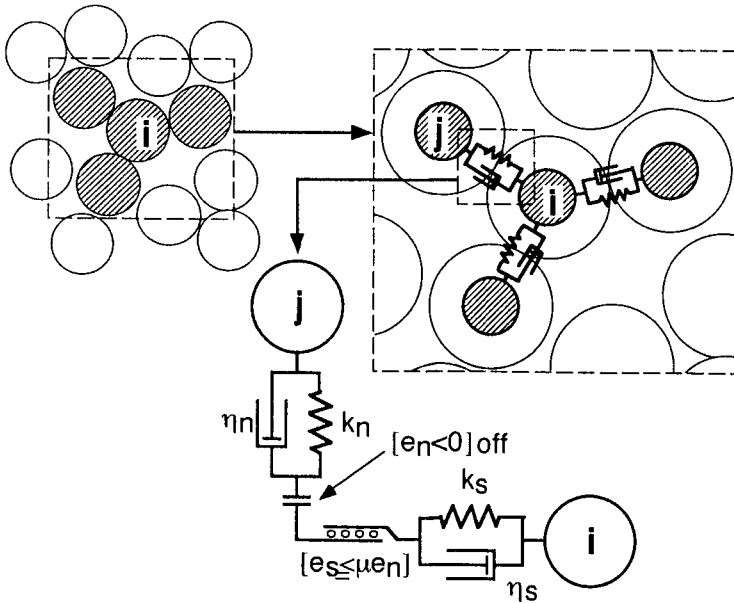

Figure 5. Schematics of the interaction between two contacting particles

are non-cohesive, hence the tensile force does not act between two contacting particles. To describe this characteristics, the joint, which no resistance to the tensile force, is assumed to exist in the normal direction. While, in the tangential direction, the friction force works. To describe this characteristics, the joint, which slips at the limit of the shear stress, is assumed to exist in the tangential direction.

initial conditions and boundary conditions

Figure 6 shows the schematic expression of the calculating domain. In this simulation, streamwise uniform condition is treated, therefore, the both sides of the calculating domain are the periodic boundaries. The bottom boundary is the fixed rough bed constituted by the particles with the same diameter as the moving particles. Before the beginning of the main calculation, the packing to determine the stable initial location of the particles is executed.

The shear stress is distributed to the particles in the neighborhood of the surface of sand layer in a following procedure. Procedure are, firstly, to set the threshold y_{th} (see Fig. 7); secondarily to calculate the area of the particles above the threshold, or

Figure 6. Schematics of calculating domain

the shaded area in Fig. 7, for the particles existing on and above the threshold; and finally to distribute the shear force to the particles existing on and above the threshold with calculating the area of particles above the threshold $S(\theta_i)$ as follows:

$$S(\theta_i) = \begin{cases} \frac{r^2}{4} \left(\pi - \theta_i + \frac{1}{2} \sin 2\theta_i \right) & ; y_i \geq y_{th} \\ \frac{r^2}{4} \left(\theta_i - \frac{1}{2} \sin 2\theta_i \right) & ; y_{th} - \frac{r}{2} < y_i < y_{th} \end{cases} \quad ; \quad \theta_i = \cos^{-1} \left(\frac{y_i - y_{th}}{r} \right) \quad (7)$$

Distributed shear force to the i -th particle is written as

$$F_{0i} = Lw_i\tau_0 \quad ; \quad w_i = S(\theta_i) / \sum_{j=1}^N S(\theta_j) \quad (8)$$

in which L =length of the calculating domain in horizontal direction; τ_0 =bottom shear stress par unit area. The test particle is 0.5 cm in diameter and 2.65 in specific gravity; and the model of bivalve is 2.0 cm in diameter and 1.30 in specific gravity (see Higano et al., 1993). In the calculating domain, 91 particles and 1 bivalve are traced. The model constants are shown in Table 1.

Initially the bivalve is contacting to the bottom constituting particles. The time step of the calculation is 2.0×10^{-5} s and the totally 80,000 cycles of calculation is executed, hence the motion of sediment particles and bivalve for 1.6 s is traced.

Figure 7. Shear stress distributed to sediment particles

Table 1. Model constants

results of simulation

Figure 8 shows the snapshots of the sediment-and-bivalve motion with 0.2 s intervals under the action of the shear stress $\tau^*(\equiv u_*^2 / \sqrt{(\sigma / \rho - 1)gd}) = 1.5$ on the surface of sediment layer. Bivalve, which is initially contacted to the bottom constituting particles, moves upward gradually, and it is picked-out-of a sand layer 0.8 s after the initiation of the shear action. Most of the particles in lower layer has laminar motion, hence the momentum exchange in lower layer is inactive. While, in the upper layer the concentration of sediment particles is less than that in the lower layer, the vertical motion of the sediment particles is less frequently obstructed by the particles in the upper layer than in the lower layer.

To understand the physics of the upward motion of bivalve, following hypothesis is proposed. The bivalve exists in the shear layer, in which the sediment particles

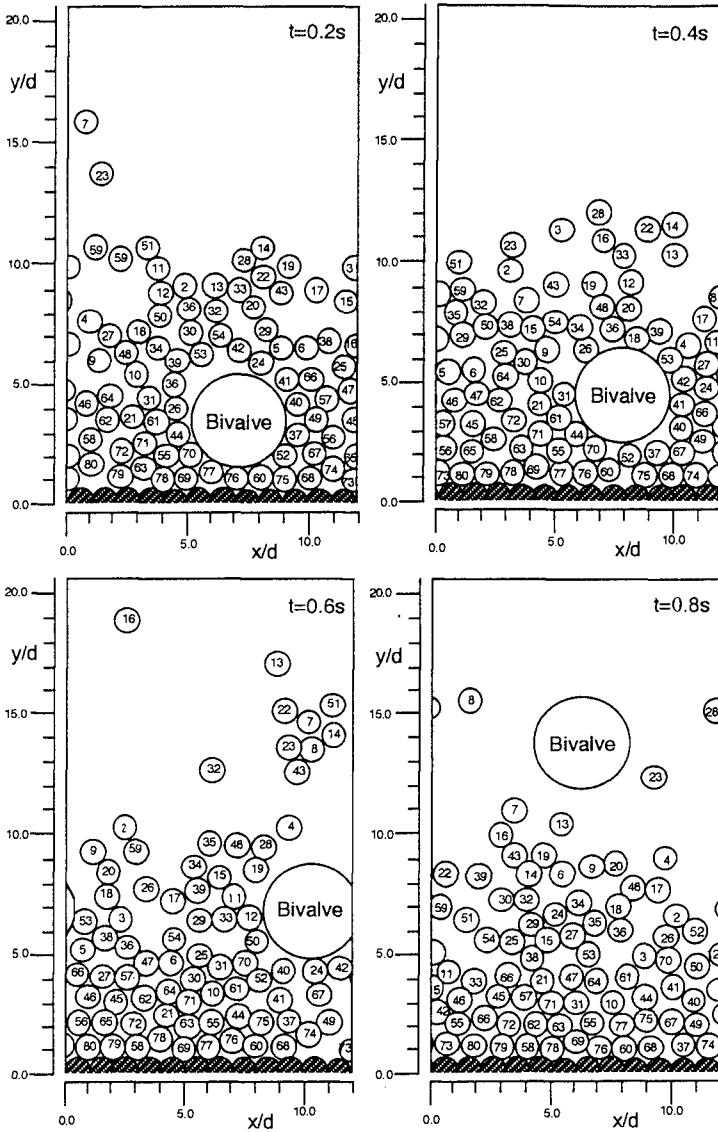

Figure 8. Snapshots of the sediment-and-bivalve motion

Figure 9. Upward motion of bivalve

have a vertical velocity distribution as schematically shown in Fig.9. Therefore the particle colliding at the upper part of bivalve is faster than that colliding at the lower part of bivalve. This velocity difference of the colliding sediment particles makes the bivalve to rotate in clockwise. Supposing the contacting sediment particle with just the lower part of the bivalve in the downstream section (hatched particle in Fig.9) and the hypothetical plane at the contacting point between bivalve and the particle, the behavior of the bivalve can be simplified as the clockwise rotating cylinder on the slope. And the clockwise rotation moves the cylinder to upward.

Figure 10 shows the time series of the rotating angle, the sign of which is positive in counterclockwise, and the elevation of the centroid of bivalve. The bivalve begins to move upward gradually accelerating the rotational motion. Around 0.6 s, bivalve moves in upward direction drastically, and at the same time the rotational motion is accelerated also drastically. From this fact, the rotational motion of bivalve can be regarded as the driving mechanism of the upward motion of bivalve.

Conclusion

The physical background of the behavior of bivalve in sand layer during storm are considered from a viewpoint of sediment transport mechanics. Two important aspects are investigated: the stochastic aspect of the burrowing process of bivalves and the reverse grading phenomena observed in a motion of mixed-size grains.

Figure 10. Rotating angle of bivalve

The stochastic model simulates the probabilistic characteristics of environment around bivalves. And the granular material model, or distinct element method, simulates the motion of bivalve in upward direction based on the sediment/sediment and sediment/bivalves interactions.

CHAPTER 334

Hydraulic Controls on Tidal Wetlands

R. Eric Katmarian, Philip A. McKee, Timothy W. Kana¹

Abstract

Tidal wetlands have long been identified as critical habitats for many species of fish, birds, and other wildlife and are protected areas in many states. For these reasons, coastal projects which impact or destroy wetland areas are difficult to permit and often require substantial mitigation. An hydraulic design procedure is presented for the creation or improvement of wetlands based on flooding duration -- the percentage of time an area is inundated by tidal waters. This is followed by a sample application of the procedure to a recent mitigation project in Savannah, Georgia.

Introduction

Tidal wetlands, sometimes called the oceans' nurseries, contain many habitats for both plants and animals. Among the many habitats that exist, the basic ones include open water, tidal flats, low marsh, high marsh, transitional wetlands, and highland (Fig. 1). These habitats are sensitively balanced for existing tidal conditions, wave climate, daily flooding duration, sedimentation rates, and climate (Kana et al., 1986). Perturbations of these factors over an extended period can result in the transformation of one habitat into another.

Because wetlands tend to exist in areas of limited topographic relief, transitions between habitats can be indistinct and often occur over some distance, making precise location of boundaries difficult. Nevertheless, it is generally recognized that the character of flooding controls species distribution, with some wetland species preferring infrequent and irregular inundation, while others have adapted to frequent flooding. As a result, many studies have been undertaken to define wetland boundaries (Teal, 1958; Redfield, 1972; Nixon, 1982).

¹ Coastal engineer, research assistant, and senior scientist, respectively; CSE-Baird, PO Box 8056, Columbia, SC 29202

Figure 1. Typical habitats in tidal wetlands near Savannah, Georgia (From CSE 1995).

One method of delineation has been to identify habitats on the basis of flooding frequency – the number of times per day that an area is inundated. On the basis of flooding frequency, the basic habitats occur as follows (Kana et al., 1986):

Highland	-- flooded rarely
Transitional wetlands	-- flooding ranges from biweekly to annually
High marsh	-- flooding ranges from daily to biweekly
Low marsh	-- flooded once or twice daily
Tidal flats	-- flooded up to half the day
Open water	-- flooded more than half the day

Additionally, an often repeated rule of thumb has developed which states that low marsh exists where the substrate elevation is roughly at the mean high water level. However, the above criteria are too general to be incorporated into procedures for quantifying impacts on wetlands or to be used in wetland design criteria.

Many investigators (Adams, 1963 in Lagna, 1975; Kana et al., 1986) have extended the “mean high water” rule, saying that the primary factor controlling the distribution of wetland species is the relationship between marsh substrate elevation and local tidal water levels. Kana et al. (1986) even developed a normalized curve to be applied to arbitrary sites (Fig. 2). To use the normalized curve, a species-specific factor is read from the vertical axis and applied to the local extreme high water level referenced to mean sea level (MSL) datum. For example, for *Spartina alterniflora*, the water level factor is approximately 0.48. Therefore, at a site where extreme high water is 3 meters (m) MSL, *Spartina alterniflora* would be found in low energy environments with a substrate elevation of about 1.44 m MSL. Despite some findings that elevation alone does not control species distribution (Lagna, 1975), the appeal of such simple methods for engineering and environmental applications is clear.

In this paper, the idea of hydraulic controls on tidal wetlands are refined and extended, and a general wetlands design method is proposed.

Figure 2. Normalized probability distribution of elevations for various wetland species (From Kana et al., 1986).

Flooding Duration as a Control on Wetland Habitat Distribution

It is generally accepted that character of inundation is the primary factor governing the distribution of wetland species. As described above, previous investigators have chosen to describe inundation in terms of substrate elevation relative to tidal water levels. However, relative elevation does not necessarily represent identical flooding characteristics at sites where tidal signature differs. For example, if two sites have equal tide ranges but one has an attenuated ebb tide, they will be flooded for differing periods for a given elevation (Fig. 3). When the effects of daily inequality, fortnightly cycles, and atmospheric affects are also introduced, relative elevation becomes an even less reliable measure of flooding character.

Figure 3. Flooding duration at equal elevations differ at sites where tidal signatures differ.

Flooding duration, the percentage of time that an area is inundated, is proposed as a more accurate measure of flooding character than relative elevation. Flooding duration is applied to species zonation in a manner similar to elevation.

It is assumed that wetland plant species are found in specific ranges of flooding duration. These ranges often overlap, and ranges for some species may be contained in the ranges of others. Indicator species may be chosen to identify specific wetland habitats. Wetland habitats are categorized by flooding duration in Table 1.

The durations listed in Table 1 are based on several wetlands surveys, the project described below, and many years of field observation. Nevertheless, minor variations should be expected on a site-specific basis. Until this method of design has gained wider acceptance, surveys of existing wetlands to confirm flooding durations for specific habitats should be conducted prior to design of new sites.

Table 1. Approximate flooding duration ranges for wetland habitats

Habitat	Flooding Duration
Upland	0 %
Transitional Wetlands	0-2%
High Marsh	2-5%
Low Marsh	5-25%
Tidal Flats	25-50%
Open Water	>50%

Although somewhat cumbersome to use, flooding duration has several advantages over elevation, particularly when broadly applied:

1. The dominant factor controlling species zonation, the character of flooding, is more directly represented by flooding duration.
2. Flooding duration can be more generally applied than relative elevation since variations in tidal signature are accounted for.
3. The effects of frequent inundation due to storm surge or other factors are more accurately accounted for using flooding duration, particularly if a lengthy water level record is available. It is likely that this factor is particularly important where the tide range is relatively small and atmospheric events are more significant.
4. Flooding duration emphasizes the need for relatively long-term, site-specific water level measurements, while elevation data is easily misapplied to areas where the tide is attenuated or otherwise different from open-water conditions (commonly where tide gauges are located).

To calculate flooding duration, *a relatively long-term, site-specific water level record must be used* to account for daily inequality, fortnightly cycles, and irregular variations in water levels. Furthermore, existing tide gauges are generally located in open water where water levels are often significantly different than water levels in wetlands. To obtain an acceptable water level record, a tide gauge may need to be deployed.

The length of the record required will depend on local conditions affecting the variability of the water levels. Judgment must be used in determining the minimum length of record required at a particular site though, in most locations, a 25-day record will suffice.

Once an acceptable water level record is obtained, flooding duration for a given elevation is calculated as:

$$\text{Flooding Duration} = \frac{\text{Cumulative time with water level above elevation}}{\text{Total length of record}} \times 100$$

In some cases, the creation or alteration of a wetland has the potential to significantly change local water levels. This is undesirable since it has the potential to cause habitat transformations in existing wetlands. Additionally, specification of a substrate elevation corresponding to a desired flooding frequency becomes very difficult when postproject water levels are uncertain. Steps must be taken to minimize the impact of projects on local water levels. This can be accomplished by specifying an appropriate substrate elevation for the new wetland or by increasing the hydraulic capacity of connections to open water to accommodate increased flooding areas.

Numerical models can be extremely helpful in predicting postproject water levels when local hydraulics are altered by wetland creation.

Sample Application: Mitigation Site Design

A recent CSE (1995) project involved hydraulic design for a 10-acre wetland at a site previously used for dredge spoil disposal near Savannah, Georgia. The site is approximately 900 m from the Savannah River and has hydraulic connection to the river via a complex network of ditches, culverts and existing wetlands (Fig. 4). The design objective was to create a tidal wetland at the site while minimizing both excavation requirements and impacts to existing wetlands.

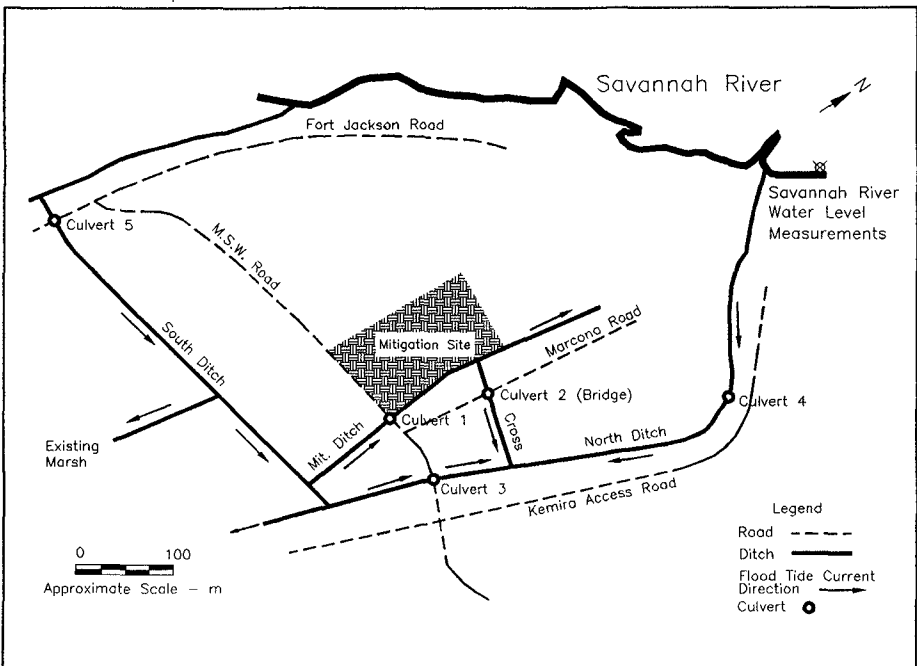

Figure 4. A complicated system of ditches, culverts, and wetlands connected the mitigation site to the Savannah River (From CSE, 1995).

The first step in applying the flooding duration method to the design was to determine the range of flooding duration for the type of wetland desired. A number of transects were surveyed through a nearby "natural" wetland. Elevation and distance were recorded at each point where species changed or where there were noticeable breaks in slope or elevation. Species types were identified with the assistance of a biologist. Elevation for each species was weighted by distance of occurrence to produce an elevation distribution for frequency of occurrence. The elevation data for all observed species were approximately normally distributed.

Local water level data were required to calculate flooding duration for the range of elevations observed for each species. Therefore, water level measurements in the surveyed wetland were taken over several tidal cycles and compared against data from a nearby permanent tide gauge. No significant water levels differences were observed between the surveyed marsh and the permanent gauge, so a 30-day record from the permanent gauge was used for flooding duration calculations. If significant differences had been noted between the marsh and gauge, water levels would have had to be measured at the site for a minimum of 25 days to provide adequate water level data for flooding duration calculations.

Flooding durations were calculated for the average elevation, and average elevation \pm one standard deviation of each species observed (Table 2). Elevations outside this range are attributed to localized variations in water levels and errors introduced by weighting approximations. *Spartina alterniflora* was chosen as the low marsh indicator species, as is the usual practice on the East Coast. Therefore, the observed flooding duration range for local low marsh was found to be approximately 5 to 21 percent.

Table 2. Wetland species flooding durations near Savannah, Georgia (CSE, 1995).

Species	Flooding Duration (% of tidal cycle)		
	Mean	Lower Bound	Upper Bound
<i>Spartina cynosuroides</i>	13.7	8.3	18.5
<i>Spartina alterniflora</i>	12.0	4.5	20.5
<i>Carex</i> sp.	9.3	2.7	19.9
<i>Juncus</i> sp.	6.3	3.2	11.3
<i>Typha augustifolia</i>	3.5	1.3	6.8

With the design flooding duration for low marsh established, the next step was to determine how to achieve this range at the mitigation site. The goal was to specify a substrate elevation range for the mitigation site which would result in the desired flooding frequency, given the hydraulic capacity of the ditch and culvert network. However, it was recognized that the addition of the 40,000 m² wetland to the existing system would change its tidal characteristics, making postproject water levels different than preproject levels. Without good estimates of postproject water levels, accurate determination of flooding duration was impossible. Furthermore, measurements of flows through existing channels and observations of flow restrictions

at culverts indicated that the existing system could not supply adequate tidal exchange to the mitigation site to sustain a low marsh. This meant that improvements would have to be made to the drainage system.

To gain some confidence in postproject conditions, DHI's Mike11 river model was used to simulate the ditch and wetland system. Figure 5 shows a schematic of the model setup. After calibration to existing conditions, the model proved instrumental in arriving at the final design by allowing the effects of ditch and culvert improvements, variation in mitigation site elevation, and impacts to existing wetland areas to be investigated.

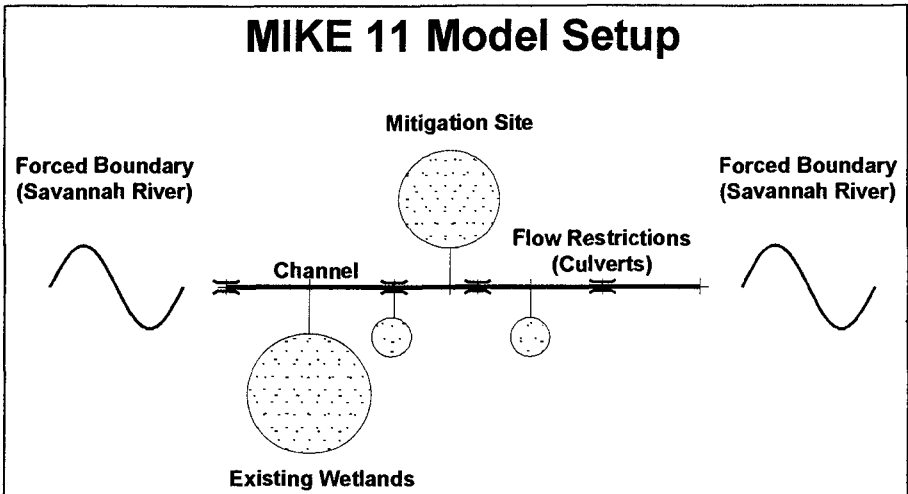

Figure 5. Schematic Mike11 model setup showing the channel/wetlands system modeled (From CSE, 1995).

Model results supported by field observations showed that both the existing wetlands and the site to be mitigated were flooded primarily by the south ditch (Fig. 4). This was primarily due to a topographic high point in the north ditch. With the high point and culvert 4 removed and the north ditch widened, the model showed that flooding of the mitigation site would occur from both the north and south. The model also showed significant increased flooding of the existing wetlands and the potential to convert them to “wetter” habitats. The final design recommendation was to isolate the mitigation site from the existing wetlands by closing culvert 1. Since the north ditch initially provided negligible flooding, the final design did not significantly impact existing wetlands.

With the hydraulic connection set, Mike11 was used to predict postproject water levels at the mitigation site. Using a simulated postproject water level record of 30 days, the variation in flooding duration at the mitigation with mitigation site elevation was established. Mike11 results for water levels at the mitigation site are shown in Figure 6, and corresponding volumetric flow rates in the improved north ditch are given in Figure 7.

Figure 6. Mike11 model results. Flooding duration variation with mitigation site elevation and ditch/culvert configuration (From CSE, 1995).

Figure 7. Mike11 model results. Volume flow rates to mitigation site for various ditch and culvert configurations (From CSE, 1995).

Despite the tidal attenuation, the mitigation site elevations were higher than those of the natural marsh. This was a result of greater attenuation of the ebb tide than the flood, which increased flooding duration at the site.

The final design for the mitigation site had the following dimensions:

Wetland area to be created:	40,000 m ²
Wetland substrate elevation:	1.22 m to 1.46 m NGVD
Wetland flooding duration:	5 to 20 %
Length of ditch to Savannah R.:	900 meters
Width of ditch:	3 meters
River to wetland tide attenuation:	0.03 to 0.15 meters
River to wetland phase lag:	30-50 minutes

Conclusions

A procedure for the hydraulic design or improvement of tidal wetlands was proposed based on the principle that wetland plant species inhabit specific ranges of flooding duration. By creating areas with the appropriate flooding duration, desired habitats can be successfully created. When calculating flooding duration, relatively long-term site-specific water levels are required. A 30-day water level record is suggested for typical conditions. Where the creation of wetlands significantly alters local hydraulics, numerical models may be required to predict postproject water levels needed to determine wetland substrate elevations.

CHAPTER 335

Enhanced Mixing Through Perforated Discs on Round Buoyant Jet

Lilun Wu¹, Jiin-Jen Lee²

Abstract

Jets have been widely used in submarine outfall diffuser systems for discharging the sewage effluents into large bodies of sea water to facilitate rapid mixing of the effluent with the ambient water. The primary goal of an outfall diffuser system is to accomplish rapid mixing of the effluent with the ambient water. In an effort to enhance the near field mixing, various obstruction devices may be placed exterior to the diffuser nozzle. This experimental study focuses on the enhanced mixing mechanisms of the jets obstructed with perforated discs.

Experiments are conducted in a deep water tank with glass walls on four sides of the tank. The tank has the dimension of 3.35 m in depth with a square cross-section of 1.15 m. The water particle velocities of the resulting flow field are measured by using a portable four-beam, two-component, fiber-optic Laser-Doppler Velocimeter system (LDV). The concentration of the entrained fluid is measured by using a Laser-Induced Fluorescence system (LIF). The data acquisition system used for obtaining data on the concentration profiles is processed by Labview's programmable virtual instruments software.

The experimental data consist of the axial (vertical) and radial (horizontal) velocities, turbulent intensities, Reynolds stresses and concentrations. It is found that velocity fluctuations in both the axial and radial velocities help to generate vorticity and to induce mixings over a larger area in the neighboring flow region. Moreover, the velocity gradient is significantly increased over the region based on the experimental data involving the perforated discs. The results also show that a large reduction in the concentration of the entrained fluid can be achieved due to the

¹ Graduate Research Assistant, Department of Civil Engineering, University of Southern California, Los Angeles, CA 90089.

² Professor of Civil Engineering, University of Southern California, Los Angeles, CA 90089-2531, Member of ASCE.

obstructing disc. The results demonstrate quite convincingly the ability of the perforated disc to enhance the mixing and entrainment of the discharging fluid with the ambient fluid.

1.0 Introduction

For the removal of municipal sewage, treated or untreated waste water must be disposed of in such a way that will generate minimal effects to the environment. An ocean discharging system is commonly used to discharge sewage effluents into coastal water and to induce mixing of the effluent with the sea water. The systems are generally comprised of embedded pipes, the main outfall, which delivers the waste water to a diffuser system. The length of the main outfall pipes normally range from 1 km to 9 km, depending upon the sea bed topography, ocean currents and environmental requirements.

There are three major factors that affect the mixing of effluent (Fischer et al. 1979). They are: jet parameters, environmental parameters and geometrical factors of the discharging jet. Both the jet parameters and the environmental parameters have been studied extensively in the last four decades. Geometrical factor is an interesting field for the scientists and engineers to study because better geometrical arrangements may result in greater dilution. Increasing dilution in an ocean discharging system would produce significant saving in the construction costs by reducing needed mixing height of the rising plume.

The present experimental investigation includes measurements of axial and radial velocity, turbulent intensity, turbulent shear stress and concentration profiles. The purpose of the measurements is to accurately measure various flow parameters in the flow field of the jets obstructed with perforated disc to provide an answer to the important question posed for the study.

2.0 Experiments

Experiments were performed in a deep water tank system with vertical glass face. The water tank has the dimensions of 335 cm high, 115 cm wide and 115 cm deep. The facilities also included a mixing tank, a constant-head tank, air bubbling hose and a manometer (flow meter). The mixing tank provides a space for adding dye or salt into effluent fluid. The constant-head tank is used for maintaining a steady flow for the effluent fluid, while the air bubbles provide enhance mixing in both the mixing tank and the glass water tank before conducting experiments. Fluid velocity and Rhodamine 6 G dye concentration can be measured by a Laser Doppler Velocimeter (LDV) and a Laser-Induced Fluorescence system (LIF), respectively. For measuring purposes, this glass walled tank is equipped with an instrument

carriage supporting a Laser Doppler Velocimeter or a Laser-Induced Fluorescence device. The carriage is able to move both vertically and horizontally with respect to the tank, thus velocities and concentrations could be measured at various axial and radial locations. The jet nozzle is located on the top of the tank and pointing down. The density of the exit fluid from the jet nozzle is greater (heavier) than that of ambient fluid. Sodium Chloride (salt) is added into the exit fluid to obtain the desired initial density difference between exit fluid and ambient fluid.

A portable four-beam, two component, fiber optic Laser Doppler Velocimeter (LDV) manufactured by TSI, Inc. was used for measuring the water particle velocities. The software of data acquisition for controlling the LDV system, *Flow Information Display (FIND) Data Analysis Package* from TSI, Inc. was used. The concentration is measured by a laser-induced fluorescence system (LIF) at various cross sections downstream from the jet nozzle. This system includes a 2W Argon-Ion laser (Spectra Physics Model 265), a CCD camera (EG&G Reticon LC300A), an analog input/output data acquisition board (National Instrument, AT-MIO-16X) and data acquisition program (Labview). The laser beam is oriented in the direction perpendicular to the centerline of the flow, and it is shot into the water tank across the entire flow field from one side of the tank. A line fluorescence light source is then detected by an array of light-sensitive photo diodes inside the EG&G Reticon LC300A camera. The data acquisition system receives signals from the camera and converts the analog signals to digital data. The data for the concentration profile is processed by Labview's virtual instruments software.

3.0 Results and Discussion

3.1 Velocity Profile and Width of Simple Jets

The results of the velocity measurement conducted for the present work are in agreement with those of Fischer et al (1979) and Papanicolaou and List (1988). This agreement ensures that the instrumentation system used for the present study can yield reliable results. Thus, comparisons can be made between the results conducted for simple jets and for jets obstructed with perforated disc.

Figure 1 shows the normalized diagram by combining all of the velocity profiles of the simple jets into one figure. Data distribution in Figure 1 is a Gaussian distribution. The jet has U_{mean}/U_c value in the range of $|r/z| < 0.2$, beyond this range the U_{mean}/U_c values tend to zero. The normalized diagrams for representing the results of jet obstructed with each perforated disc are presented in Figures 2. Most values of U_{mean}/U_c of each obstructed case are located in between $|r/z| < 0.4$. After comparing the results of velocity profiles for the case of simple jets and the cases of jets obstructed with perforated discs, conclusions can be drawn as follows: (1) For the jets obstructed with different perforated discs compared with the simple

jet (Figures 3), the axial (longitudinal) velocity distributions of the jets with perforated disc have more fluctuations exhibited in each profile. (2) The cases of the jets obstructed with perforated disc have larger plume width on each cross section. (3) For jets obstructed with various perforated disc, the axial velocity distributions are more uniform and broader when compared with the case of simple jets. (4) The centerline velocities of the jets obstructed with perforated disc have relatively smaller value with compared with simple jets.

3.2 *Turbulence Properties*

The axial (vertical) and radial (horizontal) turbulent intensities have been measured simultaneously by LDV for both simple jets and jets obstructed with perforated discs. After comparing the results on the turbulent intensity (both axial and radial) for both simple jets and jets obstructed with perforated discs, general conclusions can be made as follows: (1) Simple jets have larger fluctuations of the axial velocity around the boundary of jet. In the outer region of the cross section (beyond the boundary of the plume width), the percentages of axial turbulent fluctuation of jets with each perforated disc are much greater than those of the simple jets. This shows that jets obstructed with perforated discs can produce more turbulent fluctuation of axial velocity than the simple jets in the outer region of the cross section. (2) The distributions of turbulent fluctuations in the axial and radial component for the jets obstructed with perforated discs are much more uniform and much broader than those of simple jets. (3) The jet obstructed with the 2x8 perforated disc has an overall higher U'_{rms}/U_c value than those for other disc arrangements. (4) The percentages of radial turbulent fluctuation of jet obstructed with perforated disc have higher values than those of simple jets at all of the cross sections within the region of the jet width. Moreover, the overall percentages of radial turbulent fluctuation of jets obstructed with perforated discs are higher than those of simple jets in the region beyond the boundary of the jet for each cross section. This shows that the jets obstructed with perforated discs have higher radial (horizontal) turbulent fluctuation than simple jets beyond the boundary region.

The results from the measurement of turbulent intensity indicate that the jets obstructed with perforated discs will enlarge the region of turbulent fluctuation and resulting in more interaction between ambient and effluent fluid. This also supports the experimental hypothesis that using the perforated discs to obstruct the jets will result in larger areas of axial and radial fluctuations in the flow field.

3.3 *Reynolds Stress*

The shear layer between the effluent fluid and the ambient fluid was proved by Fischer et al (1979) as an important factor to entrain the ambient fluid into effluent fluid and to induce mixing of both fluids. The Reynolds stress ($\overline{U'V'}$ or turbulent shear stress) measurements were conducted for both simple jets and jets obstructed

with perforated discs. Experimental results have been presented in Figure 4 for the simple jets and in Figure 5 for the jets obstructed with perforated discs. Comparisons between the results of simple jets and jets obstructed, can lead to the following conclusions: (1) Fluctuations can be observed on the $\overline{U'V'}$ profiles of the jets obstructed with perforated discs. This is because the effluent fluid flows through the perforated disc (or holes on the disc) and generates many small vortices inside the boundary of the jets. Thus, it creates a larger area of shear layer and induces more entrainments for the entire flow field. (2) Results show that the jets obstructed with perforated discs have higher value of $\overline{U'V'}$ at the region outside of the jets' boundary, and this is the advantage of using the obstructed perforated discs to broaden the extents of the velocity field and the velocity fluctuation. A broader mixing area is created by the obstructing perforated discs, Thus, mixing is enhanced by a broader region possessing certain value of turbulent shear stress.

3.4 Concentrations and Dilutions

The concentration measurements were conducted and included in the present study. The simple jets' maximum concentrations obtained for the present work are in agreement with the previous studies such as Fischer et al. (1979) and Papanicolaou (1984). The widths of concentration profiles of the simple jets measured in the present study are also in agreement with those of Papanicolaou and List (1988).

After comparing the results of concentration measurements for both simple jets and jets obstructed with perforated discs, conclusions can be made as follows: (1) the results of the simple jets are similar to that reported by Fischer et al. (1979) and Papanicolaou and List (1988), (2) the maximum concentration for the cases of the jets obstructed with perforated discs are quite smaller than those of the simple jets, and (3) the concentration widths (b_c) for the jets obstructed with perforated discs are broader than those of the simple jets.

The calculations for the mean dilution achieved for the simple jets and for jets with perforated discs also were performed. The results indicate that (1) the C_{\max}/C_{ave} ratios of the simple jets are in the range of 1.315~1.592, this result is in agreement with that summarized by Fischer et al. (1979) which is 1.4 ± 0.1 , (2) for the jets obstructed with perforated discs, the mean dilution is higher than that of the simple jets, (3) the values of mean dilution reflect that both $\frac{\mu}{Q_0}$ (from velocity measurements) and C_{\max} (observed from concentration measurement) are in consistant trends, (4) the C_{\max}/C_{ave} ratios of the jets obstructed with perforated discs are in the range of 1.052 to 1.369, (5) the μ/Q (mean dilution) versus z/l_Q (normalized distance) of the simple jets and the jets obstructed with perforated discs have been plotted in Figures 6. They show that the jets obstructed with perforated

discs have a higher mean dilution than that of the simple jets for a given z/l_Q . Another measure of the effectiveness of enhanced mixing is to compare the maximum dilution for both the case of simple jet and that for jet obstructed with perforated disc. This is shown in Figures 7. It is found that there is a significant increase of the maximum dilution with perforated disc.

4.0 Conclusions

The results of the present work proved that the jets obstructed with perforated discs have wider profiles of velocity, turbulent intensity, turbulent shear stress and concentration than the simple jets. The normalized diagrams from the experimental results also indicate that the data distributions of the jets obstructed with perforated discs are flatter and broader than those of simple jets in the fields of velocity, turbulent intensity, turbulent shear stress and concentration. All of this provides evidence that jets obstructed by perforated discs have larger areas for mixing than those of the simple jets.

It is clear from the concentration measurements that for the jets obstructed with perforated discs, the concentration of the entrained fluid is greatly reduced and that the region for mixing is significantly enlarged. The results from the calculation of mean dilution and maximum dilution also indicate that the jets with perforated discs can produce significantly increased dilutions when compared with simple jets. The overall experimental results demonstrate quite convincingly the ability of the perforated disc to enhance the mixing and entrainment of the discharging fluid with the ambient fluid.

Acknowledgment

This research study has been supported by University of Southern California Foundation for Cross-Connection Control & Hydraulic Research and the San Gabriel Valley Protective Association. The authors extend special thanks to Professor Fredric Raichlen and Professor John List of the California Institute of Technology for their generosity in granting use of the deep water tank and its associated facilities at W. M. Keck Laboratory of Hydraulics and Water Resources of CalTech for the experiments.

CHAPTER 336

ASSESSING COASTAL FLOOD RISKS

by Roger Maddrell¹, Chris Fleming¹ and Chris Mounsey²

Abstract

The English and Welsh coasts of the United Kingdom are protected from coastal flooding (as opposed to coastal erosion) by some 1300km of defences, containing about 2000 defence structures. Using data from the sea defence survey of these structures and over 20 years of joint probability data on sea levels and waves, Halcrow assessed the failure risks and coastal flood risks for all these defences. The risks were examined for three Bands or return periods, namely 50 years, 100 years and over 200 years. This analysis included 50 years of relative rise in sea level (isostatic and eustatic changes). The modes of defence failure examined were from overflow, overtopping and toe failure. The results were supplied to the insurance industry, as maps and on disc, as 1km map squares giving the risk band, flood depth and the postal codes in the areas.

Flood risks were shown to be significant and even though reduced when more recent flood defence projects were included, they remain high. The impact of individual storms was later examined and obviously, while the risks were limited to specific areas and coasts, they were still significant. The insurance industry have used these results in order to assess their financial exposure to individual events and to their reinsurers.

Introduction

Potential coastal flood risks areas represent only about 3% of the area of England and Wales, but the value of their insured assets is much higher. Two major storm events in October 1987 and January 1990 sharpened the insurance companies and the "reinsurers" (who insure the insurance companies) concern about their exposure to

¹ Sir William Halcrow & Partners Limited, Burderop Park, Swindon SN4 0QD, UK

² Association of British Insurers, 51 Gresham Street, London, EC2V 7HQ, UK

weather and coastal flooding risks. No one wished to see another 1953 type disaster. Consequently, in 1992 the Association of British Insurers (ABI) asked Halcrow to categorise the flood risk from coastal storm events for the benefit of their 450 members

The ABI membership between them account for over 90% of the UK business. ABI's key objectives are to help insurance companies by representing their interests to Government, particularly on public policy issues; providing them with technical services, in particular in respect of industry statistics, market and regulatory information and reducing the incidence of claims; and promoting insurance and insurance companies generally. It also helps its members at the pre-competitive stage, to improve their chance of success in achieving a balanced underwriting account.

Naturally, ABI are the focus for presenting the industry's concerns on major issues to the Government, ministers and civil servants, MPs, European bodies, the media, consumer bodies and other opinion formers. This responsibility is taken very seriously and it is recognised that their value is diminished if based on inaccurate and illfounded information. Thus, ABI concentrates on resolving real live issues which will affect the industry, of which coastal flooding is particularly relevant.

The areas covered in the Halcrow study were those protected by 1300km of coastal flood defence, the defences of only four main estuaries, namely, Tees, Humber, Thames (Upper and Lower) and Severn, but none of the other estuaries and channels. The pilot study in 1993 examined a detailed approach and one using the sea defence survey (SDS) data from the UK's Environmental Agency (EA). As the results in terms of flood risk were similar, the latter was chosen as it had the shortest completion time and was the most cost effective.

The first main study report was presented to the ABI membership in 1994 and was subsequently updated in 1995 to include for the new and improved defences built since the SDS was published in 1990. Additional studies include the prediction of flood risk from individual storms, using data supplied by the UK's Meteorological Office, examining and reporting on those defence lengths shown to be not performing or at greatest risk and the flood risks to London from combined tidal and high fresh water flows. The latter study is nearing completion.

Study Methodology

The assessment of flood risk needs to examine the integrity of the existing sea defences and assess their likelihood of failure and the extent of the subsequent flood area. There are nearly 1300km of coastal flood defences in England and Wales, containing some 2000

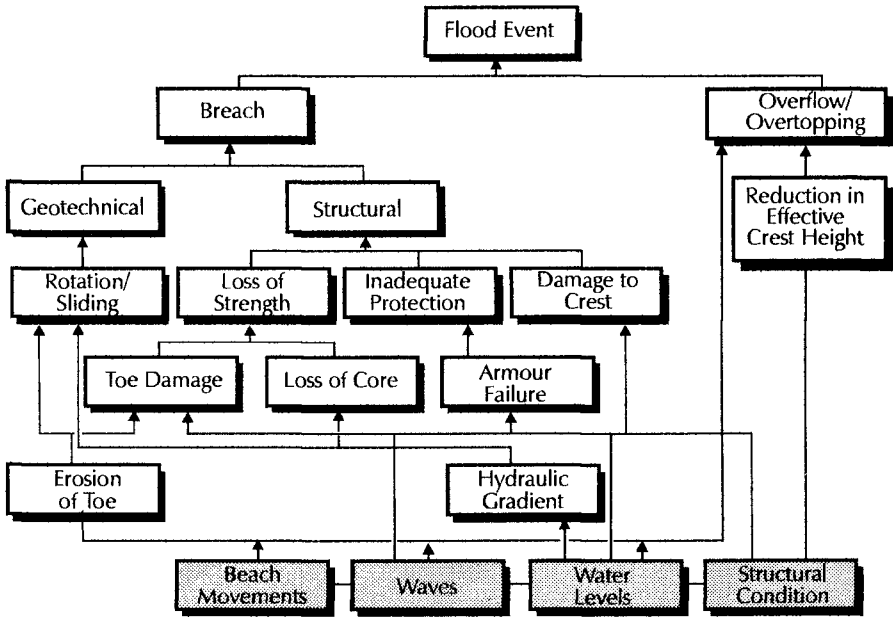

Figure 1. Key failure modes

structures and the integrity of each defence had to be examined. Flood risk can be approached in a number of ways, from highly subjective visual assessments, through to detailed probabilistic analyses based on comprehensive structural data. Whilst detailed probabilistic analyses, including all failure modes, can be applied in specific cases, the pilot study showed it was not economically viable for application on a nationwide basis.

Two methods were examined in the pilot study, which explored the relative costs and the quality of results from each approach. The first method offered a detailed approach, analysing a number of key failure modes (see Figure 1) to provide a quantified assessment of failure risks. This method also incorporated a set of screening tests to reduce the number of defences to be analysed, with the remainder requiring detailed structural information. The major disadvantage of this approach was not the amount of calculation required, which could be automated, but the high costs of acquiring detailed data which could only be acquired through structural inspections (Burgess and Reeve, 1994).

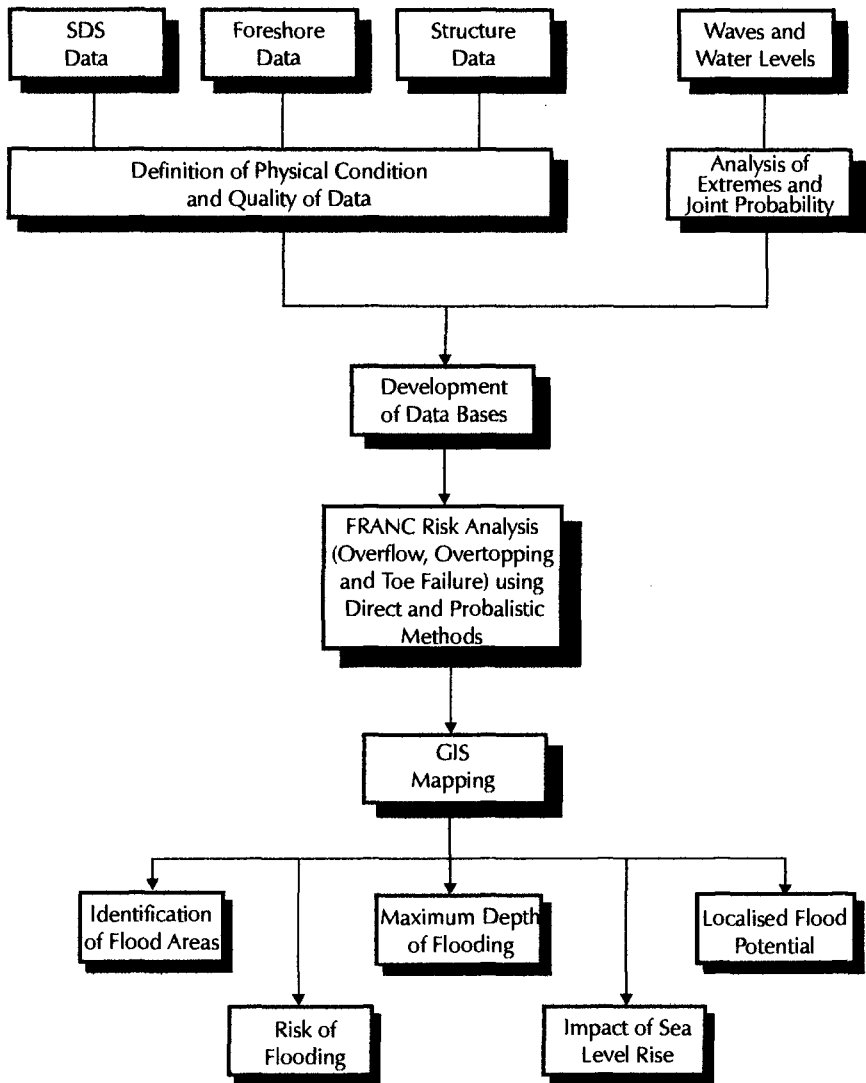

Figure 2. Methodology

The alternative second method made use of information in the UK's Environmental Agency's (EA) sea defence survey (SDS) to estimate risk of failure, supplemented with environmental data. This methodology (see Figure 2) concentrated three primary failure modes namely:

- Overflow - when the still water level exceeds the crest of the defence;

- Overtopping - when the combined effect of waves and water levels results in waves running up and breaking over the defence;
- Toe Failure - when the toe of the structure fails due to low beach levels at the base of the defence (erosion being one of the most common causes of damage to sea defences).

For open coasts, normally overtopping and toe failure and to a certain extent, overflow were critical, but for the estuaries the modes were overflow and toe failure with overtopping being less critical.

The starting point of the study was the 1990 SDS which was a major undertaking and a considerable step forward in flood defence management by updating the original 1980 Herlihy study. An analysis for each defence required a site specific knowledge of waves and water levels. Therefore, inshore study points were defined on the open coast and in the estuaries. Future relative sea level changes were also established. Water level time series covering a period of 30 years were combined with 20 years of offshore wave data, transformed inshore through modelling, to produce marginal and joint probability extremes together with a statistical description of the conditions.

The quality of available structure and beach data was, unfortunately, extremely variable and thus two types of risk assessment were developed for each defence; "direct" and "probabilistic" approaches. In general terms the "direct" approach involved determining the specific conditions and calculating to see whether a particular structure could withstand or would be likely to be at risk of failure under these conditions. The risk of failure and hence flood risk was described by risk bands, with Band 1 defined as a defence potentially vulnerable to a 1 in 50 year event ie with an annual probability of failure greater than 0.02, Band 3 as a defence withstanding conditions with a return period of 200 years, and Band 2 falling between these two limits. The "probabilistic" approach was a first order risk method to calculate the annual probability of failure and defined the risk as Bands 1, 2 or 3, depending on the annual probabilities of failure comparable with the return periods above.

The software package "SANDS" already existed, which could be used for data storage, retrieval and analysis. However, to perform the risk analysis computational software had to be developed for the project, acronym "FRANC", which enabled all three failure modes to be analysed by both the "direct" and "probabilistic" approaches. This was essential given the volume of data and the need to analyse 3 modes of failure for nearly 2000 defences. "FRANC" read the relevant data

direct from the "SANDS" database, performed the calculations, combined the results and assigned the defence classification. The software was designed to establish either an overall probability of failure risk based upon the results of all three mechanisms or to establish the worst case, ie the most likely mode of failure. The results were generated in a format that could be directly linked into the flood area mapping.

To perform the analysis of overflow and overtopping, both wave and water levels were needed. A 30 year water level time series for nearshore locations was obtained from the Proudman Oceanographic Laboratory's (POL) tide and surge model for the United Kingdom. Additional data, including annual maximum levels, were obtained for the Severn, Thames, Tees and Humber estuaries, supplemented by information gathered from the relevant Port Authorities.

Wave data at offshore locations were obtained in the form of a time series output for the North European Storms Study (NESS), which gave wave height and direction for some 32 offshore locations and covered a period of just over 20 years. For the outer areas of the estuaries, wave time series were hindcast from wind measurements covering a period in excess of 14 years for each estuary. Extreme wave heights in the upper estuaries were calculated from monthly maxima wind speeds using shallow water wind-wave hindcasting techniques.

The site specific information on waves and water levels was derived from inshore study points using wave refraction models. This required the digital reproduction of the nearshore bathymetry around the entire English and Welsh coastlines and resulted in the generation of sets of time series wave conditions at each of these locations. Shallow water effects were accounted for by spectral saturation, Bouws et al (1985), whilst wave breaking at each structure related to the beach condition and water level.

In interpolating the water level data to the study points, extreme values were adjusted to reflect the natural variation in Mean High Water Spring (MHWS). Future relative sea level changes in 50 years time for each location required the IPCC's (1990) prediction of global sea level increase due to global warming and isostatic changes described by Shennan (1989).

Extreme values of water levels, wave heights and periods were defined in terms of a return period with the marginal distribution functions determined by fitting a distribution to the data. In this case, the Generalised Extreme Value (GEV) was used to estimate extreme values from the annual maxima of each variable (Carter et al, 1986). Joint extreme values were established empirically from frequencies of occurrence (see Owen, 1980 and Hawkes, 1990), for assessing the risk

of overtopping, where the combination of water levels and waves is important. The results of these data processing exercises were incorporated into the database, for use in the risk assessment.

The results of the risk analysis were transferred to a Geographic Information System (GIS) to relate the risk classification of each defence to its associated flood area. The flood areas were defined by establishing the intersect between predicted extreme water levels and the terrain. Flood depths were established from the interrogation of the Ordnance Surveys (OS) base data and any available drawings to derive ground level estimates. Maps were produced on OS backgrounds using the GIS for 10km by 10km coastal flood areas, showing the risk bands and predicted maximum depth of flooding within each 1km grid square. This size grid was chosen mainly because of the large area that had to be covered in the short time available and the lack of detailed survey data below the 5m contour.

Two characteristics of the sea defences were of relevance to the flood risk mapping; the location of a defence and its risk classification. The location of each defence length was defined by start and end co-ordinates in the SDS database. An automated routine was used to interrogate this information and plot the defences within the GIS. The risk classification output from the defence analysis software was loaded into the GIS database and related to the plotted graphic elements using a unique defence length code identifier. When more than one defence structure existed within a defence length, the highest risk probability amongst those structures was assigned to that length.

The risk assigned to a defence length was then transferred to the area being defended. Again, the rationale of assigning the highest risk was applied so that in cases where a single flood area was bordered by a number of defence lengths of differing risk values, the highest risk value amongst those was transferred to the defended area. The seaward extent of the defended area was taken as being the line of defence and the landward extent that line at which the water level, associated with a given event, intersected the land surface ie the same methodology as that used in the SDS. The accuracy with this line could be determined was largely reliant on the availability of ground level information, some of which was poor.

The variation found in the water levels associated with the 50 and 200 year event typically ranged between 0.1m and 0.5m. This made the differentiation of discrete flood boundaries associated with the 50, 100 and 200 year events problematical, given the quality and quantity of ground level data available from OS sheets.

The protected areas were overlaid with 1km grid squares. Each 1km grid square took on the highest risk classification of any defended areas which it wholly or partially covered. Post code sector

data was provided by the UK's Post Office and the risk was related to the post code sectors.

In addition to the risk classification assigned to each grid square, an attempt was made to assess the depth of flooding using the very limited ground level data available. The approach was generally simple, making a direct interpolation of the depth of flood water calculated at available data points behind the defence and at the inland boundary of the flood water. Where possible, the influence of features such as inland embankments was included.

This method of interpolation obviously created discrepancies when assigning a single flood value across 1km grid squares, which might contain areas of higher relief. Similarly, where the level of the ground was below that defined by drawings or spot heights, underestimation of the depth of flooding occurred.

Results

Each analysis was rigorously checked for its approach and the correctness of numerical results and a further check was carried out to verify the overall output. Direct verification was restricted due to the lack of recorded instances of defence failures, despite obtaining newspaper reports. The "Effective Level of Service" recorded in the SDS provided an alternative measure against which the analysis results could be compared, details of which are given in Table 1.

Classification	SDS (%)	Halcrows' Study (%)
Band 1, 50 year	33	28
Band 2, 50 to 200 years	15	5
Band 3, > 200 years	52	67

Table 1. Overflow classification results, percentages of defences at risk

The results from the original study showed a good agreement for overflow with those in the SDS (only overflow was examined in the SDS) with 64% of all structures analysed having the same risk classification. Of the remaining 36%, the majority had a lower classification than that given by the SDS. However, notwithstanding the differences in analysis and classification techniques, a slightly lower result is expected as the Halcrow study used probabilistic calculation where possible, in preference to a direct method of determination.

Figure 3. Coastline of England and Wales, outlined by Band 1 risk areas

Consequently, the overall result was considered satisfactory and was confirmed by major coastal flood events. Consequently, the overall results was considered satisfactory and was confirmed by recent major coastal flood events such as those at Towyn in North Wales, which were shown to be in Band 1.

Toe failure results were spread between the risk bands although 22% of them fell within Band 1. Given the widespread erosion of many of the UK's beaches, this was perhaps not too surprising. Of possibly greater significance was the high percentage of defences apparently at risk from overtopping. Whilst the risk criteria were based upon well established and universally accepted overtopping thresholds (see Owen, 1980 and Hawkes, 1990), the question of whether critical damage would only result from sustained overtopping over a reasonable duration, was examined. To take account of this, the risk thresholds were therefore set an order of magnitude higher, ie assuming the defence could withstand ten times the established criteria before failure could occur. All the areas falling into Band 1 are shown on Figure 3.

It should also be noted that, with the Band 3 risk threshold as a 1 in 200 year event, the total number of potentially defences at risk falling within Band 2, was only 12%. This percentage could only be increased if the upper and lower thresholds for Band 2 were an order of magnitude apart ie taking Band 1 as a 20 year event.

The initial study was based upon the structural data in the SDS and did not include new defences or remedial works carried out since 1990. However, minor updating of the SDS information was undertaken where possible, and Halcrows recently completed an updated study for the ABI following liaison and co-operation from the EA Regions. The results, which included the most recent defence improvements, showed a reduction of 7% in the structures vulnerable to Band 1 events.

The maps produced for ABI only indicate the flood areas associated with the defined sea defences and the named estuaries. Other potential risk areas, eg the Fens inland of the Wash and other estuaries were not within the defined scope of this study and were therefore not included on the maps. In addition, the available OS maps were not up to date and recent urban developments may have been missed.

Whilst many defences and thus coastal areas were given a Band 1 classification, this did not mean that all defences protecting such areas had an equivalent risk as, in reality, the failure of only a relatively short length of defence could lead to widespread flooding. As described earlier, the weakest link in any flood area frontage was taken to represent the risk associated with that area, although the majority of the defences might have had a much greater integrity and a relatively minor amount of remedial works could be sufficient to move the areas into Bands 2 or 3.

The results provide a relative measure of flood area risks and the risk of failure does not necessarily imply that a total functional failure of a defence and subsequent flooding would definitely occur. It

simply indicates potential risks and vulnerability under particular conditions. No account could be taken of remedial or emergency action, which might occur prior to or after an event. Because of constraints in time, the impact of successive tides could not be taken into account, nor the likely time for breach repair or flood duration.

The 1:10,000 maps and Figure 3 show very large areas of the coast and specified estuaries as Risk Band 1, ie being at risk to inundation from a 50 year storm event, it does not mean that all these areas are susceptible to any one single event, simply that they have a greater probability of being affected. Thus, while a major storm event could affect large areas of the East, South and West coastal areas of England and Wales, it will not affect all coastal areas as its impact will be limited to relatively short lengths of coastline, particularly on the South and West coasts. On the East coast a major event could affect larger areas, as experienced during the disastrous 1953 event.

The impact of individual storms was therefore examined following on after the two earlier studies. As described above, the coasts of England and Wales were divided into three coastal areas: West, South and East. Meteorological records going back to the last century were analysed by the UK's Meteorological Office in order to determine generic storm types. In all, the two storms likely to have the most significant impact on each of the coasts and their associated wave and surge conditions were defined for each section of coast. Significant storms affecting more than one section of coast were also defined. While it is possible to define wave and surge levels in terms of their probability of occurrence, it is not possible with storms. This is because they are made up of many different elements eg air pressure, density and spacing of isobars, storm track direction etc, each of which can influence the other. The impact of the conditions produced (wave and surge) also varies along the coast, say being 1 in 50 year near its centre decreasing to 1 in 1 year towards its edge.

The storms produced varying conditions along the coastline and thus assigning a particular return period to an individual storm is problematical. A prime example is the 1953 East coast storm, where shoreline conditions experienced in Yorkshire were estimated to be in the order of 1 in 50 years, whilst by the time the storm surge had been driven south to Lincolnshire and East Anglia, it represented a 1 in 500 year condition.

The analysis defined the impact of potentially different storm types for each coastal area rather than specific storms. Detailed comparison of the analysis against past events was not possible, but a qualitative comparison of results and newspaper reports of flooding was made.

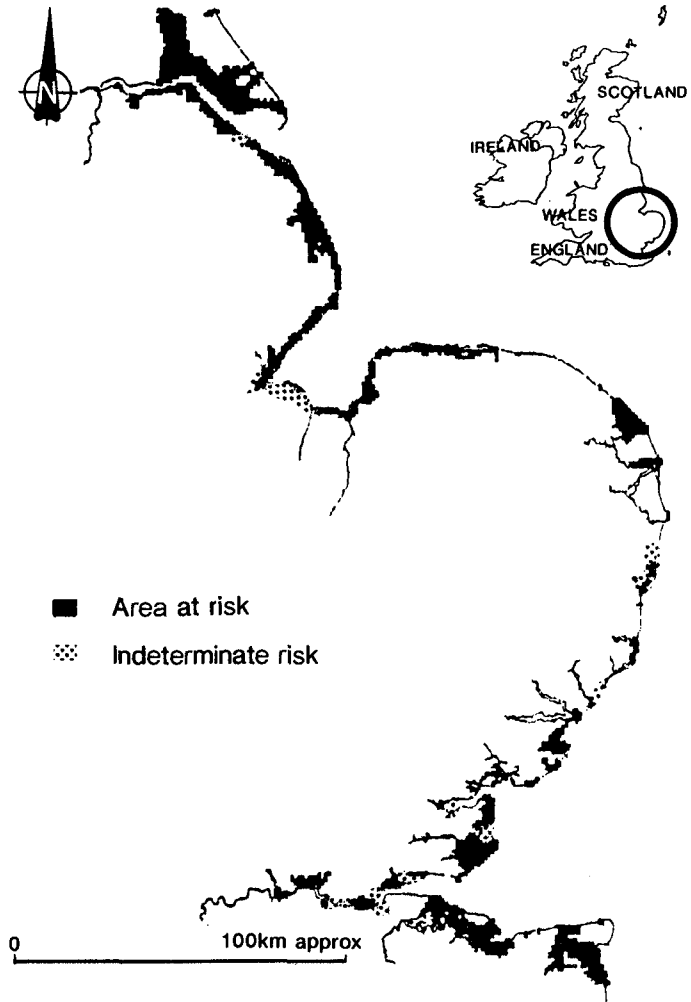

Figure 4. Flood risk areas resulting from a major East coast storm

Two storms affecting individual coasts were examined, together with one affecting both the East and South coasts, one affecting both the West and South coasts and one hypothetical storm for each coast. The hypothetical storms represent small changes of previous storms to modify the timing of the storm surge to coincide with high water. These were then compared as a way of establishing the storm scenarios with the greatest impacts.

Typical variations in the wave and water level conditions adopted for the single storms and the two earlier studies were examined, including the probabilistic wave heights and water levels for return periods of 50, 100 and 200 years. The comparison showed variation in wave height for the East coast locations were markedly different and other differences along the remaining coasts were also apparent. The variations were smaller for water levels.

The results produced by "FRANC" for these storms showed that one of the East coast storm produced the highest number of defences at risk ie 36.5% (see Figure 4) The percentages at risk from the other two East coast storms were very similar, although their distribution was different.

The South coast storms indicate that a high percentage of defences were at risk (approximately 70%). Both have an eastbound surge associated with waves of between 9m and 13m, generated by gale force winds sweeping in from the Atlantic. On the West coast, the hypothetical storm produced the worst conditions with 383 defences at risk (48.1%). Had it been coincident with high tide, the results would have been more severe.

The Insurance Industry's Application of the Results

The information from the studies was applied by the Insurance Industry in two basic ways, namely;

- the practical application of the project output data in overall portfolio exposure and in underwriting individual property risks on a geographic basis according to flood risk; and
- strategic use of the valuable data (which supplements and refines the existing knowledge base) to assist Government, through its agencies (MAFF and the EA), to target resources to exposed locations, always recognising the need for cost/benefit analyses.

The individual insurers try to obtain sufficient premium to cover their potential exposure and to do this they need to understand the underlying risk. The output of the project was therefore applied to this end by analysing the areas at risk against the locations and post codes of the insured properties to establish their aggregate portfolio exposure.

Insurers usually also have to operate with the support of reinsurers (who are also subject to the same regulatory approach) to give them added capacity or to reduce the financial consequences of a catastrophic loss eg 1987/90 storms or coastal flood. These reinsurers need to be satisfied that the insurers they are backing are

not themselves overexposed and also require some technical evidence these studies provided in order to take on these risks.

The data analyses from the study were therefore able to assist the insurers to:

- assess their overall exposure;
- determine whether correct rates are being charged; and
- provide information to reinsurers to gain their “capacity” and “catastrophe” support.

It also allows them to put pressure on the relevant Government Departments and to consider their exposure globally.

CHAPTER 337

EXPERIMENTAL STUDY ON THE BEHAVIOR OF BIVALVES BY OSCILLATORY FLOW

Toshihiko Yamashita¹, Akira Wada², Gaku Matsuoka³,
Kenji Yano⁴ and Sadamitsu Akeda⁵

ABSTRACT

To improve propagation of bivalves living in exposed sandy beach, we need to clarify the behavior of bivalves affected by water waves. Using a U-shape tube, the behavior of bivalves (surf clam and sunray surf clam) in an oscillatory flow was experimentally studied. It was found that the critical condition at which bivalves are forced out of the sand into the water is determined by the ratio between the velocity of bed erosion and the burrowing rate of bivalves, and until the bivalves are forced out into the water their own movement is significant. Also the experimental values measuring their behavior on a smooth surface fixed bed was found to be theoretically explained by setting C_D (drag coefficient), C_M (added mass coefficient) and μ (coefficient of dynamic friction) at 1.0, 0.5 and 0.1, respectively. After the bivalves are forced out into the water from the sand, therefore, their behavior is hardly affected by their own movement and we can regard them as inanimate objects.

INTRODUCTION

Japanese surf clam (*Pseudocardium sybillae*) and sunray surf clam (*Macrta cinensis*), which live in open sandy beaches along the coast of northern Japan are important fishery resources. However, there is a high mortality rate among young

bivalves, which must be minimized to ensure their propagation.

There have been reports showing an increase in young bivalves of surf clams in tranquil areas around newly constructed ports (for example, Hayase and Miyamoto , 1985). A large number of young bivalves are often cast onto the shore by high waves in winter (Photo. 1). From these examples and other on-site investigations of the clam's population (Watanabe , 1980), waves, especially high waves during winter, have been thought to be one of the major factors responsible for the mortality of young bivalves. Therefore, the process of mortality and the behavior of young live bivalves due to waves must be clarified. As the first example above shows, bivalves are deeply related to structures built on coastlines. Therefore, for the designe of coastal structures with consideration to the surrounding environment, the influence on the bivalves by waves must be clarified.

The effects of the bivalves' own active movements (burrowing) are important for investigating the behavior of bivalves due to waves. Although some experimental studies have been carried out on the behavior of dead bivalves (Watanabe ,1982; Kuwahara ,1993,1994), except for our previous studies (Yamashita et al. 1994a,1994b,1995), very few experimental studies have been carried out on the behavior and mortality of live bivalves due to waves. The effects of the bivalves' own active movements (burrowing) under water waves have still not been estimated quantitatively.

Bivalves usually dig themselves into the sand. According to our previous studies, when the sea bed erosion and accumulation occurs due to the action of waves, the bivalves keep digging into the sand by reacting to the deformation of the sea bed. However they are sometimes forced out of the sand into the water by a sudden deformation due to high waves. This movement is thought to be the first phase in the mortality process.

In this study, the following five points were investigated in order to understand the first phase of the mortality process: (1) the critical condition of release, (2) the critical condition of burrowing, (3) the burrowing rate of bivalves, (4) the bed erosion velocity and (5) the moving velocity of bivalves on a fixed bed.

Fig.1 Schematical view of the U-shape tube

EXPERIMENTS

For the experiments, a U-shape oscillatory flow tube made of acrylic resin was used (Fig. 1). Sea water and sand were put into it. In the movable bed experiments, a 16cm-deep layer of sand, with a grain size of 0.3mm, was made at the bottom of the tube. In the fixed bed experiment, a plate made of acrylic resin with a smooth surface was used. Young live bivalves (surf clam and sunray surf clam), 5mm~40mm in size, were used in the experiments. The wave period was set at either 3 sec. or 3.5 sec. The amplitude of the flow velocity (U_m) ranged from 20 cm/s to 90 cm/s. The water temperature was set at 16°C~22°C.

The following were investigated:

- (1)the critical condition at which bivalves are forced out of the sand into the water
- (2)the critical condition at which bivalves forced out into the water can burrow back into the sand again
- (3)the decrease in the energy (burrowing rate) of bivalves due to a drop in water temperature
- (4)the bed erosion velocity at which sand ripples are formed
- (5)the behavior of bivalves forced out into the water on a fixed bed with a smooth surface.

Experiments were conducted according to the following methods. Experiment (1): After the bivalves had dug themselves into the sand, we generated an oscillatory flow, and the deformation of the bed and behavior of bivalves were recorded by video camera. Experiment (2): To measure the critical flow velocity at which bivalves can burrow into the sand, bivalves were put into water where stable sand ripples had formed by varying the flow velocity. Experiment (3): We measured the burrowing rate of bivalves by changing the water temperature from 20°C to 5°C every 5°C in a controlled temperature room, and investigated the relationship

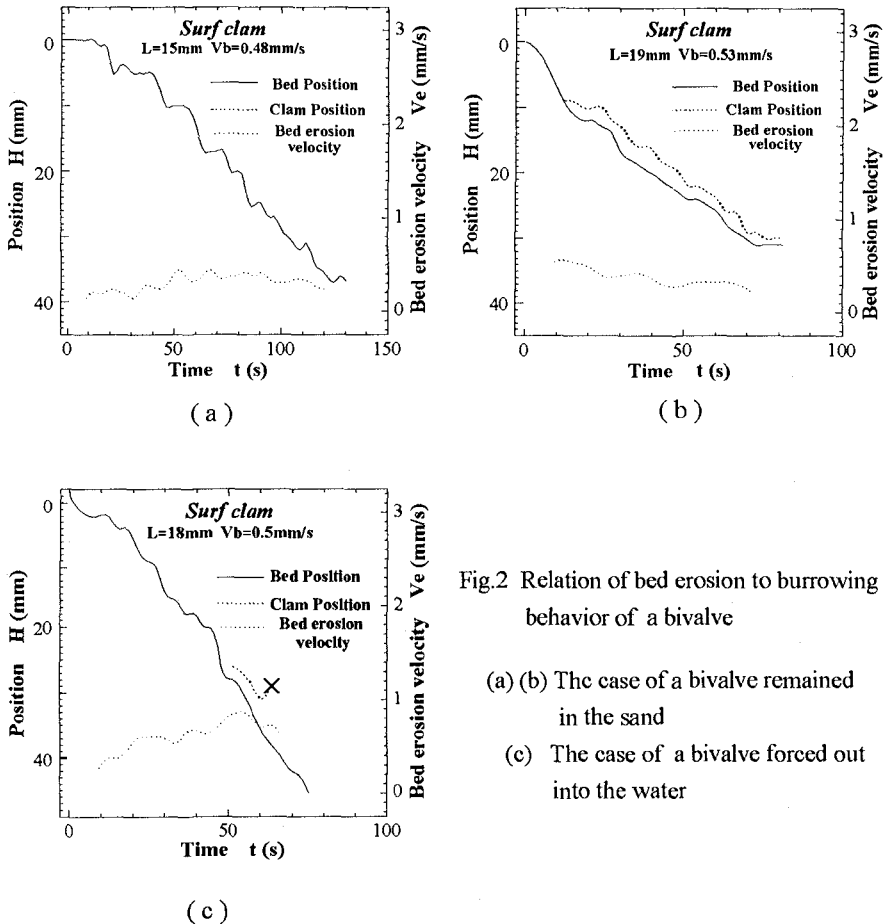

Fig.2 Relation of bed erosion to burrowing behavior of a bivalve

- (a) (b) The case of a bivalve remained in the sand
- (c) The case of a bivalve forced out into the water

between water temperature and burrowing rate of bivalves after adapting bivalves to each water temperature for three days. Experiment (4): We measured the bed erosion velocity at which sand ripples were formed from a flat condition using a video camera. Experiment (5): We measured the moving velocities of bivalves, and compared the theoretical and experimental values.

RESULTS

(1) Critical Condition of Release

Fig.2 shows typical examples of sea bed deformation and the behavior of the bivalves. The velocity of the sea bed erosion was calculated hourly from the variation in bed form. Fig.2(a) shows an example where the bivalve kept digging into the sand and remained there despite erosion of the sea bed, because the velocity of the

Fig.3 Critical condition at which bivalves are forced out of the sand into the water by the flow

sea bed erosion (V_e) was lower than the burrowing rate of the bivalve (V_b). Fig.2(b) shows another result. At the beginning of the experiment, the velocity of the deformation of the bed exceeded the burrowing rate of the bivalve, and only one-fifth of the shell length of the bivalve was washed out of the sand. However, later as the velocity of the bed erosion became lower than the burrowing rate of the bivalve, the bivalve remained in the sand. Fig.2(c) shows the following example. At the beginning of the experiment, the deformation of the sea bed occurred at a velocity almost equal to the burrowing rate of the bivalve, and the bivalve kept digging into the sand and remained there for 43 sec. after the experiment started. Later, as the velocity of the deformation of the bed exceeded the burrowing rate of the bivalve, the bivalve was at first partly washed out, and then completely forced out into the water. Fig.2 clearly shows that the critical condition at which the bivalves were forced out into the water is related to the bivalves' burrowing rate (V_b) and the velocity of deformation of the sea bed (V_e).

Fig.3 shows the relation between V_e and V_b based on data from 80 samples, using surf clams as Fig.2. Fig.3 shows the conditions of the bivalves with a certain burrowing rate at a certain velocity of deformation of the sea bed, which are categorized into the following: ○ indicates bivalves that remained in the sand completely, and × indicates bivalves that were completely forced out into the water. When the bivalves were washed out of the sand by about half the length of their shell, they tended to be completely forced out of the sand. Thus, the velocity of the deformation of the bed can be defined as the maximum value (V_{max}) in the experiment of the mean erosion velocity at which erosion of the sea bed occurred at a depth of half of the shell length. The burrowing rate of bivalves (V_b) can be calculated by dividing the shell length (L) by the time taken for bivalves to burrow into the sand.

Fig.3 shows that the critical condition at which bivalves are forced out of the sand into the water by the flow is determined by the ratio between V_e and V_b , i.e. 1.1. The present experimental results were higher than those using dead bivalves placed on the sand. Thus, until the bivalves are forced out into the water, their own movement is important.

(2) Critical Condition of Burrowing

Fig.4 shows the results using sunray surf clams of the critical condition at which bivalves forced out into the water can burrow back into the sand. In Fig.4, \circ indicates bivalves that could burrow into the sand under the water flow, and \times indicates bivalves that couldn't. The oblique line in the figure shows the critical condition. The critical flow velocity at which a bivalve with a certain burrowing rate can burrow into the sand is quantitatively obtained from this figure. It was found that when the burrowing rates of the bivalves increased, they can burrow back into the sand by themselves against higher flow velocities.

The critical flow velocity obtained in this experiment is the value that usually occurs at the sea bottom. Therefore, it seems to be difficult for bivalves which are forced out of the sand to burrow into the sand again under a rough sea for several days.

Fig.4 Critical condition at which bivalves forced out into the water can burrow back into sand again

(3) Borrowing Rate of Bivalves

The ability of the bivalves to dig into the sand by themselves greatly affects both the critical conditions at which the bivalves are forced out of the sand into the water and at which the bivalves can burrow back into the sand. Fig.5 shows one example (surf clam) of the experimental results concerning the burrowing rates of bivalves

with varying water temperatures from 20°C to 5°C. The straight lines in the figure indicate regression lines that coincide with the origin under each temperature. The result of the experiment was that the burrowing rate of bivalves below a certain water temperature is roughly proportional to the length of the shell, and decreases with a fall in water temperature.

Fig.5 Relation of shel length to burrowing rate

(4) Bed Erosion Velocity

It was observed in Experiment (1) that the critical condition at which bivalves are forced out of the sand into the water was related to the velocity of the sea bed erosion. Bivalves tend to be forced out of the sand when sand bed are eroded about shell length in depth for a short time. Major examples of local deformation at a high velocity of topography by waves are the erosion and accumulation of sand resulting from the formation of sand ripples, the movement of sand ripples, and the large scale vortex caused by wave breaking. In this experiment, we first measured the bed erosion velocity under which sand ripples were formed from a flat condition to clarify the bed erosion velocity under which sand ripples were formed by an oscillatory flow, and then the amplitude of the flow velocity $U_m = 20, 40, 60, 80$ cm/s.

Under the condition where sand ripples were formed, the erosion and accumulation of the sea bed occurred complexly. The pattern of deformation of the topography showed a wide variation from 50 sec. to 2000 sec.. The release of bivalves out of the sand into the water depended on whether the velocity of the deformation of the bed exceeded the burrowing rate of the bivalves. Therefore, the probability of the

bivalves being released is related locally to the probability of maximum bed erosion velocity occurring. Fig.6 shows the local probability of the maximum bed erosion velocity at which it exceeded a certain erosion velocity of the bed. In the calculation, as in Experiment (1), the maximum bed erosion velocity is defined as the maximum value in the experiment of the mean bed erosion velocity at which the erosion of the bed occurred at a depth of half of the shell length.

Fig.6(a) shows an example of the experimental results of the maximum bed erosion velocity for the bivalve with a shell length of 10mm. Fig.6(b) shows another example of the bivalve with a shell length of 30mm. These figures indicate that under the condition where the same flow velocity or deformation of the bed occurred, the shorter the length of the bivalve, the higher the bed erosion velocity related to the release of the bivalve became. Fig.6 quantitatively shows that as the amplitude of the flow velocity increased, the maximum erosion velocity of the bed increased.

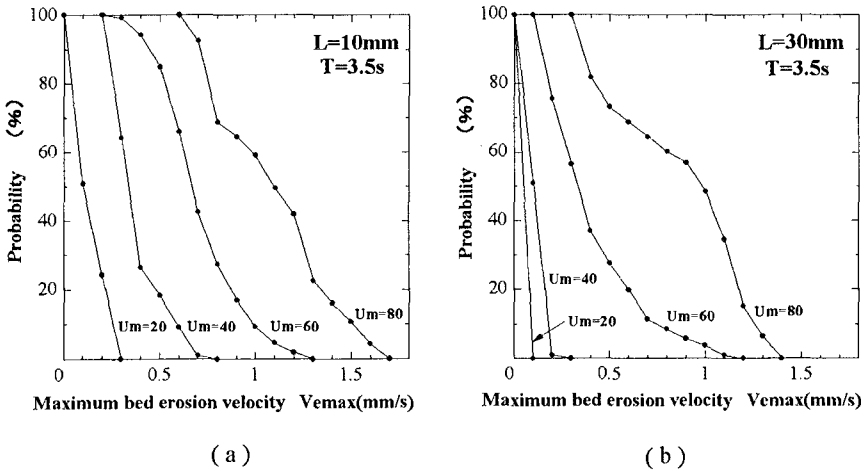

Fig.6 Probability of maximum bed erosion velocity occurring

(5) Moving Velocity of Bivalves on a Fixed Bed

We measured the velocity of moving bivalves which had been forced out into the water from the sand due to the flow, using a fixed bed with a smooth surface. Fig.7 shows a comparison between the experimental and theoretical results. The theoretical values were calculated by the following equation, and we regarded the behavior of bivalves as that of inanimate objects, which can not move by themselves.

$$M \frac{dUs}{dt} + C_m m \frac{d(Us - u)}{dt} = m \frac{du}{dt} + \frac{1}{2} C_D \rho_w A |u - Us| (u - Us) - \mu' (M - m) g \frac{Us}{|Us|}$$

Where, M is the mass of a bivalve, m is the mass of water equal to the volume of the bivalve, Us is the velocity of the moving bivalves and u is the water particle

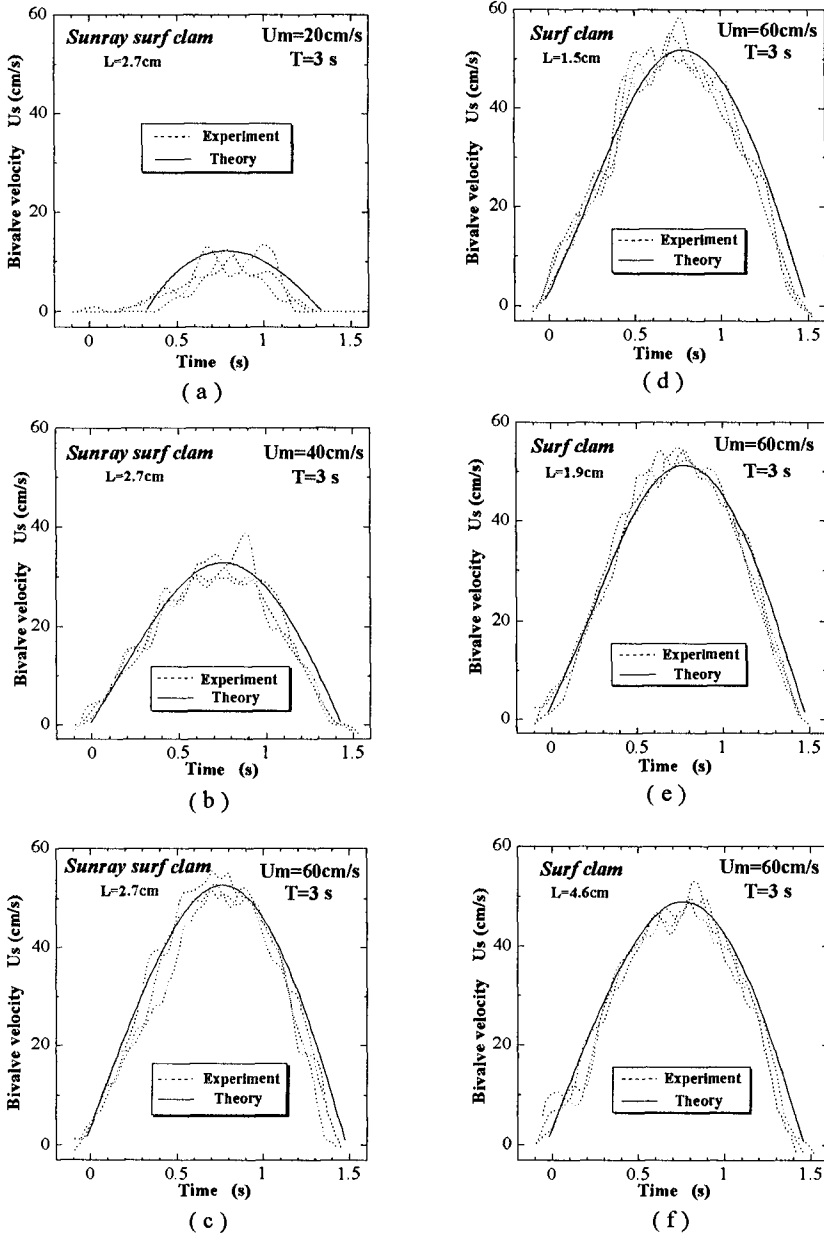

Fig.7 Moving velocity of the bivalves on a smooth surface fixed bed
 (a)(b)(c) The case of using sunray surf clams at three different amplitude of the flow velocity
 (d)(e)(f) The case of using surf clams of three different sizes

velocity. In the calculation, (1) the volume of a bivalve is converted into a globe and its projected area is regarded as the projected area A of the bivalve in the direction of the flow; (2) the drag coefficient $C_D = 1.0$; (3) the added mass coefficient $C_M = 0.5$; and (4) the coefficient of dynamic friction $\mu' = 0.1$. Fig.7(a), Fig.7(b) and Fig.7(c) show the results of experiments using sunray surf clams at three different amplitudes of the flow velocity. Fig.7(d), Fig.7(e) and Fig.7(f) show the results of experiments using surf clams of three different sizes.

The zero on the hour axis indicates the time when the main stream was reversed. The experimental values of three different velocities of moving bivalves in a one-half wave period were plotted. Turbulence was observed from experimental values because, while the flow acts on the bivalves, they turn around in various directions. However, in general, the theoretical values and experimental values agreed well.

Fig.7(a), Fig.7(b) and Fig.7(c) indicate that bivalves began moving at an early phase as the amplitude of the flow velocity became higher, and the ratio between the maximum value of the moving bivalves' velocity (U_{sm}) and the amplitude of flow velocity (U_m) approached 1.0. Fig.7(d), Fig.7(e) and Fig.7(f) indicate that the longer the shell length of the bivalves is, the lower U_{sm} becomes, although there were few differences between shell lengths because of the high flow velocity.

The results of the present study showed that once bivalves are forced out into the water from the sand, there is little effect of their own movement. Therefore, they can be regarded as inanimate objects.

CONCLUSIONS

- [1]The critical condition for which bivalves (surf clam) forced out of the sand and into the water by the water flow was determined by the ratio between V_e and V_b , which are the velocity of bed erosion and the burrowing rate of bivalves, respectively. V_e/V_b is approximately 1.1.
- [2]The critical flow velocity at which bivalves can borrow into the sand increases as the burrowing rate rises.
- [3]The burrowing rate of bivalves is related to both critical conditions, and the effects of the bivalves' own active movements (burrowing) were found to be significant for these conditions.
- [4]The burrowing rate of bivalves below a certain water temperature is roughly proportional to the length of the shell, and decreases with a fall in water temperature between 20°C and 5°C.
- [5]Under conditions where sand ripples are formed, as the amplitude of the flow velocity increases, the probability of a higher bed erosion velocity increases.
- [6]The behavior of bivalves which are forced out of sand are hardly affected by their active movements, and they can be regarded as inanimate objects. Supposing that the volume of a bivalve is converted into a globe, the behavior of bivalves could be theoretically explained by setting C_D (drag coefficient), C_M (added mass coefficient) and μ' (coefficient of dynamic friction) to 1.0, 0.5 and 0.1, respectively.
- [7]The shorter the length of the bivalves, the lower the water temperature, and the

higher the wave height, the more easily the bivalves are forced out of the sand into the water by the water flow. These are considered to be one of the major factors affecting the mortality of young bivalves due to waves in winter.

ACKNOWLEDGEMENTS

We wish to thank Hokkaido Central Fisheries Experimental Station, Muroran Branch-Hakodate Fisheries Experimental Station, and National Research Institute of Fisheries Engineering for advice on the ecology of bivalves and cooperation of the collection of bivalves.

CHAPTER 338

Wind- and Sea Level-Induced Shore Evolution in Poland

Ryszard B. Zeidler, Marek Skaja, Grzegorz Różyński & Jarka Kaczmarek ¹

Abstract

The effect of climate change factors on Polish shoreline is investigated in meso-scales of decades and tens of kilometres along the entire Baltic coast, with emphasis on the selected segment from Ustka to Łeba. Intensification of westerly wind circulation and sea level rise (SLR) are quantified as an input in computations of shoreline change by a one-line model. Joint probability distributions of wind and sea level derived under an extensive programme employing field data are used to produce input for computations of shoreline change due to rare events. The computations prove that the effects of both wind change and SLR can be perceptible in mesoscales, although it is difficult to clearly single out one from the other. In general, the westerly intensification of wind climate along the Polish coast seems to be slightly less important than SLR. A separate qualitative analysis of the acceleration of Polish shore retreat noted in recent years points to wind change as one of the possible causes.

1. Introduction: Coastal Climate Change (CCC)

The present coastal climate in the Baltic area, including Poland, is believed to undergo perceptible change due to global warming. The sea level rise, an increase in storminess and annual sea level maxima, and the changing patterns of wind circulation are the most pronounced change features affecting the coastal processes. The potential changes in precipitation, evaporation, transpiration, and their various outcomes over the Baltic coast and its drainage area, are also investigated although they are not easy to predict reliably and accurately.

An analysis of the variation of the zonal and meridional components of the geostrophic wind vector allows one to draw conclusions on the change of both components in the 40-year period from 1951 to 1990. For the more pronounced zonal component, this appears to be a trend of 0.0125 m/yr having a 95-% confidence level. By and large, one may note an intensification of the westerly air flow over the Polish coast, reflected in a shift of predominant wind directions towards W and NW, at the expense of the SW-W sector. A schematic change in the wind direction rose postulated for 50 years from 1995 to 2045 is

¹Professor, Snr Eng, Snr Res Assoc, Snr Asst, respectively; Institute of Hydro-Engineering IBW PAN; 7 Kosciarska, 80-953 Gdansk, Poland

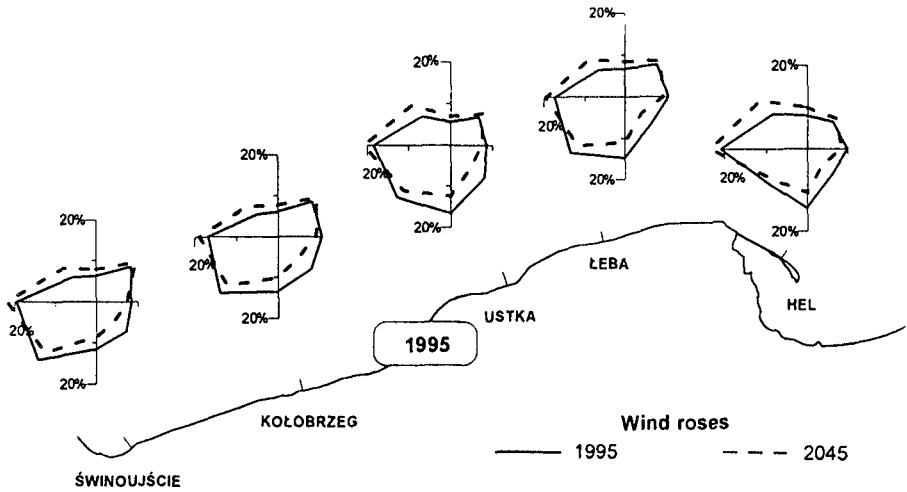

Figure 1. Frequencies of wind along the Polish coastline in 1995 (solid line) and postulated for the year 2045 (dash line).

depicted in Figure 1. In seasonal terms, the intensification of the westerly sector is particularly conspicuous in the winter season from October to March.

The mean sea level (SL) rise in Poland is presently estimated below 30 cm per century but its acceleration due to the greenhouse effect is taken into consideration (Zeidler 1995).

Another factor of climate change, i.e. storm intensity or 'storminess' can be analysed in terms of the annual sea level maximum (occurring once per year). One can prove that such storminess clearly increases over recent decades (Zeidler 1995). The growth trend of annual sea level maxima (ASLM) along the Polish coast is estimated about 10 cm per century.

It is also worthwhile to recollect that sea level increments Δh (four- or six-hourly at the Polish stations) display a certain long-term trend (Zeidler 1995). Moreover, they have been found to be correlated with high sea levels.

The present practice identifies as storm surges the events at which high sea levels alone occur, which brings about ambiguities. In order to determine the linkage between high sea levels and significant sea level increments, an analysis of the two quantities has been carried out (Wróblewski et al. 1996), with the primary objective as the derivation of statistical and probabilistic characteristics for both datasets and subsequent identification of their common features. Taken as a criterion of similarity was the condition that the numbers of occurrences of both quantities (SL and SL increments) are nearly equal. Such similarity has been concluded for 4-hourly SL increments greater than 21 cm at Ustka and Gdańsk (Nowy Port) or 26 cm at Swinoujście, versus $h \geq 563$ cm at Swinoujście and Gdańsk and $h \geq 560$ cm at Ustka (mean sea level being 500 cm). Within the above approach, regressional relationships between the time series for SL and their increments have been established.

Further on, the trend of storm winds could have been determined on the

basis of the sea level increments measured at Swinoujscie, Ustka and Gdańsk (Wróblewski et al. 1996). This was done by relying on relationships between Δh and storm winds in selected areas; a detailed analysis of statistical characteristics of storm winds and identification of their trend would have required processing of thousands of synoptic maps (e.g. above 100,000 maps taken every 4 hours in the investigated time span of 1955-1990).

The two major factors of CCC, i.e. wind and sea level in Poland are dealt with in this study while other CCC effects (primarily temperature, precipitation and groundwater changes) are incorporated in a coastal management programme led by the first author, where they contribute to changes in land-use patterns, flooding of coastal lowlands, cliff stability and other phenomena.

The basic objective of this study is to determine the effects of wind change and sea level change on the evolution of the Polish coastline.

It is interesting to note that the intensification of the westerly circulation has also been noted along the Danish coast. Figure 2 provides evidence for a time span of 100 years, showing increasing frequency of high wind speeds of the westerlies. The atmospheric circulation in Denmark has been shown to change by enhancement of the westerly winds and the clockwise turning of the predominant winds (from W to NW along the Jutland Peninsula coast investigated by Christiansen and Bowman, 1990). The wind change is accompanied by a more severe wave attack and retreat of the more exposed coastline segments.

In this paper, description of the climate change precedes shore evolution computations, from which conclusions can be drawn as to the evolution of the Polish coast in decadal scales, and these findings can be compared with the prototype data available.

The entire Polish coast measures five hundred kilometers between the mouth of the Oder (Odra) River and Poland's eastern border with Russia across the Vistula Spit. All over the Polish coast one encounters coastal lakes/lagoons of glacial origin. The same origin is assigned to the Hel Peninsula, a spectacular yet vulnerable to storms and climate change 30-km barrier separating the Gulf of Gdańsk from the open sea. Although the large-scale evolution of the Hel Peninsula is also investigated, this paper describes only some results obtained for the coastal stretch from Ustka to Łeba, belonging in part to the former category (lagoonal barrier).

The primary objectives of the study discussed in this paper consist in assessing the effects of climate change on the evolution of Polish coastline. The two basic effects tested are sea level change and wind change, treated both separately and jointly.

2. Joint Characteristics of Coastal Phenomena

In an investigation of shore evolution due to climate change one faces the necessity of focusing on joint characteristics of coastal phenomena, such as waves, sea level and wind. Also, extreme cases of coast evolution should be looked at. The selection and definition of extreme cases brings one to the problem of joint probability distributions for coastal quantities (such as sea level, wave parameter(s), wind etc.). By using the software produced for this programme one is able to compute shoreline changes or coastal evolution for every situation (sea level, wind speed and direction and at the same time the respective wave climate and other derivatives) but the open question remains how wave parameters are correlated with wind and sea level, and which combinations thereof are representative for extreme cases.

Hence four-dimensional probability distributions of wind (speed and di-

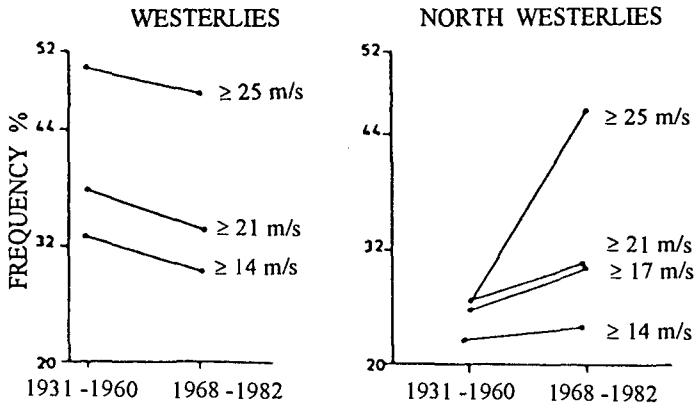

Figure 2. Change in wind direction along a latitudinal segment of NW Jutland (Klitmoller to Blokhus) shown by Christiansen and Bowman (1990).

rection), wave height and sea level have been investigated by the use of a large database for the Polish coastal weather stations, covering the years 1955–1990. At the beginning of the investigations it was realised that the probability of higher sea levels (exceeding 60 cm above the multiyearly mean value) might depend on wind direction. This would mean *inter alia* that the local growth of the mean sea level along the Polish coast due to the expected changes in wind circulation patterns could be quite pronounced by the year 2050.

As the study proceeded, wind-wave parameters were found to be correlated with wind direction as well, which is linked to the effect of fetch. At the same time, the correlation of wave height and sea level is low (about 0.2 for the stations of Hel and Gdynia) for all wind directions lumped, but a clear dependence on particular wind directions is displayed in some classes of water levels.

Figure 3 illustrates the cumulative joint probability of wind speed and sea level for N and NW winds at Hel, while Figure 4 shows the counterparts for Gdańsk (North Harbour). The two graphs stem from different datasets, not only for their locations but also because of the concept by which they were selected. The data for Hel in Figure 3 were taken for all events, i.e. at regular time steps, every three hours over nearly 5 years from 1976 to 1981 (11,500 events). The data for Gdańsk were purposefully biased to represent the impact of storm events (defined as those with significant wave height above 1 m); they also cover a shorter time lapse (1991 to 1992 and some months of 1995; about 4,500 events).

The correlations between sea level and wind speed were tested in eight principal classes of wind directions. Sea levels were arranged in sets exceeding the numbers indicated in the top lines of the tables in Figures 3 and 4. In order to examine the dependence on wind strength, the datasets were truncated in the sense that all events with wind speed below 6 or 8 m/s were rejected.

The correlations at Hel have been found very low in general; they seldom exceed 0.6 (the rightmost figures in the tables are not conclusive because of the low counts of data in those classes). The findings are certainly affected by the

Figure 4. Correlation tables and cumulative exceedance graph for sea level and wind speed at the station of Gdańsk (North Harbour, 1991-1992..1995).

very specific location of the station and the complex nature of the controlling hydrodynamic phenomena.

For the North Harbour, the correlations become significant for NE winds. The relatively high marginal correlations with both N and NE winds (given at the bottom of table) are linked to the fact that all sea levels were taken into account there (also those below 500, i.e. below MSL).

In representation of some characteristic rare events in the subsequent shoreline evolution computations, reference should be made to the exceedance graphs of the type shown in Figures 3 and 4. The following couples of wind and sea level were chosen for the selected isolines of the exceedance probability F :

- (a1) wind N 9 m/s + SL 545 ($F=2\%$);
- (a2) wind N 16 m/s + SL 500 ($F=0.01\%$);
- (b1) wind NW 9 m/s + SL 555 ($F=2\%$);
- (b2) wind NW 17 m/s + SL 500 ($F=0.01\%$);
- (c1) wind E 7 m/s + SL 535 ($F=2\%$);
- (c2) wind E 12 m/s + SL 500 ($F=0.01\%$).

3. Shore Evolution Computations

The wind change trends alone have been taken for granted by Zeidler (1995), who computed the respective sediment transport along the Polish coast in the 50-year time span, and drew conclusions on shoreline evolution. Despite a sharp change in wind direction (but not speed) the alteration of sediment transport rate and the subsequent shoreline evolution was not found dramatic, due to the wind change alone. Yet it was concluded that shoreline change might become quite conspicuous if the wind change is added to the accompanying storm surge or a sea level rise.

The shoreline computations in this study are founded on the one-line theory, which ends up with the diffusion-type equation

$$\frac{dy}{dt} = A \frac{d^2y}{dx^2} - B \quad (1)$$

in which

$$A = \frac{2}{(1-p)h_c} \frac{\partial Q_l}{\partial \varphi}$$

$$B = \frac{2}{(1-p)h_c} \left(\frac{\partial Q_l}{\partial x} + q_c \right)$$

h_c = depth of closure,

p = porosity of bed sediment,

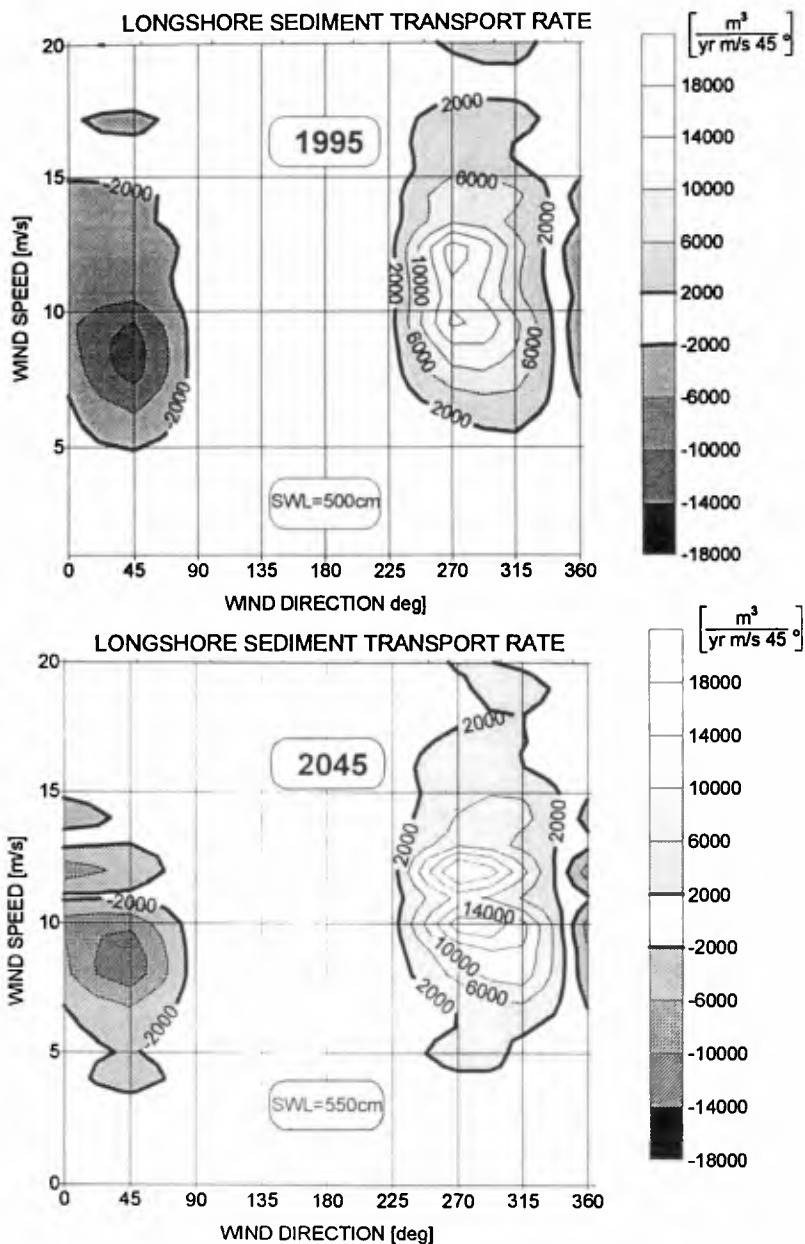

Q_l = longshore sediment transport rate,

q_c = cross-shore transport rate per unit length along shore,

t = time,

x, y = longshore and cross-shore coordinate of shoreline.

In order to determine the long-term shore evolution due to changes in wind, waves and sea level, by the above one-line scheme, an extensive computational procedure had to be employed. It encompasses five major subroutines: (1) preparation of input data with CCC quantities (wind, wind-induced waves and sea level); (2) arrangement of probability distributions for wave height and sea level in the format accepting CCC; (3) computations of sediment transport for the whole domain of wave height and sea level occurrence; (4) integration of sediment transport rate over representative time spans, with their probability distributions; (5) one-line type assessment of shore evolution over the time span of CCC.

SEDIMENT TRANSPORT VS. WIND, ĽEBA

Figure 5. Longshore sediment transport rate as a function of wind speed and direction at Ľeba, for the years 1995 (SWL datum 500, top) and 2045 (SL rising by 50 cm to SWL datum 550, bottom).

Waves are computed routinely by Krylov's 'spectral' method calibrated against field data. A Battjes/Jansen-type algorithm for irregular wave transformation is used as an input of the IBW PAN program for wave-induced currents, and the sediment transport formulae are Bijker-type for longshore movement and IBW PAN modified Bailard-type for cross-shore transport. Sea level controls the shore evolution at the places where shoaling and the closure depth intervene but is not included in nonlinear interactions with waves.

Hence in our routine, the input wind change leads to wave climate change, waves producing currents and then sediment transport. On the basis of that input, together with sea level rise, shore evolution patterns are produced.

The results of our computations of the longshore transport are depicted in Figure 5. For every cell of particular wind speed and direction one has the sediment transport rate computed for the present situation (1995) and for the future (2045). It should be noted that the future situation can arise in two versions — wind change only and wind change plus sea level rise. Hence at present one has the status shown at the top of the drawing, while in the future one may face two different situations with sediment transport for sea level change and for wind climate change.

The coefficients A and B in the one-line equation are functions of longshore sediment transport rate (partial derivatives) and cross-shore rates as well (per unit length along the shore). Those coefficients were assessed separately for every location of the study area, with respective closure depths, wave incidence angles, breaking parameters etc.

The study area was confined to the coastal stretch between Ustka and Łeba. Various climate input situations were tested. In addition to the rare cases selected from the joint probability graphs as described in Section 2 (situations a1–c2), the average year was also simulated. The latter encompassed aggregated westerly winds and aggregated easterly winds, for which one obviously had different sediment transport rates, different angles of wave attack etc.

The program USTLEB was compiled for computations of shoreline change in accordance with the one-line model, and was validated against the known analytical solutions (i.a. Larson et al. 1996). It is based on an explicit finite-difference scheme, where instability problems do not arise in practice. Some peculiarities emerge at points of discontinuity (of sediment transport rate, shoreline position) but the difficulties are overcome by locally decreasing space steps and iterative finding of shoreline derivatives. Estimates of the partial derivatives of the longshore transport rate must also be reasonably derived in a practical way.

In the computations by USTLEB for the 45-km segment Ustka–Łeba, the following conditions were adopted:

- (i) the time span 1995–2045 divided in 25 time steps 2 years each;
- (ii) two basic versions of climate change: (a) wind climate change only, (b) wind change + sea level change, 50 cm per 50 years;
- (iii) 'average year' and 'rare cases' a1–c2 as specified above for the wind ... sediment transport input.

Some results of the shoreline change computations are illustrated in Figure 6. Only the aggregated annual effects are shown to highlight the basic differences resulting from the impacts of the two major directional sectors of wind action along the Polish coast — from west to east (top) and east to west (bottom). The two annual components of shoreline change are strikingly different. The wind change effect is negligible vs. the sea level rise effect for the westerlies, and becomes of the same magnitude for the easterlies. The absolute magnitude of shoreline change is greater for the westerlies than for the winds

Figure 6. Results of one-line computations for the Polish coast segment from Ustka to Łeba, showing the 50-yr climate change effects — wind change only and wind change + SL change.

blowing from the eastern sector. If one takes into account that the former are more frequent than the latter, then one may venture the conclusion that the effect of wind change on the shoreline change is generally weaker than the impact of sea level rise.

Yet it is appropriate to note that the above conclusion is not so straightforward for the individual 'rare events' (a1–c2) tested in this study. Moreover, the contribution of the cross-shore transport to results of the computations by USTLEB also remains unclear so far. Attempts with various predictors of the cross-shore transport integrated along the shore transects (26 from Ustka to Łeba) have been inconclusive, and therefore are not reflected in Figure 6. More complementary research is required to shed light on the cross-shore effects. Needless to say, the latter may turn out fairly diversified along the Polish coast, if the research is extended far beyond the segment from Ustka to Łeba.

4. Prototype Data and Comparison with Computations

In preparation for the extended research on the entire Polish coast, as signalled at the end of Section 3, one may turn to the prototype evidence collected to date. On the basis of this data one can then venture some general observations and hypotheses relating to the evolution of the Polish coast in large scales of decades and hundreds of kilometres. Similarly, postulates can be formulated for the effects on shoreline of sea level rise and wind climate change.

For a period of slightly above one hundred years, Zawadzka-Kahlau (1994) retrieved the data on the position of Polish beach and shore features. The basic core of that collection consists of a vast database for shoreline ('waterline') and cliff/dune toe stemming from cartographic mapping dating back to

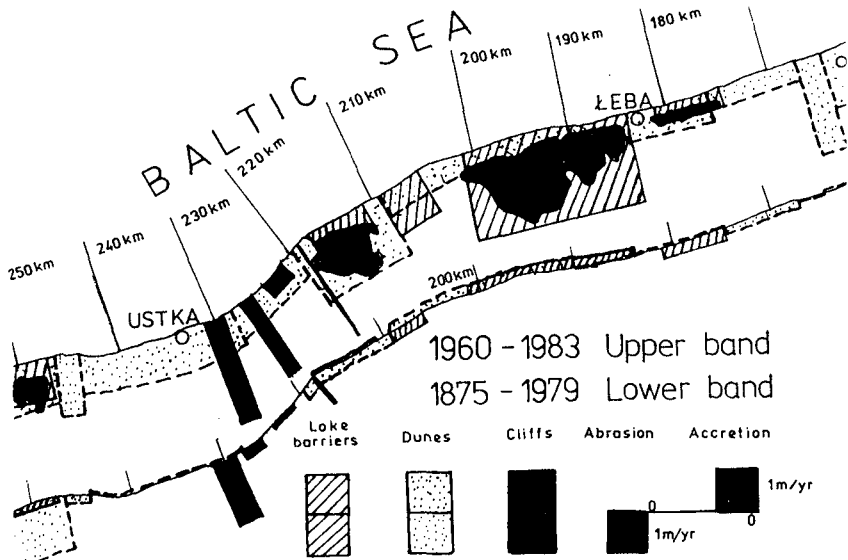

Figure 7. Decadal shoreline change along the coast segment from Ustka to Łeba (Zawadzka-Kahlau 1994).

the 19th century and extending over most of the Polish coastline. The statistical estimates obtained by processing of that database provide an opportunity of verifying the quantities resulting from our computations.

Under this study the database has been re-arranged graphically in the form illustrated in Figure 7 for the area Ustka-Łeba (although the same format was applied to the entire coast). Hence the shoreline change undergone in the years from 1875 till 1979 is shown in the lower band, while that in the more recent 20 years (1960-1983) is presented in the upper band. The purpose of such rearrangement is to provide insight into the general trends and to determine whether one faces some more conspicuous, dramatic shoreline changes in the recent years and if these changes are somehow linked to the change in wind circulation patterns and sea level change.

Consider the intensification of westerly winds, i.e. decadal increase in the frequency of W and NW winds depicted in Figure 1. More pronounced abrasion of concave shore segments could be expected, although to a different degree, depending on the coast type i.e. lake/lagoon barriers, dunes and cliffs. Indeed, such a trend is visible on many Polish coast segments. For majority of concave shore segments it can be concluded that more erosion is encountered in the recent years. There are a number of locations on concave segments where this can be claimed and where dramatic shift from accretion to erosion is noted. As a sound hypothesis, such behaviour can be assigned to the intensification of the westerly circulation. Unfortunately, this qualitative finding suffers i.a. from being embedded in the effect of sea level change. Unless differentiated more clearly, the two effects should be considered equally probable.

Figure 7 has been drawn for the stretch from Ustka to Łeba only. Accretion and erosion have been marked for three different shore types, accretion

lines progressing towards the sea and erosion being marked as lines of landward retreat. One very conspicuous feature visible in the drawing is the clear growth of the erosion rate in the years 1960–1983. Identification of the nature and cause of that accelerated growth remains a task of future investigations — the combined effects of the westerly intensification and SL change are slightly more likely than decadal cyclicity of shore evolution change.

5. Summary and Conclusions

The effect of climate change factors (wind and sea level) on Polish shoreline has been investigated in mesoscales of decades and tens of kilometres along the entire Baltic coast. Emphasis has been placed on the selected segment from Ustka to Łeba. Intensification of westerly wind circulation and sea level rise (SLR) have been quantified as an input in computations of shoreline change by a one-line model. Joint probability distributions of wind and sea level derived under an extensive programme employing field data have been used to produce input for computations of shoreline change due to rare events.

The computations carried out in this study prove that the effects of both wind change and SLR can be perceptible in mesoscales, although it is difficult to clearly single out one from the other, and/or from other natural and man-induced effects. In general, the westerly intensification of wind climate along the Polish coast seems to be less important than SLR alone, in terms of decadal and centennial coast evolution patterns. Simple one-line computations of Polish coast evolution confirm the potential effects of wind change and SLR in both interannual coast evolution and extreme events (SLR + Wind Change). Both effects are also equally probable in the light of field data for Polish shore covering the period of more than one century.

The software routine worked out in this study provides a useful tool of long-term coastal planning facing coastal climate change. The data input (wind, wave, sea level, bathymetry) and the software itself pave way for more complex investigations of coast evolution, including the modelling of joint wind, wave and sea level input and chronology effects.

ACKNOWLEDGEMENTS

This paper is based on the work done in the PACE project, in the framework of the EU-sponsored Marine Science and Technology Programme (MAST-III), under contract MAS3-CT95-0002. The work was cosponsored by the Polish Academy of Sciences (PAN) under the programme IBWPAN-Gr-tem-2-96.

CHAPTER 339

ASHDOD PORT'S EFFECT ON THE SHORELINE, SEABED AND SEDIMENT

Abraham Golik¹, Dov S. Rosen¹-MASCE, Arik Golan¹,
Maxim Shoshany², Dan DiCastro³ and Pinkhas Harari³

Abstract

During its 35 years of existence, Ashdod Port, Israel, caused changes to its physical environment. Analysis of aerial photographs and bathymetric surveys show that the port served as a sediment trap, blocking the natural northward sediment transport. Between 1958, prior to the port construction, and 1992 the beach to the south of the port underwent accretion which increased in magnitude from zero, at a distance of 2.5 km south of the port, to more than 100 m near the main breakwater. On the northern side of the port the shoreline was stable during that period. It was found that the beach north of the port did not suffer erosion because the sand of that beach was mined for building purposes prior to the port's construction. When the port was built, it was already a rocky beach.

Comparison between bathymetric surveys, which were carried out in the vicinity of the port, at various periods since prior to its construction until 1995, show that the port has trapped some 4.5 million m³ of sediments on its southern side. Of these, about 2.2 million m³ were deposited during the period of 1985-1995. It is estimated that more than half of this volume was deposited in 1992 during three very severe storms. On the basis of the depositional pattern in the vicinity of the port, and assumptions related to the net longshore sediment transport, it is estimated that more than half of the sediment volume bypasses the port northward.

³Ports and Railways Authority-Israel, 74 Dereh Petah-Tikva Ave., Tel Aviv, Israel

Introduction

Ashdod Port is located on the Mediterranean coast of Israel some 30 km south of Tel-Aviv. It was built between 1961 and 1964 on a straight sandy beach backed by sand dunes. About 200 m south of the main breakwater of the port Lakhish River discharges into the sea. The length of the existing main breakwater is 2,200 m and that of the lee breakwater is 900 m. The head of the main breakwater is at a water depth of 15 m, and the entrance of the port was 13 m deep when it was built. The port penetrates seaward from the shore to a distance of about 1,000 m.

Since the beginning of its operation in 1964, the volume of traffic in this port has continuously increased. Presently (1996), it handles some 13.7 million tons of cargo a year, but projections are for 15.4 million in the year 2000 and 16.6 million tons a year in 2010. It is therefore planned to expand the port by extending its main breakwater by 1,150 m to a water depth of about 21 m (Figure 1).

Figure 1. General plan for the planned expansion of Ashdod Port, phase I.

The increasing concern in Israel, as in the rest of the world, regarding the effect of coastal construction on the marine environment, led the authorities in Israel to impose preparation of environmental impact statements (EIS) for each major coastal structure. As part of the requests of the EIS for the expansion of Ashdod port, a numerical sedimentological model had to be carried out. This model should predict the effect of the port's expansion on the environment, and in particular on the nearby bathymetry, coastline and sediments. The present study was carried out in order to gather available information on the sedimentological development resulting from the

construction of the existing Ashdod Port, and to evaluate the effect of its breakwaters on the sedimentological balance in the area and the stability, in terms of erosion or accretion, of the seabed and of the shoreline. The results of this study should be used to calibrate and verify the above mentioned model.

Previous studies on the effect of Ashdod Port on the sedimentological processes in its vicinity were carried out by Kran (1980) who analyzed bathymetric profiles which were surveyed between 1964 and 1971 in the vicinity of the breakwaters. Computations of changes in the volume of sediment in the vicinity of the port between 1959 and 1975 were made by Finkelstein (1980) and between 1959 and 1985 by Vajda et al. (1988). Rosen (1985) assessed the longshore sediment transport rate at Ashdod on the basis of wave energy flux calculation.

Three data bases were used for this study:

- (a) Aerial photographs, taken since prior to the construction of the port until the present. They enabled to detect shoreline erosion and accretion caused by the port,
- (b) Bottom charts and profiles which were prepared before and after the port was built. These were used in order to evaluate changes in the seabed which were caused by the port.
- (c) Wave climate resulting from wave observations and measurements carried out near the port since 1957. These were used to evaluate the natural rate of sediment transport in the area, and in particular the longshore transport.

Methodology

Analysis of Aerial Photographs

The changes in shoreline position which resulted from the construction of the port were measured by comparing aerial photographs, which have been taken on different dates since prior to the port construction until 1992. To avoid errors resulting from seasonal changes in the shoreline, only photographs taken during the autumn season were used. This season was selected because the sea is calm and the beach face is steep at that period. Therefore, horizontal change in the waterline due to sea level fluctuations, is rather limited. Also, wave records showed that during the photography sortie and the days preceding it, wave height was less than 1 m. Eight aerial photographic sorties from the years 1958, 1964, 1971, 1976, 1980, 1983, 1988 and 1992 were selected for this study.

The analysis of aerial photographs was that adopted by Shoshany and Degani (1992). The analog format of the photographs was transformed into a digital one using a digital scanner. Prominent objects in the photographs were used to relate photographs from different dates into a uniform geographic system.

The line which separates the wet part of the beach from the dry one was selected to represent the shoreline because it is clear and sharp on the photograph. Also, this line does not fluctuate momentarily as the water line does. This line was further

accentuated by enhancing the brightness contrast. The 1988 sortie was selected as a reference sortie, because it contained a large number of common reference points which were seen on photographs from preceding and succeeding sorties. These reference points were used to rectify the aerial photographs and remove distortions from them. Once this was done, the shoreline was digitized for each sortie. It is estimated that the error involved in determination of the shoreline position is less than 10 m.

Bathymetric Analysis

Bathymetric surveys in the vicinity of the port, which were conducted in 1957, 1959, 1970, 1975, 1980, 1983, 1985 and 1995, were used for this study. The surveying methods which were employed in these surveys changed during this period. Until the early 1970's, navigation was carried out by sextant readings from the boat to reference points on the beach, and depth was measured using a Kelvin Hughes surveying echo sounder. After 1972 navigation was carried out by an electronic system, Decca Trisponder, and later by Miniranger. Data processing, interpolation of boat position and depth reading, and collation of these data, were carried out manually until the beginning of the 1980's and gradually changed to computer processing in the early 1980's. The survey of 1995 was carried out using a differential GPS system for navigation and a digital Odom echosounder. The collation of depth and position was carried out on board the surveying boat, using the OCEANOGRAPHER navigation and mapping computer software system, developed and written for such purposes by the third author. The charts were digitized and an interpolated grid of depth points for each survey was prepared. Each grid was subtracted from its predecessor, and depth differential maps which show the magnitude and spatial distribution of deposition or erosion on the seabed were prepared.

Wave Data and Computation of Longshore Sediment Transport

Wave data have been collected from Ashdod Port region since 1957. Some of the data (1957-1975) were based on visual observations, some (1978-1992) on a combination of instrumental measurement (wave height and frequency) and visual observation (wave direction), and for three years, 1992-1995, wave height, frequency and direction were instrumentally measured. In view of the low reliability of the wave directions of the old wave data, the final computation of the longshore sediment transport rate, was based on the April 1992 - March 1995 wave data, gathered off Ashdod with a Datawell Wavec buoy at 3 hour intervals. These data were used as an input in computer programs using the formulas of longshore sediment transport known as the CERC (USArmy CERC-1984), Komar (Komar-1977), LCHF (Migniot et Manoujan-1983) and Bijker (Bijker-1972) formulae. The longshore sediment transport was computed for each sedimentological year, namely years starting in April on one year and ending in March of the following year, to comply with the sedimentological seasonal wave regime in this region.

To account for the longshore sediment transport taking place beyond the surf zone, the joint contribution of wave stirring and geostrophic current transport, current data statistics gathered by Israel Oceanographic & Limnological Research off Ashkelon, in 27 m water depth, were used in combination with the Bijker formula.

Results

Shoreline Position

Examination of the position of the shoreline south and north of the port, as derived from the aerial photographs analysis, reveals two phenomena. First, the distance between the positions of the shorelines of 1958, prior to the construction of the port, and 1964, when it was almost completed, is very small and falls within the resolution magnitude of the analysis. The second, is the change with time in the shoreline position south of the port versus those north of it. South of the port, a distinct accretion of the shore with time is noticed, whereas north of the port, the shoreline position is relatively stable with the exception of the sector in the immediate vicinity of the lee breakwater.

Figure 2. Difference in m between the mean position of the shoreline in 1958-1964 and that of 1983-1992 south of Ashdod Port.

Figures 2 and 3 were prepared with the purpose of showing the general trend in the development of the coastline, south and north of the port. It shows the distance between the mean position of the shoreline in the years 1958 and 1964 and that of the years 1983-1992. Figure 2 shows that during the study period the shoreline has advanced westward gradually from zero at 2,500 m south of the main (southern) breakwater to about 100 m near it. North of the port, Figure 3 shows that accretion has occurred very close to the lee (northern) breakwater, to a distance of about 300 m

north of it, but from there on northward, the position of the shoreline was rather stable during the study period.

Figure 3. Difference in m between the mean position of the shoreline in 1958-1964 and that of 1983-1992 north of Ashdod Port.

Bathymetric Changes

Examination of the depth differential maps which resulted from the analysis of the bathymetric charts shows that the first impact of the port on the seabed was a severe erosion, up to 2.5 m, north of the port and deposition of up to 3.0 m next to the lee breakwater. With some fluctuations in magnitude, these effects remained throughout the history of the port.

Another phenomenon, which also started following the port's construction, is the increase of deposition near the beach south of the port as well as near the head of the main breakwater. Deposition increased both in thickness as well as in space with time. In 1975, sediment was "creeping" along the main breakwater reaching about a third of its length. In 1980, the depositional area south of the main breakwater increased, and the accumulation at the head of the breakwater increased in thickness. In 1983, deposition followed the same pattern but increased in thickness. Between 1983 and 1985, minor changes occurred in the sea bottom, but between 1985 and 1995, an impressive deposition took place along the southern part of the main breakwater and south of it, parallel to the beach, at a distance of between 700 and 1,000 m. The thickness of this deposition is mostly up to 2.0 m but in restricted areas up to 3.0 m. 4.5 million m³ of sediment have accumulated in the studied area south of the main

breakwater between 1957 and 1995. Of these, 2.3 million m^3 between 1957 and 1985, and 2.2 million m^3 between 1985 and 1995.

Assessment of Wave Climate and Longshore Sediment Transport

Figures 4-6 show the average yearly marginal distributions of the deep water wave characteristics off Ashdod during sedimentological years 1993-1995 (04/1992 -03/95) using data bases of 3 hours data, noon daily data and maximum daily data. Figure 4 shows the marginal distribution of deep water characteristic wave heights, Figure 5 shows the marginal distribution of peak wave periods, and Figure 6 shows the marginal distribution of deep water wave directions for the mentioned period.

Figures 7 and 8 provide the average yearly marginal distributions of the general current characteristics off Ashkelon (15 Km south of Ashdod Port) which were measured in 1992-1993 (Rosen, 1993). The current was measured at a water depth of 27 m, 10 m below the sea surface. Figure 7 shows the marginal distribution of hourly averaged current speeds, and the marginal distribution of hourly averaged current directions is presented in Figure 8.

On the basis of these data and the various formulas mentioned before estimates of the longshore transport were obtained. As can be seen in Figure 9, there are differences of up to four times among the various formulas. The evaluation using the CERC formulae of the net transport is about 3 times larger (720,000 m^3 /year) than that of Bijker formula (230,000 m^3 /year) without accounting for the presence of currents

Figure 4. Yearly deep water distribution of characteristic wave height (04/92-03/95).

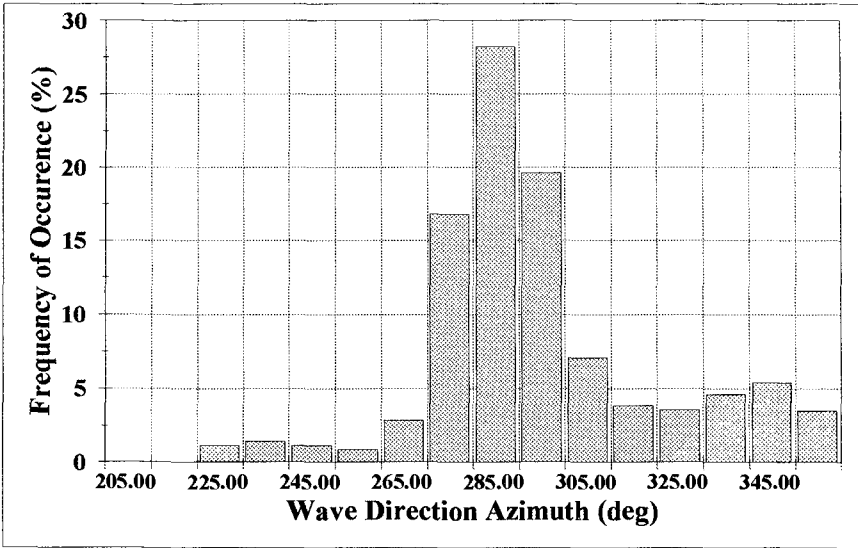

Figure 5. Yearly deep water distribution of peak wave periods (04/92-03/95).

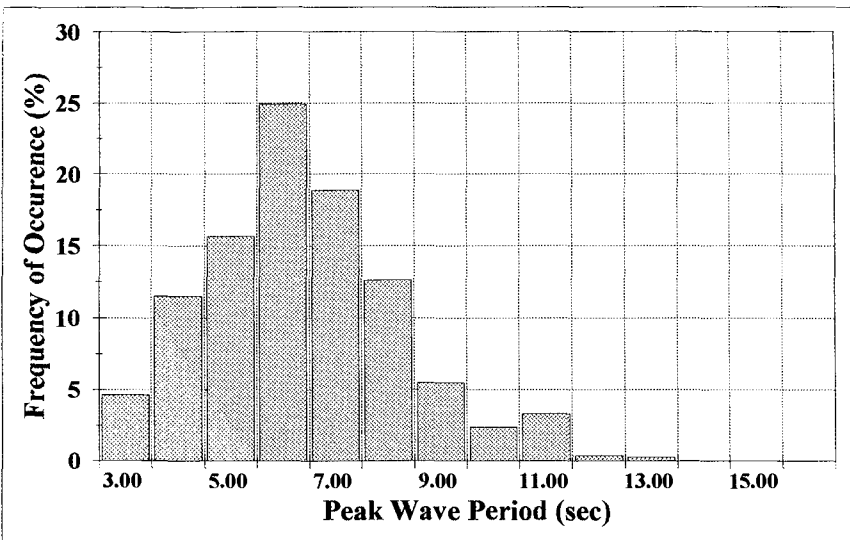

Figure 6. Yearly deep water distribution of wave directions (04/92-03/95).

Figure 7. Current speed distribution offshore Ashkelon.

Figure 8. Current direction distribution offshore Ashkelon.

beyond the surf zone. The LCHF provides a value which is about 0.75 of the Bijker formula without currents beyond the surf zone. The comparison between the estimate of the transport with and without accounting for the currents beyond the surf zone is also presented in the same Figure. As one may see, the transport assessment including currents beyond the surf zone on the basis of the current statistics given in Figures 6 and 7 leads to volumes comparable to those of the CERC formula. In Figure 10 the yearly average longshore sediment transport distribution across the shore at Ashdod, based on the period 04/92-03/95, is presented.

ASHDOD YEARLY NET LONGSHORE SAND TRANSPORT
Averaged over the period 04/92-03/95

Figure 9. Comparison among methods of evaluation using the 3 hours data set.

Considering the fact that the assessment using currents was based by one year of currents data, during a harsher weather than in the following two years, the average longshore net transport was assessed on a weighted average between assessment with currents and assessment without currents. Thus, an yearly net longshore transport of 350,000 m³ to the North was assessed as the most probable rate for a normal year.

Discussion

Shoreline Changes

The results of the shoreline analysis clearly indicate that the net sediment transport in the area of Ashdod Port is northward. Under these conditions, one would expect erosion to occur north of Ashdod Port, but no such erosion of the shoreline is noticed from the analysis of the aerial photographs. The reason for this is the sand mining activity which was very intensive on this beach until 1964. This can be seen in Figure 11, which is an aerial photograph taken in 1958, prior to the port construction. The

Figure 10. Yearly cross-shore sand transport profile at Ashdod (with currents).

scars of the sand mining are clearly seen on this picture, as well as on aerial photographs taken from the coast both north and south of this point. More than 5 million m³ of sand were mined between 1949 and 1963 from the beaches stretching along some 30-40 km of the Ashdod coastline (Zifzif Committee, 1964).

Figure 11. Aerial photograph taken in 1958 showing the scars of beach mining along the Ashdod shoreline.

This mining must have left the coast either devoid of loose sand, or close to it. The sand trapped south of the port after its construction "healed" these scars and widened the beach. However, north of the port, the beach was already rocky before the port construction, lacking sand to be removed by erosion, and this is why the position of the shoreline remained stable. The rocky beach extends today to some 3.5 km north of the port, and from there on northward, sand becomes gradually more ubiquitous on the beach.

Bathymetric Changes

The most striking finding of the analysis of the sea bottom changes is the massive accumulation of sediment, more than 2 million m³, which took place between 1985 and 1995. This raises a few questions: Was this accumulation a gradual one or an episodic event? What caused this rapid accumulation? Where did the sediment come from?

It was found that a bathymetric survey which was carried out in 1991 offshore Ashdod city, overlapped a small part of our study area in the south. Depth differential maps for the period 1985-1991 and 1991-1995 clearly showed that sediment accumulation which occurred in that area was greater in the period of 1991-1995 by many times than in 1985-1991. This indicates that the massive accumulation of sediment seen in the depth differential map for the period 1985-1995 occurred sometime between 1991 and 1995. The most prominent event that occurred in the period of 1991-1995 is a series of very severe storms which occurred in December 1991, February 1992 and December 1992. In one of them, February 1992, the deep water characteristic wave height was 7.2 m and in the others more than 5 m. Computation of longshore sediment transport rate using a simulated storm with waves of this magnitude resulted in a net transport of up to 400,000 m³ per storm. The storms of 1991-1992 are therefore responsible for the large deposition of sediment which was detected in the 1985-1995 depth differential map.

There was, however, another source of sediment input into the area. The Lakhish River, which discharges into the sea just south of Ashdod Port, has flooded during the storms, particularly during that of February 1992. According to Hydrological Survey of Israel, the water flow of this river in 1992 was the largest ever to be recorded. Figure 12, which is an aerial photograph taken 10 days after the flood, shows an extensive shoal in front of the river mouth which was formed, at least partly, by the sediment brought by the river to this area.

Sediment Bypass of Ashdod Port

The issue of sediment bypass of Ashdod Port is an important one because it implies to what degree the port acts as an obstacle to the natural transport of sand to the northern beaches of Israel. However, the evidence for such a bypass is only an indirect one. The depth differential map for the period of the port's existence clearly

Figure 12. Aerial photograph taken on 14 February 1992, 10 days after the flooding of Lakhish River, showing the shoal which was formed in front of the river's mouth.

shows that the pattern of accumulation of sediment south of the port, follows the contour of the main breakwater, surrounds it, and there are areas north of the port in which sediment accumulation is already noticed. According to reports of the Ports and Railways Authority the entrance channel to Ashdod Port is undergoing siltation. As it is unlikely that this siltation results from an on-offshore transport at this depth, it is another confirmation to the sediment bypass of the port.

It is difficult to provide the rate of sediment bypass because there is no direct way to measure it and we do not have quantitative information for all the parameters which control it. Nevertheless, an attempt was made to come up with an estimate which is based on assumptions and estimates. For the 10 year period between 1985 and 1995 some 3.5 million m^3 entered into the area as a result of the normal net yearly longshore sediment transport ($350,000 m^3/yr \times 10$ years). In addition, the storms of 1992 yielded some 0.9 million m^3 ($400,000 m^3/feb.92$ storm + $2 \times 250,000 m^3$ for the other 2 storms). It is estimated that Lakhish River contributed 0.25 million m^3 during the flood of 1992. All these add up to about 4.6 million m^3 that were input into the area south of Ashdod Port during that period of time. At that time 2.2 million m^3 of sediment were trapped in the area south of the port implying that 2.45 million m^3 , i.e. more than 50% of the sediment managed to bypass the port during that decade.

Acknowledgments

This study was supported by the Ports and Railways Authority, Israel. Wave data from Ashdod were provided by the Coastal & Marine Engineering Research Institute, Haifa, Israel. The authors wish to express their gratitude to E. Kit and J. Zwamborn for their constructive criticism.

CHAPTER 340

Tweed River Sand Bypass: Concepts and Progress

Russell J. Murray,¹ R.P. (Jock) Brodie,² Mark Porter,³ David A. Robinson⁴

ABSTRACT: The objectives of the Tweed River Entrance Sand Bypassing Project on Australia's east coast are to establish and maintain a navigable entrance to the Tweed River and to enhance and maintain the southern Gold Coast beaches, with the objectives to be achieved in perpetuity. The joint project of the New South Wales and Queensland State Governments with the support of the Gold Coast City Council offers the opportunity to achieve this co-operatively in partnership. Agreements have been established. The environmental impact assessment of the first stage (initial dredging and nourishment) has been completed, and the first component of these works involving over 2.2Mm³ of sand was successfully completed in August 1996. Environmental impact assessment and design studies for the second stage (the permanent bypassing system) are in progress. The paper describes the overall project and its key features, the investigations and analyses undertaken to date, the identified impacts, the initial dredging and nourishment works, and the issues being investigated for the permanent system.

INTRODUCTION

The Gold Coast-Tweed Heads region (28°S, 153.5°E) on Australia's east coast is a major international and national tourism destination, and a significant growing recreational and residential area, with a unique coastal environment. The beaches are subject to cyclonic(hurricane) and storm waves, and are characterised by a

predominantly northwards longshore sand transport averaging 0.5 million cubic metres (Mm^3) per year net, which is driven mainly by the predominant easterly and south-easterly waves (median significant waveheight: 1.4m, median peak period 9s). The beaches are composed of clean fine-grained quartz sand with median diameter of 0.22mm. Mean spring tidal range is 1.3m.

The Tweed River entrance which influences the continuity of the natural littoral system has been plagued by mobile sandbars which have endangered navigation since the early 19th century. Entrance training walls (rock jetties) started in 1890 offered only short-term relief. From 1962 to 1965, the training walls were extended seaward 380m to aid navigation of the entrance. These walls reduced sand transport past the entrance, Letitia Spit to the south of the entrance accreted (total accretion to 1995 of over $7Mm^3$ has filled the walls), and the downdrift southern-most beaches of the Gold Coast experienced erosion (Macdonald and Patterson, 1984). Major beach nourishments totalling over $6Mm^3$ have been successful in substantially offsetting the erosion of these beaches (Murray et al, 1993 and 1994).

Following separate and joint studies by the responsible authorities, and complex negotiations with four jurisdictions, agreement was concluded between the State of New South Wales and the State of Queensland to undertake the Tweed River Entrance Sand Bypassing Project which impacts on both States. It is being supported by the local city, the City of the Gold Coast (Murray, Brodie et al, 1995).

The project agreements are:

- (a) the Heads of Agreement signed on 31 March 1994 by the Premiers of New South Wales and Queensland; and
- (b) the formal legally-binding Deed of Agreement signed by the responsible Ministers on 2 March 1995.

The New South Wales Parliament has enacted ratifying legislation (the *Tweed River Entrance Sand Bypassing Act 1995* (NSW)), and similar legislation is proposed in Queensland.

OBJECTIVES, PRINCIPLES, AND BENEFITS

The objectives of this joint project (to be achieved in perpetuity) are to:

- (a) improve and maintain the navigability of the Tweed River entrance (in New South Wales); and
- (b) improve and maintain the southern Gold Coast beaches (in Queensland).

The project comprises two inter-related components:

- (a) an initial dredging of the bar and entrance area and beach nourishment; and
- (b) an artificial sand bypassing system, to operate in perpetuity.

The benefits are anticipated to include:

- (a) the improvement in the safety of navigation of the river entrance with the consequent benefits to recreational boating, tourism, property values and the fishing industry;
- (b) improved tidal flushing of the river estuary, improved water quality, and mitigation of flooding; and
- (c) the restoration, widening and long-term maintenance of the beaches, with associated benefits to tourism, recreation, property values and the reduction of erosion threats.

To achieve early benefit, initial dredging and nourishment was scheduled to be undertaken while permanent bypassing system options and impacts were being investigated and assessed.

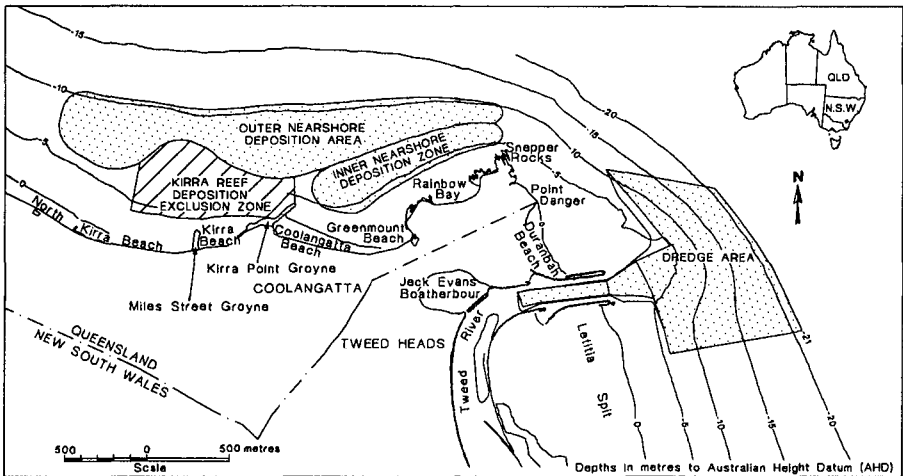

Figure 1: Location diagram, showing approximate dredging and nourishment areas

INITIAL DREDGING AND NOURISHMENT (STAGE 1)

The initial dredging and nourishment involves about 2.5Mm³ of sand to be dredged from the entrance and placed on the beaches. The environmental impact statement (EIS) was prepared to comply with the requirements of both States. Following exhibition of the document, public meetings and the receipt of twenty-six submissions, an EIS Submission Review Report addressed the submissions received and made recommendations for actions, monitoring and an Environmental Management Plan.

Impacts and issues identified included:

- (a) increased operational window for fishing trawlers traversing the bar;
- (b) improved ability of beaches of Rainbow Bay, Greenmount, Coolangatta, Kirra and North Kirra to withstand storm erosion;
- (c) improved flushing of the lower estuary, to result in improvement in water clarity, nutrients and bacterial loads;
- (d) restoration of nearshore bathymetry to a condition similar to pre-1960s (pre-wall extensions) condition enhancing conditions for beach users;
- (e) slightly increased tidal range in the estuary (high waters increased by up to 0.04m with possible impact on saltmarsh habitat and roosting and nesting sites for birds, and low waters lowered by up to 0.12m with possible impact on seagrass areas);
- (f) erosion of up to 75m from the previously accreted shoreline at the northern end of Letitia Spit;
- (g) changed surfing conditions;
- (h) concern regarding possible effects on the rocky reef community of Kirra reef if the nourishment produced conditions outside the natural range of seabed fluctuations;
- (i) potential disturbance by noise from booster pumps and mechanical equipment during upper beach nourishment; and
- (j) possible wrecks in the dredge area.

Each of these issues has been considered in detail and, where appropriate, modifications have been made to the scope and extent of the work (Brodie et al, 1995).

The lowest of six tenders(bids) from Australian and international companies for the first part of the initial dredging and nourishment (Stage 1A) was accepted. Dredeco undertook the work using three dredgers in successive campaigns from 26 April 1995 to 20 August 1996, transferring over 2.2Mm³ of sand.

The greater proportion of the work was carried out by the (144m long) *Pearl River*, the world's then largest trailing suction hopper dredger. In a six week campaign, it dredged up to approximately 9,000m³ of sand each load in typically four sweeps. The original design slope was modified to allow bench dredging to a similar volume and shape. The *Pearl River* dredged the bar and entrance area to the limits set by its draft. It deposited 0.93Mm³ through the bottom-opening doors to a predetermined profile in the outer nearshore deposition area with an upper level of minus 7m Australian Height Datum (AHD, approximately mean sea level). A further 0.59Mm³ was pumped onto the upper beaches through a single point mooring connected to a 750m long, one metre diameter submerged pipe, which came ashore at Kirra Point, and linked to alongshore pipelines which extended from Kirra Point to the limits of beach nourishment at Rainbow Bay and North Kirra.

The shallower bar areas were dredged by the smaller trailing suction hopper dredger, the *Ngamotu* which has a length of 61m, draft of 3.5m fully laden and a hopper capacity of 490m³. The *Ngamotu* established a channel through the bar, increasing the ruling depth over the bar from less than 4m AHD to more than 6m AHD, thus allowing access by larger dredgers. During suitable conditions from May to November 1995, it dredged 0.17Mm³ and placed this sand in the inner nearshore deposition area to an upper level of minus 4.5m AHD.

Subsequently, in two campaigns in January/February and July/August 1996, the 2,300m³ capacity split-hull trailing suction hopper dredger, the *Krankeloon*, removed a further 0.56Mm³ and placed this in the inner nearshore deposition zone (0.12Mm³), the outer nearshore deposition zone (0.39Mm³), and an eastwards extension of the nearshore deposition zones around Snapper Rocks (0.05Mm³).

Further dredging and nourishment (Stage 1B) is expected to be carried out in late 1997 following monitoring of the results of this work and assessment of maintenance requirements.

PERMANENT BYPASSING SYSTEM (STAGE 2)

The permanent bypassing component consists of the design, manufacture, supply, delivery and commissioning of a sand bypassing system and the continuing operation of that system including replacement of the capital equipment. Its purpose is to facilitate the natural littoral sand movement processes by conveying past the river entrance the net littoral transport which occurs at the northern portion of Letitia Spit, so as to maintain a clear navigation channel of at least 4.5m AHD and maintain a continuing supply of sand to the beaches.

Artificial sand bypassing alternatives include jetty(pier)-based systems, mobile (jack-up) systems, floating plant, and traditional dredgers. A mobile system could overdredge a buffer during low transport periods to assist in intercepting some of the sand which would otherwise be missed. A mobile system should in principle be capable of bypassing 500,000m³ per year, even though some is missed from time to time. Fixed jet-pump bypassing system options (such as used at the Gold Coast Seaway 28km to the north where 4.5Mm³ has been bypassed in the first 10 years) would require fundamental modification or augmentation because there is no buffer sand trap at the project site as, for example, provided by the Seaway training walls (Coughlan and Robinson, 1990), and fixed systems rely on, and are limited by, natural processes in bringing sand to the intakes. No system can be totally effective in intercepting all of the sand transport, particularly during storm/cyclone events when operations may have to be curtailed and sand transport may be very high. Some allowance will have to be made for sand not captured by the system before it reaches the Tweed entrance or which escapes from the operational area of the system. (Robinson, 1993).

The delivery locations are expected to be Snapper Rocks (major quantity), Kirra Point (possible on demand capability), and Duranbah Beach (possible minor quantity capability). As natural sand transport around Snapper Rocks and across the Rainbow Bay and Greenmount/Coolangatta beaches is characterised by some slug-like spurts overlying a more regular transport, there are likely to be some beach management advantages if sand can be discharged on demand at Kirra, where local shortages of sand occur from time to time. However Snapper Rocks could be a sufficient discharge site, provided a suitable discharge mechanism was designed, and operation of the bypassing rate was managed in accordance with changing transport rates. The long term average net littoral transport rate is currently understood to be 500,000m³ per year, but analysis suggests that it can vary between 270,000m³ and 900,000m³ in any single year. The delivery of sand will match the long term average net littoral transport, but will take account of the annual variations in quantities of sand delivered by natural processes to Letitia Spit and the specific objectives of the project, including coastal process issues of the beaches and the entrance, beach usage and navigation requirements. If the long term average net littoral transport rate changes, the rate of delivery will be changed accordingly.

Other issues to be considered for the system include:

- (a) system reliability and safety in the high-energy, corrosive, abrasive environment;
- (b) outlet design;
- (c) water discolouration (though the sand is clean);
- (d) public safety (for beach and waterway users);
- (e) effects on beach usage (including swimmers, surfers, and anglers);
- (f) visual impact;
- (g) noise;
- (h) operational scheduling;
- (i) performance criteria;
- (j) commercial and contractual arrangements; and
- (k) operational management.

Actions already implemented include the assembly and evaluation of the performance of the Gold Coast Seaway and other existing and planned bypassing systems, a value management study, and the incorporation of data requirements for the permanent system in the current data collection and monitoring program. A comprehensive environmental impact assessment study is in progress, and is scheduled for completion in mid-1997.

CONCLUSIONS

The objectives of the Tweed River Entrance Sand Bypassing Project are to establish and maintain a navigable entrance to the Tweed River and to enhance and maintain the southern Gold Coast beaches, with the objectives to be achieved in perpetuity. The joint project offers the opportunity to achieve this co-operatively in partnership.

The project is located on an open high-energy coastline subject to variable natural forces, in a highly-valued environment, subject to intensive usage. Accordingly, it is recognised that the project must be designed, evaluated and implemented prudently using best practice and in an environmentally sensitive way, if the long-term benefits are to be effectively achieved.

The complex bar dredging and beach nourishment have provided initial benefits, have satisfied strict environmental criteria, and have received widespread public support. Extensive environmental monitoring and public consultation has been incorporated.

The significant engineering, environmental and contractual challenges facing the permanent bypassing system are being progressively addressed.

CHAPTER 341

DESIGN CONSIDERATIONS FOR COASTAL PROJECTS IN COLD REGIONS

Craig B. Leidersdorf, M. ASCE¹

Peter E. Gadd, M. ASCE¹

Kennon D. Vaudrey, M. ASCE²

ABSTRACT

Design considerations for coastal projects in cold regions include not only the oceanographic factors that tend to assume primary importance in temperate climates, but also ice and thermal factors. This paper reviews the current understanding of each of these three types of design considerations, with emphasis on the lessons learned from recent project experience in the Alaskan Beaufort Sea. It is concluded that the environmental influences unique to cold regions introduce both increased complexities and increased uncertainties into the design process for coastal structures. In consequence, a conservative approach that incorporates damage-tolerant components and non-catastrophic failure modes is recommended for the design of sensitive facilities.

INTRODUCTION

During the past two decades, the number of coastal and nearshore projects constructed in cold regions has increased significantly. The primary motivation for these projects has been petroleum-related activities, which have resulted in the installation of more than 50 artificial islands, causeways, and coastal pads off the Arctic coasts of Alaska and Canada. Public works projects also have been undertaken by communities such as Barrow, Alaska, where bluff stabilization and beach nourishment programs have been carried out in recent years (Wiegel, 1995).

For purposes of this paper, a "cold region" is defined as an area in which the sea surface remains ice-covered for a significant portion of each year. Important

¹ Principal, Coastal Frontiers Corp., 9420 Topanga Canyon Blvd., Ste. 101, Chatsworth, CA 91311

² President, Vaudrey & Associates, Inc., 1540 Marsh Street, Ste. 105, San Luis Obispo, CA 93401

design considerations for coastal projects in cold regions include not only the oceanographic factors that tend to assume primary importance in temperate climates, but also ice and thermal factors.

The objective of this paper is to review the current understanding of ice, oceanographic, and thermal design considerations for coastal projects in cold regions. Particular emphasis will be placed on recounting the lessons learned from recent project experience in the Alaskan Beaufort Sea.

ICE DESIGN CONSIDERATIONS

Ice-related factors that may warrant consideration in the design of coastal and nearshore facilities include horizontal loads, encroachment onto the structure work surface, gouging of the sea floor by ice floe keels, and "strudel scouring" of the sea bottom by the drainage of river outflow through holes in the ice. The first two factors, horizontal loads and encroachment, can exert a major influence on structures that extend above the sea surface, such as islands, causeways, and coastal pads. The last two factors, ice gouging and strudel scouring, are particularly relevant to engineering works constructed on the sea floor, such as pipelines and toe protection.

Horizontal Ice Loads

The horizontal loads that result from ice movement can be segregated into two categories: global ice loads, which act on large structures such as gravel islands, and local ice loads, which act on small structural elements such as sheet pile walls and caissons. Global ice loads vary with the ice thickness, strength, and mode of failure. In turn, the failure mode depends on the type of ice feature impacting the structure. For exposed locations in the Beaufort Sea in water depths of 10 to 15 m, the governing global ice load is likely to be produced by encounters with multiyear floes (floes that have survived at least one open-water season). For protected locations between the shoreline and the 10-m isobath, the design global ice load results from first-year sheet ice. Such loads can be calculated probabilistically or deterministically, with the methodology for each presented in the American Petroleum Institute Recommended Practice 2N (API RP2N; 1995), and in Sanderson (1988).

In the case of exposed structures such as man-made islands, it is assumed that the kinetic energy of the moving multiyear floe is totally dissipated in ice crushing as the floe either comes to rest against the island or continues moving past while developing a maximum contact width equal to the maximum waterline dimension of the island. If a floe of mass m is traveling at velocity v , it will come to rest after a total penetration X , when:

$$\frac{1}{2}mv^2 = \int_0^X P(x)dx \quad (1)$$

where $P(x)$ is the total force exerted when the floe has moved a distance x after initial contact. The load $P(x)$ may be expressed as:

$$P(x) = \sigma(A) A(x) \quad (2)$$

where the contact area $A(x)$ varies with the penetration distance and $\sigma(A)$ is the average ice failure pressure associated with this contact area. It is assumed that the largest global ice load for any multiyear floe impact will occur at the point of maximum penetration. In order to solve Equations (1) and (2), values are required for the ice floe mass m , the initial velocity v , and the failure pressure $\sigma(A)$. The contact area $A(x)$ is determined from the interaction geometry of the floe and the structure.

Using the above ice loading scenario and Equations (1) and (2), global ice loads can be computed probabilistically by considering the input parameters as random variables. Independent distribution functions are required for the multiyear floe thickness, the floe diameter, the floe velocity, and the ice failure pressure to determine the annual probability distribution of the total ice load P acting against the structure. The maximum annual load developed from an appropriate random sampling of the four input parameters is assumed to approximate an extreme value (e.g., Type I or Gumbel) distribution, from which a design value can be determined. In the Alaskan Beaufort Sea, representative design global ice loads associated with multiyear floe impacts range from 5 to 6 MN per meter of island exposure width for a return period of 100 years.

In the case of protected sites such as coastal pads, the maximum global load P exerted by sheet ice can be estimated on the basis of an ice crushing failure using a modified version of the Korzhavin equation (API, 1995):

$$P/D = p t \quad (3)$$

where P represents the total horizontal ice force acting against the maximum exposure width D of the structure, t represents the ice thickness, and p represents the effective ice crushing or failure pressure (which varies with the ice type, temperature, movement rate, and contact area).

The maximum annual load usually will occur in late winter, when the ice temperature and thickness produce the strongest ice. Values ranging from 1 to 1.5 MPa for the effective ice failure pressure p and 0.5 to 2 m for the ice thickness t are representative of the nearshore first-year ice conditions utilized for design purposes in the Alaskan Beaufort Sea. The resulting global ice loads range from 0.5 to 3 MN per meter of exposure width for a return period of 100 years.

Small structural elements such as sheet pile walls and caissons must be designed to withstand ice pressures exerted over areas of several square meters. These local ice failure pressures can be much larger than the uniaxial compressive ice

strength because of the confinement provided by the surrounding ice. In consequence, the design local ice loads on small structural elements always exceed the global loads exerted by the same ice conditions on large structures.

As suggested by Figure 1, local ice pressures increase with decreasing contact areas. The two curves in Figure 1 represent recommended upper and lower bounds derived from an empirical local ice pressure-area relationship set forth in the API RP2N (1995). The lower bound is based upon the mean plus two standard deviations ("M+2SD"), while the upper bound is based upon the mean plus three standard deviations ("M+3SD"). Because these curves were developed from measurements acquired throughout the Arctic, site-specific experience should be taken into consideration when they are applied to specific projects. In addition, the curves should be utilized only for contact areas less than 10 m²; the product of the local ice pressure and the contact area always should exceed the global ice load calculated according to the appropriate method described above; and the local ice pressure should be regarded as acting normal to the exposed face of the structure.

Figure 1. Pressure-Area Curves for Small Structural Elements

Ice Encroachment

In the context of this paper, encroachment refers to the movement of an ice sheet or individual ice blocks onto the work surface of a man-made island or coastal pad (Plate 1). If the sheet ice is driven up the side slope intact by a storm wind, the phenomenon is considered ice "ride-up". If the ice fails in buckling or bending and breaks up into individual blocks, an ice "pile-up" is formed on the side slope. In the Beaufort Sea, ride-up and pile-up events can occur during both freeze-up (early October through mid-December) and break-up (early June through mid-July).

Plate 1. Ice Encroachment on Endeavor Island, Alaska (1982)

A number of factors influence the susceptibility of a given location to ice ride-up, pile-up, and possible encroachment. Although ice movement results from wind stress, the single most important factor in initiating a ride-up or pile-up event is the loss of confinement of the ice sheet. Reversal of the wind direction is the usual cause of confinement loss, due to the formation of cracks or small leads in the nearshore ice. An easterly wind may produce the cracks or leads in the ice, for example, after which a westerly wind can drive the relatively unconfined ice up the slope of a pad or island.

While loss of confinement represents the dominant influence on ice ride-up and pile-up events, the ice thickness and the intensity and duration of storms constitute important secondary influences. The greater the ice thickness, the larger the driving force that will be required to initiate motion. Once the ice begins to move, severe storms of long-duration will maintain sufficient driving force to keep the ice in motion. The ice typically moves at a rate of 100 to 200 m/hr during the formation of a shoreline ice pile-up. Motion ceases when the driving force is balanced by the resistance of an "infinitely" wide obstruction, such as a shoreline.

The most common encroachment event, a combination of ride-up and pile-up, occurs when the sheet ice rides up the structure slope until increasing frictional resistance or a change in slope causes the ice to rubble and form a pile-up. If the pile-up attains sufficient height, ice blocks at the top of the pile can tumble down onto the work surface. Such an event occurred in October 1982 on Endeavor Island, which is

located in a water depth of 3.7 m in the Alaskan Beaufort Sea. As is evident in Plate 1, a southwesterly storm with wind speeds of 15-20 m/s created a 7.6 m high pile-up and caused 20-cm thick ice blocks to encroach up to 5 m onto the island work surface (Vaudrey, 1983).

Because our present understanding of pile-up mechanics is limited, encroachment estimates must be based upon statistical extrapolations of pile-up characteristics observed in the general project area. The method involves four primary steps: (1) compiling a database of historical pile-up events; (2) performing an extremal analysis to estimate the pile-up height associated with the desired return period; (3) estimating the pile-up geometry; and (4) computing the encroachment distance based on the structure geometry (Figure 2). A conservative lower bound of 30° is recommended for the slope angle β of the landward side of the pile-up. This value is based on shoreline pile-ups observed on the Alaskan Beaufort Sea coast and on the west coast of Banks Island, Canada, by Kovacs and Sodhi (1980). In the Alaskan Beaufort Sea, the predicted 100-year return period ice encroachment distances typically range from 8 to 16 m for work surface elevations of 3 to 6 m above mean sea level. A buffer zone exceeding the predicted encroachment distance can be maintained around the perimeter of the work surface to insure that sensitive facilities are not impacted.

Figure 2. Ice Encroachment Geometry

Ice Gouging

The term “ice gouging” refers to the distinctive furrowing of the sea floor that results from the plowing action of ice keels. A representative example is provided in Figure 3, which displays a multi-beam sonar image of several gouges detected off the Alaskan Beaufort Sea coast in a water depth of 11 m. The single gouges were formed by individual ice keels, while the “gouge multiplet” is believed to have been caused by a multi-keeled ice feature.

Figure 3. Multi-Beam Sonar Image of Ice Gouges in the Alaskan Beaufort Sea

The frequency and severity of gouging depend upon complex interactions between the dynamic ice environment and the sea floor sediments. Although our knowledge of the process is far from complete, key parameters appear to include the ice movement characteristics, the soil characteristics, the sea floor slope, and the water depth. From a study of ice keel structure and available driving forces, Kovacs and Mellor (1974) concluded that virtually all ice keels possess sufficient strength for gouging.

Extensive ice gouge measurement programs were conducted in the Alaskan Beaufort Sea from 1970 to the mid-1980's by the U.S. Geological Survey (USGS). Based on an analysis of more than 100,000 gouges, Barnes, *et al.* (1984), reported an average gouge density of $70/\text{km}^2$ and a maximum density of $490/\text{km}^2$. The mean incision depth for individual gouges was 0.56 m (measured below the original sea floor), while the maximum measured value was 4.0 m. The dominant gouge orientation was found to be slightly onshore of contour-parallel. Additional findings from the USGS programs of potential relevance to engineering projects such as subsea pipelines include the following: (1) gouge characteristics (density, depth, and width) attain their maximum values in the zone of active ice rubble formation known as the "stamukhi zone"; (2) sea floor morphology influences the intensity of gouging, with shallower gouges typically occurring in areas protected by offshore shoals; (3) gouge frequency and size are extremely variable from year to year in any one area, and from area to area in any one year (Rearic, 1986; Rearic and Ticken, 1988).

In view of the spatial and temporal variability inherent the gouging process, repeated annual surveys are advisable to obtain an accurate statistical characterization

of the gouge population at a particular project site. Multi-beam sonar, when used in conjunction with differentially-corrected Global Positioning System (GPS) position data, has proven to be a valuable tool for such surveys. Based on two successive field programs performed in support of a planned pipeline project near Prudhoe Bay, Alaska, multi-beam sonar is capable of mapping gouge features with a resolution of less than 0.1 m.

Strudel Scour

Strudel scour depressions in the sea floor are formed in the spring, when the breakup of river ice precedes the breakup of ice in the nearshore zone. If the sea ice in the river deltas is frozen to the sea floor (as occurs in the Alaskan Beaufort Sea to a depth of 2 m), this "bottomfast" ice forms a dam that causes overflowing of the river water. The overflow water, typically 0.5 to 1.5 m deep, spreads offshore and drains through discontinuities in the ice sheet caused by tidal cracks, thermal cracks, and seal breathing holes. Such "strudel zones" usually are located immediately offshore of the river deltas, in water depths of 2 to 9 m.

In those instances where the overflow rate is high, the drainage holes become enlarged and powerful strudel jets develop. Sizable scour depressions in the sea floor can result, particularly in the area immediately seaward of the bottom fast ice where the attenuating effect of the water column on the strudel jet is minimal. Although the depressions tend to be circular in plan form, clustered scours and extended linear scours also have been detected. The probable cause of these multiple and extended scours is drainage through linear fractures in the ice sheet, such as tidal cracks.

Measurements of strudel scour characteristics, unlike those of ice gouges, have been extremely sparse. Studies conducted by the USGS in 1972 (Reimnitz, *et al.*, 1974), and 1978-80 (Reimnitz and Kempema, 1982) documented three scour depressions in the vicinity of Prudhoe Bay in water depths of 3.0 to 3.5 m. The scour depths ranged from 1.2 to 4.3 m below the original sea floor, while the maximum horizontal dimensions ranged from 12 to 25 m. Of interest for the design of nearshore structures is the data set acquired by BP Exploration (Alaska) Inc. in the vicinity of Resolution Island, which is located in 2.3 m of water off Alaska's Sagavanirktok River. Annual bathymetric surveys conducted from 1985 through 1995 revealed the formation of seven strudel scours in proximity to the island toe (Coastal Frontiers, 1996). The deepest, 2.8 m below the sea floor, re-filled with sediment to the point that it was no longer detectable five years after its discovery. A probable explanation for the high frequency of strudel scouring at this location is the tendency for the island to induce cracks in the surrounding ice sheet. The primary implication for coastal projects is that the lower slope and toe of a nearshore structure may require additional protection to withstand the strudel jets caused by the presence of that structure.

OCEANOGRAPHIC DESIGN CONSIDERATIONS

Oceanographic design considerations in cold regions are analogous to those in temperate climates, with water levels, waves, and currents often constituting the key parameters. Complications can arise, however, from factors that include a paucity of measured data and exceptionally large storm surges.

Due to low population densities, low volumes of vessel traffic, and the difficulties associated with obtaining measurements in ice-infested waters, oceanographic data tend to be sparse or non-existent in many cold regions. Of particular concern is the situation that arises in areas like the Beaufort Sea, where the most severe storm events of the open-water season often occur just prior to freeze-up. If bottom-mounted instruments such as wave gauges or current meters are removed in advance of this period, the data may be skewed toward milder conditions. Conversely, if the instruments are allowed to remain in place until after freeze-up and then recovered through the ice, the probability of damage or loss from ice keel impacts increases substantially.

In the absence of reliable measurements, the database needed to estimate extreme events at coastal project sites must be derived from hindcast analyses. Difficulties may be encountered in a number of areas, beginning with a lack of meteorological data from which to specify the wind fields. Also problematic is the influence of sea ice, whose damping effect on wave generation and propagation is not fully understood. Specification of the fetch for wave generation is further complicated by the mobility of the ice edge during storm events.

Despite these difficulties, the hindcast approach has proven to be both reliable and cost-effective in the Alaskan Beaufort Sea, where storm surge and wave models were used to hindcast the 16 most severe storms occurring between 1949 and 1980 (Oceanweather, 1982). Initially, the models were implemented for the entire region, with the surge model utilizing a grid spacing of 4.6 km (2.5 nautical miles) and the wave model a grid spacing of 37 km (20 nautical miles). Subsequently, nested grids have been used to predict extreme conditions at numerous individual project sites.

Because Coriolis force increases with the sine of the latitude, coast-parallel winds at high latitude produce storm surges and setdowns of greater magnitude than would occur under similar conditions at low latitude. One obvious implication is that flooding constitutes a major design consideration for many coastal projects in cold regions. In the Beaufort Sea, for example, the predicted 100-year surge heights are typically on the order of 2 m, and driftwood strand lines have been observed as high as 3.4 m above mean sea level (Reimnitz and Maurer, 1979).

Surge-altered water levels are important not only for their direct impact on coastal flooding, but also for their indirect influence on wave and current conditions. In those areas where the wave heights are depth-limited, the elevated water levels

that result from storm surge can cause substantial increases in design wave heights. To properly account for this phenomenon in hindcast analyses, a time-series history of water levels should be developed for each historical storm and then utilized when modeling the wave conditions for that event.

The pronounced surge and setdown events that occur at high latitude can induce accelerated coastal boundary currents. As water either builds up or draws down at the coastline, a sloping sea surface is created in the shore-perpendicular direction. The resulting pressure gradient couples geostrophically with Coriolis force to produce a strong shore-parallel flow known as a barotropic coastal jet (Csanady, 1982). Indirect evidence supporting the existence of such currents is provided by ice floe velocities recorded in the Alaskan Beaufort Sea during the 1984 open-water season (Tekmarine, *et al.*, 1985). The floe velocities measured landward of the 30-m isobath during periods of accelerating winds averaged approximately 5% of the wind speed, which is substantially higher than the value of 2 to 3% that might be expected in deep water. The implications of these accelerated currents for the design of nearshore structures include higher velocities for ice floe impacts during periods of open water, and an increased potential for current-induced scour.

THERMAL DESIGN CONSIDERATIONS

Of the many thermal design considerations unique to cold regions, those of particular importance to coastal projects include thermal erosion of ice-bonded bluff sediments, and low-temperature effects on construction materials. In the case of thermally-induced erosion, bluff retreat can result not only from sea water thawing the base of the bluff (Kobayashi and Reimnitz, 1988), but also from elevated air temperatures thawing ice lenses embedded in the bluff face.

Insight into the process of thermal erosion has been provided by an on-going monitoring program at Heald Point Peninsula, which constitutes the northeast boundary of Prudhoe Bay, Alaska. From an analysis of aerial photographs obtained periodically between 1949 and 1988, and survey data acquired annually between 1989 and 1994, it was determined that the central portion of the 5-m high western bluff was retreating at an average rate of 1.6 m/yr. The adjacent bluff areas, by comparison, were retreating at less than 0.5 m/yr (Figure 4). Annual inspections revealed the cause of the accelerated erosion to be the melting of a 2-m thick ice lens embedded in the bluff face near the top of the bluff (Plate 2). Notwithstanding the importance of factors such as wave-induced erosion of the bluff toe and the degree of soil cover on the ice lens, the dominant influence over the annual retreat rate was found to be the summer air temperature. In 1989, for example, when exceptionally high mean monthly temperatures were recorded during the summer season, the bluff edge in the area occupied by the ice lens retreated by up to 7.2 m.

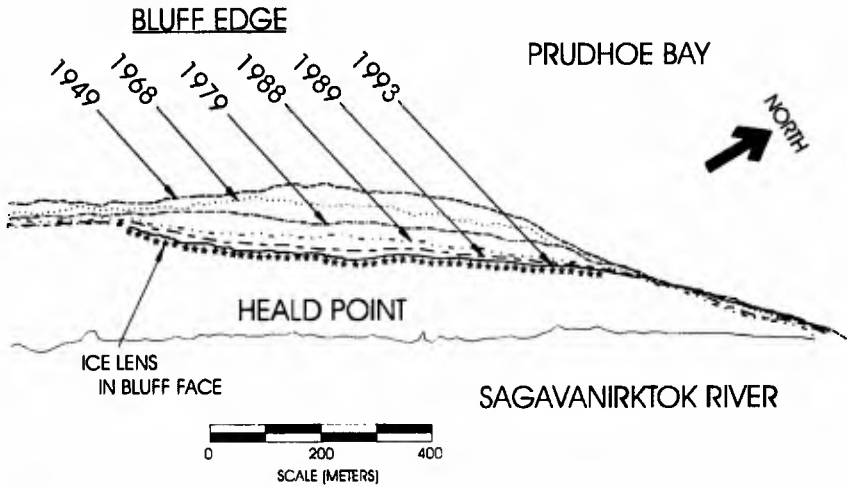

Figure 4. Historical Bluff Edge Retreat at Heald Point, Alaska

Plate 2. Thermal Erosion of Ice Lens in Heald Point Bluff Face (1993)

A particular concern with subaerial melting is that erosion can occur even in the absence of severe oceanographic events. Fortunately, however, the experience acquired with a gravel pad constructed on Heald Point suggests that the problem can be addressed by insulating the bluff face with granular fill material. Since 1993, when

gravel was installed from the blufftop to the waterline at a slope of 7(H):1(V), thermal erosion of the western bluff edge has been negligible.

Among the low temperature effects on construction materials encountered in cold regions, freeze-thaw stressing and brittle failure often assume importance for the design of coastal structures. Prior to freeze-up, when air temperatures are sub-freezing but the sea remains unfrozen, materials in the splash zone can be subjected to repeated freeze-thaw cycles. To minimize the impact on concrete structures or armor units, the concrete should be made as impermeable as possible through the use of a high cement factor, a low water-cement ratio, and pozzolan or silica fume (Leidersdorf, *et al.*, 1982). Air entrainment of 6% to 9% is recommended to limit cracking. In addition, sufficient reinforcing steel must be provided to insure that the cracks which do occur will not progressively widen.

Steel components that will be subject to impact or vibration, such as lifting eyes, should remain ductile at the lowest temperatures anticipated. Although corrosion losses over the design life must be taken into consideration, data obtained on Resolution Island suggest that corrosion rates in the Alaskan Beaufort Sea are modest. During a 4-year period in which exposed carbon steel rebar was monitored in the splash zone, corrosion rates were found to be less than 0.05 mm/yr.

CONCLUSIONS

The design of coastal projects in cold regions often is complicated by the need to consider ice and thermal factors as well as oceanographic factors. In some cases, the design process involves identifying a single governing influence; in others, the potential interactions between factors must be taken into account. A representative example of the former situation arises in determining an appropriate work surface elevation for a coastal facility. Two distinctly different phenomena, wave overtopping and ice encroachment, must be evaluated independently before selecting an appropriate minimum value. A situation where interactive environmental factors assume primary importance is in designing a slope protection system that must withstand wave and ice attack. Prototype observations have indicated that ice impacts can predispose the armor to damage under wave conditions that otherwise would be considered benign (Gadd and Leidersdorf, 1990; Leidersdorf, *et al.*, 1990).

In addition to increased complexities, the environmental influences unique to cold regions often introduce increased uncertainties into the design process. At the present level of understanding, quantitative predictions of phenomena that include ice gouging, strudel scouring, and thermal erosion can be derived only from statistical treatments of limited historical databases. In consequence, a conservative approach that incorporates damage-tolerant components and non-catastrophic failure modes is recommended for the design of sensitive facilities.

CHAPTER 342

EXPERIMENTAL STUDY ON DEFORMATION AND FRACTURE OF ICE SHEET BY PROPAGATING WATER WAVE

Shigeki Sakai¹, Xiaodong Liu², Makoto Sasamoto³
Shigeo Kanada⁴, Koh Izumiyama⁵

ABSTRACT

A criteria of ice sheet fracture by propagating waves is proposed based on an elastic bending theory. Experiments with a model ice are carried out to examine the validity of the criteria. Comparisons with experimental results show that the proposed criteria is available for a wide range of ice properties. The crack span induced by waves is between $1/4$ and $1/2$ of wave length in ice.

INTRODUCTION

In the sub-Arctic sea, wave-induced motion of ice is a dominant factor causing many coastal problems; e.g. damages to structures by ice impact forces, or beach erosion by ice drift. To estimate the wave energy inside the ice zone, it is necessary to understand how waves transform under the ice cover. Previous studies show that the presence of ice causes wave energy attenuation, and the attenuation rate depends on the ice floe size and concentration. If some floes are fractured by waves, the distribution of floe sizes will be changed, and then the effects of the ice zone on waves will also vary. Therefore, for estimation of wave energy inside an ice zone, it is important to consider the ice deformation and fracture caused by waves.

Ice-wave interaction has been mainly investigated by field observations, however it is very difficult to observe the deformation and fracture of ice since these occur in stormy sea conditions. A few experiments have been carried out, while in most of them plastic sheets were used as a model ice, and the effects of the difference in material properties between ice and plastic have not been examined. Furthermore, ice fracture cannot be simulated in the experiment with plastic sheets. In the present study, experiments with a model ice were carried out to examine wave-induced deformation of ice sheet and to verify the availability of the ice fracture criterion described hereafter.

EXPERIMENTS

Experimental Equipment and Procedure

Experiments were carried out in an ice tank which is 35m long, 6m wide and 1.8m deep, as illustrated in Figure 1. Water in the tank was doped with a solution of propylene glycol to weaken the ice which would be formed on the water surface. It took 10 hours or more to form an ice sheet of 25mm thickness and another 10 hours to set up experimental equipments, to test material properties and to observe the ice sheet deformation and fracture. Totally, 2 days were needed to perform one experiment, and one more day was necessary for the experiment with the ice sheet of 50mm thickness. The bending strength and the elastic modulus of ice were measured by a cantilever beam failure test and Plate Deflection Method, respectively.

Figure 1 Experimental equipment

The wave was generated by a plunger type wave generator. At the far end of tank, a wave absorber was set up to decrease wave reflection. The vertical displacement of the ice sheet was measured at several points along the center of the tank, by using laser sensors and ultra-sonic sensors. Each experiments

started with a very small incident wave height. If the ice sheet fracture was not observed in this condition, another experiment with a little larger wave height was carried out. This procedure was repeated till the ice sheet fracture occurred. After the occurrence of the first fracture, the above procedure was also continued to observe proceeding fracture of ice sheet. The conditions of the incident wave and the material properties of ice are listed in Table 1.

Table 1 Experimental condition

Case No.	Wave Period T(s)	Wave Height in Open Water H_0 (mm)	Ice Thickness h_i (mm)	Bending Strength of Ice σ_i (kPa)	Elastic Modulus of Ice E (MPa)
1	1.19	20.5~30.2	49.2	35.1	21.8
2	0.80	20.6~26.1	25.2	22.6	5.3
3	0.79	12.3~32.0	28.4	36.0	31.4
4	0.80	18.9~32.2	53.3	39.7	29.3
5	0.99	29.7	53.3	39.7	29.3
6	1.40	20.6~27.7	53.3	39.7	29.3
7	1.20	27.7~29.7	54.2	38.1	34.3
8	1.40	14.3~26.7	23.2	119.3	125.4
9	1.20	17.9~23.8	24.3	137.4	202.5
10	1.00	18.4~26.0	23.2	87.9	201.5

Experimental Results

As the incident wave penetrates into the ice-covered water, the wave height changes significantly near the ice edge and attenuates gradually under the ice. Figure 2 shows the effects of incident wave height on the change of

Figure 2 Wave height under ice sheet

wave height under the ice. The wave heights in this figure were normalized by the wave height in the open water. This ratio does not contain the effects of reflected wave from the ice edge since the wave height in the open water were estimated by subtracting reflected wave energy from incident wave energy. Generally, non-linear effects appear clearly with increasing of wave steepness, however there cannot exist steep waves under ice sheet since such waves cause ice sheet fracture. Figure 2 indicates that there is no effect of wave steepness on the wave height change under ice sheet in the condition where the ice sheet fracture does not occur. So, it can be concluded that the non-linearity of waves under ice sheet is to be negligible. Figure 3 gives an example of wave profile under ice sheet. The measured profile is described by a trigonometric function.

Figure 3 Example of wave profile under ice sheet

The wave celerity under ice sheet differs from that in open water and is almost constant over ice sheet, as shown in Figure 4. The non-linear effects of wave steepness on wave celerity is negligible, as well as on wave height change. A linear theory for waves under elastic plate gives a good explanation to experimental results of wave celerity under ice sheet(see Figure 5).

Figure 4 Wave celerity under ice sheet

Figure 5 Comparison between measured and calculated wave celerity

THEORY

Ice sheet fracture is to be analyzed based on an elasto-plasticity fracture mechanics. However, it will be helpful for simple theoretical analysis on ice sheet fracture to consider how the elasticity or the plasticity of ice influences on ice-wave interactions. Liu and Sakai(1996) compared the numerical calculation of wave under elastic plate with experimental results of waves under elasto-plastic plate. Their comparisons showed that the calculated wave height near the edge agrees with experimental data fairly well and that the calculated values become somewhat larger than measured one as waves penetrate deeper in the plate. This discrepancy might be brought by a lack of plasticity effects in the numerical calculation. Wadhams(1973) explained the attenuation of wave height under ice sheet by energy loss due to a time dependent plastic strain (creep), and showed that this theory gives a good explanation for field observations of wave height attenuation in sea ice. These studies indicate that the deformation of ice sheet by waves is essentially elastic and the plasticity of ice cannot be negligible with increasing of penetration. Generally, ice sheet fracture by waves occurs near the ice edge. Therefore, it is reasonable to regard ice sheet fracture as a results of elastic deformation induced by waves.

An elastic bending theory gives a stress on the ice sheet surface as;

$$\sigma = \frac{Eh_i}{2(1-\nu^2)} \frac{\partial^2 \zeta}{\partial^2 x} \tag{1}$$

where E is elastic modulus of ice, h_i is ice thickness, ν is Poisson's ratio(=0.3), ζ is wave profile of ice sheet and x is direction of wave propagation.

As shown in Figure 3, a wave profile is expressed by a trigonometric function as follows;

$$\zeta = \frac{H}{2} \sin(kx - \omega t) \tag{2}$$

where H is wave height in ice, k is wave number ($= 2\pi/L_i$, L_i is wave length in ice), ω is angular frequency ($= 2\pi/T$, T is wave period) and t is time.

When the bending stress on the surface reaches the bending strength σ_f , ice sheet fracture occurs. Therefore, a fracture criterion is expressed as follows;

$$\frac{Hh_i}{L_i^2} = \frac{1 - \nu^2}{\pi^2} \frac{1}{E/\sigma_f} \tag{3}$$

VALIDITY OF ICE FRACTURE CRITERIA

The measured wave height is not accurate since the ice separated from the main part of ice sheet moves as an ice floe, not as a continuous ice sheet, and this floe dissipates wave energy penetrating into the ice sheet. The wave height can be estimated from the wave height in open water and the distance of fracture point from the ice edge, since the ratio of wave height in ice to that in open water does not depend on the incident wave height for a given wave period, as illustrated in Figure 2. Another quantities in Equation (3) were directly measured in the experiment. The wave length in ice can be also calculated from a linear theory for wave under elastic plate, which gives a good estimation for wave celerity, as shown in Figure 5.

Figure 6 shows that the ice fracture criteria proposed herein is available over a wide range of the ratio of elastic modulus to bending strength of ice. This agreement of the criteria based on an elastic bending theory with experimental results also ensures the applicability of the elastic bending theory for analysis on ice fracture by waves.

Figure 6 Ice fracture criteria compared with experimental results

CRACK SPAN IN ICE

The cracks in ice are almost perpendicular to the direction of the wave propagation, and the crack span is within $1/4$ and $1/2$ of the wave length under the ice sheet, as shown in Figure 7. The splits of ice were fractured laterally, resulting in rectangular pieces of almost same size. This regular pattern of ice fracture is also observed in the actual sea ice.

Figure 7 Relation between crack span and wave length in ice

CHAPTER 343

An Attempt to Determine the Spanish Public Domain Border

R. Medina¹, I.J. Losada¹, F. Méndez², A.J. Fernández³

Abstract

In this paper the problem of the determination of the Spanish maritime-land public domain border is analyzed. The Spanish public domain border is defined by the Spanish Law as the limit where the waves reach during the worst storm in the area. The law also establishes that this limit must be calculated taking into account the effects of the astronomical tide, the storm surge and the wave run-up. Since the storm surge and the wave run-up are random variables, the extreme flooding level determination is carried out by means of an extension of the joint probability method, first proposed by (Pugh and Vassie, 1978), which includes the effect of the wave run-up. The proposed theoretical approach is applied to a case study of a beach located in the North Coast of Spain.

Introduction

In Spain not only the sea, but also the shoreline is considered to be public property. This consideration is linked to our cultural and legal tradition and can be found in the ancient Roman and medieval Spanish Law.

In the 6th century, for instance, Justiniano established that: *“According to the natural law, the air, the running water, the sea and its shore are common to everybody. These shores have no owner...”*. Later, in the 13th century King Alfonso X, also known as Alfonso “The Wise”, ruled that: *“The things that communally belong to all creatures living in this world are: the air, the rainwater, the sea and its shore. No building can be undertaken on the seashore that could restrain the communal use of the people”*.

The present Spanish Legislation on Coasts, passed in 1988, also protects the shore-line and defines what is called the Maritime-Land Public Domain: *“The public domain stretches as far as the waves reach (maximum flooding level) during the worst storm in the area, and it includes beaches, dunes, cliffs, swamps and other low wetlands”*.

No type of trade activities can be allowed in this property. The Legislation on Coasts extends its influence to the private lands adjacent to the public property, Fig. 1,

to avoid any use carried out on those areas which could be harmful to this space of high environmental value, (M.O.P.T.M.A., 1994). Therefore, in order to implement this policy, the Ministry of Public Works has undertaken a series of programs of actions with the first being the need to complete a precise identification of the public domain maritime-land assets in accordance to the definition set down in the Legislation on Coasts. This process has given rise to the current Property Survey Plan, whose purpose it is to fix public domain boundaries throughout the whole of the Spanish coast. This approach to the management of the coast in an integral manner has to embrace all territorial and political levels of government such as central government, states and city councils, as well as any individual with private interest on the coast.

Figure 1. Public and private uses of shoreline

For this reason, the determination of the Spanish maritime-land public domain border is an extremely important element in the Program of Coastal Actions initiated by the Spanish Government, and in the last years it has become a key reason for many law suits between the different agents with interest in the coastal area.

Public Domain Border Determination

In order to determine the limit where “the waves reach during the worst storm in the area”, the 1988 Law established the maritime and meteorological dynamics that must be taken into account. In particular, the law established that the calculation of the maximum flooding level must account for the effects of the: (1) astronomical tide, (2) storm surge and (3) wave run-up, Fig. 2. Episodic events such as tsunamis must be omitted from the calculation, and the influence of long term effects such as sea level rise is not explicitly considered in the law.

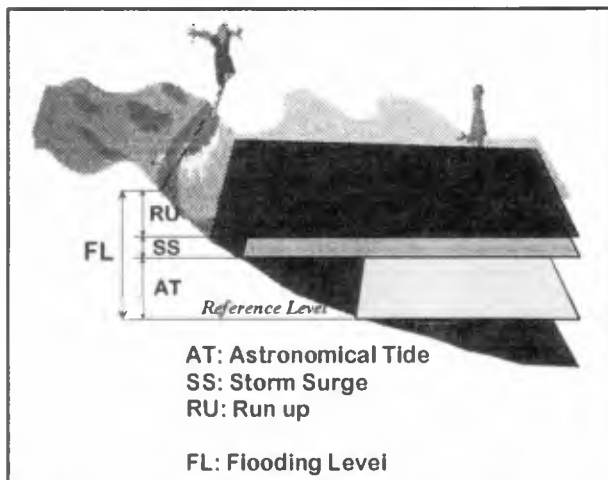

Figure 2. Dynamics to be considered in the determination of the public domain border

Since the storm surge and the wave run-up are random variables, the flooding level is also a random variable. Consequently, the determination of the public domain border is a stochastic extreme problem.

One of the consequences of being a stochastic problem is that there is not a deterministic "limit where the waves reach during the worst storm" but each level will have "a probability of being exceeded during a given storm". This probabilistic aspect is not considered in the law in which the public domain border is thought of as a deterministic line.

In this paper the extreme flooding level determination problem is analyzed by means of the joint probability method, (Pugh and Vassie, 1978), which has to be modified to include the effect of the wave run-up. The theoretical approach proposed to determine the public domain border is then applied to a case study in a beach located in the North Coast of Spain. In this case study, the probabilistic problem is also analyzed and a maritime-land public domain border is proposed.

Theoretical Approach

The existing methods for estimating the distribution of extreme sea-level at a site, using field data, can be divided into: (1) Direct Methods - in which extremes of the observed water level are analysed-, and (2) Indirect Methods - in which the constituent processes (i.e. tides, surges and waves) are modeled separately and the extreme water level is inferred.

Direct Methods

The direct methods are, mainly, the classical annual maxima approach and the r-largest annual events method.

Annual Maxima Method: The best known, simplest, and most widely used method of analysis of extreme distributions is the annual maxima method, (Gumbel, 1958). This approach has been previously used by several investigators to determine extreme sea-

levels, eg. (Lennon, 1963), (Suthons, 1963) and (Graff, 1981).

According to (Tawn and Vassie, 1991), this method is highly inefficient in its use of data and provides inaccurate results. These authors remarked that the assumptions made in using the annual maxima method are namely that hourly sea level heights are (1) independent, (2) identically distributed, and (3) that the number of hours in a year is large enough for the asymptotic approximations to hold. However, because of the nature of the tide and the dependence on the surge sequence, it is clear that (1) and (2) do not hold.

R-largest Annual Events Method: Several proposals have been made to extend the annual maxima method to incorporate all independent extreme sea-level observations into the estimation of the annual maxima distribution: (1) the peaks over thresholds method, (Davison and Smith, 1990); (2) the r-largest events method, (Tawn, 1988); and (3) the point process method, (Smith, 1989).

These methods are based on extreme value limit theory for stationary random sequences and, consequently, it is assumed the r-largest annual extreme levels are from stationary data. This assumption is critical since, due to the tide, the water level is highly non-stationary. According to this argument, the r-largest annual events method is not appropriate to determine extreme sea-levels, (Dixon and Tawn, 1994).

Indirect Methods

The existing indirect approaches, the joint probability method (Pugh and Vassie, 1978) and the revised joint probability method, (Tawn and Vassie, 1991) are the only viable options for estimating extreme levels when short data sets are available.

The main advantage of these methods is to exploit our knowledge of the tide in short data sets to which the annual maxima method could not be applied. Basically, these methods seek the probability distribution function (p.d.f.) of the different variables involved and calculate the sea level p.d.f. by combining those p.d.f.s. The nature of the combination of the p.d.f.s depends on whether there is dependence between the variable sequences.

The joint probability method assumes that extreme hourly water levels are independent. Clearly hourly water levels are not independent, but extreme levels may be only weakly dependent. (Tawn and Vassie, 1989) studied this feature and found that the assumption was false but led only to small overestimation of return levels.

In the revised joint probability method the temporal dependence of the variables is considered to be a parameter, called extremal index, θ , which is determined empirically from the data.

Although the revised joint probability method results hold for temporal dependence between variables, the existing records are not long enough to have data in the regions of both extreme tides and surges and, consequently, the external index determination is, many times, impossible.

From the previous analysis it can be concluded that direct methods cannot be used to determine extreme sea levels due to the lack of long records. Furthermore, the revised joint probability method also needs a long enough series in order to estimate θ . Consequently, the only methodology capable of giving reasonable results to the problem

under study is the joint probability method.

The Joint Probability Method (J.P.M.)

This method was first introduced by (Pugh and Vassie, 1978) to calculate extreme sea-levels due to the combined effect of tides and storm surges. At any time the observed sea level, after averaging out surface waves, has three components: mean sea level, tidal and storm surge level. Using standard methods, the first two of these components can be removed from the sea level sequence leaving the surge sequence.

Because the tidal sequence is deterministic, the p.d.f. for all tidal levels can be generated from tidal predictions, while the p.d.f. for the surge level is determined from the nontidal residual.

The p.d.f. of the sea level is finally calculated using the tidal and surge p.d.f.s'. Assuming that the tide and the surge can be considered independent, then

$$p(z) = \int_{-\infty}^{\infty} p_T(z - y) p_S(y) dy$$

where $p_T(z - y)$, $p_S(y)$ and $p(z)$ are the probability density functions for tide, surge and sea levels respectively.

Wave-Surge Joint Modelling

As stated previously, wave run-up is an important factor that must be included when determining the maximum flooding level on a beach. The inclusion of wave run-up leads to a two stochastic variables problem, surge and wave run-up, extending the J.P.M. developed by (Pugh and Vassie, 1978), which considers the surge only.

This new problem is one of bivariate extremes and the extrapolation of the distribution tail is required for both the surge and the wave run-up. Furthermore, the dependence between the extremes of these variables must be accounted for.

If surge and wave run-up are related, the probability density function for the sea level (flooding level) can be written as:

$$p(z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p_T(z - y - x) p_{S,Ru}(y, x) dx dy$$

where $p_{S,Ru}(y, x)$ is the combined p.d.f. of surge and wave run-up.

If surge and wave run-up are independent, then

$$p(z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p_T(z - y - x) p_S(y) p_{Ru}(x) dx dy$$

It should be noted that the availability of wave run-up data for a particular beach is usually scarce and, consequently, wave run-up p.d.f. must be inferred from wave data and wave run-up theory.

The study of wave run-up on artificial and natural beaches has received considerable attention by researchers over the last several years; e.g. (Guza and Thornton, 1981), (Holman, 1986), (Nielsen and Hanslow, 1991), (Holland and Holman, 1993).

In this study, (Nielsen and Hanslow, 1991) results for wave run-up distribution on a natural beach are used. Using run-up distributions measured on a wide spectrum of sandy beaches, these authors showed that, for a sea state, the Rayleigh distribution is a reasonable statistical model for the maximum level reached by individual waves. This result was also obtained theoretically by (Battjes, 1971) for the special case of perfect correlation between wave height, H and wave period, T . That is,

$$F(R_{\text{run}} \geq R) = \exp \left[- \left(\frac{R - R_{100}}{L_{R_{\text{run}}}} \right)^2 \right]$$

where R_{100} is the highest level transgressed by 100% of the waves and $L_{R_{\text{run}}}$ is the vertical scale of the distribution.

For extreme wave conditions, the beach can be assumed to be dissipative and, $L_{R_{\text{run}}} \approx 0,05 (H_{\text{rms}} L_o)^{0,5}$ where H_{rms} is the mean squared root wave height and L_o is the deep water wave length. Notice that for a typical relationship $T_s = \alpha_1 H_s^{0,5}$, $L_{R_{\text{run}}} \approx \alpha_2 H_s$ where α_1 and α_2 are two constants, depending on the wave climate of a given region.

Notice that the wave run-up p.d.f. is a Rayleigh distribution that depends on a random variable H_s , which has its own p.d.f. (e.g. Weibull), consequently the flooding level p.d.f. can be written as:

$$p(z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p_T(z - y - x) p_S(y) p_{Ru}(x) dx dy$$

with

$$p_{Ru}(x) = \int_{-\infty}^{\infty} p_{Ru}^*(x, H_s) p_{H_s}(H_s) dH_s$$

$p_{Ru}^*()$ where is the Rayleigh $p_{H_s}()$ p.d.f., and is the significant wave height p.d.f.

Application

In this section, the wave-surge joint modelling is applied to a beach located on the North Coast of Spain.

Study Site

The study site is Oyambre Beach, located close to the city of Santander, on the Cantabrian coast of Spain, Gulf of Biscay, Fig. 3.

The northern coast of Spain is divided into a series of pocket beaches and small inlets isolated between rocky headlands. Most of the headlands extend into deep water and appear to be effective in confining littoral sand to the embayments. Therefore, the coast can be analyzed as a series of littoral cells.

One of these littoral cells is the beach of Oyambre. The beach is bound westward by Cape Oyambre and eastward by Cape El Moro. Several reefs can be found in intermediate water as part of Cape Oyambre along the northwest part of the beach (e.g. La Molar Shoal, San Francisco Shoal, Fig. 3).

Figure 3. Location Map

More than three-quarters of the deep-water waves approach Oyambre Beach from the northern - northwestern sector. The annual average significant wave height is about 1 m with typical winter storms waves of $H_s \sim 4 + 6$ m. Tides at Oyambre Beach are semidiurnal with a mean tidal range of 3 m and spring tidal range of 5 m.

Maritime and Meteorological Data

In order to apply the methodology presented in section "Wave-Surge Joint Modelling", different data sets of waves and sea-level were analyzed. These data sets are continuously recorded by the Spanish Network for Maritime Recording and are presented in several publications from the Ministry of Public Works, Transportation and Environment, called R.O.M., (Losada et al, 1996).

Sea-Level Data

Sea-level data used in this study were recorded at Santander. This sea-level data set consists of hourly sea-level measured during the last five years and include three additive components: mean sea-level, tidal, and surge level.

Standard tidal analysis, (Godin 1978), is used to separate the astronomical tide and the surge from the sea-level data. The astronomical tide distribution shown by a probability density function in Fig. 4, is bi-modal. This kind of distribution is typical of

semi-diurnal dominated tides, with the modes occurring at levels corresponding to mean high and low water tides.

Figure 4. Tide, surge and wave run-up p.d.f.'s

The surge series is defined as the residual of the tidal series; i.e. the difference

between the observed sea-level and the predicted tide. The difference between observed levels and tidal predictions is due to meteorological forcing in the form of changes in air pressure and winds which constitutes the surges forcing.

Due to the location of the tidal gauge, inside Santander Bay and in water depth of about 10 m, most of the surge is caused by air pressure. This hypothesis was further corroborated by correlating the 5 year surge data to air pressure data. Using this correlation, a probability density function of the surge was estimated by means of pressure data from the last 50 years, Fig. 4. The surge distribution is uni-modal, with the mode close to zero, and is positively skewed, leading to large positive surge levels being more likely than large negative surges (not shown).

Wind surge cannot be determined from Santander sea-level data. Furthermore, since the variability of wind-surge from coast to coast due to local bathymetry is so high, theoretical wind-surge estimation from wind data is the only feasible way to determine wind-surge at Oyambre Beach. Different simulations were run to estimate the combined surge due to air pressure and wind at Oyambre Beach. The main conclusion was that wind surge can be considered negligible when compared to air pressure surge, especially in extreme events when a low pressure is close to Oyambre. This characteristic of the surge at Oyambre Beach is due to the kind of low pressure reaching the northern Spanish coast and the bathymetry of Oyambre Beach and cannot be generalized for other locations.

Wave Data

Wave data used in this study was recorded at Gijón (about 100 km west of Oyambre). These data are deep water measurements of wave characteristics monitored by the Spanish Network mentioned above. Wave characteristics were propagated to the study area using a numerical wave propagation model. The model used, called REF/DIF, (Kirby and Dalrymple, 1985), solves the parabolic approximation of the mild slope equation and is adequate to estimate the effect of the different shoals located northwestward the beach, Fig. 3.

Since the wave characteristics varies from point to point along the beach, a zoning was made in order to set zones in which the wave characteristics can be assumed to be homogeneous. At Oyambre Beach this classification led to three areas called A, B and C, shown in Fig. 3.

For these three areas, different combinations of wave height, H_s , and wave period, T , at deep water were propagated in order to obtain the wave height distribution at shallow water in front of zones A, B and C. Using this wave distribution and (Nielsen and Hanslow, 1991) empirical distribution for wave run-up, the wave run-up p.d.f. at the different zones is calculated Fig. 4. The wave run-up distributions are also uni-modal and positively skewed. Zone C, which is exposed, has higher run-up probabilities than zones A and B.

Maximum Flooding Level

Using the p.d.f.s shown in Fig. 4 and the Joint Probability method described above, the flooding level p.d.f. is estimated, Fig. 5. The probability that the flooding level is less than x is:

$$F(z) = \int_{-\infty}^z p(x) dx$$

FLOODING LEVEL

Figure 5. Flooding level p.d.f.

This distribution function $F(z)$ is shown, for the maxima, in Fig. 6.

Figure 6. Flooding level distribution function

Although the probability of a level to be exceeded by the combination of tide,

surge and wave run-up can be determined from Fig. 6, the application of the results to the determination of the public domain border is not straightforward since the law is not expressed in terms of probability but in terms of number of waves. ("The limit as far as the wave reach during the worst storm").

Changing flooding probability into number of waves is a straightforward technique but it adds a new random variable to the problem; i.e. the number of waves in a given period of time. This new variable can also be determined by means of the data from the wave buoy network.

In Fig. 7, the flooding level distribution, in terms of number of waves, is presented for zone B of Oyambre Beach. If the number of waves is limited to "one wave" we will obtain the limit reached by one wave in a mean year.

Figure 7. Flooding level distribution in terms of number of waves

Upper flooding levels will have an exceeding probability average less than "one wave per year" but they can be exceeded if we increase the number of years of observation. In this way we can determine the return period (years) of a level to be exceeded by one wave, Fig. 8.

Figure 8. Flooding level exceeded by one wave versus return period (years)

Public Domain Border

From Fig. 8 it is clear that, a given flooding level will be exceeded if we have enough years of observations. At this point a criteria must be selected in order to establish the return period to be adopted in the calculation of the public domain border.

Since the Law of 1988 does not fix that criteria, the Spanish Recommendations for Coastal Works R.O.M. 02-90, (Puertos del Estado, 1990) is used. These recommendations give the designer an estimate of the minimum life and the risk to be adopted as a function of the type of maritime work and the security level demanded. With these two parameters, the return period can be calculated. For a public domain border determination, a mean return period of 500 years has been estimated.

Conclusions

This paper presents a methodology to determine the Spanish public domain border, which is the theoretical line that separates the public and the private properties in the Spanish coastal zone.

The methodology is based on the joint probability method (J.P.M.) first introduced by (Pugh and Vassie, 1978) to estimate extreme sea-levels due to the combined effect of tides and storm surge. In this paper an extension of the J.P.M. has been developed in order to include the wave run-up on a beach.

To account for the probabilistic character of the problem a methodology is presented consistent with other Spanish coastal works recommendations. The given methodology provides an engineering tool to determine the public domain border based on available field data and on hand numerical models.

CHAPTER 344

EDUCATION OF COASTAL ENGINEERS FOR THE 50th ICCE

Henk Jan Verhagen¹

INTRODUCTION

In general the problem in education is that we teach nowadays students the knowledge from five years ago, to be applied in the next 5 to 15 years (I admit, the student of today will have reached his retirement when he will participate in the 50th ICCE, the title is exaggerating reality). When one analyses the developments in the profession, it is clear that teaching present day facts is not very useful. We have to teach approaches, design-philosophy, concepts, etc. What the meaning is for education of coastal engineers will be worked out in this paper.

CHANGES

In the past engineers only had to look at the technical aspects. Nowadays, the impact on society and environment, the costs and the sustainability are at least as important. The consequence of this is that the role of coastal engineers has changed considerably in the past few years. Recently a joint IAHR-UNESCO panel addressed the current developments in hydraulic engineering and their implications for the education of hydraulic engineers [KOBUS *ET AL.*, 1994]. Being specialized hydraulic engineers, many of the conclusions of this panel are also valid for Coastal Engineers. With reference to the UNCED '92, the panel concluded that "hydraulic engineering should be taught in a broad context of the natural and social environment and must enhance the *engineer's sense of responsibility* for sustainable water development within environmental and societal limitations."

Fortunately, also the tools for the engineers have changed considerably. In the past much was done based on experience, engineering judgement and empirical formula. Verification was usually only possible by means of measuring in prototype or by physical modelling. Worldwide research in coastal sciences and coastal engineering has shown the following two developments:

- a considerable increase in the domain knowledge (knowledge of coastal processes);

¹ Associate professor in coastal engineering, Int. Inst. for Infrastructural, Hydraulic and Environmental Engineering (IHE-Delft), P.O. Box 3015, 2601 DA Delft, The Netherlands

- advanced tools have been developed like mathematical models (in various dimensions) and decision support systems. For design and project development the role of the physical models is almost completely taken over by the mathematical models.

A general trend can be observed from applying rules to more conceptual thinking. Rules will change fast, so it is more important for an engineer to know the design philosophy. Also engineers have to learn where to find the most up-to-date knowledge regarding the design which he is making at a certain moment. Because the increased growth in science, rules are outdated faster than in the past; this means that in most cases engineers should not apply the rules they have learned in university. So they should be trained always first to verify if the design method they learned in university is still valid.

Engineers should be trained in a flexible application of the design methodologies they have learned.

For design purposes the use of complicated computer software is increasing. The packages become more and more user friendly, but the insight in the computational process becomes less. This means that the direct link between output and input is less obvious. Engineers have to become more and more aware of the need of checking the output of these programs in inconsistencies (rather than on numerical accuracy). Because of the high quality of presentation methods of modern software, input inconsistencies are often not recognised in time. Engineers have to be trained to become more and more keen on this problem.

TYPES OF ENGINEERS

Because of this development one may distinguish nowadays three types of coastal engineers:

- the research-engineers, involved in expanding the understanding of the coastal processes; using advanced analysis of field data and sophisticated physical models;
- the "toolmakers", engineers involved in translating the newly gained knowledge into mathematical models and encapsulate this knowledge in various knowledge based systems (Hydroinformatics, see ABBOTT [1994]);
- the design engineers (the tool-users), contributing in solving the coastal problems in a multi-disciplinary team.

The first two types of engineers produce products which can be used globally. Results from research done in Australia can easily be used in Iceland. Also (the better) tools can be used anywhere. Tools, developed in the Netherlands can easily be used in Sri Lanka. However, applying the tools for solving local problems requires the specific local knowledge of the various parameters of the system. In his keynote speech to Copedec IV, professor Hildebrando [HILDEBRANDO, 1995] gave an overview of the labour market for coastal engineers (based on Brazilian experiences), and he came to the conclusion that the demand for coastal engineers will grow in the following main fields of activities: Design, Construction, Operation and Research. He came also to the conclusion that the demand for researchers is relatively limited, compared to the other fields.

WHAT IS A (COASTAL) ENGINEER ?

An engineer is a trained person, able to solve practical problems in society (and in our case of course related to the coast), using technical means. In this paper I focus on the engineer with an academic education. From such an engineer it is expected that he is able to solve problems which cannot be solved by applying standard handbook solutions. Therefore he has to be able to understand the problem (analyze the cause of the problem), find in a creative way a path towards a solution of the problem, and implement that solution

(make a "construction", however in this sense a "construction" is not necessarily concrete and steel, it may also be a beach nourishment or the implementation of a set-back system). Usually this process is called "design".

An important point is that the academically trained engineer has to bear "design responsibility". This means that he is responsible for the effect of the construction on the human and non-human environment. This includes of course the aimed effects (an erosion protection should protect against erosion), but also not non-aimed effects (an erosion protection should not increase downstream erosion without consultation with the downstream coastal manager).

So the main objective of the engineer is to solve the problem, only understanding is not sufficient. Understanding is only an intermediate step.

At this moment the process description in our profession is in many cases weaker than in other engineering professions. Many formulas used in coastal engineering are empirical or have important empirical coefficients (examples are the sediment transport formulas and the formulas for the stability of armour units). Apart from this, we usually have to work with considerably unreliable input data (e.g. wave data, waterlevels). And last but not least, the materials used in coastal engineering (rock) have a highly variable strength. The result of this all is that the main art of coastal engineering is the handling of uncertainties.

Because uncertainties are so important (and even will become more important in the future), a coastal engineer should have a good knowledge of statistics and probabilistic methods. In many engineering professions uncertainties can be handled by using a "safety-coefficient" or the use of a characteristic value (like the 95% value used in concrete engineering). However, because of the wide standard deviations in the distributions of the parameters common in coastal engineering, often only a full probabilistic approach leads towards acceptable solutions.

In coastal engineering the "client" is often the government. Especially when considering coastal protection works (notably beach nourishments), the link between the paying organisation and the beneficiaries are sometimes unclear. This makes that financing coastal protection works is sometimes quite difficult and prone to an other form of uncertainties.

SCIENCE AND ENGINEERING

This also shows the main difference between a scientist and an engineer. The objective of a scientist is to understand the world. For a coastal scientist it means understanding the coastal processes. Sometimes this understanding is expressed in models. Some scientists think they understand a system when they are able to model the system (usually with mathematical descriptions). Personally I think models can help to understand the process, but the fact that you are able to model a process does not necessarily means that you understand the system. The aim of a scientist is to make this understanding as complete as possible. Also an engineer needs understanding, otherwise he is not able to solve any problem. But his research will be focused towards the needed solution of the problem, not towards a full understanding of the process.

An important point to mention is the worldwide focus on the "pure science" in coastal engineering. Much research in coastal engineering leads to longer formulas, not to better applicable formulas, as is proclaimed by SMITH [1994]. Reviewing most journals on coastal

engineering, he came to the conclusion that only very few papers were focusing on engineering, while most papers were focused on coastal science.

TRAINING

At most universities emphasis is put on the study of various coastal sciences for increasing our knowledge of the coastal processes. This is very important work, that has to be continued; however the consequence is that most students are only trained for this kind of research, and much less for practical engineering. So, in fact, we are mainly training the first 2 types of engineers, and neglecting the type 3 (the design engineer). Therefore it is necessary that apart from the education of coastal researchers attention is also paid to the education of engineers, i.e. people who are able to solve practical problems and design solutions.

When one analyzes "problem coasts", in most cases the coastal engineer is confronted with several types of problems. Among others, the following types can be distinguished:

- the "obvious" mistake;
- lack of data (no accurate boundary conditions);
- no accurate design method available.

The most usual problem is the "obvious" mistake. For example, buildings constructed too near to the waterline at an eroding coastline, undesirable effects of downstream erosion due to coastal works, etc. In these cases the origin of the problem is not really an engineering problem, but absence of awareness of coastal behaviour at (political) decision making level. It is more a political problem than a technical problem. A better technical training of engineers will never solve this kind of problems, one has to create coastal awareness at the group of clients. This requires communicative skills and the ability to compose clear and understandable reports. Usually this is a weak point of technical people, therefore special attention has to be paid to this point in the education of engineers.

Also very often no detailed input data are available for making an appropriate design. Accurate long-term wave data are very scarce. This means for an engineer:

- he has to learn how to "generate" data (hindcasting, combining several sources of data, etc.)
- he has to learn to make the design in such a way that the influence of unreliable input data is as minimal as possible (for example using probabilistic methods).

In order to solve the third kind of problem (no design method available to the designer), he first has to find out, if such a design method exists somewhere in the world. This means that he should be trained in searching this type of information. And finally in those cases where no design method is available, our engineer has to perform his own research (or write an research assignment to be executed by a specialized institute). In some cases this is necessary. But in 90 % (or more) of the design cases, this is not relevant.

Having made a (far from complete) overview of academic coastal education in the world, the conclusion is that in those universities where coastal engineering is presented, it is usually a specialisation of civil (or hydraulic) engineering, offering only a few graduate courses really in coastal engineering. The most common situation is that in the final year, the hydraulic engineer can follow a few lectures in specialised coastal engineering topics, followed by a thesis on the subject. In the very few more specialized universities, in the last year of the programme more coastal topics are presented and the thesis is usually linked to the current faculty research programme of the institute. Hardly anywhere an M.Sc.-

programme is offered, focusing on coastal engineering only, and give the student the possibility to gather real engineering (design) qualifications.

For a practising engineer, working in a multi-disciplinary team, it is vital to know the physical processes instead of only knowing the mathematical approximation of these processes². In education this point is often underexposed. Especially in the education of engineers from developing countries attention has to be paid to the education of the design (type 3) engineers, see VERHAGEN [1995].

GENERAL REQUIREMENTS FOR COASTAL ENGINEERS

In our institute we have 39 years of experience in giving coastal engineering courses to participants from countries which do not have a tradition in training of coastal engineers. The conclusion is that there is a great need for engineers who are able to plan, design, construct, maintain and manage coastal structures. The need for engineers with abilities to design coastal structures of a very complicated technical nature is much less. Although the interest of both universities and politicians is often different, maintenance and management of coastal structures are important and costly matters. It is important to include maintenance and management aspects already in the design phase, see VERHAGEN AND YAP [1992]. Based on our experience we came to the conclusion that for the design engineers the following requirements are the most important ones:

- good understanding of the basics of the physical processes;
- insight in the effect of reliability of data, used in the design processes (also including the ability to design a construction as less as sensitive to uncertain input data);
- select the appropriate tools for analyzing the problem and designing a solution;
- develop capabilities to organise the design work in a straightforward way, given the limited resources available;
- develop to ability to cooperate with specialists from other disciplines in a inter-disciplinary coastal zone management project;
- develop capabilities to come to practical solutions given the local constraints;
- the ability to formulate research assignments.

Because, according to our experience, the engineering qualities and the design and management skills are the most important requirements for coastal (design) engineers, we started to define the required qualities and skills, instead of a list of subjects to be taught. For the engineering qualities and the design and management skills, we have worked this out into the following general objectives:

Engineering qualities:

The coastal engineer:

- has a good quality engineering attitude, i.e. he is able to analyze practical problems in his profession, is able to generate solutions and is able to implement the engineering

² A clear example can be found in wave-mechanics. Often teaching starts with the dispersion equation for gravity surface waves (in fact a mathematical model description). And then, for example, refraction is explained by combining the dispersion equation with the continuity of wave crests in order to get a formula for the ray curvature. Usually this is not very clarifying for students with an engineering attitude.

solutions in a sound way; doing this the engineer is knowledgeable with respect to his profession, but also aware of the surroundings and the environments of the project, and is able to organize the solving the problem and implementing the solution in a interdisciplinary environment.

- has some knowledge of technical and scientific developments in fields adjacent to his own field and is able to communicate with experts in those fields; examples for coastal engineers are: river engineering aspects, inland navigation, merchant shipping, port management, information technology, environmental sciences.
- has knowledge of modern design methodologies, like the probabilistic approach and the policy analysis approach to select alternatives, and is able to apply them.
- is aware of the fact that hydraulic engineering structures always have a large impact on the environment in its widest meaning; the engineer has to be able to make an inventory the impacts of his work with the aid of specialists in environmental sciences and to execute an environmental impact assessment.
- is able to define the required input data for his problem; he is able to judge the required accuracy of the data; he is able to compose an adequate dataset from an ambiguous dataset.
- is able to search in international literature and databases for relevant design methodologies.

design skills

The coastal engineer is able to:

- analyze coastal (erosion) problems, to generate alternative coastal protection methods (including "soft" methods), to select a protection method, to design the protection and to supervise the construction of the protection.
- protect low-lying coastal areas from flooding by means of the construction of dikes and revetments; he is able to determine the functional requirements of the protection, to generate alternative flood protection methods, to select a protection method, to design the protection and to supervise the construction of the protection.
- evaluate the necessity and to design closure dams, causeways, etc. in a coastal, tidal environment; he is able to determine the functional requirements of the dam, to generate alternative lay-outs and construction methods, to select an alternative, to design it and to supervise the construction of the dam.
- design the entrance to a harbour, i.e. the design of the access-channel and the design of the breakwater; he is able to determine the design boundary conditions, to generate alternative solutions, make a selection, make the detailed design and supervise the construction.
- design mooring facilities, both at offshore jetties as along quay-walls, he is able to develop and select alternatives and is able to design the structure; he is able to specify the boundary conditions for quay-wall and jetty construction; he is able to design a jetty and a quay-wall.
- design earth structures and foundations in the coastal zone (dikes, sheetpiles, soil improvement techniques), the coastal engineer has a workable knowledge of pile foundations.

managerial skills

The coastal engineer:

- is able to organize and cooperate in a multi-disciplinary group to set-up and implement an integrated coastal zone management plan.

- has specific knowledge of construction methods specific for coastal engineering, i.e. wet and dry earth moving; related to dredging he has to be able to define the working method, to know the possibilities of the industry, to prepare terms-of-reference and contract and price estimate; he is able to select the contractor and to supervise the work.
- is able in case of environmental emergencies in the coastal zone (oil-spills, hurricanes, etc) to organize the appropriate actions to mitigate the impact.
- has some knowledge regarding the organization of the profession, the international institutions, the organization of large contractors and consultants.

Having defined these more general qualities and skills, the next step is to define the required knowledge for individual subjects, like "design of breakwaters" or "short waves". Only those aspects of the several subjects should be taught, when they contribute to the general qualities and skills, as defined above. If one neglects this point, the result is usually a programme which consists of a set of hobbies of the teachers. Because of the limited scope of this paper, this step will not be worked out.

ATTAINMENT TARGETS

Of course these objectives, but also a list of topics within a series of lectures gives no information regarding the level, depth or orientation of the subject. Often one sees in curricula of universities descriptions like:

Short waves

linear and non-linear regular gravity waves, wave properties and transformation in shallow water, forecasting and hindcasting of waves.

In fact, such a description gives not very much information. For example, after having followed this course, is the student able to derive refraction equations, is he able to make a refraction calculation by hand, is he able to interpret the results of a refraction calculation by a computer programme, is he able to define whether a refraction calculation is necessary or not, and if yes, what are the input variables ???

Therefore it is more appropriate to describe as detailed as possible the attainment targets a student has to meet in order to get his diploma. For "refraction", such targets could be described as follows:

- *Know the phenomenon of refraction, be able to calculate refraction in case of parallel depth contours, using Snell's law, be able to determine refraction in a qualitative way in case of non-parallel depth contours, know the advantages and problems of ray-refraction programs, be able to interpret two-dimensional wave penetration programs.*

Attainment targets can be worked out for all course objectives, mentioned above. As an example the attainment targets for the design capabilities are given below:

Attainment targets for design capabilities

- be able to translate a vague (political) question into exact requirements and formulate them in terms-of-reference for a study to be performed
- be able to analyze the problem on main aspects and distinguish between essentials and matter of secondary importance
- to be able to analyze the functional requirement of the construction needed, in order to determine design criteria

- be able to collect data for a (real world) project from the general available data sources (like libraries, information retrieval systems, already existing consultancy reports)
- be able to analyze the above mentioned data and to be able to use them in order to come to a complete, relevant and unambiguous set of boundary conditions (including the reliability of the given figures)
- be able to determine scenarios to describe unknown future effects
- be able to determine alternative designs
- be able to make global designs of the alternatives, in order to make a selection; be able to make a choice between the various available computational and design methods; be able to apply these methods
- evaluate the designs on at least the following aspects
 - costs
 - environmental acceptance
 - social acceptance
 - maintenance cost
 - robustness of the design
 - executionability
- be able to read technical drawings, to be aware of the effects of distorted scales (especially in coastal profiles)
- be able to make a bill of quantities given the design drawings
- be able to make a set-up for an Environmental Impact Assessment for the design
- be able to write a systematic report on the design process followed
- be able to write readable well-structured reports, with clear set-up, and with a good quality lay-out.
- be able to organize the design work, define various subtasks and have these subtasks executed by various group members
- be able to make a time planning for a design work, and be able to produce the design report; i.e. to deliver the report (1) in time, (2) with the subjects as determined in the original plan, (3) with the required quality; the sequence of these points is important
- be able to present the results of a study or design work orally in a short period (10-30 minutes) for various types of audiences (such as technical experts, decision makers, financial experts); be able to make good quality overhead sheets (both from a viewpoint of contents as lay-out)
- be able to gather additional skills and knowledge on a rather specialistic field (not treated in detail in the teaching programme) in order to solve the design problem.

THE MASTER DEGREE

The engineering study is usually completed with a Master degree. Unfortunately there is not really a world-wide standard for a master degree. Especially for students from developing countries this is a real problem. For most of them their career depends completely on the fact if they have paper indicating a Master degree, and not on their knowledge or skills. So in fact it is for them very unattractive to follow a high quality course. Usually these courses are long (and therefore costly), with a high risk of failure for the candidate; so why not go to an easy course ? This strong focus on "paper" degrees is a clear problem in the developing world. But on the other hand, for an outsider it is indeed difficult to assess the quality of a diploma. Therefore the detailed described attainment targets can be very useful. In fact, by issuing the diploma, we guarantee that the candidate has reached all the described attainment targets, so a future employer can easily see what is the knowledge and skill of the degree-holder.

There is a variety of Master titles, a taught masters, a master by thesis, a master of engineering, a master of science, etc. In our institute we provide two types, a Taught

Masters and a Master of Science. The first is given to a student who has followed the complete (2000 study hours) program, has done all exercises sufficiently and who has passed all examinations. Students with sufficient high marks for the Taught Masters programme are academically admitted to the Master of Science programme, which consists of an additional individual assignment of approx. 1000 hours. This individual assignment can be a research work, but can also be a design work. Of course not all design work automatically has sufficient level for M.Sc. We use the following list of requirements for a subject for design-work at M.Sc.-level

- It has to be a complex problem, i.e.:
 - The boundary conditions are ill-defined
The criteria are not clear on beforehand
 - There are several, complex scenarios.
- The technical solution is complicated, this means that it is not possible to apply straightforward existing design formulas.
- It is not possible to determine the best alternative by a simple (one-dimensional) computation.
- The problem has to be realistic and relevant, preferably for the home-country of the participant.

CONCLUSIONS

Because of the focus on research in most universities of the world, the training and education of design engineers is somewhat problematic. Many design engineers have been trained as researchers. In future there is a need for trained designers with understanding of coastal processes, the ability to design in a flexible way coastal "constructions" and able to communicate with others. Training programs can be improved considerably by defining the attainment targets which have to met by the students at the end of their education, and not only by defining the subjects to be dealt with in the curriculum.

CHAPTER 345

Risk-Based Analysis of Coastal Projects

Edward F. Thompson¹, Member, ASCE, Michael Wutkowski², Member, ASCE,
and Norman W. Scheffner¹, Member, ASCE

Abstract

Coastal engineering usually embodies large uncertainties about attacking forces and coastal/structure response. The coastal engineer must address these uncertainties with judgement and experience, supplemented with some level of direct probability analysis. The nature and scope of risks related to coastal projects are reviewed. Analysis approaches developed for wider engineering application, where risks are usually better defined (e.g. Ang and Tang 1975, 1984; Harr 1987), may be less effective in coastal engineering. Two accepted general approaches for risk-based analysis of coastal projects are discussed. The approaches are illustrated with an example shore protection project.

Introduction

The approach for analyzing coastal projects is undergoing some fundamental changes, shifting from the traditional deterministic emphasis to a more comprehensive probabilistic, risk-based methodology. The changes strongly impact both planning and engineering phases of project formulation and design.

The changes, which can be expected to be distilled into a new standard for coastal practice by the end of the decade, are driven by several progressive developments. First, our understanding of probabilistic coastal processes continues to advance, particularly due to advances in field measurement, physical modeling, and numerical modeling.

¹ Research Hydraulic Engineer, US Army Engineer Waterways Experiment Station, CEWES-CR, 3909 Halls Ferry Road, Vicksburg, Mississippi 39180-6133, USA.

² Civil Engineer/Programmer, US Army Engineer District, Wilmington, CESAW-EN-C, P.O. Box 1890, Wilmington, NC 28402-1890, USA.

Second, standard computing capabilities are increasing rapidly, facilitating lengthy probabilistic calculations which would have been impractical in the past. Third, engineers, cognizant of limitations in the traditional approach, are often eager to implement better procedures, provided that they are well-founded and clearly improve the analysis. Finally, the public is becoming more aware and concerned about coastal project performance, and they expect realistic project analyses. In the U.S., public involvement in coastal projects is further intensified by legislation which increases the proportion of costs borne by the client (typically state or local government) in Federal projects.

Traditional vs. Risk-Based Analysis

Traditional analysis treats a coastal project in deterministic terms. The forces of nature are often represented as a design significant wave height, period, and direction, a design water level, etc. Coastal response is described as *the* response if no project is implemented, *the* response if one plan is implemented, *the* response if another plan is implemented, etc., without much formal recognition of the wide variation in possible responses.

In contrast to traditional analysis, some significant developments in probabilistic treatment of coastal projects have appeared during the 1990's. Most relate to coastal structure design (CIRIA/CUR 1991, ICCE 1992). Within the U.S. Army Corps of Engineers (CE), water resource planning guidance has moved from a deterministic to a risk-based approach, which incorporates considerations of risk and uncertainty. Similar concepts are now being adapted to CE coastal engineering studies (U.S. Army Corps of Engineers 1996).

Reasons for Risk-Based Analysis

There are a number of reasons why coastal projects in the broader sense, not just structure design, may be effectively analyzed from a risk-based point of view, as follows (Table 1):

1) *Coastal forcing is probabilistic.* Wave characteristics vary greatly both over short term (individual waves) and long term (from one sea state to another). Similar considerations arise with winds, water levels, infragravity waves, and currents.

2) *Coastal engineering embodies major uncertainties.* Knowledge of both the forcing processes and coastal response usually involves major uncertainties.

Table 1. Reasons for Risk-Based Analysis of Coastal Projects

- | |
|--|
| <ol style="list-style-type: none"> 1) Forcing is probabilistic 2) Major uncertainties in behavior 3) Damage & functional performance change incrementally 4) Benefits & risks not fully represented in deterministic terms 5) Uncertain effects on adjacent areas |
|--|

Deterministic representations mask the uncertainties and can be misleading.

3) *Damage and functional performance change incrementally.* Coastal projects rarely progress from the design condition to total failure during a single storm event. Damage usually occurs incrementally. For example, damage to a rubble mound breakwater (when it occurs) typically begins during an unusually severe storm and progresses during subsequent severe storms until repairs are done. Similarly, beach fills erode incrementally in response to storms over a period of years. Coastal projects often continue to provide some measure of functional benefit even in a damaged state. A damaged breakwater continues to provide some protection from incident waves; a partially eroded beach fill continues to reduce coastal flooding risks.

4) *Benefits and risks not fully represented in deterministic terms.* Because of the above factors, positive impacts and risks of coastal projects cannot be fully represented in deterministic terms. Some projects provide benefits beyond the design configuration, which are generally ignored in traditional practice. For example, a nearshore berm which is over-built to allow for progressive deterioration provides increased coastal protection during its early life. Another example is an over-dredged entrance channel giving increased vessel access depths until it shoals to the design depth.

5) *Uncertain effects on adjacent areas.* In addition to the uncertainties associated directly with coastal projects, the projects can introduce significant possibilities for changing adjacent areas. While projects are designed with the intent of minimizing adverse impacts on adjacent areas, it is important to recognize that uncertainties and risks can increase beyond the without-project condition. In effect, a project can transfer risk from one area or party to another. When the risks of *all* major aspects of a project are represented as best they can be determined, better-informed final decisions can be made.

Experienced coastal engineers are well-aware of the concerns in Table 1. Even with deterministic methods, they can be expected to produce project plans which include a large measure of professional judgement to insure a technically successful project. However, the ultimate fate of a project can depend upon higher level decision-makers who must weigh technical concerns against economic, environmental, aesthetic, social, and political concerns. By quantifying risks, the coastal engineer can better pass his or her experience and judgement on to other decision-makers, who may not have coastal expertise.

Considerations for Including Risk-Based Analysis in Project Design

Objectives. The main objectives of adopting a risk-based analysis approach rather than a traditional approach are to explicitly identify uncertainties, provide improved information for assessing tradeoffs between risks and cost, and improve decision-making

for project optimization (Table 2).

Key Variables. Although a large number of variables affect any coastal project, a small subset can usually be identified as *key variables*, that is variables which strongly relate to project performance. The key variables will embody the

main forcing mechanisms, project sizing, and project response. For example, some of the key variables for a beach nourishment project might be significant wave height (forcing), beach fill width (project size), and erosion width (response).

Professional Judgement. Coastal engineering requires an unusually large measure of professional judgement because of the number and complexity of processes and responses involved. Analytical and modeling tools help to represent the variability affecting coastal projects, but the judgement of an experienced engineer is a vital ingredient in risk assessment and project optimization.

Resistance and Functional Performance Vary with Time. Both the resistance to damage and functional performance often vary significantly over a coastal project's design life. For example, the resistance (or structural strength) of a rubble mound breakwater may decrease in time due to deterioration of stone such as loss of angular corners, cracking, and breaking. Resistance may also decrease due to displacement of stone and exposure of underlayers to wave attack, which would also decrease protection provided by the breakwater (functional performance). For a beach nourishment project, loss of material to storms decreases the resistance of the beach to future storms. The effectiveness of the beach as a deterrent to coastal flooding is also decreased (functional performance). In some cases, resistance *increases* with time, as in the progressive growth of protective vegetation on coastal dunes and natural cementation of beach sediments rich in calcium carbonate.

Construction Season and Mobilization Concerns. Often maintenance of coastal projects requires major mobilization efforts and is confined to a *construction season* dictated by climate and environmental factors. Therefore the risk during the *interval between construction seasons* rather than during a single storm becomes a key concern. During an unusually stormy winter (such as the winter of 1987-88 in southern California), this risk can be significantly greater than that for individual storms.

Environmental, Aesthetic, Social, and Political Concerns. The role of environmental, aesthetic, social, and political factors in the ultimate planning and design of a coastal project is often at least as important as the technical engineering factors. An optimized final design includes appropriate consideration of these factors and their

Table 2. Objectives of Risk-Based Analysis

- Explicitly identify uncertainties
- Provide improved information for assessing risk vs. cost tradeoffs
- Improve decision-making for project optimization

associated risks and uncertainty.

Frequency-Based vs. Life Cycle Approach

Risk-based analysis of coastal projects can be done by either of two fundamentally different approaches. The *frequency-based approach* deals with frequency-of-occurrence relationships among the key variables. By combining key forcing variables with various occurrence frequencies, information about the frequency-of-occurrence of key project responses can be developed. For example, a traditional stage (water level) vs. frequency curve and a stage-damage curve can be combined to generate a damage vs. frequency curve. This approach can be applied as an add-on to traditional planning and design procedures.

The *life cycle approach* deals with multiple realizations of possible evolution of the project with *time* during the span of its design life. The suite of life cycle realizations is constructed with consideration of the probabilities of key variables. For example, the realistic time variation of key forcing and response variables during a 50-yr life cycle can be generated for 1000 different possible life cycles. Uncertainty in the data and models relating natural forcing to coastal response can be represented as another source of variability. Probabilities and risks associated with the project are then compiled by analyzing project performance over the 1000 life cycles.

An example shore protection project helps to illustrate the life cycle approach in comparison to a more traditional frequency-based approach. The project area is a relatively uniform stretch of beach with several rows of houses along the shore (Fig. 1). The example project is a beach nourishment to widen the existing beach and dune (Fig. 2). The frequency-based approach used for this example is based on a set of six storms representing 5-, 10-, 25-, 50-, 100-, and 500-year events. Expected erosion of the existing or project beach profile and property damages are calculated for each storm. An average annual damage is calculated by integrating over the range of storm probabilities. For each year of the project life span, the shoreline is retreated according to a long term erosion rate and calculations of annual damage are repeated. Total damage over the project life span is the sum of the annual damages. This more traditional approach produces a single result based on a single set of storms and response parameters. There is no indication of confidence level of the answer. The example project shows net benefits of \$980,000 over a 50-year life span and a benefit/cost ratio of 2.4.

The life cycle approach in this example embodies sequences of storms (including provisions for multiple storms of varying intensity during each year of the life cycle), erosion and post-storm recovery during each event, partial and complete property damage during each event (depending on water level, waves, extent of storm erosion, and type of building construction), cumulative property damage due to a succession of storms, optional repair or rebuilding after a suitable time lag (with conformance to any stricter building codes in effect), and periodic renourishment of the beach when needed

FIG. 1. Sample Section of Coastline

FIG. 2. Example Project Profile

and feasible during the life cycle. A key result from this analysis is the renourishment required during each life cycle, which can be converted to an economic present worth dollar value. The costs and net benefits in this example vary over a wide range, depending on the occurrence of major storms during the life cycle simulation (Fig. 3). The expected cost and economic risks associated with maintaining the beach can be realistically assessed by condensing information from many different life cycle simulations (Figs. 4 and 5). The mode and mean net benefits are \$275,000 and \$814,000, respectively (Table 3). There is a 65% probability that the net benefits will be less than the \$980,000 amount calculated by the more traditional frequency-based approach. There is a 7% probability that the net benefits will be negative (cost of the project exceeds the damages prevented). Negative benefits come from simulations with mild storm climates. While net benefits are used to optimize a project, the benefit/cost ratio is also of interest (Table 3 and Fig. 6).

Statistic	Net Benefits (\$1,000)	Benefit Cost Ratio
Mode	275	1.50
Mean	814	3.09
Standard deviation	649	1.59
Maximum value	3557	8.92
Minimum value	-119	0.67
Number of cases	7000	7000

The life cycle approach appears better suited to most coastal engineering applications. Variation with time is an essential ingredient in most coastal projects, and it is directly incorporated into the life cycle approach. Time variation of resistance and functional performance, constraints imposed by construction season and mobilization, even some economic, environmental, and political factors, can be conveniently and flexibly introduced into the life cycle approach. This approach leads to a unified analysis of technical performance and many economic factors which are critical to project success. As illustrated in the above example, the life cycle approach provides valuable information relative to the objectives of risk-based analysis (Table 2). In addition to its technical and economic strengths, the life cycle approach is more easily understood by nontechnical parties involved with a project. This type of approach is evident in the Empirical Simulation Technique (Scheffner et al. 1996) and CE guidance in preparation (U.S. Army Corps of Engineers 1996).

Typical Project Elements

Risk-based analysis can be integrated into the major planning steps of a coastal engineering project. Typical project elements which are especially well-suited to

FIG. 3. Unsorted Risk Results

FIG. 4. Net Benefits, Probability Density Distribution

FIG. 5. Net Benefits, Cumulative Probability Distribution

FIG. 6. Benefit Cost Ratio, Cumulative Probability Distribution

risk-based analysis include the following:

Site Characterization. Significant uncertainty can arise in documenting past and present behavior at a site. The uncertainty can be estimated based on data quality and quantity, methodologies used, observed variability, etc.

Without Plan Alternative. Evaluation of what would happen in the future if no project were built involves speculation about the natural processes and human interventions which would affect the site during the proposed project life. The impact of the *without plan* alternative is conveniently described in probabilistic terms.

Formulate, Evaluate, and Compare Alternative Plans. Risk-based analysis can be a powerful tool for formulating and comparing alternative plans. It enables decision-makers to intercompare not only the expected level of performance, but also the probabilities of enhanced or reduced performance levels, which can differ greatly among alternatives. Typically, alternatives involve hard structures (such as walls, revetments, breakwaters, and jetties) and/or soft structures (such as beach nourishment projects, coastal dunes, and nearshore berms). Risk-based analysis of hard structures is increasingly being considered in planning and design (CIRIA/CUR 1991, ICCE 1992). Soft structures involve calculated risks about the movement of sediment through time and the need for future maintenance. Uncertainties arise in forcing processes, sequencing of storms, initial state of nearshore profile when storms occur, and evolution and recovery of storm profiles (especially three-dimensional aspects). The life cycle approach to risk analysis has been shown to be a powerful tool in this type of application.

Conclusions

The following conclusions are reached regarding risk-based analysis of coastal projects:

- Risk-based approaches provide a powerful tool for analyzing coastal projects.
- Risk-based analyses can lead to improved decision-making for project optimization.
- The life cycle approach is especially well-suited to coastal engineering.

CHAPTER 346

DESIGNING FOR PROPELLER ACTION IN HARBOURS

G.A. HAMILL ¹, J.A. MCGARVEY ²

Abstract

The scour produced by the action of a ship's propeller is an increasing problem. There is a need for an accurate method of velocity prediction so that adequate steps can be taken to design suitable bed protection systems. The velocity characteristics of the jet produced by the rotating propeller are presented as an aid to the engineer.

Introduction

One consequence of the increases in ship size, installed engine power, and volume of marine transport is an increase attack by propeller slipstreams on the bed and banks of harbour basins and navigation channels. In restricted waterways the situation has been exacerbated since the introduction of bow thrusters in the 1960's which has increased the navigability of large ships to such an extent that they can now operate without tug assistance.

A ship's propeller produces thrust by drawing in water, accelerating it and discharging it in the form of a wash. This wash is a highly turbulent submerged jet, the velocities within which depend upon the operating characteristics of the propeller and the speed of advance of the ship. The wash entrains the surrounding water and so the velocities within it decay with distance from the propeller. In this way the jet expands and dissipates its energy by diffusion. If the ship is moving in a confined area, for example in the shallow waters of a harbour basin, the diffusion process within the wash will be restricted and the energy remaining within the jet may cause damage to the bed and nearby quay structures.

Related Research

A survey of harbours in Sweden (Bergh 1981) has shown that 16 out of the 18 ports surveyed have suffered propeller induced damage in recent years. Similar problems have been encountered in several United Kingdom ports and the British Ports Association commissioned a review (Prosser 1986) of existing knowledge. In a survey of all British ports in 1994, Qurrain (1994) found that 42% of these encountered scouring as a result of propeller action, of which 29% regarded this scouring to be a serious problem causing damage to quays, with expensive remedial repairs and costly facility downtime. The diffusion characteristics of a propeller jet have been examined by numerous authors. Investigation which include the influence of the rudder on the diffusion process however, are not extensive and the majority of all predictive equations do not allow for it's inclusion.

1) Lecturer 2) Research Student

The Queen's University of Belfast, Department of Civil Engineering, N. Ireland

Robakiewicz (1966), Verhey (1983) and Fuehrer (1985) have studied the velocities within the propeller jet in the presence of a rudder, and presented equations for estimating bottom velocities. These equations are limited in that a full velocity distribution cannot be calculated and they are related to an efflux velocity equation, i.e. the maximum velocity on the propeller face, which has been found to be up to 20% in error.

Experimental Set-up

Detailed velocity measurements were taken within the diffusing jets, produced by two propellers with differing characteristics, up to a distance of 10 diameters from the propeller plane. Four jets, corresponding to four speeds of rotation, were investigated for the first propeller which was 0.076m in diameter, while three jets were investigated for a second propeller 0.131m in diameter. Axial and radial measurements of velocity were taken using a twin component Laser Doppler Anemometry system.

Rudder Effect

The magnitudes of the axial and radial velocity components within the wash were measured within the formation stages of the propeller jet, i.e. up to $2.0 D_p$. To provide a better understanding of the jet diffusion, velocity vector diagrams were plotted for all experimental results with and without the rudder present. These provided a 2D schematic representation of the flow within the propeller jet. Figures 1(a) to 1(c) are typical of those obtained during the current investigation.

FIGURE 1(a) Resultant velocity vectors (without rudder)

FIGURE 1(b) Resultant Velocity Vectors (Rudder at Zero Degrees)

Figure 1(a) shows the velocity distributions obtained without the rudder. The magnitude of the velocities at the hub is lower than across the blades, and the jet is diffusing away from the propeller centreline due to the radial velocity component. It can be seen that the vectors revert to the horizontal with distance from the propeller, indicating the reduction in the magnitude of the radial velocity component. The velocity distribution at each vertical section from the propeller is approximately symmetrical through the propeller axis which confirms the results of previous work. The results obtained with the rudder situated at zero rudder angle or midships position is shown in figure 1(b).

FIGURE 1 (c) Resultant Velocity Vectors (Rudder at +35 Degrees)

It can be seen that the resultant velocity distribution at the face of the propeller is similar to the distribution obtained without the rudder present. There is a significant change in the flow with distance from the propeller, as the jet is circulated around the rudder. There is a rapid reduction in the magnitudes of the velocities at the first section behind the propeller. In subsequent sections the velocities are greater as the flow moves along the sides of the rudder.

It can also be seen that the vectors in subsequent section along the rudder are almost to the horizontal. This indicates that the magnitudes of the radial velocities are insignificant, and that the rudder has a straightening effect on the jet. The velocity distribution appears to vary at each section and it can be seen in some sections that there are higher velocities below the propeller centreline than at the corresponding position above the centreline.

Figure 1(c) shows the results obtained when the rudder is placed at an angle of 35 degrees to the propeller axis. The velocities at the face of the propeller are approximately symmetrical through the propeller axis and therefore appear to be unaffected by the rudder. It is the distributions in the subsequent sections that are interesting as the magnitude of the velocity below the centreline can be seen to be greater than above the centreline. This is due to the effects of splitting of the flow by the rudder. The vectors shown represent the velocities in a stream directed towards the bottom. The distribution shows that there is only one position of maximum velocity, unlike the axi-symmetrical profiles found in the absence of the rudder.

In order to provide a better understanding of the propeller diffusion characteristics with the rudder present, velocities were measured throughout the jet using a system of pitot tubes. These results were then plotted in the form of an isovel plot for each speed of rotation, which provided contours of the velocity distribution within the propeller jet. Figures 2(a) to 2(d) show the sequence of isovel plots with the rudder positioned at zero degrees, and is typical of the velocity distributions obtained for all the jets tested at this angle. Figure 2(a) shows the velocities obtained at a distance of $0.46 D_p$ behind the propeller, at the location of the rudder. The velocities obtained at this section are unlike those obtained for the jet without a rudder as the velocities are not symmetrical through the propeller axis (Stewart 1992). The rudder splits the main wash into two separate streams of jets. one jet is directed towards the water surface, while the other is deflected towards the sea bed. The jets are just forming at this position and the bottom jet below the centreline is clearly defined, with the

FIGURE 2(a) Isovels at 0.46 D_p for zero rudder angle

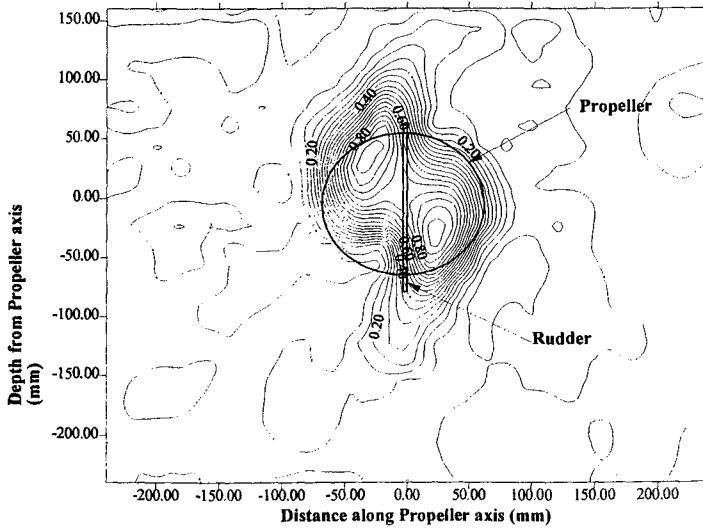

FIGURE 2 (b) Isovels at 0.92 D_p for zero rudder angle

FIGURE 2(c) Isovels at 3.05 Dp for zero rudder angle

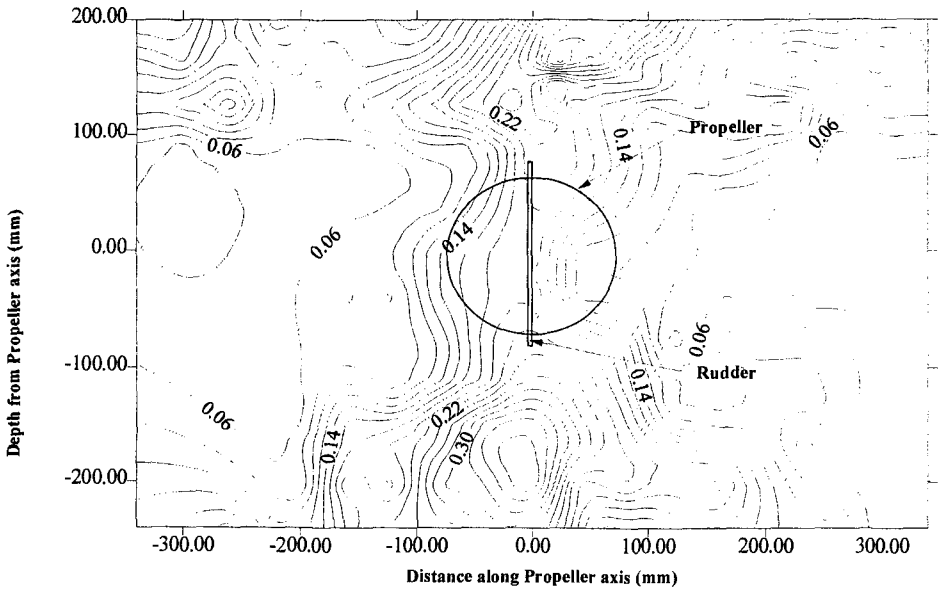

FIGURE 2(d) Isovels at 6.95 Dp for zero rudder angle

surface stream just becoming visible. Figure 2(b) which is located at a section subsequent to the location of the end of the rudder, shows the formation of the two streams, represented by the two high velocity peaks shown on each side of the rudder. This trend continues with distance from the propeller and the two streams are visible at $3.05 D_p$, as shown in figure 2(c). This position has previously been termed the end of the zone of flow establishment for the jet without a rudder, at which location the maximum velocity would be located on the propeller centreline. It can be seen that with distance from the propeller there is a gradual increase in the distance between the streams, and therefore the maximum velocity is not likely to revert to the propeller centreline. The divergence of the streams continues and this is confirmed in figure 2(d), at $7 D_p$, where the two jets are still separating.

It has been shown that the rudder splits the jet into two streams and their deviation continues throughout the remainder of the diffusing jet. The rudder has the effect of altering the diffusion characteristics of a propeller jet and this has resulted in the formation of a different type of jet. There is no further alteration of the streams, other than by natural diffusion with the surrounding fluid, once they have been established. The zone of established flow could therefore be considered to commence at the position of the formation of the two streams. Figure 2(a) showed the formation of the two streams, although not clearly defined. However, it can be seen in figure 2(b) that the two streams are clearly defined and diverging away from each other. This position represents approximately the end of the rudder. It can therefore be concluded that the jet is fully established from the location of the trailing edge of the rudder.

It is evident from the findings of this investigation that the processes of formation and diffusion of a propeller wash, under the influence of a rudder, can in no way be described by the predictive equations that are currently available as the two streams formed by the rudder have been shown to behave as independent jets.

Characteristics of a propeller jet

Efflux Velocity Distribution

The magnitudes of all velocities within the wash produced by the rotating propeller are dependent on the magnitude of the initial velocity within the wash. This velocity, termed the efflux velocity, is found on the cutting edge of the propeller. As can be seen from figure 1 the velocity distribution along the cutting edge, or the efflux distribution, remains unchanged in the presence of the rudder, with an axi-symmetric distribution being developed. It is this initial distribution, along with the subsequent rudder interaction, which forms the wash. The velocity distribution at efflux will be proportional to the thrust developed by the propeller blade. The thrust produced by a ships propeller depends on the geometry of the propeller blades and the speed of rotation. The main characteristics which influence the developed thrust include the pitch and chord length. These characteristics vary with radial distance from the hub, and hence the thrust and therefore the velocity must also vary with distance along the blade.

The position along a propeller blade at which the greatest thrust is produced generally corresponds to the position of maximum velocity, termed the efflux velocity, V_0 . Several authors have proposed equations which determine the magnitude of the efflux velocity. The original efflux velocity equation, as reported by Blaauw et al (1978) and adopted by most authors, was based on the Froude momentum theory,

$$V_0 = 1.59nD_p\sqrt{C_t}$$

The assumptions made in the momentum theory have been shown to be invalid. These short-falls in the theory have led to modifications of the theoretical efflux equation by Stewart (1992). These modifications take account of the propeller characteristics as follows,

$$V_o = E_o n D_p \sqrt{C_t} \quad 1$$

where

$$E_o = \left[\frac{D_p}{D_h} \right]^{-0.323} [C_t]^{-0.1459} [P]^{0.44} [\beta]^{0.513}$$

The magnitude of the axial velocities at the face of the propeller have to date been estimated by solving equations developed by Albertson (1950). He proposed that the velocity distribution within the jet, close to the propeller, follows the Gaussian normal probability function.

Stewart modified the Gaussian equation and presented the following equation, to describe the axial velocity distributions within the propeller jet, based on his own investigations:

$$\frac{V_{xr}}{V_{\max}} = EXP\left(-\frac{1}{2} \frac{(r - R_{mo})^2}{\sigma^2}\right) \quad 2$$

where the standard deviation of velocity, σ , was equal to $0.5 R_{mo}$ and the maximum velocity, V_{\max} at the face of the propeller is equal to the efflux velocity, V_o . Berger et al. (1981) proposed that the distance to the position of the maximum velocity at the face of the propeller, R_{mo} , could be determined as follows,

$$R_{mo} = 0.67 R_p - R_h \quad 3$$

where R_h is the radius of the hub and R_p is the propeller radius.

The velocity distribution along the face of the propeller can be determined by solving equations 1,2 and 3. Velocity profiles were plotted comparing the results obtained from existing equations and the measured data. The profiles, as shown in figures 3 and 4, indicate that the measured velocity increases from the hub to a distance of approximately $0.7 R_p$ along the blade, and then decreases rapidly to the blade tips. This is in contrast to the profile predicted by existing equations, where the velocity increases to approximately $0.5 R_p$ and then gradually decreases to the blade tips. The position of the maximum velocity can also be seen to vary greatly from that determined from existing equations, when compared to the measured velocities. The distance to the maximum velocity, in all of the profiles that were plotted using existing equations, was underestimated when compared to the measured results. The existing equations, which are based on the momentum theory, have been revised and updated on several occasions by replacing the experimental constant. The magnitude of the constant varied in several investigations using different propellers, more recently Stewart updated the equation to relate the constant to the propeller characteristics. This was a calibration of a theory, which is inherently flawed, to suit experimental results. It was decided to investigate a more realistic method by which the magnitude of the axial velocities along the face of the propeller could be obtained.

FIGURE 3 Velocity Distribution Comparison for 76mm propeller

FIGURE 4 Velocity Distribution Comparison for 131mm propeller

A literature survey revealed that Koumbis (1981) investigated the thrust produced by a ship's propeller and developed a computer program which relates the thrust to the characteristics of the propeller blades. The program is based on the Vortice Lattice theory.. In designing a propeller the naval architect determines the most suitable characteristics to provide the optimum thrust for each blade. It therefore seemed reasonable to relate the distribution of velocity on the propeller face to the characteristics which produce this thrust.

The blade cross sections, as shown in figure 5, were obtained for positions along the propeller blade where the velocity measurements had been recorded. It was decided to attempt the derivation of a relationship in which the magnitude of the axial velocity could be expressed in terms of the characteristics of the propeller blades.

Figure 5 Propeller Blade Characteristics

A literature survey provided detailed information on the design of a propeller, and revealed the properties considered by the naval architect in designing the geometry of the propeller blade. Considering the axial velocity V_{ax} , it can be written as:

$$V_{ax} = f(n, N, r, \mu, \rho, p, t, c, h_D, h_T)$$

- where n = number of rev/sec N = number of blades
- r = radius of propeller μ = kinematic viscosity
- ρ = density of fluid p = pitch of blade
- t = thickness of blade c = chord length
- h_D = helical distance from blade section leading edge to rake datum line
- h_T = helical distance from blade section leading edge to position of maximum thickness

Using the Pi theorem the equation can be written as:

$$\frac{V_{ax}}{Nnr} = f\left(\frac{\rho nr^2}{\mu}, \frac{p}{r}, \frac{c}{r}, \frac{t}{r}, \frac{h_d}{r}, \frac{h_r}{c}\right)$$

It was found from the literature survey that the effect of viscosity could be neglected if the Reynolds number of the jet was greater than 10^4 . In the present investigation the Reynolds numbers were greater than 10^4 , and could therefore be neglected from further analysis. This analysis resulted in an equation with a correlation coefficient R^2 of 0.985:

$$\begin{aligned} \frac{V_{ax}}{Nnr} = & 1.261 - 0.974\left(\frac{p}{r}\right) + 0.733\left(\frac{c}{r}\right) + 18.527\left(\frac{t}{r}\right) + 5.028\left(\frac{h_d}{r}\right) \\ & + 0.106\left(\frac{p}{r}\right)^2 - 7.277\left(\frac{h_d}{r}\right)^2 - 4.093\left(\frac{h_r}{c}\right)^2 \end{aligned} \quad 4$$

The high correlation obtained for the experimental data shows the assumption that the velocity distribution along the blade was a function of the varying blade characteristics was valid. The velocity distribution obtained from equation 4 and the results obtained from existing equations, were plotted with the experimental results. Figure 6 is typical of that found for the present investigation. It can be seen that there is a significant improvement in the correlation with the measured data, when compared to the results of existing equations. This was found to be the trend of the results obtained for all experiments.

FIGURE 6 COMPARISON OF EXPERIMENTAL DATA WITH THE RESULTS FROM EXISTING AND PROPOSED EQUATION

FIGURE 7 LOCATION OF THE MAXIMUM AXIAL VELOCITY WITHIN THE BOTTOM STREAM OF THE DIFFUSING JET

The magnitude of the axial velocity distribution at the face of the propeller can now be determined by solving a single equation, equation 4, instead of the three equations as proposed by existing work. The derivation of this equation is based on the physical properties of the propeller blades rather than the momentum theory which is inherently flawed. Equation 4 will accurately determine the magnitude of the maximum velocity, V_0 , and the position at which it occurs along the blade. Its use beyond the scope of the current experimental programme will require further verification. However, when compared to the equations which are currently used, which themselves are based on a limited test programme, it shows great potential.

Location of the maximum velocity

The location of the maximum velocity within the bottom stream was plotted with distance from the propeller. Figure 7 shows the location of the maximum velocity in the bottom stream for each speed of rotation for a zero rudder angle. It can be seen that there is

no significant variation in the location of the maximum velocity, with an inclination of approximately 12 degrees observed towards the bottom for each speed of rotation. This is in sharp contrast to that obtained when there was no rudder fitted where the maximum velocity was located along the horizontal propeller axis. It would therefore appear that for a zero rudder angle the location of the maximum velocity is independent of propeller speed of rotation.

FIGURE 8. LOCATION OF THE MAXIMUM AXIAL VELOCITY WITHIN THE BOTTOM STREAM OF THE DIFFUSING PROPELLER JET FOR CHANGES IN RUDDER CONFIGURATION

FIGURE 9. EXPERIMENTAL CONSTANT 'C' VS. RUDDER ANGLE

The vertical location of the maximum velocity in the bottom stream of the jet was then plotted for all experiments and the results obtained for a typical rotational speed, with a varying rudder angle, are as shown in figure 8. The location of the maximum velocity appears to diverge at approximately the same rate for each rudder angle. The greatest depth to the maximum velocity was observed when the rudder is placed at 15 degrees up to a distance of 3 D_p and generally thereafter is greater when the rudder is positioned at zero degrees. The divergence angle was found to be approximately 12 degrees and this was found to be the general trend for this propeller at different rudder angles. The general trend showed that the greatest depths to the maximum velocity were observed when the rudder was placed at positive rudder angles. It can therefore be concluded that the depth to the maximum velocity is dependent of the rudder angle.

Equation for location of maximum velocity

Analysis of the change in position of the maximum velocity showed that its location could best be described by a linear decay equation of the type

$$\frac{R_{mx}}{R_{m0}} = Const. \left(\frac{X}{D_p} \right)$$

where R_{mx} is the maximum velocity location at any distance X from the propeller.

It was obvious that the constant term was a function of the rudder angle, as the location was seen to shift as the rudder angle changed. Figure 9 shows a plot of these constant values against the rudder angle, and it is clear that a significant variation can be observed between the positive and negative rudder angles. This is to be expected as the

negative angles cause the rudder to be turned into the bottom stream therefore hindering the flow, while with positive angles the stream is free to expand. Based on this physical interference two separate equations have been developed by which the position of the maximum velocity can be obtained, and these depend on the rudder angle range as follows;

Rudder angle range $-10 < \theta < +35$ degrees

$$\frac{R_{mx}}{R_{mo}} = (-0.659 + 0.002\theta) \left(\frac{X}{D_p} \right)$$

Rudder angle range $-35 < \theta < -10$ degrees

$$\frac{R_{mx}}{R_{mo}} = (-0.772 - 0.012\theta) \left(\frac{X}{D_p} \right)$$

These equations are a first approximation based on the current experimental investigation and further work would be recommended to provide a clearer understanding of the influence of the rudder on the location of the maximum velocity between the zero and -15 degree rudder position.

Decay of Maximum Axial Velocity

It has been shown that for a jet without a rudder, the decay of the maximum axial velocity is not constant throughout the jet, Qurrain. The present investigation has shown that the jet is fully established from the location of the end of the rudder and therefore a single relationship must be considered to describe the decay of the maximum velocity within the propeller jet with a rudder present.

The rate of decay of the maximum velocity was found to be independent of propeller rotational speed. The rate of decay of the maximum velocity however, varies significantly when compared to previous work due to the presence of the rudder. In order to establish a relationship for the rate of decay, the values of the maximum velocity, V_{max} , within the jet were non-dimensionalised with the maximum velocity at the face of the propeller, V_o , and the distance from the propeller, X , was divided by the propeller diameter, D_p . Analysis of the results was carried out on all the data and it was found that the following type of equation provided the best correlation for the results, as can be seen in figure 10.

$$\frac{V_{max}}{V_o} = A + B \left(LN \frac{X}{D_p} \right)$$

It was found for all tests that the B coefficient was constant and equal to 0.293. This shows that the actual rate of decay is independent of the rudder angle. There was however a significant variation observed in the values found for the A coefficients. This indicated that although the rudder had no influence on the rate of decay of velocity it clearly was influential in the initial magnitude of the maximum velocity. As was the case in the location of the maximum velocity the A coefficients were compared to the respective rudder angles and again positive and negative angles were seen to influence the magnitude of velocity. Again this is not unreasonable as has already been discussed. As before two equations by which this coefficient should be determined have been produced, again depending on the rudder angle considered.

Rudder angle range $-10 < \theta < +35$ degrees

$$A = 0.915 - 0.004(\theta)$$

Rudder angle range $-10 < \theta < -35$ degrees

$$A = 1.0 - 0.007(\theta)$$

Concluding Comments

The present investigation has studied the influence of the rudder within a ship's propeller jet, and has confirmed the formation of two high velocity streams, one directed upwards to the surface and the other directed downwards towards the bottom.

The axial velocity distribution at the face of the propeller could only be determined by solving a number of equations based on the results of previous work. The present investigation found that the velocity along the face of the propeller was related to the characteristics of the propeller blade. An equation was developed which related the magnitude of the axial velocity at any point along the blade to the properties of the blade at that point.

It was found that there was an increase in magnitude of the axial velocities by as much as 30% with the rudder present when compared to the jet without a rudder.

The location of the maximum velocity within the propeller jet was on the axis of each stream which were established from the position of the rudder. This led to a redefinition of the zone of established flow. Equations are presented which locate the maximum velocity in the vertical direction allowing for changes in rudder position. The maximum deflection of the bottom stream was observed for the zero rudder angle position and was found to be approximately 14 degrees.

Results have shown that the decay of the maximum velocity within each of the streams was the same at each of the angles tested and was independent of the propeller rotational speed. It was found that there was a logarithmic decay of the maximum velocity at each of the rudder angles tested and the magnitude of the velocity encountered was found to be dependent on rudder position.

By using the equations presented it is now possible for the engineer to establish the maximum velocity at any depth below a rotating propeller. Given the bed clearance conditions it is therefore possible to predict the magnitude of the velocity which will impact on the sea bed. Knowing this velocity, and an understanding of sediment movement prediction techniques, it is possible to design either suitable bed armour units or to predict eroded depths.

CHAPTER 347

MODELING INLET SAND BYPASSING

Christopher G. Creed¹

Abstract

Consideration of the magnitude and phasing of sand bypassing events with respect to incident wave conditions is necessary when modeling shoreline change adjacent to tidal inlets where sand bypassing occurs. Likewise, the effects of wave transformation over nearshore bathymetric features (i.e., ebb tidal shoals, bypassing bars, etc.) and the resulting variations in alongshore sand transport rates relative to bypass discharge locations should also be considered. This paper presents a method for developing time-dependent inlet sand bypassing data for use in predicting future shoreline change. The method includes developing a relationship between the local offshore wave climate, longshore sand transport regime and inlet sand bypassing utilizing coincident time series of (1) local wave climate and (2) sand bypassing. The proposed model is compared to two other typical sand bypassing models to demonstrate the importance of relating the wave climate and bypassing. The proposed method was used successfully to create a representative time series of both mechanical and natural sand bypassing data for a shoreline change study conducted for the downdrift shoreline of South Lake Worth Inlet, Florida.

Introduction

Shoreline change adjacent to inlets where sand bypassing occurs is directly related to the characteristics of bypassing conditions. Specifically, sand bypassing is responsible, in part, for the manner in which both the updrift and downdrift shorelines of an inlet respond to the offshore wave climate and longshore sand transport regime. That is, the rate at which sand is removed from an updrift shoreline or added to a downdrift shoreline relative to the magnitude of the longshore transport potential affects the rate of shoreline change. For example, if the bypassing rate is below average during

¹ Coastal Engineer, Olsen Associates, Inc., 4438 Herschel Street, Jacksonville, FL 32210.

above average transport conditions, the net effect would be an impoundment of sand along the updrift shoreline and erosion along the downdrift shoreline. Therefore, when modeling shoreline change adjacent to inlets where sand bypassing occurs, it is important to represent both longshore transport and bypassing conditions accurately. This requires that the magnitude and phasing of sand bypassing events with respect to incident wave conditions be considered.

Background

Shoreline change models are typically used to predict future response of shorelines where a beach fill or coastal structure may be constructed. The characteristics of the mechanisms which contribute to future shoreline change (i.e., the wave climate, longshore transport regime, updrift sand supply, bypassing, etc.), however, are generally not known *apriori*. Therefore, accurate prediction of future shoreline change requires assumptions regarding the future characteristics of mechanisms which contribute to shoreline change. Typically, the assumption is made that future conditions can be represented by average historical conditions.

In the instance where a time-dependent model is used, annual and seasonal variations in the shoreline change mechanisms are also represented. Time-dependent shoreline change models often require a time series of input conditions to represent the annual and seasonal variations in shoreline change. For example, a shoreline change model may require a wave time series to represent wave conditions. In predicting future shoreline change, wave conditions may be representative of historical average annual and seasonal conditions.

When modeling shoreline change for a shoreline adjacent to a tidal inlet where sand bypassing occurs, the time dependent nature of bypassing events and the relationship of sand bypassing to incident wave climate and transport regime must also be considered. It is known that inlet sand bypassing events, both mechanical and natural, are related to the incident wave climate and the resulting longshore sand transport regime. Considering this relationship, a *sand bypassing time series* which is correlated to the incident wave climate and resulting longshore sand transport regime is required to represent bypassing conditions accurately.

In instances where it is known that shoreline change adjacent to an inlet is directly affected by bypassing activities, bypassing data must be developed which are representative of the magnitude of bypassing quantities and a function of the incident wave climate. Developing representative wave and bypassing data, without consideration of their interdependence, may not produce an accurate representation of the mechanisms which contribute to shoreline change. A method for the development of this data is presented in the following.

Method

The purpose of the proposed method is to determine the relationship between wave conditions, longshore transport conditions, and sand bypassing. The method is therefore based upon the assumption that sand bypassing around an inlet is a function of both the incident wave climate and the resulting longshore sand transport regime. That is, it is assumed that sand bypassing occurs only when the wave and longshore transport conditions are such that a sufficient volume of material is transported toward an inlet which is mechanical or natural bypassing.

The method requires that coincident time series of historical wave and bypassing data are available. The wave data times series can be either from measured or hindcast sources. Bypassing data may be available from bypass plant records or other measurement efforts. Application of the method results in a correlation expression which describes the relationship between the magnitude and occurrence of bypassing events relative to that of wave and longshore sand transport events. This relationship can then be used along with an assumed representative wave data to formulate bypassing data for use in predicting future shoreline change.

Application of the method includes computing longshore transport conditions from offshore wave time series which correspond to the period for which sand bypassing data are available. Simplistically, the transport conditions may be computed with a longshore sand transport equation such as the CERC formula (Shore Protection Manual, 1984). The general CERC formula can be expressed as

$$Q = K H_b^{\frac{5}{2}} \sin 2\theta_b \quad (1)$$

where Q is the longshore sand transport rate, H_b is the incipient breaking wave height, θ_b is the local breaking wave angle relative to shore normal and K is a calibration coefficient. Incipient breaking wave heights can be computed from the offshore wave data assuming the wave climate is linear and monochromatic and the offshore bathymetric contours are straight and parallel. A time series of longshore transport data can then be compiled to correspond to the period and frequency of the bypassing data. The resulting longshore sand transport time series can be calibrated with the coefficient, K , to produce average annual transport conditions equivalent to known quantities for the region.

To determine the relationship between the transport and bypassing, the data are plotted and a best-fit expression is derived. This resulting expression implicitly describes the phasing and magnitude of bypassing relative to the offshore wave data.

Alternate Method. In instances where historical bypassing records are not available, an inlet sediment budget may be utilized along with the assumption that bypassing is proportionately related to the local longshore sand transport potential. Although this method does not strictly include the relationship between actual wave and bypassing data, it generally describes annual and seasonal variations in the wave climate and bypassing for modeling purposes. The technique simply describes bypassing as a fraction of longshore sand transport.

Once the relationship between transport and bypassing is determined, the wave time series may be applied to the expression to develop a corresponding bypassing time series which represents future bypassing conditions. This technique was applied for a shoreline change investigation described below.

Application

The proposed method was applied during a shoreline change model study conducted for South Lake Worth Inlet in South Florida. The intent of model study was to simulate shoreline change along approximately 12,000 feet of shoreline immediately downdrift of the inlet for purposes of formulating a Federal Shore Protection Project for the Town of Ocean Ridge, Florida ("Palm" 1996). Analysis of historical shoreline change data, as well as the general morphology and littoral transport patterns, suggested that sand bypassing across the inlet, both mechanical and natural, strongly influenced the downdrift shoreline. The shoreline change model GENESIS, developed by Hanson (1987) and Hanson and Kraus (1989), was used for the investigation. GENESIS is a one-line shoreline change model which computes time-dependent shoreline change using a time series of input wave and sand bypassing conditions. Realizing the importance of sand bypassing to the study shoreline, both mechanical and natural sand bypassing which occur at the inlet were modeled as input to the updrift boundary condition.

Background. South Lake Worth Inlet is located in southern Palm Beach County on the southeastern coast of Florida (Figure 1). The inlet was mechanically cut through the sandy barrier which separates the Atlantic Ocean and Lake Worth in 1927. The inlet is stabilized by two jetties; the north jetty extends about 122 meters farther seaward than the south jetty and is curved towards the southeast. In 1967, the inlet was modified to its current configuration in an attempt to improve its bypassing capacity and reduce interior shoaling. The regional net sand transport in the vicinity of the inlet is from north to south, with approximately eighty-five percent of the gross transport being southerly directed.

Figure 1: Location of South Lake Worth Inlet, Florida.

Despite natural and mechanical sand bypassing, the inlet acts as a partial littoral barrier to the net southerly drift of sand along Florida's southeast coast. Sand which drifts towards the inlet from the north is intercepted by the inlet's north jetty or diverted to the inlet's ebb and flood tidal shoals. Sand intercepted by the inlet's north jetty is impounded either in the fillet along the northern shoreline or mechanically bypassed to the southern shoreline. Sand diverted to the ebb shoal is stored either in the shoal platform, transported to the flood shoal and sand trap, or naturally bypassed to the southern shoreline. It is estimated that approximately 18 percent of the net southerly drift is intercepted and lost to the inlet system, resulting in a net sediment deficit along the downdrift shoreline. The net southerly sand transport in the vicinity of the inlet may vary between 134,000 and 172,000 cubic meters per year.

Sediment Budget. To quantify sand transport in the vicinity of South Lake Worth Inlet, Olsen Associates, Inc. (1990) developed a detailed nine-component sediment budget which quantitatively described sediment transport paths at South Lake Worth Inlet. The sediment transport components of the sediment budget are highlighted in Figure 2. Six of the nine sediment transport components of the sediment budget were

developed from available data. Using these values and the governing equations of the sediment budget, estimates of the natural bar bypassing and the net drift rate south of the inlet were calculated for a range of net littoral drift rates north of the inlet.

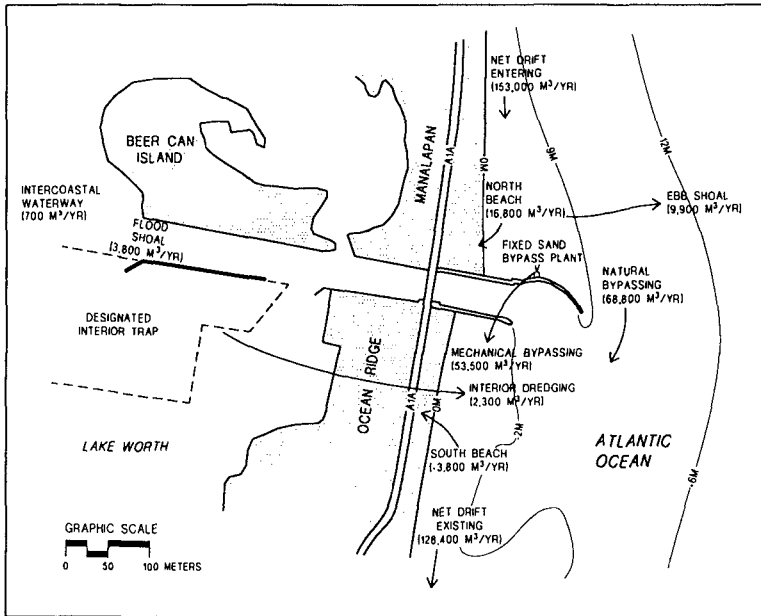

Figure 2: Sediment transport components for South Lake Worth Inlet, Florida.

Data collected since the 1967 modifications suggest that approximately 45 percent of the southerly net drift is bypassed across the ebb tidal shoal and bypassing bar. An additional 35 percent of the net southerly drift is bypassed by the fixed sand transfer plant.

Mechanical bypassing at the inlet is achieved with the inlet's sand transfer plant, which transports sand from the northern shoreline to a location between 60 and 150 meters south of the inlet. The plant is located atop the north jetty and bypasses sand from the northern to southern shoreline at a typical rate of about 53,500 cubic meters per year. Natural sand bypassing occurs along the inlet's ebb tidal shoal and bypassing bar platform. The bypassing bar attaches to the southern shoreline about 600 to 900 meters south of the inlet.

Because approximately 80 percent of the net transport is bypassed across the inlet, it was essential that this input to the study shoreline be included in model simulations.

Therefore, both mechanical and natural sand bypassing data (which were assumed to represent future bypassing conditions) were developed with the method described herein.

Mechanical Sand Bypassing Data. The relationship used to develop mechanical sand bypassing data representative of future conditions was determined from comparison of longshore sand transport data -- computed from offshore wave hindcast data -- and historical sand bypassing records. Mechanical bypassing records are available for the South Lake Worth Inlet sand transfer plant for the period from 1967 to the present. The bypassing rates are compiled from operation records and measured bypassing rates at the plant. WIS hindcast data are available for the area offshore of South Lake Worth Inlet for the period from 1956 to 1995. A time series of longshore sand transport was computed using these WIS hindcast wave data. The period for which the two databases overlap and are most reliable is 1970 to 1990. Therefore, it is this twenty year period for which longshore sand transport and mechanical sand bypassing data were compared.

The sand bypassing data were compared to both the net and southerly longshore transport components. This comparison revealed that mechanical bypassing is more closely correlated to the southerly transport component than the local net transport rate. (In fact, the mechanical sand bypassing plant operates only during periods of southerly directed transport.) The computed southerly transport data are plotted against the measured bypassing data in Figure 3. These data represent the twenty year period from 1970 to 1990. Inspection of the figure suggests a general trend in the data, where the magnitude of bypassing is related to the magnitude of southerly directed sand transport. The best-fit curve is of the form:

$$MB = aQ^b \quad (2)$$

where Q is the computed southerly transport rate from Eq. 1 (with $K=1.0$), MB is the reported mechanical bypassing rate, each in units of cubic meters per month, and a and b are coefficients. In this instance, the coefficients a and b were 29.0 and 0.54, respectively.

To demonstrate the effectiveness of this expression to represent actual mechanical sand bypassing data, a 9-year time series of southerly sand transport was applied to the expression to create a predicted 9-year time series of mechanical bypassing. The actual and predicted bypassing data for this period are presented in Figure 4. It is noted that areas of disagreement between actual and predicted bypassing records (such as the predicted spike in the latter part of 1974) may result from operational limitations of the sand bypass plant. Nonetheless, the comparison suggests that the mechanical sand bypassing at the inlet is correlated reasonably well with the incident wave climate.

Figure 3: Correlation between actual mechanical sand bypassing (1967-1990) and computed southerly sand transport at South Lake Worth Inlet, Florida.

Natural Sand Bypassing Data. A time series of natural sand bypassing related to the longshore sand transport time series was also required as input to the shoreline change model. Actual measurements of the quantity and occurrence of natural bypassing, however, are not available at most inlets, including South Lake Worth Inlet. Therefore, the inlet's sediment budget and the assumption that natural bypassing occurs only during periods of southerly directed transport were used to formulate a natural bypassing time series. That is, the "natural bypassing" time series was developed by assuming that north to south sand transport across the bypassing bar is proportionately correlated to the southerly longshore sand transport component. This assumption was based, in part, upon the comparison of computed southerly sand transport and recorded mechanical sand bypassing. The proportionality constant for natural bypassing (0.45) was determined from the inlet's sediment budget (Figure 2); i.e.,

Figure 4: Time Series of actual and computed mechanical sand bypassing at South Lake Worth Inlet, Florida.

$$NB = 0.45 Q \quad (3)$$

where NB is the rate of natural bypassing and Q is computed southerly transport rate from Eq. 1 (with $K=1.0$).

Shoreline Change Simulations. For purposes of predicting future shoreline change, a representative four year wave time series was developed for input to the GENESIS model. This time series was selected from the entire 38 year WIS hindcast time database as being most representative of average annual and seasonal variations in wave conditions offshore of the study site. Using this representative wave time series, corresponding mechanical and natural bypassing time series were computed using Eqs. 2 and 3, respectively. Both the wave and bypassing time series were used as input to the GENESIS for model simulations.

Bypassing Locations. The locations along which bypassed sand is supplied to the shoreline were also considered in the shoreline change investigation. As noted above, the study shoreline is supplied with bypassed material along two general areas. The sand which is mechanically bypassed is supplied to the shoreline within 60 to 150 meters south of the inlet. The sand which is bypassed naturally is supplied to the shoreline at the point where the natural bypassing bar attaches to the shoreline. This attachment point is some 600 to 900 meters south of the inlet.

Consideration of the locations along which the sand is supplied to the study shoreline was necessary because the alongshore distribution of sand transport is characterized by extreme accelerations and decelerations due to the effects of the inlet's ebb tidal shoal and bypassing bar on the incident wave climate. Because of these variations, shoreline change is strongly influenced by the locations along which bypassed material is supplied to the shoreline. To accommodate this sensitivity, sand was added to the model at the locations representative of the mechanical sand bypass plant discharge points and the average location at which the natural bypassing bar attaches to the shoreline.

As configured, the GENESIS model does not consider changes to the wave climate caused by such shallow features at South Lake Worth Inlet's ebb tidal shoal and bypassing bar. Because these changes to the wave climate are important to shoreline change and the movement of bypassed sand, a method was developed by Bodge, et.al. (1996) to consider the effects of nearshore bathymetric features on the wave climate. Briefly, the method computes the breaking waves conditions through a grid-based refraction analysis for wave conditions which are representative of the offshore time series. The breaking wave information is then "back-refracted" to a nearshore wave reference line which the GENESIS model is designed to accept. This technique,

therefore, includes the variations in breaking wave conditions created by nearshore bathymetric features (such as ebb tidal shoals and bypassing bars) in the wave data input to the GENESIS model. This provides for more accurate representation of the local transport conditions in the areas where sand is supplied to the shoreline through bypassing.

Comparison Bypass Model Comparison. To demonstrate the necessity of accurately representing the relationship between longshore sand transport and sand bypassing, two other representations of sand bypassing were developed. These include assuming that an annual equivalent volume of bypassing is supplied to the shoreline at a constant rate (*uniform*). The other assumes that an annual equivalent volume of bypass sand is supplied at the beginning of each year (*plug*). A graphical representation of these concepts is provided in Figure 5.

Figure 5: Concept of sand bypassing models.

These two bypassing models along with the bypassing model proposed herein (*time-varying*) were used to develop bypassing data for comparative model simulations. The representative four year wave time series described above was used to develop the bypassing data. Each representation of bypassing supplies an equivalent volume of sand to the model domain over the simulation period. For verification purposes, where both initial and final measured shorelines are available, model simulations were conducted for the 18 year period between 1975 and 1993. The results of the three comparative simulations are shown in Figure 6. In the figure, it is clear that the *time-varying* bypassing model provides a more accurate representation of measured shoreline change. The *uniform* and *slug* bypassing models fall short of the time-varying model by producing a significant build of sand along the northernmost section of the study shoreline. This is due to sand being supplied to the shoreline during periods of inactive longshore transport; thus allowing a build up of material which is not transported away when transport becomes active. To more clearly demonstrate these results, the differences between measured and computed shorelines are provided in Figure 7.

Figure 6: GENESIS shoreline change results using three sand bypassing models.

Figure 7: Difference between measured and computed shorelines.

Conclusions

A method is proposed to relate mechanical and natural inlet sand bypassing to the incident wave climate and develop a time series of bypassing for use as input to shoreline change models. Data requirements for the method include coincident time series of (1) local wave climate and (2) sand bypassing are required. Application of the model indicates that the magnitude and phasing of sand bypassing events with respect to incident wave conditions should be considered when modeling shoreline change adjacent to tidal inlets where sand bypassing occurs. The proposed method was used to successfully simulate shoreline change for the downdrift shoreline of South Lake Worth Inlet, Florida. U.S.A.

CHAPTER 348

AN APPROACH TO MODELING INLET AND BEACH EVOLUTION

Mark B. Gravens¹, A. M., ASCE

Abstract

Improved understanding of the physical processes controlling inlet and adjacent beach morphology is required to manage sand resources in the vicinity of tidal inlets and to reduce costs associated with structural rehabilitation, maintenance dredging of navigation channels, and mitigation of adverse impacts on adjacent shores. A quantitative modeling capability for estimating sediment fluxes, morphology evolution, and the interaction between the inlet and adjacent beaches is a goal of engineering research. This paper presents the initial phase of work aimed at developing empirical relationships between the physical processes and resulting inlet morphologic response, which are needed to formulate a modeling capability. First, the technical and computational requirements of the model are outlined. Then, a conceptual model of inlet sediment bypassing and a brief overview of a recently developed model (De Vriend et al. 1994) which appears to satisfy most of the model requirements is given. Finally, preliminary results of an empirical analysis of inlet ebb shoal geometric characteristics are presented.

Introduction

The presence of tidal inlets along a mainland or barrier island sandy shoreline represents a major morphological perturbation in the otherwise generally linear features (dune, berm, shoreline, longshore bar) that make up the coastal zone. The shoreface morphology at tidal inlets is a product of the changes in the physical forces that form the beachface. In the vicinity of tidal inlets, longshore currents generated by waves breaking at oblique angles to the shoreline interact with concentrated cross-shore currents that pass through the inlet gorge. Littoral sediments carried in the longshore current are swept into the inlet interior or are jetted offshore by the tidal currents. Over time, if the

¹ Research Hydraulic Engineer, U.S. Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Rd., Vicksburg, MS, 39180-6199, USA.

inlet cross-section is stable, depositional shoal features will develop. Walton and Adams (1976), Marino and Mehta (1987), and others have shown that the ebb shoal tends toward an equilibrium volume which can be related to the tidal prism. If flood shoal volumes are also assumed to approach an equilibrium condition or a near constant growth rate, then it follows that under natural conditions, an inlet system could form and in time (10's to 100 years), reach a near-equilibrium condition, in which a large percentage of the littoral drift bypasses the inlet to downdrift shorelines.

However, because navigable tidal inlets represent an important economic resource, many inlets have been stabilized with jetties or improved for navigation by dredging. Inlet stabilization by jetties has been shown to produce a seaward displacement of the ebb shoal (Kraus et al. 1994). Seaward movement of the ebb-tidal shoal can result in an increase in the volume of material comprising the shoal. Dean (1993) presented a conceptual model together with field examples that indicate that maintaining a channel through a tidal inlet that is deeper than the natural channel depth causes sediment to flow into the maintained channel, which comes at the expense of volumetric erosion of the beaches adjacent to the inlet. Consequently, engineering practices involving inlet stabilization by jetties and navigation channel dredging are increasingly cited for their role in the observed persistent erosion of adjacent shorelines.

In the United States, federal responsibility for the design, operation, and maintenance of inlet stabilization structures and navigation channels lies with the U.S. Army Corps of Engineers. Improved sand management in the vicinity of tidal inlets will reduce costs associated with structural rehabilitation, maintenance dredging, and mitigation of adverse shoreline impacts. However, a better understanding of the physical processes controlling inlet morphology is required, including estimating sediment fluxes, morphology evolution, and the interaction between the inlet and adjacent beaches. A quantitative modeling capability can help improve our understanding of the interaction between an inlet system and its adjacent beaches. The model to be developed is intended to aid in the analysis and prediction of inlet adjacent shoreline evolution over mid- to long-term time scales (1 to 10's of years), and spatial scales up to 10's of kilometers.

Model Requirements

Goals and Development Philosophy. The primary goal of the research discussed in this paper is to develop a predictive methodology to estimate quantitatively the potential impacts of engineering activities on shorelines adjacent to modified or engineered inlet systems. The desired use of the numerical model is to predict shoreline response within the reach of shoreline influenced by the inlet in response to different engineering activities. An inlet-shoreline response model is recognized for its value in providing a quantitative basis for the comparison of alternatives. Procedures for application also will include guidance for producing an ensemble of solutions based on Monte Carlo-type simulations produced from a combination of plausible input

conditions. The ensemble of solutions then may be examined to determine the range and the frequency of the outcomes within that solution set. Because this model is being designed for use by practicing coastal engineers, model development is being undertaken with the expressed intent of capturing the evolutionary trends of the shoreline and maximizing range of applicability. This development philosophy stems from the observation that models the engineer is most likely to use are those which he or she can understand and defend, and those which require minimum adjustment of calibration parameters. Traditional approaches to coastal engineering design are expected to become more reliable with the addition of objective and quantitative estimates of an inlet's total littoral impact, which will be provided by the numerical model.

Prediction Requirements. Inlets impact adjacent shores primarily by their action as a sediment sink; therefore, a fundamental requirement of the model is the capability to predict whether and to what degree an action will change the net volume of sand lost (trapped against stabilization structures or otherwise stored in inlet associated shoal features) from the adjacent shorelines. A related requirement is the need to predict the distribution of that sand deficit along the adjacent beaches. Furthermore, regulatory agencies asking for a prediction of project performance resulting from both natural and engineered site changes leads to the requirement for model prediction of, for example, sea-level rise, extended mechanical failure of bypassing equipment, and/or planned or unexpected delays in renourishing a project or performing routine maintenance dredging of a navigation channel. The parameter of primary interest in many situations and therefore required from the model predictions is the shoreline location. For other situations the profile geometry is also of keen interest and less frequently sediment volume in various locations around the inlet-adjacent beach system are required. Table 1 provides a list of specific model requirements. Predictions are required for engineering time scales (1 to 10's of years) and spatial scales corresponding with the total longshore extent of the inlet's impact (up to 10's of kilometers).

Physical Processes. Conceptually, inlets impact adjacent shorelines in two fundamental ways. One impact is the inlet channel as a sediment sink which results in a net loss of sediment from the adjacent beach systems. The second impact is the altering of wave and current patterns, which results in a change in sediment transport patterns. Therefore, the physical processes responsible for these fundamental functions of an inlet system must be captured in the numerical model at some appropriate level. The physical processes important to determining an inlet's overall impact to the littoral system are those which result in net sediment impoundment, jetty leakage, channel shoaling, and shoal formation. Sediment conservation requires that the net volumetric impact to the adjacent shorelines equal the net volume of sediment lost to the inlet. To be useful (to estimate the inlet's impact on adjacent shores), the model must compute the rate at which sediment is delivered to the inlet, the rate at which sediment is moved through the inlet (along its axis), and the rate at which sediment is transported across, around and away from the inlet. These quantities will enable estimation of that fraction of the littoral drift which bypasses the inlet from that which is trapped within

Table 1. Model Requirements

Model Requirement	Comments
Foreshore slope changes	Beach profile slopes at stabilized tidal inlets are typically steeper updrift of the inlet and milder downdrift of the inlet as compared to beach profiles not influenced by inlet system.
Sediment point/line source and sink capabilities	To effectively evaluate many typical engineering activities (e.g., sand bypassing, beach nourishment), the capability to model point and/or line sediment sources and sinks is required.
Structure specification	To evaluate the influence of modifying inlet stabilization structures, the model must be sensitive to user-specified characteristics of the structures (e.g., length, orientation and configuration, permeability, weir sections, elevation, etc.).
Wave transformation and the possibility of multiple wave breaker lines	Wave transformation, including shoaling, refraction, diffraction and the possibility of multiple wave breaker lines with differing breaker characteristics, is required to capture the influence of the ebb shoal feature on the incident wave climate.
Hindcast capability	To demonstrate reasonability in predictions, the model must be able to simulate pre-project adjacent beach evolution.
Forecast capability	To be useful in evaluating the relative merits of competing design alternatives, the model must be able to provide mid- to long-term (1 to 10's of years) existing- condition forecasts as well as with-project forecasts.
Scoping mode / design mode applications	To quickly and efficiently provide estimates of the impact of preliminary design considerations, as well as to provide detailed estimates of refined design alternatives, the model is required to have the capability of being operated with differing levels of sophistication and data requirements.
Input data requirements	Data required to operate the model must be consistent with typically available data and/or data which can be reasonably collected.
Compatible with sediment budget methodology	Model input and output should be compatible with classical sediment budget methodologies (e.g., sediment budget information can be input to the model and model outputs can be integrated back into the sediment budget).

the inlet or is otherwise lost to the littoral system. How the net volumetric impact of the inlet is distributed along the adjacent shores is determined by hydrodynamic and sediment transport processes which exist away from the inlet. In short, modeling sediment movement in the vicinity of inlets ultimately involves essentially all of the most complicated processes of coastal sediment transport.

Target Inlet Type and Behavior. In nature, inlet systems vary widely in their characteristics and behaviors, and it is doubtful that one model or even one modeling approach would be equally applicable to all inlet systems. It is expected that the developed model will not be able to adequately predict all inlet behaviors and, therefore, will be more applicable to certain types of inlets than to others. Consequently, it is essential that the target inlet type and behavior are clearly defined. The inlet systems for which the model is being developed may be characterized as being relatively stable, often the result of stabilization structures for the purpose of providing safe navigation. The system is viewed as being in a state of dynamic equilibrium, meaning that the inlet system responds to seasonal variations in the wave and water level climate as well as to storm events. However, it is assumed that these responses are short-term or seasonal variations imposed upon an underlying state of equilibrium and do not have a destabilizing effect on the inlet system nor do they significantly alter the underlying equilibrium state. Engineering activities, on the other hand, can both temporarily displace the system from its equilibrium condition (e.g., sand mining from the ebb shoal) and in some cases change the inlet's equilibrium state (e.g., by changing the tidal prism). In either case, the inlet system will evolve toward either its old or new equilibrium state with impacts ultimately occurring on the adjacent beaches. Natural sediment bypassing is assumed to be a semi-continuous process, and the possibility of random or periodic bar welding on downdrift shorelines is excluded. The model will not allow the inlet to migrate as many natural inlet systems do. Furthermore, because sediment transport along the outer ebb delta is computed as a function of the incident wave energy the model will be more applicable to wave dominated and mixed-energy inlets than it will to tide dominated inlets.

Conceptual Model of Inlet Sediment Bypassing

Inlet sediment bypassing is the process by which littoral material delivered to the inlet from the updrift beach makes its way across the inlet system and is integrated into the littoral material on the downdrift beach. In a series of papers (Bruun and Gerritsen 1959, Bruun 1967, and Bruun 1978), a model has been presented that describes two possible pathways for inlet sediment bypassing by natural action: 1) bypassing on an offshore bar, and 2) bypassing by tidal flow action. In bar bypassing, littoral material that is delivered to the inlet from the updrift shorelines is transported along a submerged bar in front of the inlet system and delivered to the downdrift shoreline. In tidal flow bypassing littoral material is pulled through the inlet by flood currents and then discharged out of the inlet by ebb currents in the downdrift direction. Though sediment may cycle several times through the inlet, it is ultimately bypassed to the downdrift

shoreline. Bruun indicated that in most cases a combination of both of these mechanisms for natural bypassing is active but that the dominant process could be identified by examining the ratio of the tidal prism over the total littoral drift.

FitzGerald (1988) presented three conceptual models to explain inlet sediment bypassing along mixed energy coasts. These models are categorized according to the stability of the inlet throat and movement of the main ebb channel. These are: 1) inlet migration and spit breaching, 2) stable inlet processes, and 3) ebb-tidal delta breaching. In the first model, the entire inlet migrates downcoast leaving a trailing spit extending from the updrift barrier. The resulting elongation of the inlet channel becomes hydraulically inefficient for tidal flow between the ocean and the bay. Ultimately the spit is breached during a storm and the new channel which provides a shorter route for tidal exchange will normally remain open while the less efficient old inlet channel closes. In the second model, the inlet throat position and the main ebb channel do not migrate. Sand bypassing at these inlets occurs through the formation, landward migration and welding of large bar complexes to the downdrift shoreline. In the third model, the location of the inlet throat is stable, but the main ebb channel migrates. The dominant direction of longshore sediment transport causes a preferential accumulation of sand on the updrift side of the ebb-tidal delta which results in a deflection of the main ebb channel. Similar to the first model, the migration of the ebb channel ultimately results in a hydraulically inefficient channel and a new channel breaches through an updrift spillover lobe channel. Ebb-tidal delta breaching results in the bypassing of a large portion of the ebb delta sand bodies. Some of this sand fills the abandoned channel while the rest forms a large bar complex that ultimately migrates onshore and attaches to the downdrift shoreline. FitzGerald summarized by indicating that during the history of a particular inlet, all three bypassing processes may dominate at one time or another. He also states that Bruun and Gerritsen's (1959) bar-bypassing mechanism (the movement of sand around an inlet by wave action along the terminal lobe of the ebb-tidal shoal) is an active but secondary process at most mixed-energy tidal inlet systems.

For the target inlet type and behavior described previously we believe that the bypassing models of Bruun and Gerritsen (1959) are more applicable than those of FitzGerald (1988). From a long-term (10's of years) perspective the net effect of FitzGerald's bypassing models could be idealized as a sediment drift along the outer edge or crest of the ebb delta from the updrift to the downdrift island. However, for shorter time periods (up to 10 years) which are of interest to us, FitzGerald's models are not compatible with the approach we have adopted. For the development of a computational model for inlet adjacent beach evolution the mid- to long-term (1 to 10's of years), net transport patterns near the inlet are idealized as shown in Figure 1. This idealization is a substantial simplification of the real situation, but it is consistent with typically available data, the level of schematization envisioned for the computational model and our capability to estimate details of sand transport at tidal inlets.

Figure 1. Conceptual model of inlet sediment bypassing.

Computational Approach

The computational approach selected for development of the inlet and adjacent beach evolution model falls into the class of models described by Kraus (1989) as multi-contour line models. This class of model was selected because the capabilities and characteristics of the model best satisfied the needs identified in a requirements analysis for inlet adjacent beach evolution modeling (Truitt and Bodge 1995). The initial development of a morphological behavior model for the outer delta of mixed-energy tidal inlets (De Vriend et al. 1994) tends to confirm that the selected computational approach has some merit and the interest of researchers. In the outer delta model, the two-line model concept of Bakker (1968) is extended to a situation where the coast is interrupted by a tidal inlet. The behavior of adjacent island coasts are modeled directly utilizing a two-line modeling approach (evolution of a beach line and a foreshore line); at the inlet, the beach line is discontinued because there is no subaerial beach profile at this location. The foreshore or inshore line, however, protrudes seaward at the location of the inlet, thereby representing the inlet delta or ebb shoal. Based on empirical relationships for the equilibrium state of the ebb shoal, the protrusion distance and geometric configuration of the ebb shoal are determined. The inlet-adjacent beach system and its evolution are described by: 1) computed wave-driven sediment fluxes along the adjacent island coasts and along the seaward edge of the ebb shoal, 2) specified net sediment fluxes through the inlet channel, and 3) the requirement for sediment continuity at six locations.

The outer delta model includes consideration of sediment fluxes through the main ebb channel as well as sediment fluxes through flood channels located near the beaches adjacent to the inlet. Sediment flux through the flood channels is fed by both the beach line and the inshore line. The equilibrium state of the delta (volume, seaward protrusion) is described using empirical relationships. A sediment balance is maintained throughout the evolution, and the sediment demand or supply by the basin is taken into account as an input parameter. The model output consists of the cross-shore positions of the beach line and the inshore line as a function of time and the longshore coordinate. It is noted, however, that the model developers (De Vriend et al. 1994) caution that the model results should be interpreted at a higher aggregation level (e.g., the trend of predicted change should be given more weight than the predicted magnitude of change). For more details on the outer delta model and its validation the reader is referred to the Master's thesis of Bilse (1993).

Empirical Analysis

Goals. To refine and expand on the initial model developed by De Vriend et al. (1994), a focused empirical analysis and parameterization of inlet geometry and processes has been undertaken. The goal of this research is to characterize the volume, geometric shape, and general location of the ebb shoal based on estimable quantities such as tidal prism, magnitude of net and gross longshore sand transport rates, and tidal range. U.S. inlets with rich temporal and spatial historical data sets are being analyzed. Specific analysis to be conducted include: 1) confirmation of the ebb shoal volume tidal prism relationship proposed by Walton and Adams (1976), 2) investigate the shoal volume to shoal protrusion relationship assumed by De Vriend et al. (1994), 3) the correlation, between the ebb shoal aspect ratio (longshore extent/cross-shore extent) and the tidal prism and/or net or gross longshore sand transport rates, 4) the relative stability of updrift and downdrift shoreline offsets, and 5) the correlation, between ebb shoal skewness (offset between ebb shoal centroid and inlet throat at jetty tips) and net and gross longshore sand transport rates.

Status. At present this analysis has included the geometric analysis of four tidal inlets along the eastern US Atlantic coast. The four inlets are: 1) Ocean City Inlet located in Ocean City, Maryland, 2) Barnegat Inlet located in central New Jersey, 3) Moriches Inlet located between Fire Island and Westhampton Beach on Long Island, New York, and 4) Shinnecock Inlet located between Tiana Beach and Southampton Beach on Long Island, New York. The analysis has not progressed to the point where new or refined empirical relationships can be proposed, but procedures for the geometric analyses of ebb tidal shoals have been developed, and their application to the four inlet systems will be discussed in the remainder of this paper. (We plan to extend this geometric analysis to a number of other inlet systems in the future at which time a database of the physical driving forces will be integrated for the development of new or updated empirical relationships.)

Methods. The bathymetry data were obtained by three methods, standard hydrographic surveys using a vessel mounted fathometer, sea-sled beach profile surveys, and airborne LIDAR (L*ight* D*etection* A*nd* R*anging*) surveys obtained using the helicopter based SHOALS (S*canning* H*ydrographic* O*perational* A*irborne* L*idar* S*urvey*) system. In all cases some combination of these survey methods were used to obtain the complete bathymetric coverage data sets. The procedure begins by developing a digital terrain model (DTM) using the original bathymetric data as input. Contours were then generated with reference to the National Geodetic Vertical Datum (NGVD). A polygon was then drawn around the ebb shoal. Typically, the offshore boundary of the polygon followed along the 10- to 11-m NGVD contour (the landward most contour that does not protrude seaward at the ebb shoal). The landward boundary followed along the 0-m NGVD contour. The lateral boundaries were selected at an alongshore location corresponding to where the contours began to protrude seaward around the shoal. A least-squares best-fit line was computed for contours at 1-m intervals outside the ebb shoal polygon. These computed best-fit contours on either side of the ebb shoal polygon were joined and then smoothed using the cubic B-spline method. The “no ebb shoal” bathymetry was estimated by digitizing the smoothed best-fit contours and then generating a DTM of the result. The next step involved taking the difference between the idealized “no ebb shoal” DTM and the original bathymetry DTM within the ebb shoal polygon. The result of this differencing operation is a DTM that we will refer to as the “residual” ebb shoal topography. This terminology describes the morphological residual of the formation of the ebb-tidal shoal; topography is used because the residual is described in terms of positive elevations and no longer represents a bathymetry. The residual ebb shoal topography was used to estimate the volume and geometric configuration of the ebb shoal. Figure 2 provides plots of the ebb shoal bathymetry, the idealized no ebb shoal bathymetry, and the residual ebb shoal topography for each of the four inlet systems examined. This procedure is similar to that used by Dean and Walton (1973) but employs modern terrain modeling software which, to some extent, reduces the subjectivity of the analysis.

Results. Figures 3-6 are contour plots of the residual ebb shoal topography with the extracted geometric characteristics indicated for Barnegat, Ocean City, Shinnecock, and Moriches inlets, respectively. Shown in the figures are the 1-, 3-, and 5-m contours of the residual ebb shoal topography with their alongshore and offshore dimensions. Also indicated is the location of the centroid of the residual ebb shoal topography with respect to the inlet throat at the tips of the inlet jetties. Without examination of the site-specific physical driving forces (e.g., tidal prism, tide range, wave energy, net and gross longshore sand transport rates etc.), we are unable at this time to draw conclusions or explain the differences in the geometric configuration of these four inlet systems.

Conclusion

This paper documents the initial phase of work that has been undertaken to develop a needed modeling capability in the vicinity of tidal inlets. The requirements

of the numerical model from a philosophical and practical standpoint were documented. The characteristics of the inlet system for which the tool is expected to be applicable were identified. A conceptual model of inlet sediment bypassing consistent with the envisioned computational model and sediment budget methodology was presented. A recently proposed computational approach to modeling the behavior of inlet and adjacent beach systems that appears to satisfy many of the model requirements defined herein and, which we plan to extend through this research, was briefly reviewed. Procedures for characterizing the geometry of an inlet system were presented together with the application of those procedures to four inlet systems located along the central U.S. Atlantic coast.

CHAPTER 349

Hydrodynamics of a bar in a flood channel - the Westerschelde estuary

Claire Jeuken¹

Abstract

Several long-term current meter observations (30 days) over a complex flood shield, i.e. an estuarine bar, display major temporal and spatial variations in current asymmetry. The variations in current asymmetry indicate the presence of small-scale circulations of sediment that are induced by smaller channels that penetrate the bar. The current meter observations and depth-averaged current patterns obtained with an ADCP revealed processes of advective flow acceleration and deceleration, as well as flow convergence and divergence, over the bars in the small channels.

Introduction

Estuaries are important coastal systems, providing natural navigation channels as well as habitats for marine flora and fauna, and recreational space. The Westerschelde forms the seaward, marine part (length 60 km) of the Schelde estuary (total length 160 km) and has a well-developed system of channels and intertidal shoals (Fig. 1a). The meandering ebb channels form the main navigation channel for ocean shipping to the harbours of Antwerpen and Gent. The shorter, straight flood channels are only suitable for small ships as the landward channel-margin of the flood channels is marked by a shallow extensive bar. Moreover, the bars in the flood channels display a complex topography due the presence of migrating connecting channels, the smaller channels that penetrate the bar and connect the main ebb and flood channel. To maintain the shipping lane dredging is carried out at the deeper bars in the main ebb channels. At present approximately $8 \cdot 10^6$ m³ of sediment is dredged annually. A further deepening of the bars, to enable the passage of larger ships, is planned for the near future. A better understanding of the morphodynamics of channels and shoals and the processes over bars in tidal channels in particular, is important for the management of the estuarine system and for determining the optimal dredging strategies. Recent developments in understanding the morphodynamics of channels and shoals have resulted in the formulation of different types of models (De Vriend (1996), De Vriend and Ribberink (1996)). Bars in tidal channels are however still understudied (Dalrymple and Rhodes, 1995 for a review).

This paper discusses the hydrodynamics of a complex bar at the end of a main flood channel, based on field observations. Flow computations with a 1D-network model indicate that this bar largely determines the distribution of tidal flow between the main ebb and flood channels during the periods of maximum flow (Jeuken, submitted). Objective of this study is to identify spatial and temporal variations of the tidal flow that are important for bar morphology and sediment transport patterns over the bar. Herein two aspects of tidal flow are considered: 1) Spatial velocity gradients and 2) differences between the velocity during ebb and flood, often referred to as current asymmetry. Spatial velocity gradients largely control processes of erosion and sedimentation. In literature tidal current asymmetry is often used as a first indicator for the direction of net sediment transport (e.g. Aubrey, 1986; Dronkers, 1986; Friederichs and Aubrey, 1988; Van de Kreeke and Robaczewska, 1993; Lessa and Masselink, 1995). In most studies current asymmetry is based on the amplitude of velocity components, often derived from a harmonic analysis of the velocity record. In this study a different approach is used to quantify variations in current asymmetry.

Figure 1 Location and channel configuration in the study area. a) the Westerschelde, b) the main study area. FC= main flood channel, EC=main ebb channel, c#=connecting channel (#=number), B= bar in main channel, b= bar in connecting channel.

The study area

An overview of the general hydraulic and morphologic evolution of the Schelde estuary is given by Van den Berg et.al. (in press). The main characteristics are described in this section. The Schelde is a tide-dominated meso-tidal estuary. The vertical tide displays a general asymmetry characterized by a faster rise than fall. This asymmetry increases in landward direction. In addition the vertical tide shows a pronounced neap-spring tidal variation as do the surface gradients and tidal currents. Maximum depth-averaged current velocities are in the order of 1-1.5m/s.

The larger channels in the Westerschelde display a regular returning pattern consisting of a meander-shaped ebb channel and a straight flood channel, separated by shoals (Fig. 1b). The shoals are bisected by smaller channels. These so called connecting channels form connections between the main ebb and flood channel and owe their existence to water level differences between the channels. Most connecting channels occur in the area of the bar in the main flood channel and tend to display a cyclic behaviour on the timescale of one to several decades. The shallow bar in the main flood channel is marked by various connecting channels, that originated and developed from 1986/1987. The small bars in the connecting channels are superimposed on the large bar in the main flood channel. The connecting channels C3 and C4 together reflect the morphologic characteristics of the main ebb and flood channel with respect to channel alignment and location and depth of the bars. At present (september 1996) channel C3 is rapidly degenerating. A new connecting channel has formed north of connecting channel C4.

Field observations

'Flachsee' impeller-type current meters were deployed at several locations during five measurement campaigns between April 1994 and February 1996 (Fig. 2). The current meters registered current velocity and direction for periods of thirty days with a sampling interval of ten minutes and a sampling period of one minute. At each location two current meters were deployed at the same measurement height, for validation purposes. A comparison of the double current meter deployments revealed an average difference in speed of about five percent, whereas the average difference in current direction approximated three degrees.

Detailed observations of the flow response over the small bars in two connecting channels were obtained in the summer of 1995 with a ship-borne, broad-banded two pulse Acoustic Doppler Current Profiler (ADCP). Measurements were carried out along a straight transect, oriented parallel to the general alignment of each channel, for a period of thirteen hours (Fig. 2b). The measurements along transect 1 were carried out during mean tide in June 1995. The measurements along transect 2 were obtained during spring tide in August 1995. The settings and instrumental accuracy of the ADCP during the two surveys are summarized in Table 1.

Table 1 System configuration of the ADCP during the two surveys

Transect	1	2
Acoustic frequency (kHz)	600	600
Pings per ensemble	5	20
Horizontal sampling interval (m)	10-15	40-50
Vertical bin size (m)	0.5	0.5
Depth range (m)	2.74-20	2.85-20
Velocity precision (m/s)	0.06	0.03
Compass precision (°)	1	1

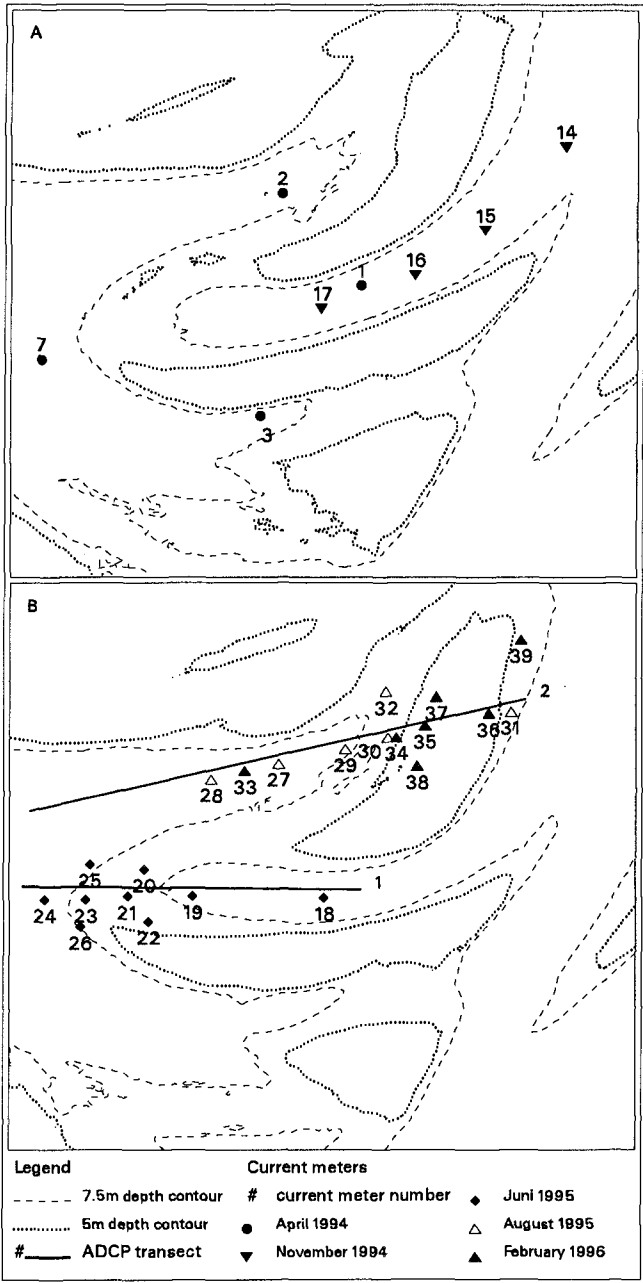

Figure 2 Locations of measurements. a) measurements in 1994 b) measurements in 1995 and 1996. For location of the bar see inset in Figure 1b.

Data-analysis

The current meter data were used to quantify temporal and spatial variations in current asymmetry and to characterize the current patterns over the small bars in the connecting channels. Prior to further analysis, the noise in the velocity data was reduced by applying a low-pass smoothing filter to the North-South and East-West velocity components.

The relative height of the current meters changed with time as a result of the large tidal range (3.3-4.75m) and the small water depths (5-13m). This variation in measurement height inhibit a comparison of measured ebb and flood velocities. Therefore measured current velocities (not direction) were converted to depth-averaged values, by assuming the logarithmic velocity profile of steady and uniform flow and an averaged roughness length based on bedform dimensions ($z_0=0.033k_s$, $k_s=0.4m$). In areas of major advective flow acceleration and deceleration this results in under-estimated (flow deceleration) and over-estimated (accelerating flow) depth-averaged velocities. These effects were not taken into account. The obtained time-series of the depth-averaged velocity vectors were then used to compute significant current vectors for each ebb and flood period. The significant velocity is defined as the mean of the 1/3 highest current velocities and represents the conditions near maximum flow over a period of about two hours. For each current meter location relationships between significant velocity (ebb and flood) and observed tidal range were determined by applying a linear regression analysis. The linear relationships were then used to compute significant ebb and flood velocities during mean, neap and spring tide. This was done by substituting the tidal range for neap, mean and spring tide in the linear relationships. Current asymmetry was then defined as the natural logarithm of the ratio of significant ebb velocity over significant flood velocity. A positive current asymmetry indicates ebb-dominated flow. A negative asymmetry indicates flood-dominated flow. The advantage of the significant velocity is, that it gives a better weighting of the tidal variation of current velocities than the often used maximum velocity.

The ADCP observations were used to determine variations in the depth-averaged flow patterns over the small bars in the connecting channels. Prior to further analysis the noise in the ADCP data was reduced by applying a low-pass, infinite impulse response filter to the North-South and East-West velocity components (Stanley et.al. 1984).

The computation of depth-averaged velocities implies extrapolation of the velocity profiles towards bottom and water surface. Extrapolation of the velocity profile was done by fitting a series of three shapefunctions through the data using a least squares method. This method has been derived from the shapefunction approach described by Zitman (1992) and has been previously applied by Van de Meene (1994). As winds were low during the ADCP measurements, the contribution of wind stress to the current velocity was neglected. Then the vertical velocity profile in North-South and East-West direction can be expressed as (Zitman, 1992):

$$u(\zeta) = \sum_{k=1}^m F_k \cdot f_k(\zeta) \quad (1)$$

where f_k is the series of shapefunctions, ζ is the dimensionless vertical coordinate and m is the number of shapefunctions ($m=3$ in the present analysis). The weights F_k are the unknowns to be determined using the measured velocity profile $u(\zeta)$. Figure 3 shows the applied shapefunctions together with an example of a curve fitted through observations. The shapefunction approach was used only as a statistical, curve-fitting tool, essentially to compute the depth-averaged current vectors in an objective way. The advantage of this approach is that it is possible to

describe velocity profiles that deviate from e.g. a parabolic profile.

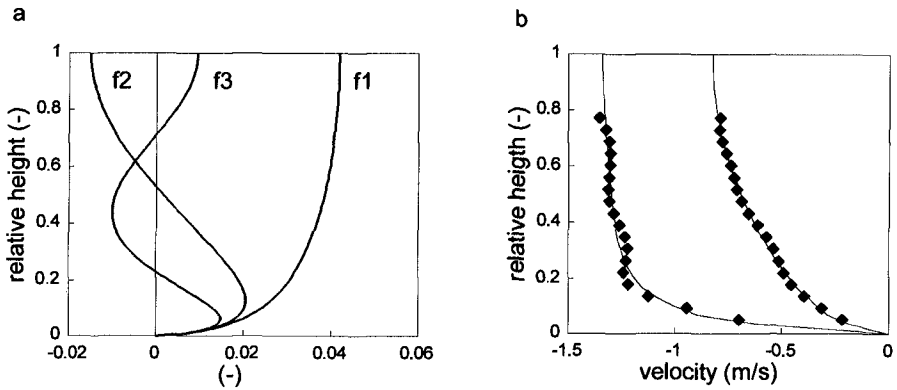

Figure 3 Shapefunction approach. a) the three shapefunctions used in the analysis, b) comparison of measured velocity components (\blacklozenge) and fit (-).

Variations of current asymmetry over the bar in the main flood channel

Figure 4 shows spatial patterns of current asymmetry over the bar in the main flood channel for mean, neap and spring tide. The spatial variation of current asymmetry in Figure 4a is related to the presence and morphology of the connecting channels. In the connecting ebb channel and at the landward side of the bar in the connecting flood channel current asymmetry ranges between 0 and 0.11, indicating that ebb velocities exceed flood velocities by about 0 to 12 percent. In the connecting flood channels and at the seaward side of the bar in the connecting ebb channel, negative current asymmetries of -0.12 to -0.31 occur, indicating flood-dominated flow. In these areas flood velocities are 12 to 40 percent stronger than the ebb velocities. The bars in the connecting channels form the transition zones between ebb-dominated and flood-dominated flow. Current asymmetry changes with tidal range (Fig.4b). In the connecting ebb channel and at the landward side of the bar in the connecting flood channel, current asymmetry decreases with 6 to 25 percent when tidal range increases from 3.3 to 4.75m. At some locations in the connecting ebb channel tidal flow becomes even slightly flood-dominated during spring tide (locations 15, 20, 21 and 22 in Fig. 2). In the connecting flood channels and at the seaward side of the bar in the connecting ebb channel current asymmetry increases with 10 to 34 percent with increasing tidal range.

The spatial variation in current asymmetry indicates small-scale circulations of net sediment transport over the bar in the main flood channel, that are induced by connecting ebb and flood channels (Fig. 5a). This means net ebb transports in the ebb channel and net flood transports in the flood channel. The circulations confirm the concept of mutually evasive ebb and flood channels of Van Veen (1950), who identified the presence of ebb-dominated and flood-dominated channels on the basis of net water transports and the location of the bars in tidal channels. The changes in current asymmetry with tidal range, has two important implications for the small-scale circulations (Fig. 5b): 1) The intensity of the circulation is not constant in time and 2) the circulation is not closed. The changes in current asymmetry over the neap-spring tidal cycle indicate that the magnitude of net sediment transport, the intensity,

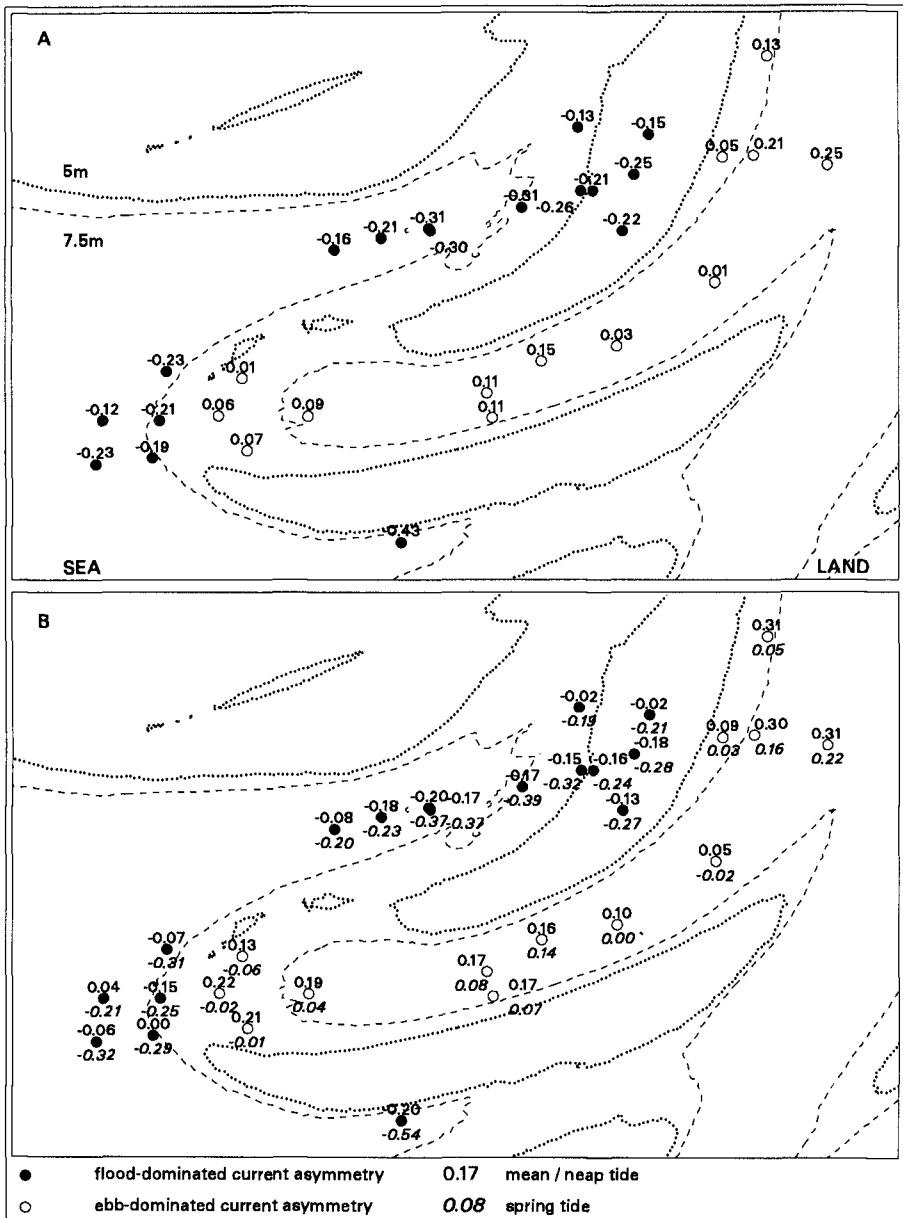

Figure 4 Patterns of current asymmetry. a) mean tide, b) neap and spring tide

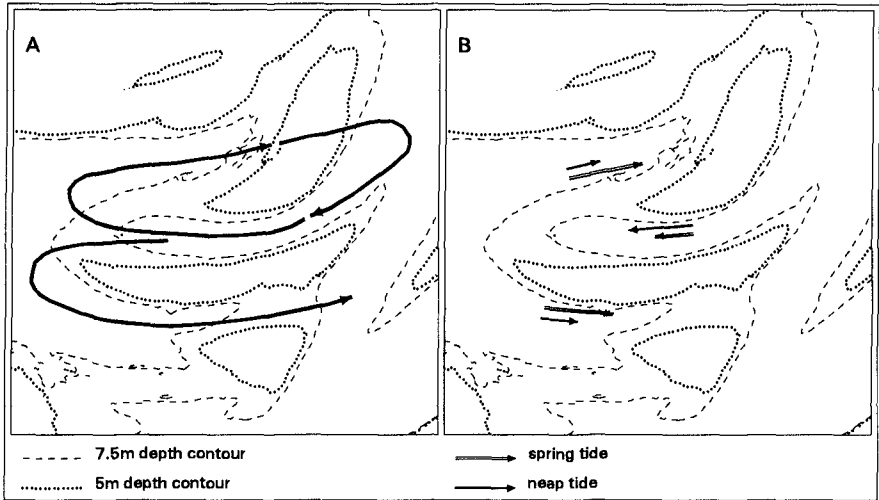

Fig. 5 Implications of the variations in current asymmetry for the patterns of net sediment transport. a) Small-scale circulations, b) the relative magnitude of net sediment transports during neap and spring tide

changes with tidal range. The decrease in current asymmetry in the ebb channel with increasing tidal range indicates larger net ebb transports in the ebb channel during neap tide than during spring tide. The increase of current asymmetry in the flood channel indicates smaller net flood transports during neap tide than during spring tide. This difference between ebb and flood channel means that the circulation is not closed. A net flood-dominated component that increases with tidal range is likely as the flood-dominated current asymmetry is larger than the ebb-dominated current asymmetry. Moreover the morphology of the bar is dominated by connecting flood channels. Computed sediment transports (not shown), based on the current observations, confirm the above inferred spatial and temporal variations in net sediment transport.

Flow response over the bars in two connecting channels

Figure 6 and 7 summarize the flow characteristics over the bar in the connecting ebb channel during mean tidal conditions. Figure 6 shows the pattern of significant current vectors in June 1995. Figure 7 displays the pattern of depth-averaged along-transect and cross-transect velocities during accelerating, maximum and decelerating tidal flow. During ebb the pattern of significant current vectors displays an ebb flow flowing around the bar (Fig. 6a). At the upstream side of the bar the ebb flow diverges and shows minor flow decelerations towards the bar of about 7 percent (0.08m/s). Significant current directions at location 20 and 22 differ by twenty degrees (see Fig. 2b for locations). At the downstream side of the bar the ebb flow converges and strongly decelerates with about 25 percent (0.25m/s). The ADCP observations confirm the patterns of flow deceleration (Fig. 7). The depth-averaged velocity pattern shows an instantaneous drop in current velocity as soon as the ebb flow passes the top of the bar. The depth-averaged velocity reduces with 28 percent (0.3m/s) on average. The flow reduction tends to increase with time and decreasing

water level. In addition the ADCP observations show a tendency towards small flow acceleration just before the top of the bar during maximum and decelerating ebb flow. The small cross-channel velocity component, both during ebb and flood, indicates tidal flow approximately parallel to the ADCP-transect (with 5°). Thus the ebb flow diverges and decelerates towards the bar, slightly accelerates near the top of the bar and converges and strongly decelerates after passing the top of the bar.

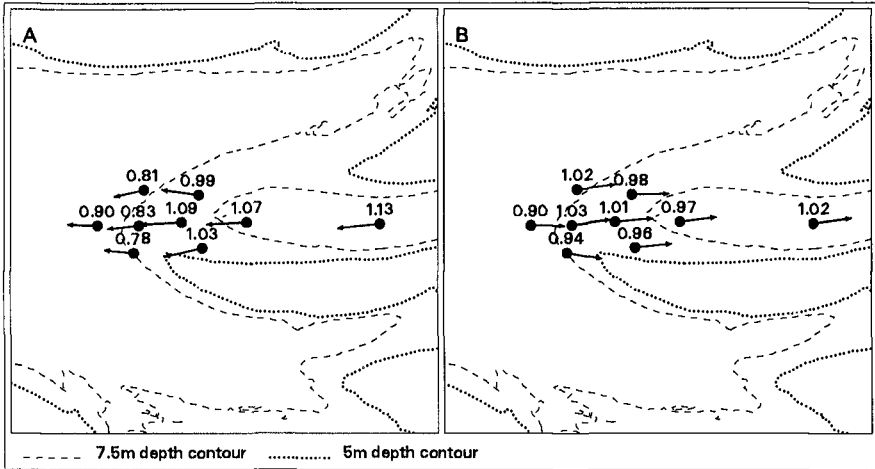

Fig. 6 Mean significant current vectors over the bar in the connecting ebb channel during mean tide in June 1995. a) ebb, b) flood.

The flood displays a small tendency towards flow around the bar (Fig. 6b). The pattern of significant current vectors shows flow divergence at the upstream (seaward) side of the bar that is accompanied by an increase in current velocities of about 14 percent (0.13m/s). At the downstream side of the bar the current vectors are aligned more or less parallel and only minor velocity gradients are observed. The ADCP observations also display flow acceleration at the upstream side of the bar (Fig.7). Depth-averaged velocities increase with about 10 percent (0.1m/s). At the downstream side, between 500 and 1200 meters, reductions in current velocity of about 10 percent (0.1m/s) are observed. Thus the flood flow slightly diverges and accelerates over the bar.

The characteristics of the flow pattern over the bar in the connecting flood channel during spring tide, measured in August 1995 and February 1996, are summarized in Figures 8 and 9. During ebb the significant current pattern displays flow deceleration over the bar (Fig 8a). At the downstream side of the bar current velocities are 15 to 30 percent smaller than near the top of the bar (location 36, Fig. 2b). The gradual change in current direction between locations 37 and 38 of fourteen degrees, indicates a tendency towards flow convergence. The ADCP observations (Fig.9) reveal deflection of the ebb flow at the upstream side of the bar, where the current vectors are inclined towards the ADCP-transect by 15-25 degrees (not shown). Despite this current deflection a major velocity gradient over the bar can be identified. On average current velocities at the top of the bar exceed currents at the upstream and downstream side of the bar by 30 percent (0.4-0.5m/s). These large velocity differences indicate flow acceleration at the upstream side of the bar and

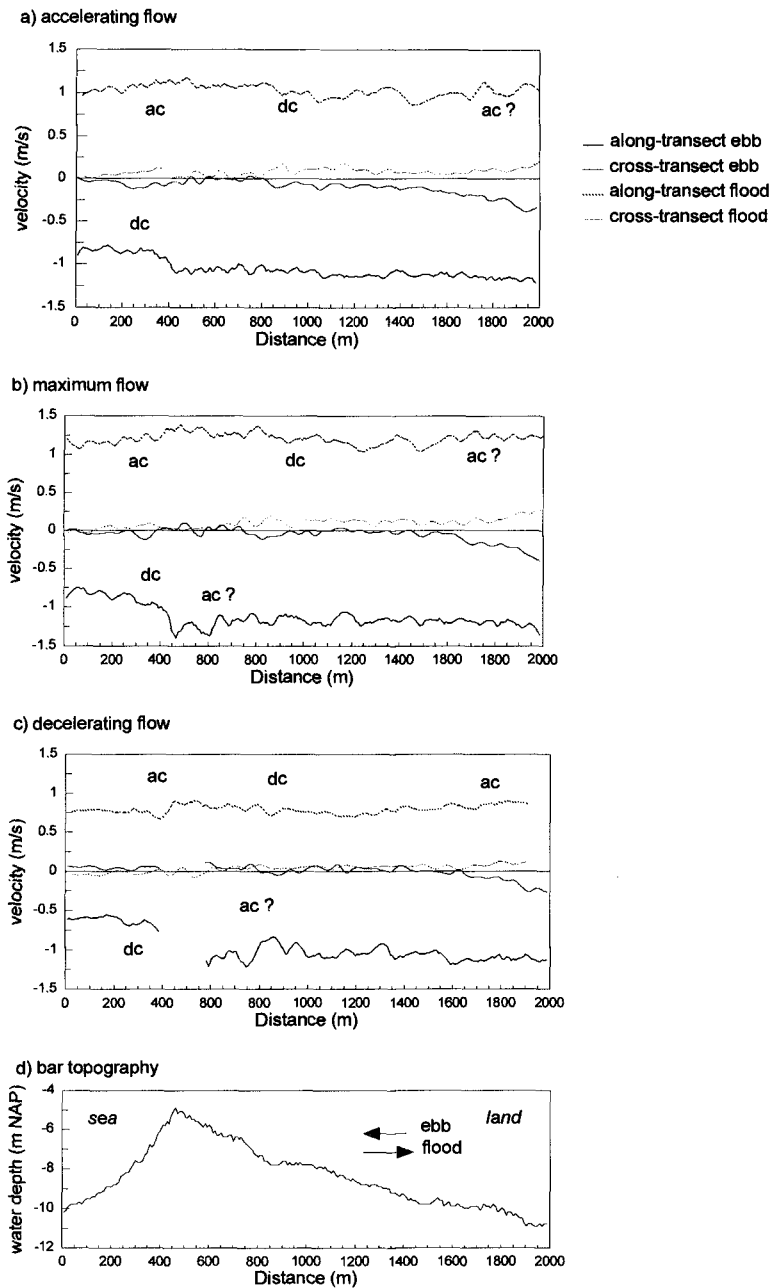

Figure 7 Depth-averaged along-transect and cross-transect velocity over the bar in the connecting ebb channel during ebb and flood on 29 June 1995. Ebb is negative, flood is positive, ac=acceleration, dc=deceleration.

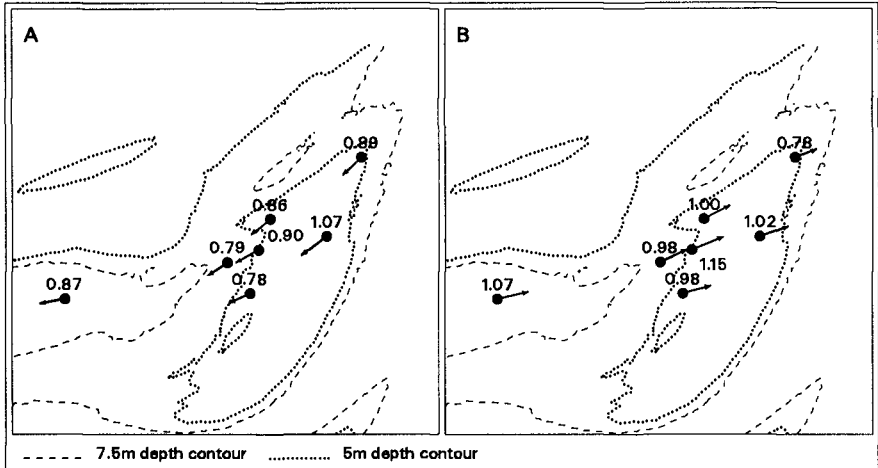

Figure 8 Mean significant current vectors over the bar in the connecting flood channel during spring tide in February 1996. a) ebb, b) flood.

flow deceleration at the downstream side of the bar. Thus the ebb flow accelerates towards the top of the bar and decelerates and converges at the downstream side of the bar. During flood the significant current vectors show a flow acceleration of about 17 percent (0.17m/s) at the upstream side of the bar (Fig. 8b). Significant current directions gradually change with twelve degrees between locations 37 and 38 (see Fig. 2b for locations), indicating minor flow divergence. The current velocity at the upstream side of the bar is 12 to 22 percent ($0.13\text{-}0.22\text{m/s}$) stronger than at the downstream side of the bar. This means that the flood flow decelerates over the bar. The ADCP observations show a flow deceleration of about 20 percent just before the bar (between 1700 and 2200m , Fig.9), where the flood flow diverges (not shown). At the upstream side of the bar the flood flow accelerates with about 30 percent ($0.3\text{-}0.4\text{m/s}$). At the downstream side flow decelerations of 40 to 50 percent ($0.5\text{-}0.7\text{m/s}$) are observed. The cross-transect velocity components indicate that the flood flow is less deflected by the topography of the bar than the ebb flow (inclination of $6\text{-}12^\circ$ with respect to the ADCP-transect, not shown). Thus the flood flow diverges and decelerates towards the bar, accelerates near the top of the bar and strongly decelerates after passing the top of the bar.

The ADCP observations are marked by second-order fluctuations. The amplitude and length scale of these fluctuations increase with time and decreasing water level. The unfiltered velocity data display similar fluctuations. The cause of the fluctuations is not clear. Both turbulence and depth variations may cause such fluctuations.

The pronounced topography of the small bars in the connecting channels is reflected in the hydrodynamics: 1) The bars in these channels demarcate the transition zones between ebb-dominated and flood-dominated flow, 2) Neap-spring tidal variations in current asymmetry change over the bar and 3) The ebb and flood flow tend to flow around the bars of the channels and display non-uniform velocity patterns. In the connecting ebb channel largest velocity gradients are observed during ebb. In the connecting flood channel largest velocities and velocity gradients tend to occur during flood. Fluid continuity across the bar may explain the observed flow

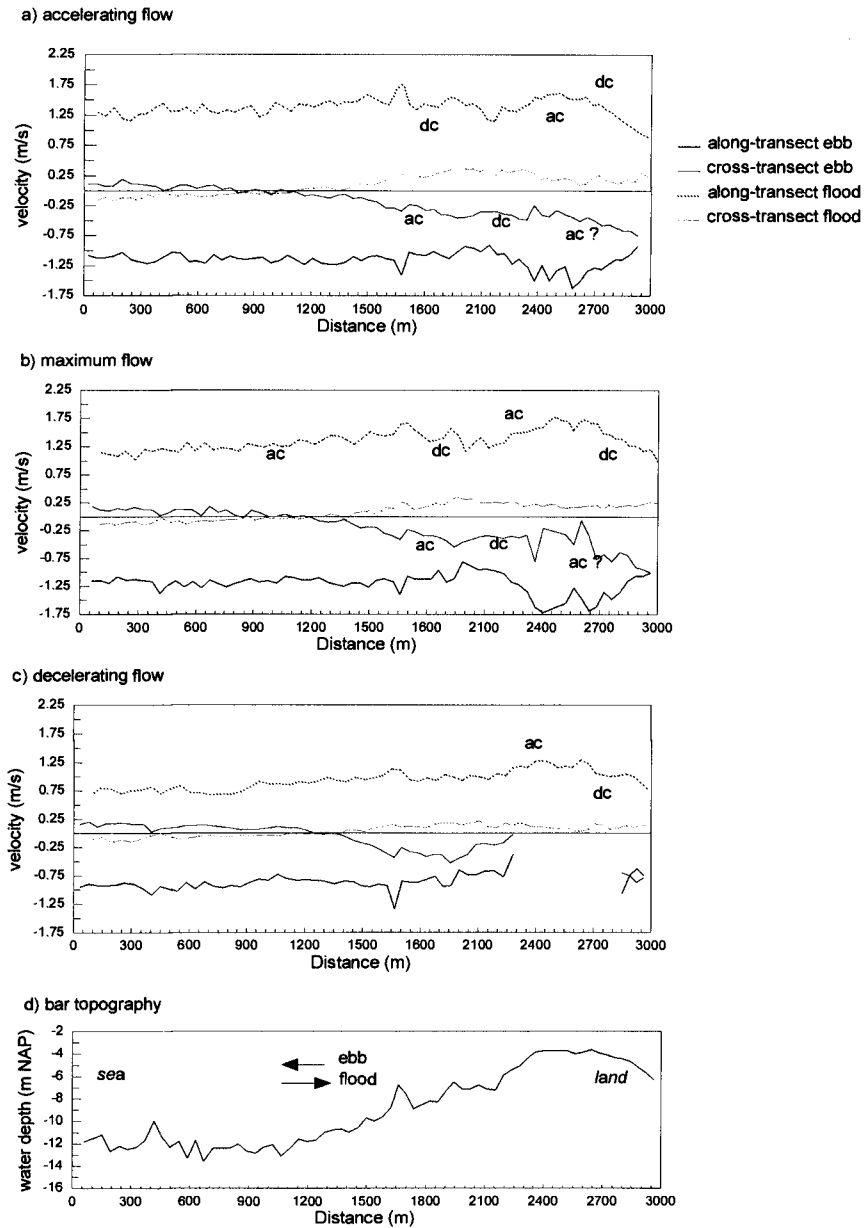

Figure 9 Depth-averaged along-transect and cross-transect velocity over the bar in the connecting flood channel during ebb and flood on 30 August 1995. Ebb is negative, flood is positive, ac=acceleration, dc=deceleration.

around the bars. Fluid continuity implies that the discharge Q (m^3/s) does not change much across the bar. The overall discharge Q is defined as $Q=b\cdot\bar{u}\cdot h$, where b is the width of the imaginary stream tube (m), \bar{u} is the depth-averaged current velocity and h is the water depth. The changes in channel depth over the bar may result in changes in the width of the stream tube and the depth-averaged velocity. At the upstream side of the bars the flow diverges. The width of the stream tube increases. At the downstream side the flow converges. The width of the stream tube decreases. In addition to these changes in width the depth-averaged velocity increases and decreases across the bars, whereas the water depth increases and decreases. The flow over the bars shows a tendency towards flow deceleration and accelerations at the upstream side of the bar and deceleration at the downstream side. The pattern reverses every tidal phase. The implications of these flow phenomena for sediment transports, the patterns of erosion and sedimentation and the net effect over e.g. one semi-diurnal period are not evident. The implications depend on the magnitude and duration of flow accelerations and decelerations, as well as the effect of variations in stream tube width and water depth, differences in current asymmetry and the dominant sediment transport mode. The small bars are stable morphological features despite the observed flow accelerations and decelerations. This indicates that relaxation of the suspended transport may be important for the maintenance of the estuarine bars.

Conclusions

Variations of the tidal flow over the bar in the main flood channel are strongly determined by connecting channels:

- 1) Spatial variations in current asymmetry indicate the presence of small-scale net circulations of tidal flow and sediment transports over the bar, that are induced by connecting ebb and flood channels.
- 2) The changes in current asymmetry with tidal range indicate that the intensity of the circulations is not constant and that the circulations are not closed.

The flow over the small bars in the connecting channels is non-uniform and displays tendencies towards divergence, decelerations and accelerations of the flow at the upstream side of the bar and convergence and deceleration of the flow at the downstream side of the bar. The implications of the flow patterns for sediment transports and the maintenance of the bars are not evident and will be further elaborated on the basis of computations with a mathematical model and morphological analysis.

CHAPTER 350

Interactions between a Sand Barrier and Flood Terrace at the Abukuma River Mouth

Akira Mano ¹and Masaki Sawamoto ¹

Abstract

The sand barrier at the Abukuma River mouth flushed by floods in autumn firmly recovered within a half year by stretching its tip to the cross river direction. However, the direction suddenly changed upstream since 1993. This paper analysis the mechanism of the change.

The river has a large terrace formed by the flood in 1986, the maximum in the observed floods over fifty years. Bathymetric data sounded once a year reveal gradual development of a channel on the terrace off the river axis. From wave ray analyses, it is shown the development accompanies change of the refraction characteristics of waves. The channel becomes to function as a half mirror; reflecting waves incoming from one direction and transmitting from the other direction. This is shown to modify direction of dominant waves near the barrier and to turn the stretch direction of the barrier.

The channel evolution is also shown to correlate with the flood outflow.

1 Introduction

Development of sand barriers at river mouths has close influences on the river management such as flood passage and voyage. The barriers also control water salinity inside the river, which relates with water resources and ecological environments. Although the barrier has important roles in the various aspects near the mouth, the mechanism of the development or deformation is not well known.

The difficulties to find the mechanism may mainly come from complexity of the dual external forces of river flows and waves. The complicated topographies inherent to the mouth like flood terraces and sand barriers also tangle the affair, because they cause flow fields and wave fields to considerably deform. Furthermore broadness of the time scale band on the topography change, which would

¹Department of Civil Engineering, Tohoku University, Sendai 980-77, Japan

relate with the characteristics of the external forces, requires vast set of observed data in the analyses.

Over twelve years, we have been surveying the sand barrier at the Abukuma River mouth in Japan. The details of the observations on the Abukuma River and the characteristics of the barrier deformation in various time scales have been reported (Mano et al. 1995). This river has a catchment of 5,400 km² and a main channel of 239 km. The maximum flood over fifty years of observation by Ministry of Construction occurred on August 1986 with the peak discharge of $Q=7,900\text{m}^3/\text{s}$ near the mouth. This flood flushed out the sand barrier so far and made a large flood terrace off the mouth.

After the flush by the flood, the barrier started to recover. The tip of the barrier advanced in the cross river direction. Then within a half year, it reached equilibrium such that the minimum opening width at the mouth is maintained by the usual river flows and tides. This elongation is the earliest process in the recovery then thickening barrier followed until the next year's flush caused mainly by typhoons in autumn. After the 1986 event, this cycle of flush and recover had continue for seven years always accompanying transverse elongation of the barrier.

However in 1993, the barrier changed its development from cross-river direction to upstream direction. The typical shapes are shown in Fig.1 (a) and (b).

(a) March, 1991.

(b) April 1994.

Fig. 1: Aerial photographs for the typical sand barrier shapes.

After a lapse of more than a half year, both photographs show the fully developed barriers in length. However the shapes are quite different. Figure 1 (a) shows the barrier stretching transversely from the right side bank and very narrow opening width, about 70 m. However Fig.1 (b) exhibits the barrier stretching upstream and the widely opened mouth. Waves are intruding inside the river and two typical arced beaches are formed in the river.

The barrier as Fig.1 (b) has less resistance for the flood passage and provides safer routes for the voyage. Therefore it looks like as if the nature is helping river management since then. The purpose of this paper is to find the mechanism that the sand barrier that had firmly stretched in the cross river direction for seven years changed the direction.

Fig. 2: Topography near the Abukuma River mouth.

2 Topography near the mouth

The Abukuma River flows into the Pacific Ocean, crossing the coast line that has the azimuth, N5°E as shown in Fig.2. No jetties are constructed about the mouth. Waves are observed by the Ministry of Transport off the Sendai Harbor that locates about 25 km north of the mouth. Annual deep water wave energies that are the integration of the energy flux in a year and the averaged values in the period, 1984 to 1992 are also plotted in this figure. The most dominant waves are those of E and have the energy of 11×10^5 J/m that is about 60 % of the total energy. The next dominant waves are those of ESE sharing 35 %. Depending on the directional distribution of the wave energy, the longshore drift around the coast orients north.

The bathymetric charts near the mouth are shown in Fig. 3 (a), (b), (c), and (d) for various stages. Before the 1986 flood, there existed a small terrace in front of the sand barrier and a small channel off the opening, while the barrier was thick. These characteristics correspond to the history of flood activity. Fig. 3 (b), sounded one month after the 1986 flood, showed formation of a large terrace. The top surface of the terrace was very flat with the depth, 4 m. The foot of the terrace reached as deep as 13 m. The mouth was still widely opened.

In 1988, although outline of the terrace was preserved, several deformations were advancing. The shoulder part of the terrace was rounded and the front part of the barrier became shallower. The most remarkable change is the development of a channel on the terrace in the offshore direction from the opening. The opening was usually fixed next to the left side bank by the transverse stretch of the barrier. On the other hand, the terrace was formed along the center line of the river since it was formed by the huge flood that flushed the barrier thoroughly. The position of the channel, therefore, shifted northward from the center of the terrace. In 1993, the channel on the terrace extended offshore.

3 Refraction analysis

To know the influences of the topographic deformations, we have executed wave refraction analysis. Among several numerical methods dealing with the refraction, the wave ray method is especially superior in grasping physical images moreover has the advantage in computational feasibility. Thus we employed the wave ray equation (Mei, 1983) and the refraction coefficient equation (Munk et al., 1952) as follows;

$$\frac{dy}{dx} = \pm \frac{K}{\sqrt{k^2 - K^2}} \quad (1)$$

$$\frac{d^2\beta}{ds^2} + p \frac{d\beta}{ds} + q\beta = 0 \quad (2)$$

$$K = k_o \sin \alpha_o, p = p(c, \alpha), q = q(c, \alpha), K_r = 1/\sqrt{\beta}. \quad (3)$$

Where, x is the local coordinate taken to the steepest gradient of the bottom, y is perpendicular to x , s is the coordinate taken along a wave ray, α is direction

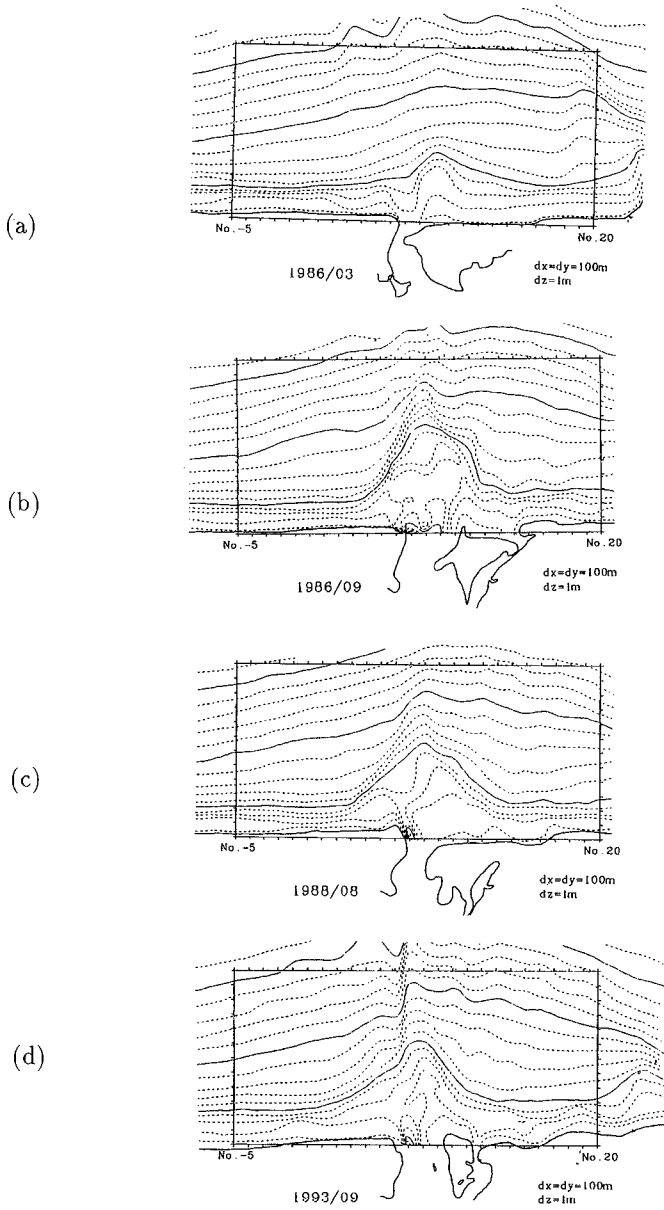

Fig. 3: Bathymetric charts at various stages.(a): March, 1986,(b): September 1986,(c): August 1988,(d): September 1993.

of wave ray, k is the wave number, c is the phase velocity, K_r is the refraction coefficient, and subscript o denotes the boundary value. These equations are solved together with the dispersion relation and boundary conditions by the finite difference method. The employment of the local coordinate x has such an advantage that it is required to solve only once the dispersion relation for each space step marching.

After digitizing the contour lines of the bathymetric charts, we made bathymetric mesh data and expressed the topography by the sets of plane triangle elements. The wave rays started from the offshore boundary were advanced step by step through the integration of the equations with the local coordinate system.

For the topographies mentioned in Figs. 3 and the corresponding annual mean waves, wave rays were computed as shown in Figs. 4 (a), (b), (c), and (d). The incident wave height and period are 0.77 to 0.88 m and 7.4 to 8.4 s respectively. The breaking point for each wave ray was evaluated by using the breaking index (Goda, 1970) and plotted by the filled circle near the shoreline.

In Fig. 4 (a) indicating wave refraction before the 1986 flood, the wave rays approaches uniformly in the longshore direction except very near the river mouth. The small terrace in front of the barrier gathers the wave rays and focuses at the barrier. While for the topography just after the flood, the large terrace gathers more wave rays and focuses about the middle of the terrace. Most of the wave rays passed the focus reach the north coast of the river. Local focuses are again formed. The sand barrier is outside such wave rays and reached rather direct waves that make the barrier stretch in the transverse direction.

In Fig.4 (c), according to the deformation of the terrace, the wave refraction changes. The sand barrier becomes to get two wave groups; direct waves that are almost straight incident and reflected wave at the channel on the terrace. The intensity of the reflection increases with the development of the channel as shown in Fig.4 (d). Along the long channel from the mouth to the contour of 10 m, caustic, that is, the envelop of the wave rays, is formed. Almost all the wave rays reflected at the channel concentrate at the tip of the barrier in such a way that these waves prevent the crosswise stretch or promote the upstream elongation.

Figures 5 (a), (b), (c), (d), and (e) show the effect of the off shore wave direction for the topography of 1993. Here the direction is taken anti-clockwise from the normal to the coastline. For the positive directions, (a) and (b), although the terrace refracts wave rays complicatedly, it transmits the wave rays and makes them concentrate at the tip of the barrier. On the other hand, for the normal to the negative directions, the caustic is firmly formed along the channel moreover makes concentration at the tip of the barrier. Therefore for the waves of positive direction, the terrace is transparent and acts like a convex lens. However for the waves of negative directions it functions as concave reflector. As a whole, the channel functions like a half mirror. Thus the deformed terrace gathers waves of all direction and focuses at the tip. This an-isotropic characteristic of the refraction comes mainly from the position of the channel that is shifted north

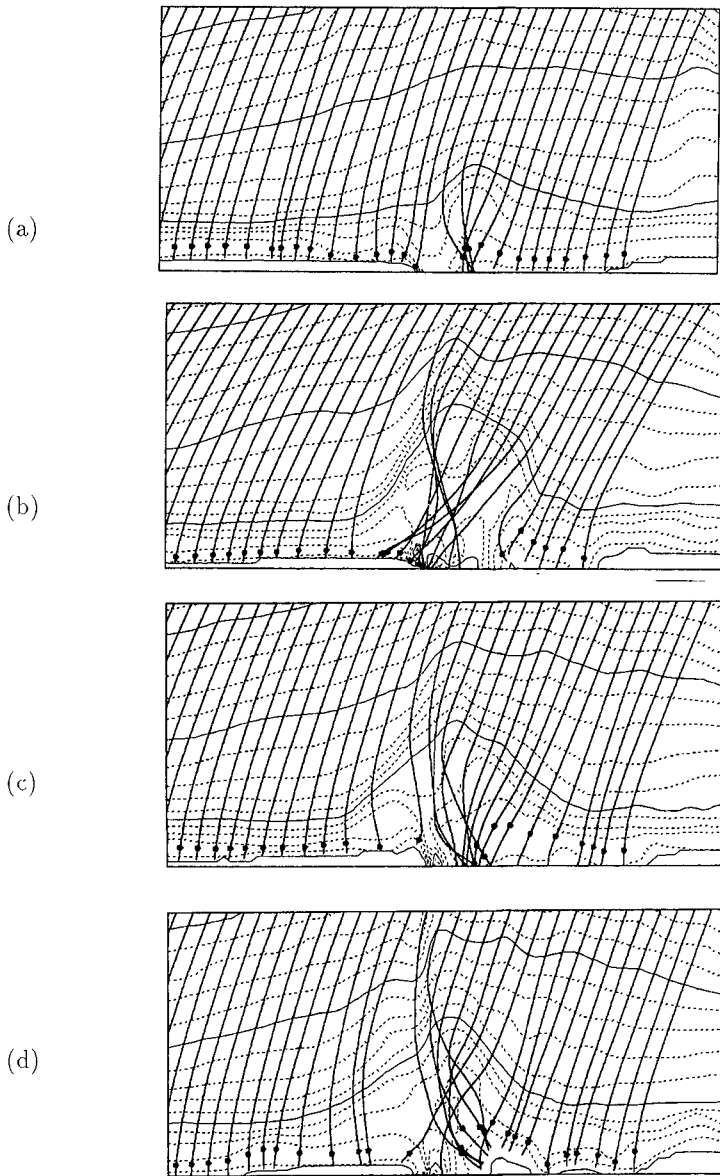

Fig. 4: Wave rays for the topographies at various stages.(a): March, 1986,(b): September 1986,(c): August 1988,(d): September 1993.

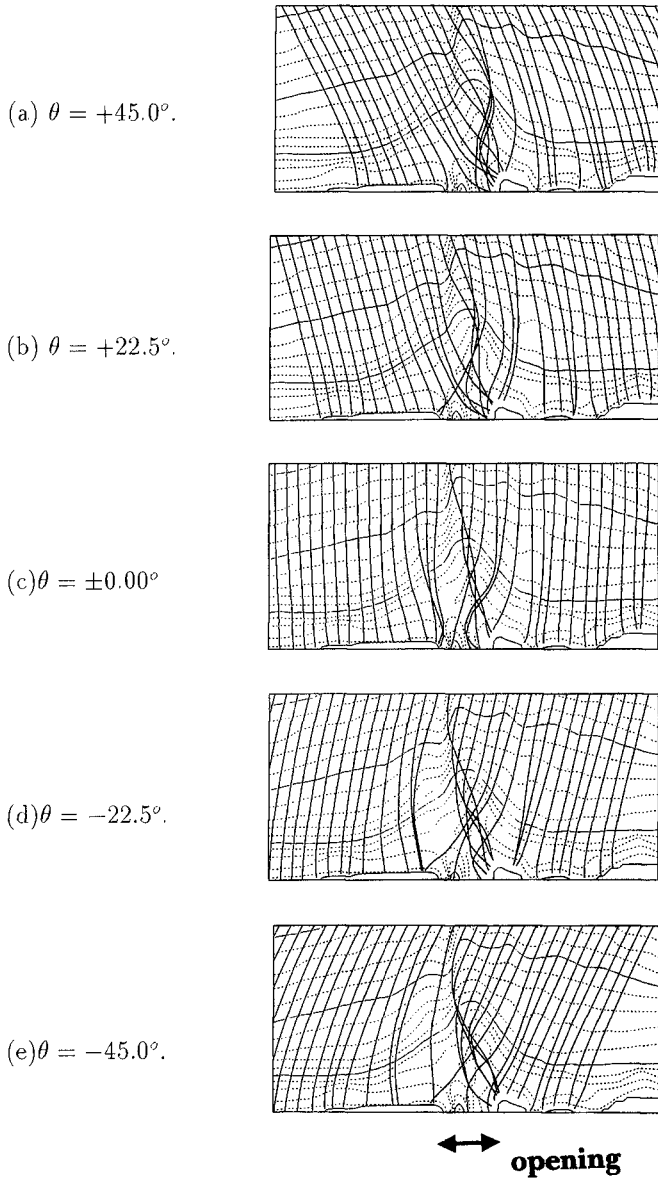

Fig. 5: Effect of wave directions.

from the center of the terrace as stated before.

4 Channel evolution

The next step is to examine how the channel has been developed. The cross sections of the terrace along shore are shown in Figs .6 (a) and (b) for each off shore distance y . The initial shape of the terrace formed by the 1986 flood was almost trapezoidal. Near the mouth there was a broad channel with banks in both sides. Then the banks were disappeared at $y = 400\text{m}$ and a very flat and horizontal surface appeared. The depth was about 3 m here.

(a) September, 1986.

(b) January 1992.

Fig. 6: Profiles of the terrace.

As time passing, the shoulder parts and the banks near the mouth were eroded to become round and the channel on the terrace was developed. The cross sections on January 1992 (Fig. 6 (b)) indicate a wide and triangular channel on the terrace. By using these profiles, we calculated the channel area that is bordered by the line connecting apexes at both sides. Then the volume of the channel was obtained by integrating the area to the offshore direction till $y = 600\text{ m}$, beyond which the evaluation of the area is not so precise.

Time histories of the volume and the outflow that is the integration of the discharge during the flood are shown in Fig. 7. This figure reveals correlation between the flood activity and the channel evolution. In 1991, we had many floods including large one and the channel volume remarkably increased after the floods. While for the inactive year in the floods, the change of the volume is small. Here the case for the 1986 flood is exceptional. After the largest flood of 1986, the increase of the channel was not so large. This is because the 1986 flood mainly deposited considerable amount of sediment off the mouth. The counted volume was due to the local score very near the mouth and bank formation on the terrace near the mouth.

Fig. 7: History of floods and channel evolution.

Fig. 8: Correlation between the outflow of the floods and increment of the channel volume.

The correlation between the flood activity and the increase of the volume is examined in Fig. 8. The ordinate indicates the increment of the channel volume obtained from the successive bathymetric charts. The abscissa is the sum of the outflow in the corresponding period. For the large value of the outflow, these two quantities are in linear relationship. While for the small value, the decrement of the channel volume appears, which would correspond to the deposition by waves. Thus the evolution of the channel on the terrace is related with passage of the small to middle scale of floods, except such a huge flood as to make a terrace.

5 Considerations

Fig. 9: The river mouth system at the Abukuma River

Starting from the terrace formation by the 1986 flood as an initial stage, here we summarize the flow of the cause and effect in the morphological change in the river mouth system. In the early stage after the terracc formation, the large terrace refracts waves to stretch the sand barrier in the cross river direction. The stretch takes half a year at most. Thus till spring, the opening of the mouth reaches equilibrium maintained by tides and usual river flows with narrow width. Then it is forced to lie adjoining the left bank of the river. Then thickening of the barrier as the following step of the development continues until next flood season. In autumn we have several floods mainly caused by the rainfall due to typhoon. For the small to middle size of floods, they may flush the barrier partly, however the major part of the flow runs out through the old opening. Then it erodes the terrace. The channel on the terrace gradually evolves along the flow axes.

The evolution of the channel also changes the refraction characteristics on the terrace. The reflected waves at the channel are gradually intensified and gathers at the tip of the barrier such a way as to suppress the cross ward stretch. When the reflected waves become dominant to the direct waves, the barrier stops transverse stretch and turns to the upstream direction. The transverse stretch lasted about seven years, while the fixation of the opening to the left bank contributes the channel evolution.

After the turning point, since the opening remained widely open, the reflected waves intrude inside the river and transport the sediment upstream. The waves also make the circular shore lines as shown Fig. 1 (b).

Figure 9 summarizes the interactions between the typical topographies; the sand barrier and flood terrace under the action of the external forces; floods and waves.

6 Conclusions

Based on the bathymetric chart, sand barrier survey, hydro-graphs of floods and wave data over ten years as well as the refraction analysis, we have shown the interactions between the sand barrier and flood terrace under the action of floods and waves. The different time scales on the deformation of these topography also have roles on turning the stretch direction of the barrier.

CHAPTER 351

A Unique Look at Oregon Inlet, NC USA

Herman C. Miller¹, M ASCE, William A. Dennis², M ASCE, and
Michael J. Wutkowski²

Abstract

Oregon Inlet (OI) in North Carolina (NC), the only inlet along a 170 km stretch of coast, supports an active commercial fishing and recreational boating industry. Severe erosion, because of the ongoing migration of OI, resulted in NC constructing a terminal groin to prevent the highway from being severed from the south side of the OI bridge. Construction of this structure provided a unique opportunity to monitor and assess project impacts which could be directly related to the twin jetties which are proposed for this site. The monitoring program included a directional wave gauge, aerial photography, and semi-annual sled-surveys extending 6 km north and south of the inlet. The terminal groin returned the shoreline to its pre-1986 position and has successfully protected the highway abutment to the bridge through many severe storms. This paper presents the results of 6 years of monitoring the morphologic changes. The results document how the coast has adjusted to the construction, a multi-year wave climate reversal, and placement of 1.5 million m³ of dredged material on the beach. The surveyed area generally lost material both on the up and downdrift sides, much of which apparently has been deposited in the inlet. The effect of these changes on the coast and the inlet's stability are discussed.

Introduction

Oregon Inlet (OI) is the only inlet along a 170 km stretch of coast from Cape Hatteras, North Carolina (NC) to the south, to Rudee Inlet in Virginia to the north, as

¹US Army Engineer Waterways Experiment Station Coastal & Hydraulics Laboratory Field Research Facility, 1261 Duck Road, Kitty Hawk, NC 27949, USA

²US Army Engineer Wilmington District, Coastal, Hydrology, & Hydraulics Section, PO Box 1890, Wilmington, NC 28402, USA

shown in Fig 1. The inlet provides an important link between the Atlantic Ocean water and the expansive estuarine Albemarle/Pamlico/Currituck Sound system. The inlet supports an active commercial fishing and recreational boating industry.

During the peak summer months, over 12,000 vehicles a day use the bridge across OI to work and enjoy the beaches in the Cape Hatteras National Seashore. OI and Roanoke Inlet before it, have been migrating south at a rate exceeding 2 km per century. By 1989 this ongoing southerly migration threatened to sever the southern abutment of the bridge to the highway that provides the only land route to the southern beaches. In 1990, NC Department of Transportation (NCDOT) constructed a 953 m rubble mound terminal groin to stabilize the south shoulder of OI. The terminal groin was intended to create a fillet in its lee and return the shoreline to the pre-1986 position. Documenting how the adjacent shoreline and nearshore waters adjusted to construction of the terminal groin was important to the local residents, NC, and the US Army Corps of Engineers (USACE).

This construction provided a unique opportunity to monitor and assess project impacts which could be directly related to the twin jetties which are proposed for this site. Although the function of the terminal groin and jetties (which provide for safe navigation through the inlet) is quite different, it was believed that information gathered concerning the project induced changes resulting from stopping the southerly migration of the inlet would be extremely beneficial in the planning and design of the jetties.

With local and state support for funding, the USACE Wilmington District and the USACE Waterways Experiment Station Coastal and Hydraulics Laboratory, Field Research Facility (FRF) jointly developed a monitoring program to assess the impacts of the terminal groin. The close proximity of OI to the FRF, located in Duck, NC, made it possible to take advantage of the equipment and experienced staff to conduct a long-term monitoring program.

Fig. 1. Site Location. Note, location of USACE Field Research Facility 48 km north of OI. (Kilometers = Miles * 1.61)

This paper presents the results of 6 years of monitoring. In addition to the presence of the terminal groin during that time, there was an unusual long-term wave climate reversal, and material dredged from the inlet was disposed of on the beach on four occasions. The paper organization is generally as follows: monitoring program, monitoring results which document the response of the coast, a discussion of the effect on the inlet stability, and conclusions.

Monitoring Program

The OI area is subject to both hurricanes and northeasters and has one of the highest wave climates on the US east coast. The average annual significant wave height and period for the area are 1 m and 9 sec, respectively (Leffler, et al, 1996). The mean tide range on the open coast is 1.2 m and 0.7 m for the inlet gorge (NOAA 1996). OI separates Bodie Island to the north from Pea Island to the south. The monitoring program consisted of semi-annual nearshore sled-surveys along a portion of the coast extending approximately 6 km on both Bodie and Pea Islands. These surveys were conducted along 38 profile lines spaced at 300 m intervals, Fig 2. The profiles begin behind the dune and extend to the 9 m depth contour. All of the profiles are surveyed in January during the winter storm season and July during the summer recovery season. In addition to these surveys, a directional wave gauge has been operated at the inlet since 1990. Also, aerial photographs were collected approximately every other month.

The sled-survey system (Miller, 1991) consists of an amphibious vehicle and a sled with an 11 m tall mast, Fig 3. The sled, which slides across the ocean bottom virtually unaffected by waves and currents, carries a ring of reflective target-prisms. HYPACK software on a PC is used to collect position and depth measurements every 1 m along a profile using a Geodimeter 140T tracking total-station that is aimed at the prisms. Processing the profile data was facilitated by the Interactive Survey Reduction Program (Birkemeier, 1991). Summaries were generated using Intergraph Inroads/Insite software.

Results

By Halloween in October, 1991, the terminal groin was completed, the fillet had formed, and the shoreline had been returned to the desired location, just in time for a major storm, Fig 4. The road and bridge abutment was protected, accomplishing the primary function of the construction (Dennis and Miller, 1993). As can be seen, the breaking waves define a well formed ebb-shoal which is the main pathway for sand to bypass the inlet. Seeing that this natural pathway was well established, it was not expected that the terminal groin would have a major impact on sediment transport past the inlet. What was expected was that the inlet would narrow, since only the downdrift shoulder was stabilized. The effect of this realignment on the hydraulics of the inlet and on the adjacent coast was of primary interest.

The results are summarized by showing the changes that occurred from the winter of 1991 through the winter of 1994, then from the winter of 1994 through the winter of 1996. This separation shows the different responses of the coast to apparently different processes resulting from an infrequent long-term annual wave climate reversal during 1991 through 1993.

Figure 5 shows the elevation changes over 3 years on the Pea Island (south) side of OI. Every other profile is numbered starting with "15" closest to the inlet and ending with "239," 6.8 km to the south. The February, 1994 shoreline position is included to distinguish the sub-aerial from the

Fig. 2. Sled-survey profile lines. Note, directional wave gauge location at end of Profile #70 off of Pea Island. (Kilometers=Miles* 1.61)

Fig. 3. Survey sled and amphibious vehicle. The sled mast carries the prism array at an 11m elevation.

Fig. 4. OI during "Halloween Storm" on 31 October, 1991. Surge from 4 m, 22 sec. waves have flooded fillet behind the terminal groin at end of the old ferry landing road.

sub-aqueous portions. The terminal groin extends from the "Feb 94" shoreline position at "15" approximately 1 km to the west. The inlet would be to the north (right side) of the terminal groin. Positive elevation changes indicate accretion and are shown as light shaded contour areas. Negative contours in the dark shaded portion of the figure are areas of erosion.

From March, 1991 to February, 1994, near the inlet, there was inshore accretion and offshore erosion along the ebb-shoal. South of "140" there was nearshore erosion that resulted in shoreline retreat, overwash, and destruction of some dunes that were 60 years old. However, the overwhelming feature in the area during this time was the 1.5 million m³ of dredged material disposed of on the beach between profile lines 50 and 130. As can be seen, much of the disposal material moved offshore. Material also moved north along the inshore bar and trough into the fillet and around the terminal groin into the inlet.

More recently, from February, 1994 to April, 1996, Fig 6, the pattern of changes is quite different in comparison to the earlier time shown in Fig 5. Now the inshore erosion is along the entire length of the survey area. However, there is accretion offshore along a pathway consistent with transport along the ebb shoal toward the south.

Corresponding changes on the Bodie Island (north) side of OI from March, 1991 to February, 1994 are shown in Fig 7. For orientation, the inlet is 0.6 km south (to the left) of "39." Clearly, changes during this time are quite different than those for the Pea Island side shown above. Erosion pervades almost the entire area with the exception of an area of sub-aerial accretion near "59."

An almost opposite response is seen from February, 1994 to April, 1996 as shown in Fig 8. During those 2 years there is sub-aerial and sub-aqueous accretion over most of the area. One exception is the shoreline retreat south of "85" which corresponds to a swing of the Bodie Island spit toward the west. To document what was responsible for these different adjustments before and after February, 1994, it is informative to look at the wave data.

Historic estimates of the annual rate of sediment transport along this portion of coast, (Jarrett, 1978, Birkemeier, et al, 1985, Inman & Dolan, 1989, USAEDW, 1995),

Fig. 5. Pea Island elevation changes from March, 1991 to February, 1994. Terminal groin is at profile 15; inlet is to the north (to right). (Meters = Feet*.3048)

Fig. 6. Pea Island elevation changes from February, 1994 to April, 1996. (M=Ft*.3048)

show that annually approximately 1.5 million m³ of sediment moves south primarily during the Fall and Winter storm seasons; 800,000 m³ moves north during the Spring and Summer, for a net southerly transport rate of 700,000 m³ per year. Potential longshore transport volumes using the energy flux method in the Shore Protection Manual (SPM, 1984) based on hindcasted wave data since 1956 (WIS, 1993), historic wave climatic summaries (Thompson, 1971), and FRF measurements (see FRF WWW page at HTTP://FRF.WES.ARMY.MIL) show that this trend of net annual southerly longshore transport has been consistent over the past 4 decades with one exception in the early 1980's when the southward and northward transport approximately balanced.

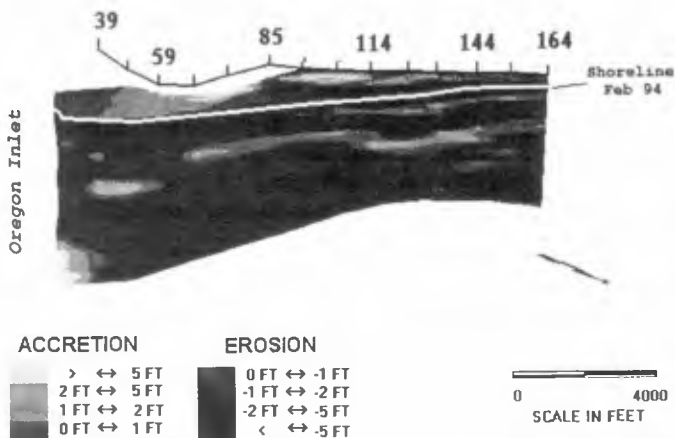

Fig. 7. Bodie Island elevation changes from March, 1991 to February, 1994. Inlet is 2 km south (to left) of Profile #39. (Meters = Feet * .3048)

Fig. 8. Bodie Island elevation changes from February, 1994 to April, 1996. Shoreline retreat near inlet accompanied growth of spit toward south. (Meters = Feet * .3048)

Computations based on the FRF's linear directional wave array, (Long and Oltman-Shay, 1991), are shown in Fig 9. The complete data record from the FRF was used, instead of the directional measurement from the self-recording gauge at OI, because of intermittent gaps in the OI data. However, comparison of computations from both gauges, (Miller and Dennis, in prep.), show the wave climate summaries at the FRF are representative of the wave climate at OI. From January, 1990 through February, 1991 and from 1994 through 1996 there is southward transport during the storm seasons, consistent with historic trends. However, during 1991 through 1993, with only a few exceptions, each month the net transport is toward the north. It can also be seen that beginning with the Halloween 1991 storm, frequently, the northward transport rates were quite high. The annual net transport rates during these years approached 2 million m^3 toward the north. One explanation we have considered for this is that there was a long El Nino event in the Pacific Ocean during that time which may have diverted the "jet stream" across the United States causing mid-Atlantic extratropical storms to move inland south of OI instead of typically moving up the coast to the north. Whatever the cause, it provided a unique opportunity to study how the coast adjusted to the changing coastal processes.

Fig. 9. Monthly net potential transport. Wave climate during 1991-1993 resulted in predominately northward net transport close to 2 million m^3 per year. ($M^3=Yd^3*.028$)

The effect of an inlet is often categorized in terms of the up drift or downdrift sides of the inlet. Figure 10 summarizes the adjustments of the coast at OI in light of the wave climate reversal that caused the up/downdrift categories to change during the monitoring period. Cumulative volume changes for each of the semi-annual surveys are presented for both Pea and Bodie Islands. During 1991 through 1993, Bodie Island is in the lee because of the wave climate reversal and shows a consistent loss of volume.

By the summer of 1994 the wave climate is more climatologically consistent and the volume shows signs of recovery. On the other hand, the Pea Island side remains approximately neutral through 1994 with some indication of a trend toward loss of material more recently while in the lee of the inlet. However, recall that 1.5 million m³ of material was deposited on the Pea Island side prior to 1995, and so it too lost volume during the monitoring period. So both sides lost volume, particularly during the times when in the lee of the inlet. Where did the sand go? We believe it went into the inlet. Unfortunately, we do not have volume changes in the inlet. However, using the aerial photography it is possible to gain some insight into the inlet's stability during this time.

Fig. 10. Pea and Bodie Islands volume changes. Note, while Bodie Island shows loss of volume through July, 1994, Pea Island remains unchanged because of 1.5 million m³ of dredged material placed on the beach. (M³ = Yd³ * .028)

Figure 11 was constructed from photography taken on 13 April, 1992. Notice the width of the channel under the bridge. For reference note the “dark spot” on the bridge. This is a repaired section caused by a dredge that washed through the bridge during a storm in October, 1990. Also, note the shape of the ebb shoal. It has a parabolic “flattened bell” shape with a wide base that is asymmetric on the Bodie Island side.

Figure 12 is 1.5 years later on 11 November, 1993. The spit has grown to well south of the repaired bridge section. The Bodie Island side continues to move south as has been the tendency for the past 150 years since OI opened. The narrowing and realignment of the inlet can be seen in the shape of the ebb shoal, which now has an “arrow head” form, less wide at the beach and asymmetric on the Pea Island side. However, the shoal does not extend any further offshore. Higher currents associated with a decreasing inlet cross-section would tend to wash the shoal further offshore which is not seen at this time. The pond in the middle of the fillet behind the terminal groin is the result of mining 250,000 m³ of sand which was placed on the beach south of the monitoring area.

Fig. 11. Mosaic of aerial photography of OI taken on 13 April, 1992.

More recently, as seen in Fig 13 taken on 23 May, 1996, the spit is very near the navigation span under the bridge and an island has formed between the south “Davis” slough and the main OI channel. The volume of material in the inlet, although unknown, appears to have increased dramatically in comparison to Fig 11. We believe this accounts for a large part of the volume losses off of Pea and Bodie Islands.

Inlet Stability

The growth of the Bodie Island spit and development of the shoals have had an effect on the inlet stability. The effect of the shoal under the bridge is that instead of having to dredge to keep the authorized 4.3 m depth in the navigation channel at the bridge, as during the 1991 disposal projects, the depth has now approached 20 m. This equates to approximately 15 m of scour primarily over the past 3 years. Although scour in the navigation channel is unusual, scour has been a problem at OI in the past and has required that remedial measures be taken to reinforce the bridge at “Davis” slough on the south end. The deep scour has not, as yet, been measured in the inlet on the ocean side east of the bridge. In May, 1996 the inlet width, using the traditional method of measuring the minimum distance from the Bodie Island spit to the south side of the inlet (now to the terminal groin), is 820 m. This is the narrowest it has been since 1983, yet the inlet has been more narrow, on a few occasions, such as in 1975 when it was just 640 m wide (USAEDW, 1977). Since the inlet in recent years appears to have maintained a consistent cross-sectional area, (McCafferty, 1996), and is expected to continue to narrow, additional scour can be expected.

Fig. 12. Aerial photography of OI taken on 11 November, 1993. Note spit now well south of "dark spot" on bridge.

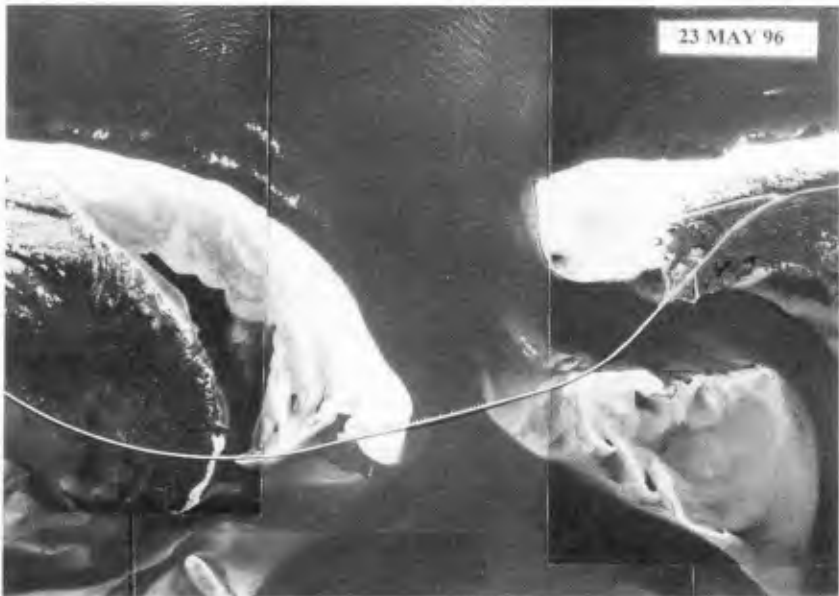

Fig. 13. Aerial photography of OI taken on 23 May, 1996. Development of shoal under bridge has resulted in 15 m of scour in navigation channel.

However, the scour in the navigation channel under the bridge suggests the inlet may be more narrow there. The “effective width” of the inlet might be considered the width measured at the bridge. Considering the shoal, that width is 720 m at this time. As the material continues to enter the inlet and the spit continues to migrate toward the south, it is possible that the main flow channel will shift to “Davis” slough. Should that occur, the spit and island under the bridge would tend to coalesce making it very difficult to maintain the navigation channel at the narrow navigation span of the existing bridge. Also, as the channel moves up against the terminal groin, the scour could increase, possibly, putting the structure in danger. The terminal groin was designed, however, anticipating the channel moving toward the structure by adding a 12 m wide scour apron along the inlet toe.

OI has always been an effective sink for sediment as evidenced by the extensive shoals west of the bridge. The inlet’s stability and downdrift beach erosion rates are highly dependant on the natural bypassing of material past the inlet. Unfortunately, with or without the terminal groin, natural bypassing is not efficient at OI. Dredging, in the past used primarily for maintaining the navigation channel, may become an almost mandatory bypassing supplement. This may not be satisfactory since dredging is also not efficient. It requires dredging quantities approaching the annual gross transport of material, which is more than three times the net. An alternative would be to stabilize the inlet with jetties that would prevent the material from entering the inlet and mechanically bypassing the net transport as needed on the downdrift beaches.

Conclusions

A terminal groin was constructed at OI to prevent the important only highway route to popular beaches from being severed from the bridge. The construction was intended to establish a fillet in its lee that would return the shoreline to the pre-1986 position. The structure has been well tested by many large storms and has been very successful.

A long term measurement program, including semi-annual sled surveys, has documented the response of the coast to the construction. Measurements made over the past 6 years captured the unique response of the inlet to an unusual wave climate reversal. During the reversal, erosion was measured on both the up drift and downdrift sides. Since the processes have returned to more normal conditions, there has been recovery on the up drift side and the ebb-shoal is accreting on the downdrift side. However, erosion on both sides indicates that natural bypassing continues to be insufficient at OI.

Apparently, the eroded material is ending up in the inlet. The inlet has adjusted by the growth of the spit toward the south and the rapid development of a shoal under the bridge. The “effective width” of the inlet is now 720 m, near the minimum in half a century, which has caused 15 m of scour in the main channel under the bridge.

The monitoring program at OI has been successful documenting the adjustment of the inlet and adjacent coastal region to construction of the terminal groin. Future efforts will include quantifying the volume changes within the inlet particularly on the shoals. Continued monitoring, as the Bodie Island Spit moves further south, will provide valuable data for future engineering activities that seem inevitable at OI.

Approvals

The authors would like to acknowledge the late, Robert Williams, Chairman of the Oregon Inlet and Waterways Commission, for his support for the monitoring program, efforts to fund the study, and open mind concerning the findings...he will be missed. Permission to publish this paper was granted by the Chief of Engineers.

CHAPTER 352

IMPACTS OF INLET STRUCTURES ON CHANNEL LOCATION

William C. Seabergh¹, Mary A. Cialone¹, Donald K. Stauble²

Abstract

Barnegat Inlet, New Jersey, has undergone a variety of structural changes in an attempt to provide a navigable channel from bay to ocean. These structures have included shoreline revetments, arrowhead jetties with their crest elevation at mean tide level, a sand dike to better align interior channel flow, a raised impermeable jetty, and now parallel jetties. Each of these structures has had significant influence on inlet hydraulics and sedimentation, which in turn has impacted channel location.

Introduction and Historical Overview

Barnegat Inlet, New Jersey (Figure 1), is an inlet worth detailed examination as it is rich in history of man's struggle to control nature's scheme. A paper written in the 1970's about the inlet entitled "Barnegat Inlet, Nature Prevails" (Caccese and Spies, 1977) expressed the frustration an inlet can cause coastal engineers and scientists. The natural inlet migrated to the south 1600 m from 1839 to 1932. An inlet shoulder revetment and groin to protect Barnegat lighthouse anchored the south side of the inlet. A pair of "arrowhead" jetties was constructed in the late 1930's, followed in 1943 by a sand dike in the adjacent bay that caused a redirection of flow. Important in understanding the response of the inlet channel in this time frame were the jetties' low crest elevations at mean tide level. These jetties were functioning as "weir jetties," which allowed tidal flow, wave-generated currents, and sand to be transported over these inlet structures. This resulted in creation of sand spits at the inlet gorge and became a new control for channel location, withstanding many dredging attempts to control channel position. During a twenty year period the sinuous channel was completely inverted as this new regime interacted with structural controls.

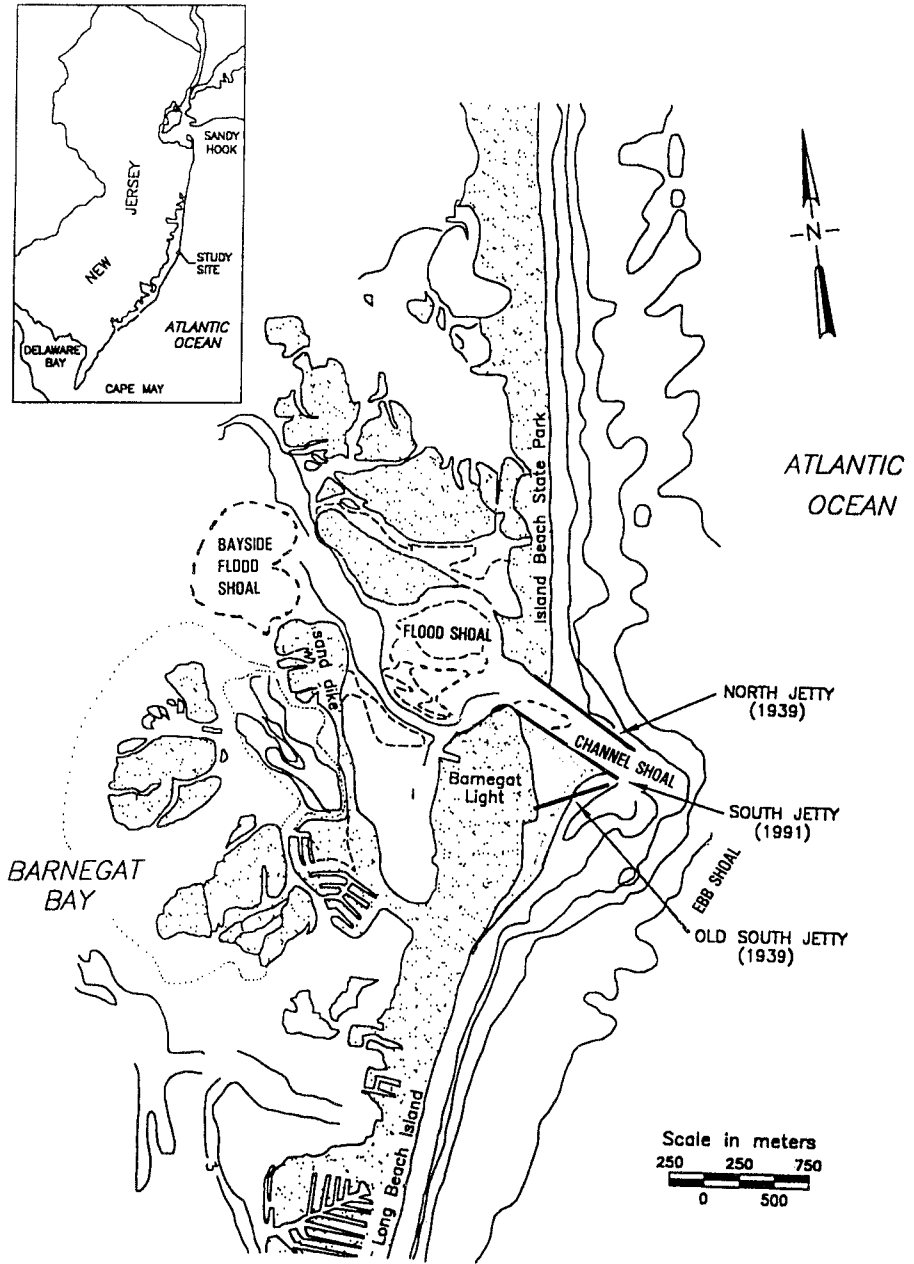

Figure 1. Barnegat Inlet, New Jersey location map and project elements.

In the early 1970's, a sequence of steps to improve channel dynamics was developed from a physical model study (Sager and Hollyfield, 1974) which included raising the north jetty and making it impermeable plus the addition of a new south jetty paralleling the existing north jetty. In 1972-74, the north jetty was raised 1.8 m. Sand was diverted offshore along the impermeable jetty and growth of the ebb shoal resulted. The channels adjusted to a reduction of sediment from the north beach.

A significant amount of dredging was done in the late 1970's to maintain the channel at the inlet throat. However, the increase in ebb shoal volume created additional maintenance dredging in that location. Another phase suggested by the model study was implemented beginning in 1989, with the construction of a new south jetty located within the arrowhead system. This jetty paralleled the original north jetty and served as a replacement to the original low south jetty. Upon completion of the project, a monitoring study was initiated to understand the response of the navigation channel to the most recent inlet structures, but, in doing so, an understanding of the historic interaction of the channel and structures was also necessary.

Physical Factors

The inlet separates Island Beach, a spit to the north, from Long Beach Island, a barrier island to the south. These barriers are characterized by medium to fine sands. Within the inlet region, medium to fine sands (0.25-0.5 mm) are on the ebb and flood shoals and coarser sands (0.50-1.0 mm) are in the deeper channel areas (Stauble and Cialone, 1995). The inlet provides access for commercial fisherman, day fishing excursion boats and small craft. The inlet's design channel is 91.5 m wide by 3 m deep (relative to mean low water), extending through the ebb shoal. The mean ocean tide range is 1.28 m and mean wave height is 1.20 m. Littoral transport estimates at the inlet are 840,000 cubic meters gross transport, with a net of 110,000 cubic meters to the south. These estimates are based on wave heights hindcasted at the 20-m contour near the inlet.

Effect of Inlet Hydraulics on Channel Dynamics

Throughout the recent history of Barnegat Inlet there has been the interaction of structures, changing sedimentation patterns and inlet hydrodynamics. The inlet system now contains four consecutive, fully-developed shoal features (compared to typical one ebb/one flood shoal), with an ebb shoal seaward of the jetties, a shoal in the intra-jetty region (particularly evident for the arrowhead configuration), a large flood shoal contained by the sand dike and finally a bayside flood tidal delta where flow exits into Barnegat Bay (Figure 1). Development of these shoals initially created a higher friction environment, which with the initial structural configuration, created increased sedimentation and a gradual decrease in tidal prism. Raising the north jetty reduced sediment input from the north beach, and coupled with dredging, and the construction of the new south jetty, some flow efficiency was regained as evidenced by increased tidal prism.

Important in relating the channel response to inlet structures is an understanding of the inlet's hydrodynamics. This inlet has maximum flood currents near high water elevations and maximum ebb currents near low water and is typical for an inlet lagoon which has very large surface area relative to channel cross-sectional area. Essentially the lagoon level fluctuates very little and the ocean tide range oscillates about that level, resulting in maximum head differences across the inlet near high and low waters. This phasing of flow relative to structure crest elevation and flow over shallow shoal areas is important to channel location. Figure 2 shows flow patterns for maximum ebb and flood flows as determined for 1968 conditions from a physical model study (Sager and Hollyfield, 1974). For the mean tide level elevation jetties, maximum flood currents (strongest near high water) had a great potential for introducing sediment to the inlet system and thus the development of a large flood shoal complex. Low water ebb currents are more channelized. This permits shoals to be more effective ebb shields; that is, ebb flow will tend to be deflected around the shoal area if the shoal elevation is higher than low water. Also, maximum ebb flows at low water elevation can lead to incising of channels.

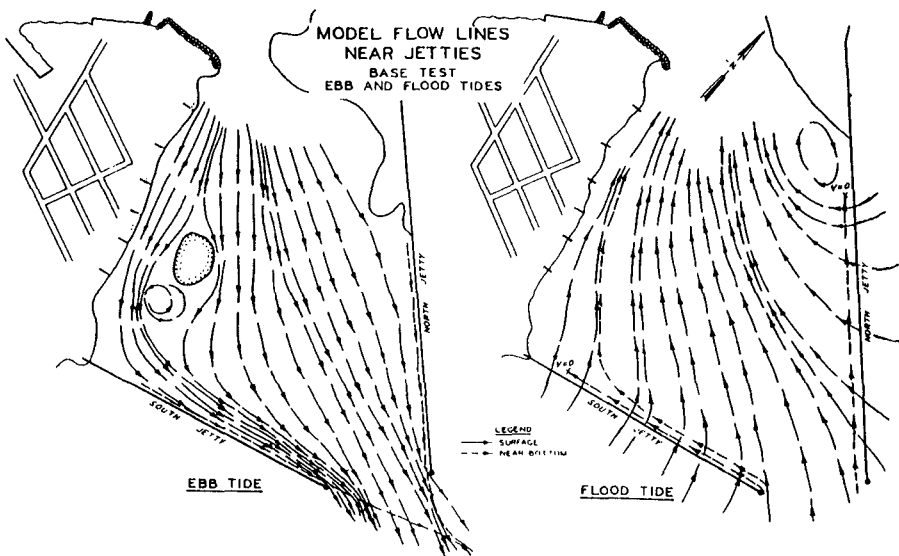

Figure 2. Model study flowlines, ebb and flood currents.(Sager and Hollyfield, 1974)

Historic Bathymetric Analysis

A review of historical bathymetry was performed to provide a basis for interpreting recent bathymetric changes at Barnegat Inlet and in providing guidance to anticipate future changes. Some historical information was derived from US Army Engineer District, Philadelphia, (1981) and Fields and Ashley (1987).

Pre-jetties In 1937 (Figure 3a) the pre-jetty inlet bathymetry shows that the interior channel swept south then turned east to northeast to exit the inlet, then turned southeast, on the ebb shoal, in response to predominant waves from the northeast. The 1937 interior channel was more than 460 m southeast of its current position (1996). The channel probably owed its large curvature to the infilling of the natural inlet on its north side as the inlet and channel both migrated south. The predominant portion of the tidal prism exited the bay from the north, channelizing around the large flood shoals due to a strong ebb shield factor resulting from this inlet's hydraulic phasing.

Arrowhead Jetties In 1939 arrowhead jetties were constructed and a channel, about parallel to the north jetty, was dredged into the bay in an attempt to provide a more direct route to the bay. Figure 3b shows the new interior channel in 1941. Also note the deflection of the ocean channel resulting from having the south jetty placed directly in its path.

Sand Dike By 1943 (Figure 3c), the sand dike was constructed in order to cut off the strong ebb flow from the dominant interior channel which was causing excessive scour on the inside shoulder of the inlet behind the lighthouse. It was anticipated that flow would be diverted to the straight interior channel, providing a deeper direct channel connecting ocean and bay. In addition, groins were constructed along the ocean shoreline inside the south jetty to mitigate shoreline erosion.

The 1946 bathymetry (Figure 4a) indicated a slight deflection of the navigation channel at the inlet's intersection with the shoreline as sediment moved over the low jetties at this location. On the south side of this region there was a shoal extending seaward from the lighthouse area, probably derived from sediment moving toward the inlet gorge along the shoreline inside the south jetty, then deflecting seaward on ebb. A buildup of sand at the shoreline is noted just inside the south jetty indicating an influx from the south beaches.

By 1953 (Figure 4b) the main navigation channel had shifted slightly south and rotated somewhat to the southeast. Sediment was moving over the low north jetty into the inlet gorge region. The interior region between the inlet gorge and the north tip of the sand dike contained flood shoals and three smaller channels. On the ocean side of the inlet, the navigation channel was close to the north jetty, as it had been for the previous ten years.

As of 1959 (Figure 4c) the navigation channel through the inlet gorge rotated away from the north jetty to the south and a scour area reappeared adjacent to the outer portion of the south jetty. The influx of sediment over the north jetty contributed to this rotation. Interesting to note was the shifting of the deepest area at the bayward end of the sand dike, which moved to the southeast side (compared with earlier conditions).

-----	-30' MEAN LOW WATER

Figure 4. Barnegat Inlet bathymetry, July-August 1946, July 1953 and August-September 1959.

Nineteen-sixty-two (Figure 5a) showed a new part of the flood shoal developing from sediment stripped from a spit which extended further from the north beachline into the inlet gorge. The minimum width of the inlet was reduced considerably due to sediment movement over the north jetty. The seaward portion of the channel migrated against the south jetty.

By 1968 (Figure 5b), the flood shoal occupied the location of the original dredged interior navigation channel. The interior channel was still bifurcated, but the region south of the flood shoal was widening and becoming the main interior ebb channel. It was forming in a similar configuration as was seen for the pre-jetties condition, except not as far southeast due to the presence of the sand dike. Sediment movement over the north jetty almost closed off the inlet gorge. The region between the arrowhead jetties was shoaling considerably except for the channel which had migrated against the south jetty. This sinuous channel was eroding the ocean-facing shoreline inside the south jetty and creating toe erosion which endangered the integrity of the oceanward portion of the south jetty. The trend of flood shoal growth and interior channel shifting south continued until the north jetty was raised 1.8 m from its original mean tide level crest elevation in the 1972-74 period.

Raised North Jetty The 1975 bathymetry (Figure 5c) indicated a major reorientation of the navigation channel through the jetty region. Dredging at the inlet gorge combined with cutting off sediment input by raising the north jetty permitted a straighter channel which was more in alignment with and closer to the north jetty. This channel orientation is reinforced by a concept presented by Keislich (1981) where a channel at a single-jettied inlet migrates toward the structure independent of whether or not the jetty structure is situated on the side of stronger longshore sediment drift. The Barnegat system probably can be considered a single jetty system in this respect due to the free flow of sediment and currents over the mean tide level south jetty, which helps move the channel toward the "single" north jetty.

Raising the north jetty caused a significant change in sediment pathways. The ebb shoal began to increase in magnitude (Figure 6a). This most likely can be attributed to the movement of sediment along the outside of the north jetty which previously had passed over the landward end of the low north jetty and contributed to flood shoal building and the movement of the inlet gorge towards the south. The same trend of channel alignment seen in the 1970's continued through the 1980's (Figure 6b). The interior navigation channel moved more towards its pre-project (1930's) location and the channel between the jetties was concentrated on the north side adjacent to the raised north jetty. This configuration was maintained until the construction of a new south jetty which occurred between late 1987 and 1991.

Hydraulic Response to New South Jetty

In order to build the new south jetty (Figure 7) from the revetted region on the south shoulder of the inlet beneath the lighthouse, shallow shoals were removed from

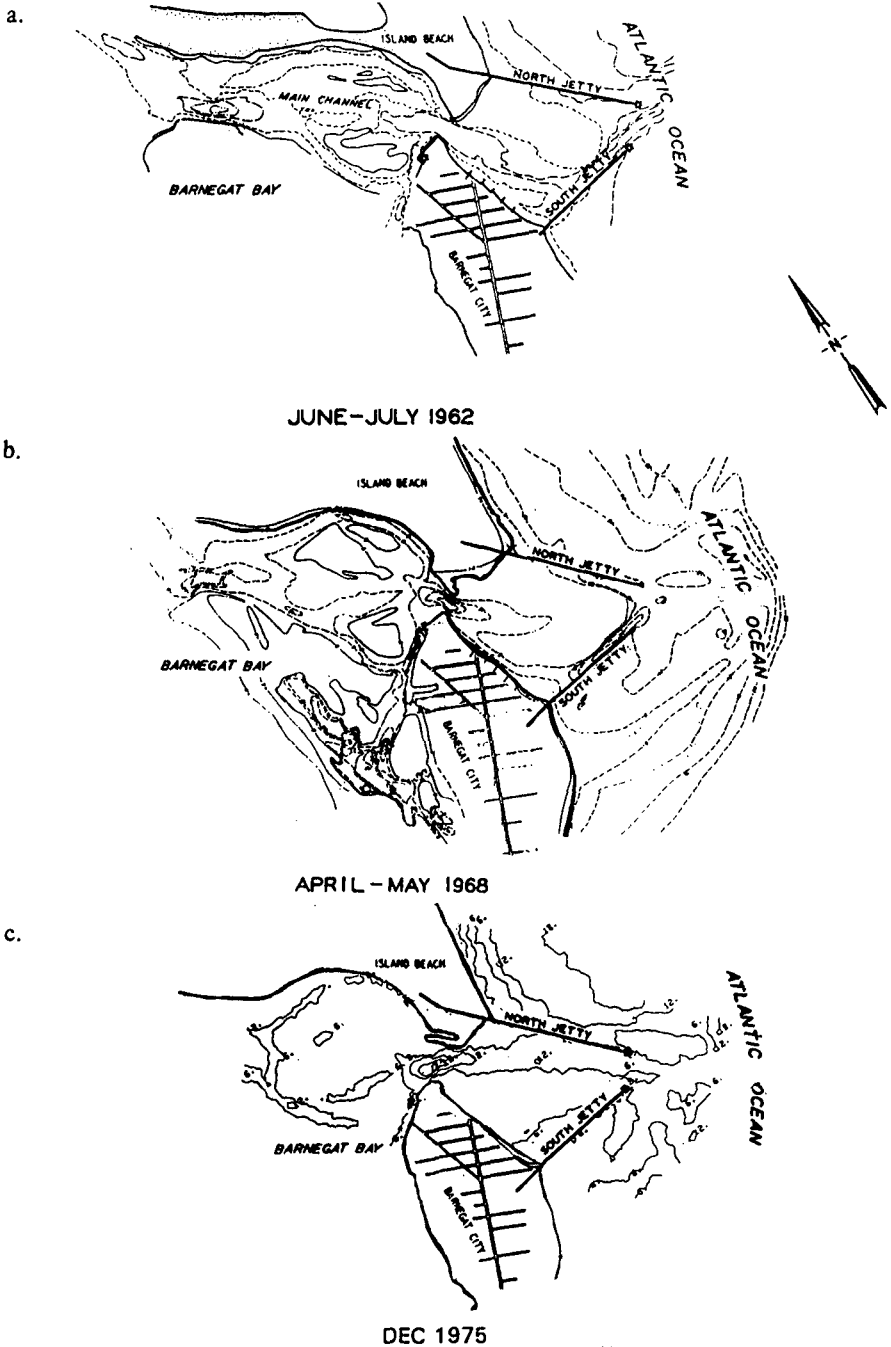

Figure 5. Barnegat Inlet bathymetry, June-July 1962, April-May 1968 and December 1975.

Figure 6. Barnegat Inlet bathymetry, June 1979 and December 1986.

this region. The inlet system became more efficient hydraulically due to an increase in minimum cross-sectional area which resulted from this shoal removal. This follows from O'Brien's (1969) relation between minimum inlet area, A_C (m^2) and tidal prism, P (m^3) at dual jettied systems: $A_C = 7.489 \times 10^{-4} P^{0.86}$. With minimal sediment entering the inlet system the increase in prism has been maintained since completion of the new south jetty. Figure 8 shows the variation in prism for the duration of the project. After the construction of jetties (1941), the inlet initially had the same tidal prism as the natural inlet, but the addition of the inside sand dike (Figure 1) lengthened the inlet channel and the newly dredged interior navigation channel had a reduced channel area compared to the old sinuous one. Sediment influx reduced areas and thus prism. The new south jetty prevented the influx of sediments that had previously occurred for the low south jetty and so the new, larger, minimum area has been maintained.

Figure 7. Barnegat Inlet 1994 bathymetry and 1996 air photograph.

Figure 8. Historical measured tidal prism variation.

Channel Response To New South Jetty

Analysis of the channel response to the most recent addition of the new 1250-m long south jetty reveals what appears to be an evolutionary change in channel depth in the region between the north jetty and new south jetty (Figure 9). The net sediment

Figure 9. Average channel depths between jetties, 1991 and 1995.

mass is translating bayward in the region of the parallel jetties. An important aspect of this is the flood dominance of currents on the south side of the intra-jetty region of the channel. Flood currents tend to enter the inlet region from the north jetty side (due to greater ebb shoal depth on the north and shallower ebb shoal depth on the south side, Figure 7a) and sweep toward the south jetty. Also the outer 305 m of the north jetty remains at the mean tide level elevation, permitting maximum flood currents to flow over this low section into the channel perpendicular to flow coming through the oceanward jetty tips. This also helps guide flood currents to the south side of the intra-jetty region. The occurrence of a shoal region between stations 200 and 400 is essentially a nodal point between ebb and flood flow dominance. Flood flow pushes sediment through the channel mostly on the south side, (based on velocity distribution measurements taken in 1994-96 by the authors). Ebb currents from the curved interior channel shear this shoal and sediment moves along the north side of the shoal (where ebb flows are concentrated) towards the ocean. Dredging of the channel shoal and, evidently, a net oceanward sediment circulation out of the intra-jetty region have caused a progressively deeper channel.

The interior navigation channel is moving southward, as the flood shoal flattens out since sediment is not reaching it from the north or south adjacent shorelines or the ebb shoal. This channel has migrated south about 90 m in the last three years (1994-96). Flood currents plus ocean waves traveling with the currents move sediment towards the bayside of the flood shoal. On ebb, the current shears off sediments from the back edge of the flood shoal and moves it counter-clockwise along the edge of the shoal. Sediment settles out on the south edge of the flood shoal as strong ebb currents move away from the shoal to the outside of the curved channel. This spreading out of sediment may decrease the effectiveness of the flood shoal as an ebb shield and gradually permit more ebb flow over the shoal. Some incised cutting of the center of the flood shoal can be noted in Figure 7b.

Lessons Learned

The concept of arrowhead jetties to provide concentration of ebb flows at the oceanward terminus (in order to cut through the ebb shoal) and for wave attenuation due to diffraction as waves propagated into the expansion area, were positive design attributes. The hydraulics of such a system with regard to the velocity phasing at Barnegat Inlet (maximum flood currents near high water and max ebb near low water) combined with mean tide level jetties would permit broad, less concentrated flood currents to approach the inlet, presumably having less potential to carry sediments into the inlet. Strong ebb flow concentration in the navigation channel would flush sediments out of the channel as water surface elevation dropped. However, the sediment influx over these low jetties overshadowed the positive elements of the plan. Apparently most of the sediment movement was at the shoreline intersection with the jetties.

It was learned from the historical analysis of bathymetries that the interior navigation channel moved back to its pre-structure alignment, probably due to the influx of sand coming over the low north jetty, which enlarged the flood shoal significantly and helped deflect ebb currents coming from the bay towards the southeast. There was a similar situation for the natural inlet, which had been migrating south, thus infilling on the north side and accumulating sediments to help deflect ebb currents to the south.

Raising of the north jetty crest elevation cut off direct sediment influx from the north but sediments from the south maintained the same minimum area at the inlet gorge. Channel migration to the now dominant north jetty, plus dredging, cut off input to the flood shoal and redirected beach sediments to the ebb shoal.

The effects of sediment input into an inlet system in equilibrium usually is balanced by sediment moving out. At Barnegat Inlet, initially structural changes effectively lengthened the channel which led to increased friction, reduced currents, followed by sedimentation and reduction in tidal prism. The addition of a new higher south jetty paralleling the north jetty along with an increase of minimum channel area due to dredging and the prevention of sediments entering from the south into the inlet gorge permitted a larger tidal prism.

It took over 20 years (1941 to 1965) for the straight interior navigation channel to move to the south back to its historic curved configuration. However, recent incising of the flood shoal and the apparent reduction in sediment supply to the flood shoal indicates a potential for ebb currents to eventually "short-cut" across the flood shoal and deepen a channel there.

Conclusions

Inlet channel location is a complex function of inlet hydraulics, littoral influx to the channel system, and inlet structures. Historic analysis of structural effects has provided a clear picture of inlet response and impacts on channel location. Initially low arrowhead jetties followed by an interior sand dike, then sand tightening of one jetty with increased jetty elevation, and finally conversion to a parallel jetty system, affected inlet hydraulics and sediment input, which in turn changed shoaling patterns and thus channel location. With the low arrowhead jetty system, sedimentation reduced channel cross-sectional area with a corresponding reduction in tidal prism. Today's inlet, which is still adjusting to the new parallel south jetty, appears to allow a more stable channel to exist due to the restriction of sediment input into the navigation channel. These factors along with an increase in minimum channel area due to dredging have changed the tidal prism back to pre-structure conditions.

Acknowledgments

The work was funded through the Monitoring Completed Navigation Projects Program and the Coastal Inlets Research program. Assistance of Mr. Keith Watson and others at the US Army Engineer District, Philadelphia, is appreciated. Work performed by previous co-investigators, Ms. Monica Chasten and Mr. John McCormick, is also recognized. Permission to publish was granted by the Office, Chief of Engineers.

CHAPTER 353

Complete Closure of The Nanakita River Mouth in 1994

Hitoshi Tanaka¹, Fumihiko Takahashi² and Atsushi Takahashi³

ABSTRACT

Very severe draught occurred in Japan during the dry season in 1994. Due to considerably reduced river discharge, complete closure was induced five times at the Nanakita River mouth in Japan during this period. Detailed field observations were carried out immediately before and after the closures. By analyzing hydraulic characteristics measured at the mouth, date of the closure occurrence can be estimated. An analytical solution is derived for predicting time-variation of river mouth width under the combined influence of incoming waves and effluent river discharge.

1. INTRODUCTION

There have been a lot of field measurements of topography change at a river mouth in connection with practical problems such as flood control and maintenance of a navigation channel. Most of them are, however, made at relatively large rivers due to their practical importance, and, consequently, very few attention has been paid to small ones.

The authors have been conducting field measurement of topography change at the mouth of the Nanakita River, one of typical small rivers in Japan, since 1988 (Tanaka and Shuto, 1989, 1991, 1992; Tanaka, Kabutoyama and Shuto, 1995; Tanaka and Ito, 1996). The Nanakita River originates at the northern part of Sendai and pours into the Pacific Ocean as shown in Fig.1. The catchment area and the length of the river are 229km² and 45km, respectively.

From 1988 to 1993, the complete closure at the Nanakita River mouth has been observed only twice (Tanaka and Shuto, 1991), whereas in 1994, the closure

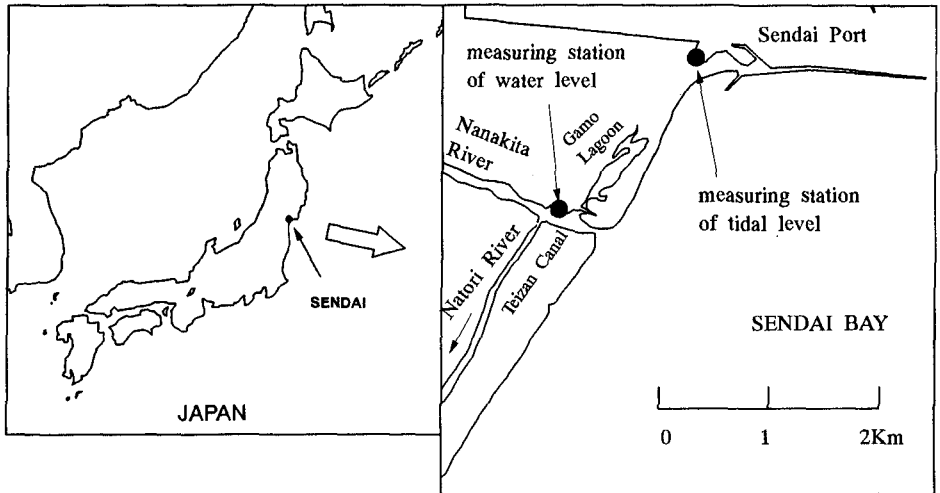

Fig. 1 Location map of the Nanakita River mouth

occurred five times in contrast, probably due to remarkable reduction of the fresh water discharge during the dry season. In this paper, results of detailed field surveying of the topography change will be firstly shown along with corresponding external forces acting at the river mouth. Furthermore, a mathematical model, considering littoral drift by waves and sediment flushing due to river discharge, will be applied to the Nanakita River in order to reproduce the change in the river mouth width.

2. RESULTS OF FIELD OBSERVATION

Figure 2 shows the significant wave height H , the wave period T , the wave incident direction θ measured clockwise from the north, and the river discharge Q_r . The wave characteristics are measured 4 km offshore from the river mouth at the mean depth of 20m, while the fresh water discharge is measured at a gauge station 9km upstream. In Fig2, the dates when the river mouth closure was firstly observed are also drawn by thick arrows. It should be noted that these are not the dates when each closure occurred, but the dates when the authors firstly noticed the closure. It is seen that the river discharge is considerably small due to draught as compared with other years (Tanaka and Shuto, 1989, 1991) and that very high waves immediately before each closure are common to all events.

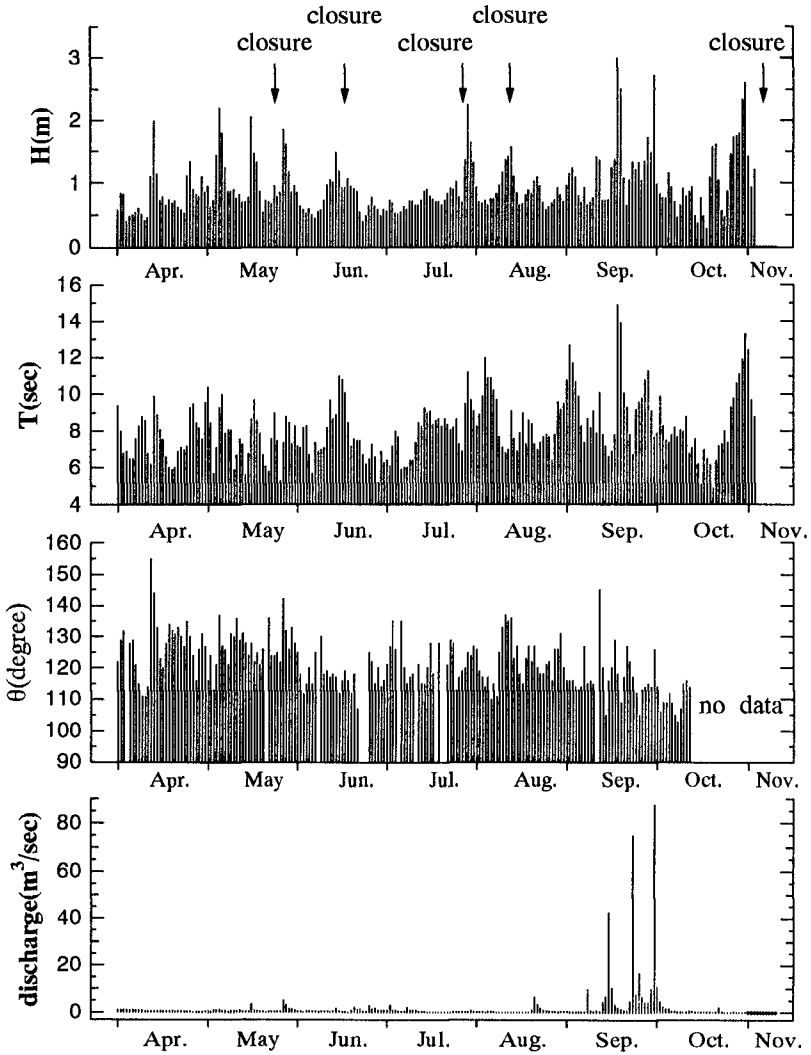

Fig. 2 Time-variation of waves and river discharge

According to Tanaka and Shuto's (1991) study on river mouth closure at the Nanakita River, the incoming waves with incident angle of about 100° are the most unfavorable for keeping the mouth open, suggesting that onshore sediment transport is more effective for the river mouth closure than the longshore sediment movement. In 1994 data set shown in Fig.2, though, such a relationship between the occurrence of closure and the wave incident angle can not be observed.

Water level variation in the mouth is shown in Figs.3 and 4 for June and November respectively, along with the tidal variation measured in the Sendai Port. The location of the measuring stations can be found in Fig.1.

In June, the closure was firstly observed on 17th, and artificial excavation was carried out on 20th. The water level in the mouth shows less variation before and after 17th and is always higher than the tidal level. Even after the closure, slight time-variation can be seen in the Nanakita River mouth. This is due to the tide propagated through the Teizan Canal shown in Fig.1, which connects the Nanakita and Natori River mouths.

The closure in November was firstly observed on 6th. However, judging from Fig.4, it seems that the closure of the mouth progressed gradually from the end of October. Figure 5 shows a temporal variation of the shoreline in the process of river mouth closure in November. Since it can be confirmed that the topography change affected much the water level inside the mouth (Tanaka and Shuto, 1991), the ratio

Fig. 3 Water level variation in June

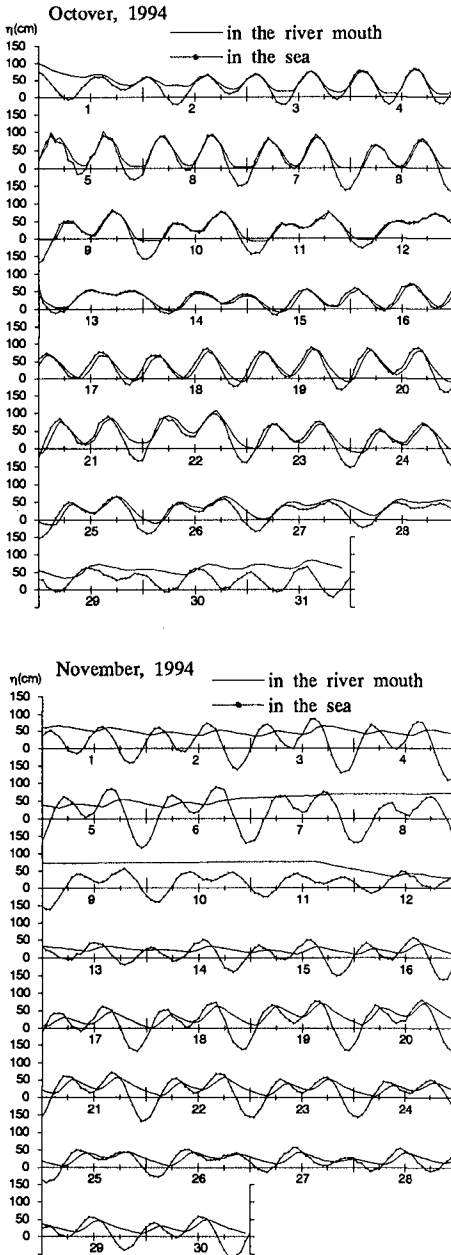

Fig. 4 Water level variation in October and November

Fig. 5 Shoreline change at the Nanakita River mouth

Fig. 6 Water level ratio and lag time

y_R/y_O and the lag time Δt are plotted in Fig.6, where y_R and y_O the daily highest water levels in the river mouth and the sea, respectively, and Δt the time difference between y_R and y_O . At first, the water level ratio shows gradual increase from 1.0 on October 26th to 1.4 on November 1st, and then distinctly decreased to 0.6 on November 3rd, while Δt shows an increase from 0 hour up to 3 hours. Thus, this figure suggests that the river mouth closure was completed on November 3rd. The water level rise in the mouth immediately before the closure in Fig.6 was induced by wave set-up due to wave breaking in front of the river mouth (Tanaka and Shuto, 1992), and the wave set-up height measured in the mouth shows close relationship with the wave height.

3. MATHEMATICAL MODELING

3.1 Governing Equations

A mathematical model proposed by Ogawa et al. (1984) will be employed for predicting closing process at a river mouth owing to predominant wave motion. It is assumed that the wave motion is responsible for the intrusion of sediment into the mouth, while the river discharge is effective for flushing sediment out of the mouth as illustrated in Fig.7. Thus, the corresponding governing equation is expressed as follows (Ogawa et al., 1984).

$$(1 - \lambda)Lh \frac{dB}{dt} = e_r q_r B - e_w (1 - \lambda) Q_w \quad (1)$$

where λ the porosity of sand, L the width of sand spit, h the water depth at a mouth, B the width of a river mouth, and e_r and e_w the efficiency of sediment inflow by waves and that of sediment outflow by current, respectively. The sediment transport rate due to current, q_r , and that induced by wave motion, Q_w , can be evaluated by means of conventional formulae, Eq.(2) (Brown, 1950) and Eq.(3) (CERC, 1984), respectively.

$$q_r = K \left(\frac{u_*}{sgd} \right)^m u_* d \quad (2)$$

$$Q_w = \alpha (Ec_g)_b \sin \theta_b \cos \theta_b \quad (3)$$

where K is the constant (=10.0), u_* the shear velocity, s the immersed specific weight

Fig. 7 Schematic explanation for the model

of sediment, g the gravitational acceleration, d the grain diameter, m the power (≈ 2.0), α the empirical coefficient, $(Ec_g)_b$ the incident wave energy flux evaluated at the breaker line, and θ_b the breaking wave angle to the shoreline. The coefficient α in Eq.(3) has already been evaluated to be 0.05 by Tanaka and Shuto (1991) by applying the one-line model to shoreline change adjacent to the Nanakita River mouth.

3.2 Analytical Solution

The following exact solution can be derived from Eq.(1), assuming the wave condition and the river discharge are constant.

$$(B^* - 1) + \frac{A_1^*}{4} \log \left| \frac{(B^* - A_1^*)(1 + A_1^*)}{(B^* + A_1^*)(1 - A_1^*)} \right| - \frac{A_1^*}{2} \left[\tan^{-1} \left(\frac{B^*}{A_1^*} \right) - \tan^{-1} \left(\frac{1}{A_1^*} \right) \right] = -t^* \quad (4)$$

where the dimensionless quantities in Eq.(4) are defined as

$$B^* = \frac{B}{B_0}, \quad A_1^* = 4 \sqrt{\frac{A_1/A_2}{B_0}}, \quad t^* = \frac{A_2 t}{B_0} \quad (5)$$

$$A_1 = \frac{e_r K d (\sqrt{gnQ})^{2m+1}}{(1-\lambda)Lh(sgd)^m h^{7(2m+1)/6}} \tag{6}$$

$$A_2 = \frac{e_w Q_w}{Lh} \tag{7}$$

in which B_0 denotes the initial river width, n the Manning's friction coefficient and Q the effluent discharge consists of fresh water and tidal prism.

Some interesting asymptotic behaviors of a river width can be derived from Eq.(4). First of all, if the river discharge is zero, substitution of $A_1^*=0$ into Eq.(4) yields the following simplification.

$$B^* = 1 - t_* \tag{8}$$

Namely, the dimensionless river width shows linear reduction with the passage of time until it closes completely at $t_*=1$. Secondly, the width of equilibrium stage can be easily obtained by substituting $dB/dt=0$ in Eq.(1). The dimensionless form normalized by B_0 is

$$B_\infty^* = \frac{B_\infty}{B_0} = A_1^* \tag{9}$$

According to Eq.(4), it takes infinite duration to reach equilibrium width, though, t_∞ will be herewith defined as the duration when B becomes $0.99 B_\infty$. A dimensionless form for t_∞ can be derived from Eq.(4).

$$t_\infty^* = A_1^* \left\{ a^* - \frac{1}{4} \log \left| \frac{1+A_1^*}{1-A_1^*} \right| - \frac{1}{2} \tan^{-1} \left(\frac{1}{A_1^*} \right) \right\} + 1 \tag{10}$$

where $a^*=0.722$ for $A_1^*>1$ and $a^*=0.711$ for $0<A_1^*<1$. As A_1^* approaches infinity, Eq.(10) can be approximated by the simple expression,

$$t_\infty^* = 0.723A_1^* \tag{11}$$

Time-variation of dimensionless width, B^* , computed from Eq.(4) is depicted in Fig.8. The parameter A_1^* denotes the ratio of sediment transport rate out of a river mouth due to river discharge to sediment intrusion into a river mouth caused by wave

Fig. 8 Time-variation of river mouth width

Fig. 9 Relationship between t^*_∞ and A_1^*

motion, as defined by Eq.(5). Thus, the horizontal line for $A_I^*=1.0$ in Fig.8 corresponds to dynamic equilibrium state, in which sediment transport rates out of and into a river mouth are balanced, whereas the family of curves for $A_I^*>1.0$ and $A_I^*<1.0$ represents widening and reduction processes of river mouth. In case of $A_I^*=0.0$, the river mouth closes completely at $t^*=1.0$ as mentioned earlier because of no sediment flushing out of a river mouth. According to the existing theory for river mouth closure without sediment outflow from a river mouth, the solution is given in terms of exponential function, denoting that infinite duration is needed for completion of closure (Tsujimoto et al, 1989). It seems that the present solution, in which closure can be completed within finite duration, is more realistic.

Figure 9 shows the relationship between t_{∞}^* and A_I^* obtained from Eqs.(10) and (11). At $A_I^*=0$, sediment movement at the mouth is in dynamic equilibrium state as described before. Therefore, t_{∞}^* is exactly zero at $A_I^*=0$. The accuracy of Eq.(10) is sufficient as long as A_I^* is higher than 2.0.

3.3 Comparison with Field Observation

The measured shoreline change at the river mouth shown in Fig.5 can be now compared with the present theory. The open circles in Fig.8 denote measured data at the Nanakita River mouth in 1994. Since the wave characteristics and the fresh water discharge are assumed to be constant in the theory, the quantities shown in Fig.2 except wave direction are averaged from October 4th through November 7th, whereas the averaging of wave direction is done from October 4th through November 12th due to lack of the data after November 13th as depicted in Fig.2. As for the coefficients, e_r and e_w in Eq.(1), the values determined by one of the authors (Tanaka, Kabutoyama and Shuto, 1995) are used for the present computation. It is observed that the measured change in the river mouth width shows reasonable agreement with the present theory.

4. CONCLUSIONS

River mouth closure was observed five times at the Nanakita River mouth in Japan in 1994. Conclusions drawn from this study can be summarized as follows:

- (1) One of the authors has already reported that the closures of the Nanakita River mouth in 1988 and 1989 were induced by high waves having a incident angle 100° . In 1994, however, the incident angle of high waves which caused the closure did not show this tendency.
- (2) By analyzing the ratio and lag time between the water level measured in the mouth and that in the ocean, the date when the closure had completed can be determined. Distinct rise of water level in the mouth caused by wave set-up can be observed immediately before the completion of the closure.
- (3) A mathematical model proposed by Ogawa et al. (1984) is used for predicting

time-variation of width at a river mouth under the combined influence of incoming waves and effluent river discharge. Analytical solution can be obtained, assuming constant wave characteristics and fresh water discharge. The measurements and the theory showed reasonable agreement.

5. ACKNOWLEDGMENT

The authors would like to express their grateful thanks to the members of River Engineering Laboratory and Tsunami Engineering Laboratory, Tohoku University, for their cooperation during the course of the field measurements. Their appreciation should be extended to the Shiogama Construction Office, Ministry of Transport, and the Higashi Sendai Construction Office, Miyagi Prefectural Government, for their offer of the field data. A part of this study was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan.

CHAPTER 354

THE EROSION OF A SALT WEDGE TRAPPED BEHIND A BARRAGE ACROSS AN ESTUARY

Walker¹, S.A., Hamill², G.A. , Johnston³,H.T.

Abstract

The problems associated with the stratification of fluids, particularly in estuaries, are of growing concern. Based on water quality problems which occurred at the River Lagan, N. Ireland, an experimental investigation was undertaken into the fluid mixing process within a stratified flow. High quality temporal measurements have been used to examine the processes of erosion of a saline stratification trapped behind a barrage. Two distinct mechanisms of wedge erosion have been identified, both of which involve the formation of a mixed layer.

Introduction

Density stratification in fluids occur due to variations in momentum, temperature and salinity. Mixing between such strata plays a critical role in various phenomena of meteorology, hydraulics and oceanography. Barrages are now frequently used to improve the visual appearance of estuaries by controlling water levels in a semi-tidal impoundment. In such impoundments fresh river water and salt water from the sea normally mix. However, under certain circumstances a stable stratification occurs between the two fluids. When the flow in a river is low, there is little mixing and therefore limited transfer of oxygen between the fresh and salt water layers. This can lead to oxygen depletion and possibly anaerobic conditions at the bed, with subsequent damage to the aquatic environment.

¹ Research student, ² Lecturer, ³ Senior Lecturer

Department of Civil Engineering, The Queen's University of Belfast, David Keir Building, Stranmillis Road, Belfast. BT7 1NN

Background

Belfast developed along a tidal reach of the River Lagan and many industries were established along the banks of the river. At low tide extensive areas of unsightly mudflats were exposed and so a weir was constructed across the river in 1934 to create, on part of the river, a semi-tidal pond which would cover the muds at all tide states. However, the construction of this weir led to periodic water quality problems. During periods of low river flows, the fresh and saline waters entering the pond from the river and the tidal flow stratified, and there was little flushing of the denser saline water trapped behind the weir. The oxygen content of the trapped water was rapidly depleted by the decomposition of organics in the water and the bed muds. This damaged the fish and plant life in the river and led to the production of hydrogen sulphide.

The demise of riverside industries and the poor river water quality resulted in the city turning away from the river front which rapidly became polluted. The result was that extensive inner city areas were blighted and had little development potential.

In 1969 the construction of a new weir downstream of the Queen's Bridge was proposed to regulate river levels and create an attractive water environment. This proposal was renewed by the River Lagan Working Group in the 1970s and specialist studies were instigated. In 1988, the Civil Engineering Department of The Queen's University of Belfast was commissioned to undertake a study seeking to establish design parameters for a structure which would control the water levels, protect the city against tidal flooding and improve the water quality in the river. The proposed impoundment was just under 5 km. in length with a surface area of 40 ha. This pond would have river flow and urban drainage inputs, some of which would have high biochemical oxygen demand levels.

Research Programme

A research programme was undertaken in which a physical model of some 8 km. of the tidal channel and harbour area, including the proposed impoundment, was constructed to a horizontal scale of 1:150 to establish design and operation parameters for the weir. A scale distortion factor of three was used to ensure adequate depths for the study of salinity profiles in the model.

In conjunction with the construction of the physical model a monitoring programme was established on the River Lagan. Velocity and salinity measurements were taken at a number of stations on the river for use in calibrating the model. The measurements were taken for river conditions ranging from low to flood flows, and at a variety of tidal conditions. The velocity measurements were used to establish boundary roughness values in the model at different water levels. The model was then validated by reproducing salinity profiles measured in the river at different tide states.

Salinity profiles at high tide, established after a number of tide cycles in the model, behind the existing weir showed that for a river flow of 2 cumecs the stratification was well defined and extended over the full length of the impounded reach. When the river flow was increased to 5 cumecs, the entrapped wedge retreated

showing a significant reduction in both volume and concentration. A new weir placed at the proposed downstream site resulted in a pond with characteristics similar to that behind the existing weir. This showed that the construction of a fixed crest weir at the new site would simply replicate the problems of water quality being experienced behind the existing weir.

An active weir design was considered whereby the impoundment would be controlled by a gated weir structure incorporating a system for withdrawal of water at a low level. A gated weir would have the added advantage of being able to exclude high tides as well as controlling water levels in the impoundment. It was decided to use a gate system which would be able to exclude surge tide levels above that which would be reasonable expected at present but which might occur if there was a rise in tide levels due to global warming.

A low level withdrawal system was included to evacuate saline water from behind the weir on an ebb tide, when stratification problems were present in the impoundment. On a flood tide, the weir would allow saline water into the impoundment over the lowered gates. At high tide, the gates would be raised and the low level withdrawal system would be opened. This would allow drawdown of the impoundment, during the ebb tide period, through the low level withdrawal system which would have a capacity of 25 cumecs.

It became clear from the model study that the mixing process involved in this highly stratified situation was unclear. The lack of information for the design engineers to predict the quantity of saline material which would be removed under normal flow conditions indicated the need for a fundamental investigation of the process. This programme of work commenced in 1993, and the initial findings are reported in this paper.

Related research

It has already been established that the entrainment of the salt water is a function of the Richardson number, Ri , of the flow (Ellison 1959). The Richardson number is a measure of the ratio of the gravity forces to the inertial forces in a shear flow having a vertical density gradient. It is widely used as a measure of the stability of the flow with regards to vertical mixing. It generally takes one of two forms, the bulk Richardson number

$$Ri_b = g \frac{\Delta\rho H}{\rho V^2}$$

where $\Delta\rho$ is the density difference, H is the depth of fresh water and V is the average velocity, and the gradient Richardson number

$$Ri_g = -g / \rho \frac{\delta\rho / \delta z}{[\delta v / \delta z]^2}$$

where $\delta\rho/\delta z$ is the density gradient and $\delta v/\delta z$ is the velocity gradient. Turner (1973) and Christodolou (1985) further classified the type of mixing to be dependent on the magnitude of the Richardson number. A critical gradient Richardson number of 0.25 was found to be the limiting criteria between stable and unstable flow.

Experimental facility

To allow a wide test range, upto prototype conditions, a new facility was constructed within the Civil Engineering Department. This new facility consisted of a testing area 20m long, 0.75m wide and 0.75m deep a schematic of which is shown in Figure 1. The salt water was retained between two baffles which were 17.5 m apart. The salt water depth was kept constant at 0.25m whilst the fresh water depths were varied by means of an adjustable weir. The ability to produce conditions in which the saline water was either stationary or flowing, either with or against the prevailing river flow, was included thus allowing the simulation of tidal movements. The results

Figure 1 Experimental Facility

presented here represent the condition of a fully trapped saline wedge. Fresh water was mixed with dried salt and dye in the storage tanks and then pumped into the salt water impoundment to a depth of 0.25m. Fresh water was then filled slowly on top, over the course of 12 to 15 hours. Flow was initiated slowly in the upper layer by starting the fresh water pump. Once the flow had reached the required rate the water in the storage tanks was changed slowly by opening the waste valve and filling from the supply. This was necessary due to the contamination of the fresh water which occurred as a result of mixing. The degree of contamination was relatively small in most cases, but large enough to change the salinity of the fresh water over a substantial time period.

The scanning process was commenced after flow was initiated. Velocity and density profiles were obtained at the centre of the channel. Velocity measurements were obtained using LDA with a fibre optic attachment to limit the effect of differing refractive indices. Density measurements were obtained using a conductivity probe with small measuring volume. The probe consisted of two wires 5 mm thick which

were completely covered except for 2 rings, 2mm thick, near the bottom. Both probes were mounted on a linear actuator which was computer automated. The probes were placed in the salt water, usually about 20 to 30mm below the interface in order to obtain a reading of maximum salinity. An average was taken over a period of 30 seconds and the probes were then moved in a 5 mm step so that the vertical density profile could be obtained. Due to the temporal nature of the experimental investigation it was necessary to obtain as many profiles per hour as possible. The profile obtained was therefore not a full vertical traverse but was limited to 120mm around the interface. With time the interface moved downwards, as salt water was removed by entrainment from the impoundment, and it was necessary to incorporate movement of the base profile position into the scanning program.

Figure 2 Density profiles (a) After 25 minutes (b) After 1 hour 30 minutes (c) After 5 hours

Development of Interfacial Layer.

The development of the mixing interfacial layer, as fresh water was allowed to flow across the stationary salt wedge, was studied with time. Figure 2 (a) shows the initial condition used in all tests. It clearly displays the fresh and salt water zones. Figures 2 (b) and 2 (c) are for the same situation, but with time having advanced to 1 hour 30 minutes and 5 hours respectively. The presence of a flow in the fresh water can be seen to have developed an interfacial layer, in that there is no longer a clear distinction between the fresh and salt water. It is from within this interfacial layer that the majority of entrainment of the saline liquid takes place.

This is clearly visible by the changing density gradient within the interface. The density within the interfacial layer was taken to be the average value within the density gradient of the layer. Figure 3 shows the interfacial layer in detail. It can be seen that the layer is defined by that position of the mixing region over which the variation of density occurred, this variation being taken as linear for purposes of analysis. The thickness of the interfacial layer was also obtained on this basis.

Figure 3 Definition of interfacial layer

It was found that the behaviour of this layer varied with certain combinations of flow, depth and density difference, and two mechanisms of erosion existed. In the first of these the wedge was eroded by sequential stripping of the interfacial layer, this process was labelled as oscillating due to the cyclic nature of the event. The second mechanism showed no such cyclic behaviour, with the density of the mixing layer decreasing to a steady state value. This mechanism was labelled as being non-oscillating. Significant differences in the temporal development and entrainment process was found for each mechanism.

Oscillating mechanism

Using the density profiles obtained from the experimental investigation, the layer position was plotted with time. Figure 4 represents a typical test which displayed the cyclic behaviour. On it can be seen the change, with time, in thickness of the interfacial layer and the density within that layer. The decrease in layer density corresponds with an increase in the layer thickness, this is as would be expected and closely mirrors the initial stage of the steady state condition. However, a critical point is reached where upon the density within the layer starts to increase again, with a corresponding decrease in the layer thickness. This corresponded to a period of rapid upper boundary movement when part of the layer was washed out. When the layer was at its thinnest there appeared to be an increase in the lower boundary movement,

Figure 4 Relative interfacial layer density and thickness (oscillating mechanism)

as the free stream was now much closer to this boundary. This resulted in entrainment from the salt pool within the wedge. It would appear that for the oscillating process as the density of the layer decreases, the interfacial slope increases in order to resist the interfacial shear stresses. Figure 5 shows the variation of typical velocity and density gradients. These also show a definite cyclic behaviour with the maximum velocity gradients occurring when the layer was most dense.

If the change in the gradient Richardson number is examined, as shown on Figure 6, it can be seen that when the upper part of the layer was removed, the value of Ri dropped to approximately 0.25. As this represents the critical Richardson number it implies that the flow becomes unstable at these times, and this was confirmed by the presence of large amplitude breaking waves.

Figure 5 Interfacial velocity and density gradients (oscillating mechanism)

Figure 6 Variation of gradient Richardson number (oscillating mechanism)

Non Oscillating mechanism

Whenever no oscillation of the mixing layer characteristics occurred the removal of the trapped saline solution progressed steadily with time. The time taken to achieve this varied with the magnitude of the circulation velocity within the mixing layer. Figure 7 shows the typical variation of the interfacial density and layer thickness for those tests which eroded at a steady rate. An initial high growth rate of the mixing layer occurred both in thickness and density, where upon almost constant conditions prevailed, and the saline pool was steadily depleted. Comparison with the equivalent figure for the oscillating test (figure 4) shows clearly the different mechanism of erosion in action. The velocity and density gradients also can be seen, in figure 8, to remain constant once the layer became established, as did the gradient Richardson number. Figure 9 gives an indication of typical variations in the Richardson number for non oscillating tests. The accepted threshold of instability in the flow occurs when the Richardson number fall below a value of 0.25.

Figure 7 Relative interfacial density and thickness (non oscillating mechanism)

Figure 8 Interfacial velocity and density gradients (non oscillating)

Figure 9 Variation of gradient Richardson number (non oscillating)

At no point during any of the tests which showed no oscillation did the Ri_g number approach this threshold. The key to the two mechanisms is therefore clearly a function of the flow instability.

Transport Rates

The changes in the density profiles obtained at different times during each test were used to determine the rate of erosion of the salt water impoundment. Transport across the upper boundary gave the overall rate of salt water removal during the test. This was calculated by approximating the profile, as can be seen in Figure 10, based on the position of the boundaries and the density of the layer. This allowed the volume of salt to be calculated very easily, with the differences between profiles at different times being taken as the as the volume of salt water transported. Any change in density of the interfacial layer, or drop in position of the upper boundary, was deemed to be due to transport across the boundary. Transport rates across the lower boundary were determined in a similar manner.

Based on a dimensional analysis, a dimensionless form of transport was used. This dimensionless transport, T, was defined as

$$T = \frac{t}{\Delta\rho V H}$$

where t is the average transport (kg/s), $\Delta\rho$ the initial density difference, V the initial average fresh water velocity and H the initial fresh water depth.

Figure 10 Stepped approximation for density profile

Figures 11 and 12 show the average transport rates obtained for the oscillating and non oscillating mechanisms respectively, plotted against the bulk Richardson number. It can be seen that in each case there exists a strong linear relationship between the rate T , and the Ri_b value, and that the rate obtained for each mechanism is similar, with the major difference occurring in the rates across the upper and lower boundaries.

Figure 11 Dimensionless transport rates (oscillating mechanism)

Figure 12 Dimensionless transport rates (non oscillating mechanism)

Figure 13 Dimensionless tranport rates for both mechanisms

Figure 13 is a combined plot for the transport rates obtained for both mechanisms of erosion. It can be seen that within each mechanism the transport rates were similar and could be best described by equations of the form

$$T_u = 447.2 Ri_b^{-1.303}$$

for the transport across the upper boundary and

$$T_l = 184.2 Ri_b^{-1.2}$$

for the transport across the lower boundary.

Conclusion

In all cases interfacial mixing resulted in the formation of an interfacial or mixed layer which was around 30 to 40 mm thick. Only those tests conducted with low values of Reynolds number (i.e. <2000) showed no mixing.

Two mechanisms of erosion have been observed. These were classified as oscillating and non-oscillating, depending on the behaviour of the layer in terms of its relative density and thickness. In some tests the density of the layer decreased rapidly, and then remained constant and these were classified as non-oscillating. In a number of cases the density within the layer decreased initially and then increased again after the upper part of the layer was removed. These tests were classified as oscillating as a cyclic behaviour was observed in the layer density.

The gradient Richardson number remained approximately constant during those tests which did not oscillate, indicating a stable flow. For those tests which showed the oscillating behaviour, the value of Rig was found to show a cyclic behaviour. When the layer was washed out, the value of Rig dropped towards 0.25, indicating unstable flow. Mixing occurred as a result of large amplitude breaking interfacial waves.

After the start of a test greater rates of transport were observed at the upper boundary as the layer formed. This resulted in a decrease in density until the layer washed out and a peak rate was observed at the upper boundary. Greater rates of transport were observed at the lower boundary when the layer was thinnest. This caused the density of the layer to increase with time.

Average transport rates were calculated during each test from the change in density profiles. Rates were averaged over the duration of the test and calculated for both boundaries. Dimensionless transport rates were found to be best related to the bulk Richardson number (Rib) with higher rates of transport for low values of Rib .

It is hoped that the ability to estimate the removal rate of trapped salt water will aid the process of barrage design, and act as a tool for river management schemes by which the inducement of natural mixing can be accounted for.

CHAPTER 355

Near-Field Measurements of a Buoyant Jet in Waves and Currents.

K.H. Kwan¹ & C. Swan².

Abstract.

The present paper concerns the near-field characteristics of a jet discharged into a wave environment, and contrasts the results of two new experimental studies with a modified integral solution based upon a quasi-Lagrangian description of the flow field. This solution differs from previous attempts to model near-field wave mixing (namely Koole and Swan, 1994) in that it is formulated within an absolute frame of reference, and therefore adequately incorporates the momentum flux associated with the entrained fluid. Having implemented this important modification, the Lagrangian model is shown to provide a good quantitative description of a buoyant hot-water jet discharged into either a steady current or an unsteady wave field. In particular, there is no uncertainty regarding the magnitude of the entrainment coefficients, and as such the model is suitable for design calculations. In addition, detailed comparisons between the temperature profiles ensemble-averaged with respect to the phase of the wave cycle hint at a new mixing mechanism. Experimental data is presented which suggests that the wave-induced oscillatory motion leads to the division of the jet at certain phases of the wave cycle. If this effect is indeed important, then it implies that the average dilution will be enhanced when a jet is discharged into the plane of the wave motion.

Introduction.

Under most practical conditions outfalls discharge their pollutants, whether it be unwanted heat or partially treated effluent, into coastal waters which are dominated by the effects of wave action. However, present design practice largely ignores the wave motion and applies a simplistic approach in which both the

¹ Research student & ² lecturer, Department of Civil Engineering, Imperial College, London. SW7 2BU. United Kingdom.

concentrations and the velocities arising within the near-field are predicted using some form of integral solution (Morton et al, 1956) based upon the conservation of mass, momentum, and where appropriate species concentration. This approach is often justified on the basis that the wave motion will, at worst, produce additional mixing and thus the design calculations are conservative. Unfortunately, recent studies (Koole and Swan, 1995) have shown that this does not necessarily follow, and that under some circumstances the wave motion may produce local increases in the concentration levels. Furthermore, previous studies have also clearly demonstrated that the occurrence of any additional wave-induced mixing is critically dependent upon the flow conditions at the exit nozzle. In particular, the ratio of the exit velocity to the local wave-induced velocity is a significant parameter. This in itself has important design implications given the increasing tendency to build long-outfalls. These are constructed so that firstly, the source of the pollutant is far removed from the adjacent coastline; and secondly, it is discharged in deeper water so as to reduce the pollutant concentrations arising at the water surface. Although, at first sight, these objectives appear desirable, the construction of a long-outfall may inadvertently move the pollutant source to a location at which the effective wave-induced mixing is negligible. As a result, the increased construction costs may actually produce higher concentrations at the water surface, and therefore potentially increase the risk of pollutant contamination arising on an adjacent coastline.

However, in order to incorporate these effects within the design process, and thereby optimise the efficiency of a given outfall design, one first requires a quantitative model capable of predicting the additional wave effects within the near-field. Although previous studies (notably Chin, 1988 and Koole and Swan, 1994) have considered this problem, quantitative comparisons with laboratory data are at best inconclusive. The present paper addresses this point, and provides a brief description of a corrected model which is subsequently shown to be in good quantitative agreement with new laboratory data describing a buoyant hot-water jet discharged into both a steady current and an unsteady (or time-dependent) wave field.

Background.

Although previous studies have clearly demonstrated the potential importance of wave-induced mixing (Sharp (1986), Chyan et al. (1991) and Hwung et al. (1995)); the only papers to have considered an appropriate mixing model are Chin (1988), Koole and Swan (1994) and more recently Chu and Lee (1996). In the first two cases the models were written with the specific intention of incorporating wave effects, while the latter model has to date only been applied to the description of pollutants discharged in a steady current. However, each of these models are similar in that they apply a quasi-Lagrangian representation of the flow field in which elements of the pollutant jet are tracked within the ambient flow.

Detailed comparisons with laboratory data involving both two-dimensional plane jets and three-dimensional round jets suggest that the model outlined by Koole and Swan (1994 and 1995) provides a good qualitative description of a jet discharged in waves. In particular, this model provides a plausible explanation for the non-Gaussian characteristics of the time-averaged radial distributions (both in terms of velocities $u(r)$ and concentrations $C(r)$), and suggests that the occurrence of a bi-peaked or flat-topped distribution is simply dependent upon the local ratio of the jet diameter to the wave-induced displacement of the jet axis. Furthermore, the multi-stage centre line decay (i.e. $u(z)$ or $C(z)$ at $r=0$) first noted by Chyan et al. (1991) may also be explained (at least qualitatively) by the wave-induced displacements, and is a clear consequence of applying a time-averaged representation of a cyclic process.

Unfortunately, quantitative comparisons between the laboratory data and the model predictions proved more difficult. In particular, Koole and Swan (1995) demonstrated that good agreement along the time-averaged jet axis could only be obtained if the coefficient of forced entrainment (Winiarski and Frick, 1976) was set at $\beta=1.0$; and, in addition, the coefficient of radial entrainment was increased three-fold with respect to the value typically adopted in a stagnant ambient (i.e. $\alpha=3 \times 0.055$). The first of these points is consistent with previous studies, and stresses the importance of forced entrainment in non-stagnant ambients. However, the three-fold increase in the coefficient of radial entrainment is perhaps more difficult to explain. Koole and Swan (1994) argued that this change was justified by the large increase in the turbulent shear stresses ($\rho u'v'$) measured along the boundary of the jet discharged in a wave environment. However, no attempt was made to correlate the Reynold's stresses with the increased entrainment, and consequently it remains unclear whether a large increase in the coefficient of radial entrainment represents a genuine increase in the rate of mixing, or merely arises due to some inadequacy within the model formulation.

To help clarify this point the Lagrangian model proposed by Koole and Swan (1994) was applied to the case of a vertical jet discharged in a steady cross-flow (i.e., the ambient fluid flow is perpendicular to the initial jet axis). Although a Lagrangian model is equally applicable to this case, or indeed any other, there is a clear distinction between the cross-flow and waves cases in that previous researchers (Lee and Cheung, 1990) have already confirmed that for the case of a jet discharged into a steady cross-flow the appropriate entrainment coefficients are given by $\beta=1.0$ and $\alpha=0.055$. In other words, in this case it is well known that the ambient flow has no effect upon the coefficient of radial entrainment.

If (x,y,z) represent the usual Cartesian coordinates in which (x,y) defines a horizontal plane and z is measured vertically upwards; the trajectory of a vertical jet subject to a cross-flow orientated along the x axis may be represented on the (x,z) plane. Figure 1 concerns four such cases corresponding to $u_j/u_a=45.1, 20.0, 16.2$ and 11.7 ; where u_j is the exit jet velocity and u_a is the ambient cross-flow velocity. In each of these cases laboratory data describing the jet trajectory (Patrick, 1967) is

compared with the results of the Lagrangian model proposed by Koole and Swan (1994) in which the entrainment coefficients are defined as $\alpha=0.055$ and $\beta=1.0$. The agreement between the measured data and the model predictions is clearly very poor, and suggests (at least in this case) that this Lagrangian description of the flow field is fundamentally incorrect.

Figure 1. Jet trajectory: comparisons with a Lagrangian model formulated in a relative frame of reference.

Improved Integral Formulation.

In attempting to explain the apparent inadequacy of the previous Lagrangian models (namely Chin 1988 and Koole and Swan 1994) the recent formulation proposed by Chu and Lee (1996) was noted. Although there are many similarities between these three models, the latter solution is quite distinct in that the integral equations are formulated in an absolute frame of reference. The distinction between this and the relative frame of reference, used in the former models, is shown to be very important and in particular accounts for discrepancies within the momentum conservation equation. Figure 2 concerns a simple jet element of area A_j which has a velocity u_j measured relative to the ambient fluid, which itself has a velocity u_a . The vector sum of u_j and u_a defines the instantaneous jet axis such that u_j and u_a are respectively at angles of γ and δ to the ξ -axis. In a relative frame of reference, or one moving with the ambient flow, the conservation equations relating to mass and momentum are given by:

Figure 2. Definition sketch.

$$\frac{\partial}{\partial \xi} \int_{A_j} u_j \cos \gamma d\eta = \alpha u_j 2\pi b_j \cos \gamma + 2b_j \beta |u_j \sin \gamma|$$

1a.

$$\frac{\partial}{\partial \xi} \int_{A_j} (u_j \cos \gamma)^2 d\eta = 0$$

1b.

where again α is the coefficient of radial entrainment, β is the coefficient of forced entrainment and b_j is related to the radius of the jet element. In contrast, the same conservation equations written within an absolute frame of reference are given by:

$$\frac{\partial}{\partial \xi} \int_{A_j} u_j \cos \gamma d\eta = \alpha u_j 2\pi b_j \cos \gamma + 2b_j \beta |u_j \sin \gamma|$$

2a.

$$\frac{\partial}{\partial \xi} \int_{A_j} (u_j \cos \gamma + u_a \cos \delta)^2 d\eta = u_a E$$

2b.

where E corresponds to the total mass of fluid entrained into the jet element, and is given by the right hand side of equation 2a (or 1a). Comparisons between these equations immediately confirm that while the mass conservation equation is unaltered (since the entrainment of fluid is dependant upon a relative velocity effect), the equations defining the conservation of momentum (1b and 2b) differ significantly. In particular, equation 2b incorporates the momentum of the entrained fluid.

In light of these differences a new Lagrangian model was written in which the integral equations were formulated in an absolute frame of reference. A complete description of this model is beyond the scope of the present paper (see Kwan and Swan, 1997), but comparisons with the previously noted cross-flow data (Patrick, 1967) suggest that this modification is sufficient to explain the inadequacy of the previous model highlighted in figure 1. Indeed, figure 3 shows a similar set of comparisons with the new model, and confirms that a good description of the jet trajectory can indeed be achieved with the previously recorded entrainment coefficients ($\alpha=0.055$ and $\beta=1.0$).

Figure 3. Jet trajectory: comparisons with a Lagrangian model formulated in an absolute frame of reference.

Experimental Work.

To further clarify the near-field behaviour of a jet discharged into a wave environment a new experimental programme was undertaken. In the first stage a buoyant hot-water jet was discharged horizontally beneath a series of regular waves having a period of $T=1$ s and a wave amplitude of $a=0.032$ m. These measurements were undertaken within a small wave basin located in the hydraulics laboratory within the Civil Engineering Department at Imperial College. This facility has a plan area of 6m x 10m, and has an effective working depth of 0.46m. At the upstream end of the basin the waves were generated by 10 individually controlled random wave paddles each 0.6m wide; while at the downstream end the wave energy was dissipated on a one in ten sloping beach, with further passive absorption provided by several large blocks of poly-ether foam. The hot-water jet was introduced in the centre of the wave basin through a horizontal nozzle of diameter $D=6$ mm, with its centre line

located 150mm above the bottom boundary. Although several orientations of the jet relative to the direction of wave propagation were considered, the present paper only addresses one case in which the jet was discharged perpendicular to the plane of the wave motion. In this case the exit characteristics of the jet were such that its temperature was 17°C above the ambient water temperature, and its velocity was 0.76m/s. These conditions correspond to a densimetric Froude number of $F_{ro}=45$ and a velocity ratio of $u_j/u_a=10.9$, where u_a now represents the maximum wave-induced ambient velocity at the elevation of the discharge nozzle. A sketch describing the layout of this test case is given on figure 4a.

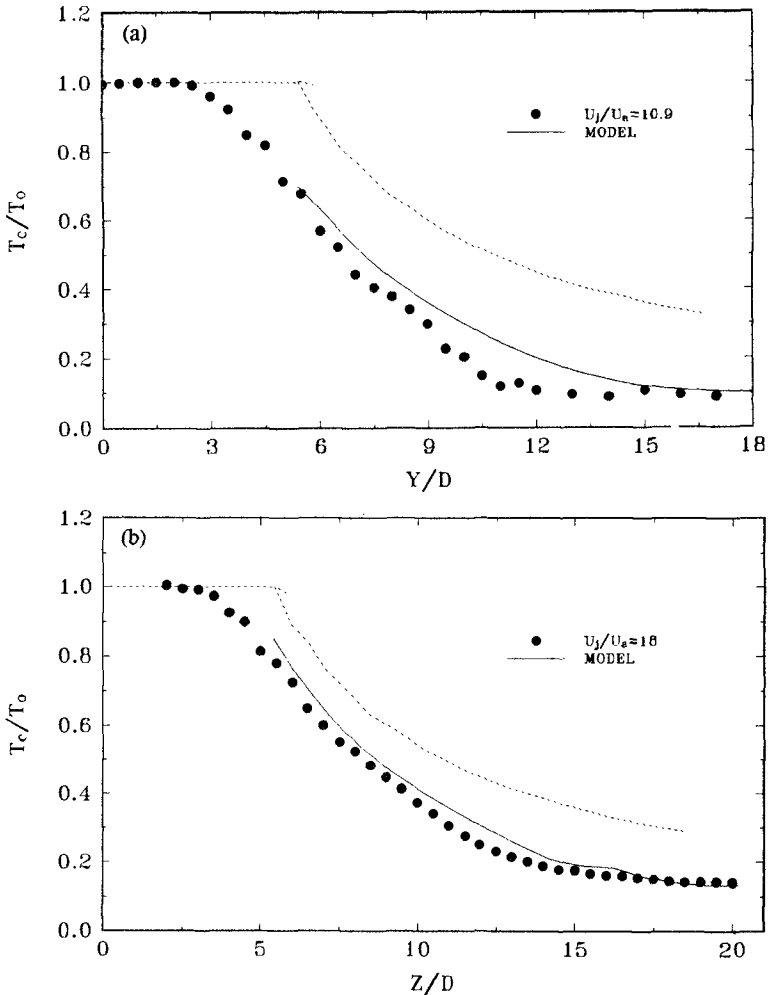

Figures 4a-4b. Experimental apparatus: (a) horizontal jet, and (b) vertical jet.

In a second series of tests a vertical hot-water jet was discharged from a similar nozzle located 75mm above the bed of a two-dimensional wave flume. This facility, which is again located in the Civil Engineering Department at Imperial College, is 25m long, 0.3m wide, and (for the duration of the present tests) had a working depth of 0.62m. The wave conditions again consisted of a regular wave train having a period of $T=1.0$ s and wave amplitude of $a=0.3$ m. Likewise, the exit temperature of the jet was again 17°C above the ambient water temperature and the exit velocity was 0.76 m/s. These conditions are similar to those occurring in the previous test case, and correspond to a densimetric Froude number of $F_{\rho}=37.8$ and velocity ratio of $u_j/u_a=18$. A sketch showing the layout of this case is given on figure 4b.

In both test cases the near-field mixing was quantified using an array of thermocouples. These were supported in a two-dimensional traverse having a positional accuracy of ± 0.5 mm in both the horizontal and the vertical directions. Each thermocouple was constructed from k-type thermocouple wires having an external diameter of 3 microns, and fused at one end to produce a measuring volume with a diameter of $\phi \leq 0.2$ mm. Although probes of this type were difficult to handle, their size was essential to ensure the required accuracy and response (0.1°C in 0.01 s). After careful calibration this measuring apparatus was able to resolve the temperature fluctuations within an individual wave cycle, and was thus deemed appropriate to determine the nature of the mixing processes.

Discussion of Results.

Figures 5a and 5b respectively concern the horizontal and vertical jets discussed above, and describe the decay in the time-averaged temperatures measured on the central axis of the jet. In both cases the measured data is compared with two models. The first, indicated by a dashed line, represents a standard integral solution based upon the assumption that the jets were discharged into a stagnant ambient; while the second, indicated by a solid line, represents the results of the new Lagrangian model outlined above. In this latter case it is important to note that although the Lagrangian model is not in perfect agreement with the laboratory data, it provides a significant improvement over the stagnant ambient model. Furthermore, unlike the previous formulations proposed by Koole and Swan (1994), there is no uncertainty with regard the entrainment coefficients (α , β). Indeed, the calculations presented on figures 5a and 5b are based upon the widely accepted entrainment coefficients commonly applied in both stagnant and steady flows (i.e. $\alpha=0.055$ and $\beta=1.0$).

Figures 5a-5b. Centre-line temperature decay: (a) horizontal jet and (b) vertical jet.

To further examine the success of the Lagrangian solution figure 6 concerns the time-averaged temperature profiles at five elevations above the vertical jet, and contrasts the measured data with the model predications. These comparisons clearly suggest that the modified Lagrangian solution is, in general, in good quantitative agreement with the laboratory data. However, on closer inspection it is apparent that the temperature profiles become increasingly asymmetric at higher elevations above the discharge orifice. This pattern has been observed in several other test cases and is, at first sight, very difficult to explain since one would assume that the cyclic nature of the wave motion effects both sides of the jet in an identical manner. However, if one considers that the central core of the jet, at least in the near-field region, provides

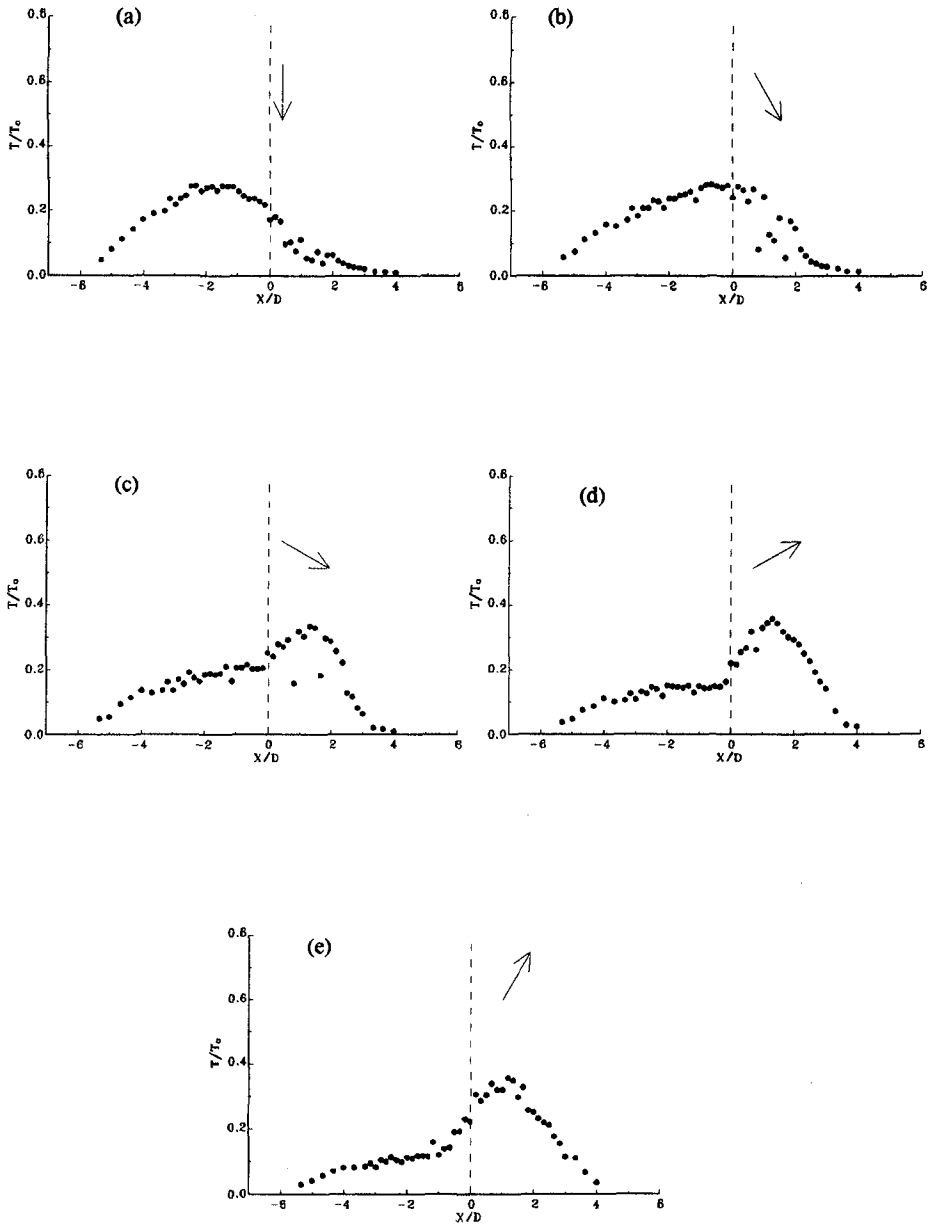

Figure 6. Time-averaged temperature profiles measured above the vertical jet.
● laboratory data, — Lagrangian model.

an effective barrier to the wave motion in the vicinity of the jet, it becomes apparent that the upstream and downstream sides of the jet (measured relative to the direction of wave propagation) experience very different flow regimes. Adopting the usual notation whereby a co-flow corresponds to the movement of ambient fluid in the same direction as the jet velocity, and a counter-flow opposes the jet velocity, it can easily be shown that the upstream side of the jet is subject to a transition from a co-flow to a cross-flow, while the downstream side of the jet experiences a transition from a counter-flow to a cross-flow. These changes occur between phase angles $0 \leq \theta \leq 0.25$ and $0.5 \leq \theta \leq 0.75$ respectively, where $\theta=0$ corresponds to a zero up-crossing. The difference between these regimes provides a plausible explanation for the jet asymmetry observed in figure 6.

Indeed, if one further considers the temperature profiles in a phase-averaged sense (or ensemble-averaged at specific phases of the wave cycle) there is evidence of a new wave-induced mixing mechanism which specifically effects the downstream side of the evolving jet. Figures 7a-7e describe the ensemble-averaged temperature profiles at $\theta=0.5, 0.6, 0.7, 0.8$ and 0.9 respectively, where $\theta=0.5$ corresponds to a zero down-crossing and $\theta=0.75$ is in phase with the wave trough. During this portion of the wave cycle, the vertical jet is first subject to a counter-flow ($\theta=0.5$), followed by an increasing cross-flow which is orientated towards the downstream side of the jet. In each of these five figures the large arrow positioned above the temperature data indicates the approximate direction of the ambient flow. In this case the effect of the ambient motion appears to divide the jet so that although a large proportion of the jet is swept upstream (in the positive x direction), a significant proportion also appears to remain almost static. This apparent division of the jet only arises during this stage of the wave cycle, and in particular does not occur 180° later, when the jet is subject to a co-flow ($\theta=0$) followed by an increasing cross-flow orientated towards the upstream face. In this latter case the entire jet is swept downstream (in the negative x direction), and thus the pattern looks very different to that presented on figures 7a-7e.

Concluding Remarks.

The present study has addressed the case of a buoyant hot-water jet discharged in a wave environment, and has sought a quantitative description of the near-field mixing based upon a quasi-Lagrangian formulation of the integral equations. Previous attempts at a solution of this type have provided a good qualitative representation of the flow field, but detailed quantitative comparisons have been limited due to the apparent uncertainty in the entrainment coefficients. In particular, a three-fold increase in the coefficient of radial entrainment was necessary to model the centre-line decay. To investigate this point an existing Lagrangian model, formulated in a relative frame of reference, was used to describe a vertical jet discharged in a steady cross-flow. Although in this case there is no ambiguity regarding the entrainment coefficients, the agreement between the model predictions

Figures 7a-7e. Phase-averaged temperature profiles at $z=13D$.

(a) $\theta=0.5$, (b) $\theta=0.6$, (c) $\theta=0.7$, (d) $\theta=0.8$, (e) $\theta=0.9$.

and laboratory data were poor. On closer inspection, it has been shown that a Lagrangian model formulated in a relative frame of reference neglects the momentum flux associated with the entrained fluid. In contrast, an alternative model, formulated in an absolute frame of reference, is shown to be in good agreement with all cases involving buoyant jets discharged in both steady currents and unsteady wave fields.

To further validate this latter model, new experimental studies were undertaken in which both horizontal and vertical jets were discharged within a wave environment. Laboratory data describing the near-field mixing is shown to be in good agreement with the modified Lagrangian solution, and perhaps most importantly there is no ambiguity with regard the entrainment coefficients. As a result, the proposed solution is appropriate to design applications. Furthermore, detailed consideration of the phase-averaged temperature data measured within the near-field provides evidence of a new wave-induced mixing mechanism. This effect provides a plausible explanation for the development of non-symmetric time-averaged temperature profiles. More importantly, it provides the first quantitative evidence which suggest that the average dilution will be enhanced if a pollutant is discharged in the plane of the wave motion.

CHAPTER 356

COST EFFECTIVENESS OF WAVE POWER EXTRACTION AT EROSIIVE COASTS

HIDEO KONDO*

ABSTRACT

Cost of wave power extraction is investigated for the coasts where erosion has been continuing without suitable countermeasures. By a wave power extraction, a shoreline accretion is expected due to the mean sea level drop. Cost effectiveness is discussed with the concept of total cost instead of the generation cost only.

INTRODUCTION

Wave power utilization has not essentially been commercialized yet except small size navigation buoys though remarkable progress has been achieved in the last two decades. The reason is simply that the cost of electricity from waves is still much higher compared with those from fossil fuels and of nuclear. However, it is required to remove unfavorable gases like CO₂ etc. exhausted in the process of burning fuels from the standpoint of global environmental protection. This process needs an additional cost which we may call the environmental cost. The cost is known presently to be no less than that of power production itself.

Meanwhile continuous retreat of coasts by wave and meteorological tidal actions has become serious at most coastal countries in the world. Coastal engineers have worked extensively to solve the problems by constructing coastal structures or by feeding sand in eroding beaches. Extraction of wave power decreases apparently the transmitted wave power shoreward and will weaken beach erosion with similar actions as the above two methods do.

In the present study the author proposes an approach to evaluate the total cost as well as the production cost of wave power extraction at erosive coasts which is subsequently examined for case studies.

TOTAL COST ESTIMATION

The total cost Pt (¥/ kWh) consists of the market or generation cost Pm , the environmental cost Pe and the social cost Ps as (Kondo et al,1991 and 1993),

$$Pt = Pm + Pe + Ps \quad (1)$$

Pm is estimated with conventional procedures. Defining $E_{p,j}$ as the environmental value of j th factor, Pe , the cost to repair the environmental damages occurred in power production process is estimated as,

$$Pe = \sum \Delta P_{i,j} = \sum \frac{\partial E_{p,j}}{\partial x_i} \Delta x_i \quad (2)$$

In the above equation $\Delta P_{i,j}$ is the repair cost brought by the variation of j th environmental factor by the variation of the environmental factor i in the course of production. Pe of fossil-fired electricity includes expense of removing and treatment of harmful waste gases such as CO₂.

The environmental cost is positive for the cases of fossil-fired and nuclear powers. For the cases of renewable energies it can be minus when they bring better environment than that without extraction. The social cost Ps may be the expenses of moving houses and structures, compensation for damaging fishing industry, and the expenses dispatching troops to keep the sea-lane safe to tankers for imported oil, etc.

WAVE POWER BUDGET AND DEFORMATION

The incident wave power through the extracting device and structure is divided to the reflected, the power extracted, the loss by extracting process and structure, and the transmitted shoreward. The ratios of these depends on types of device, structure and the operating conditions. Approximate figures for the extracted and the transmitted are estimated for later calculation as in the following.

TABLE-1 WAVE POWER BUDGET (Extracted / Transmitted)

TYPE OF SYSTEM	IN OPERATION	STOPPED
Floating (OWC)	30 / 50	0 / 100
Bottom Fixed(Pendolor)	50 / 20	0 / 50

SHORELINE ACCRETION BY MSL DROP

Continuous retreat of shoreline by wave and meteorological tidal action has become one of the most serious problems in all coastal countries. It has been accelerated by the remarkable trend of mean sea level (MSL) rise. The power extraction from waves in offshore or inshore zone decreases the incident power and the height of transmitted wave and the size of MSL.

We know that a MSL rise brings a retreat of shoreline more than that anticipated from the static geometry in sandy coasts. Thus we may apply the relationship between the MSL rise versus the shoreline retreat to MSL drop at beach versus shoreline accretion by the wave power extraction. Several approaches have been proposed for the relationship between MSL rise and beach retreat we will use the one by Mimura et al (1994) for later calculation.

The environmental cost for the wave power extraction is minus since it makes natural beaches wider or saves constructing revetments on shores.

PENDULOR WAVE POWER EXTRACTOR

Fig.1 Pendulum Wave Power Extractor in Caisson

We have studied Pendolor power extractor of bottom standing type which can be installed in upright caisson breakwaters since 1980 (Kondo et al, 1984, Yano et al,1985, and Watabe, 1993). Two basic types of it are sketched in Fig.1. It consists of pendulum plate in a concrete caisson with seaside open and a hydraulic power transmission system. A back wall, two side walls and the bottom plate of caisson together with the pendulum plate forms a water chamber where a standing wave system is generated by oscillation of the plate.

Originally it had been developed as the cylinder pump type (the upper one in Fig.1). Laboratory and field experiments has proved it to have high efficiency and to lower the cost compared with the other kinds of extractors (Watabe, 1993).

The rotary pump type, the lower one in Fig. 1, was proposed later and has been being studied (Watabe et al, 1996).

STUDIED LOCATIONS

Three locations of Japanese coast which are typical ones at Hokkaido, Touhoku and Kantou area, respectively of different wave climate have been chosen to estimate the total cost for electric power production employing Pendolor system.

TABLE -2 WAVE CLIMATE OF THREE TYPICAL COASTS

COASTS (Oceans)	AVERAGE WAVE			DESIGN WAVE	
	H1/3	T1/3	W	H1/3	T1/3
Hokkaidou (Japan Sea)	1.1(m)	4.9(sec.)	5.3(kWh/m)	7.5 (m)	12.0(sec.)
Touhoku (Pacific)	1.0	7.4	6.3	7.5	14.0
Kantou (Pacific)	1.5	7.4	11.5	11.0	15.0

COMPUTATION PROCEDURE

The generation or market cost P_m was computed according to a conventional way for the case of electricity in Japan. Table-3 presents the computational process for the case of KANTOU coast.

The environmental cost has been computed from the two approaches:

- (a) From the difference of expenses to construct a revetment at shoreline.

The revetments are designed for the two cases of with and without power extraction to the design waves shown in Table-2. The expense to construct a

revetment is estimated from which P_e is computed.

(b) From the expense of filling the eroded shores every year.

The volume of beach eroded by the average annual wave shown in Table-2 is estimated for each location. Then the cost of sand filling to eroded shore is estimated from which P_e is computed.

TABLE - 3 Estimation of Market Cost, P_m (KANTOU COAST)

(1) DESIGN CONDITION

Water Depth:	10 m below LWL
Tidal Range:	1 m
Mean Wave Power:	11.5 kW/m
Design Wave;	$H_{1/3} = 11$ m, $T_{1/3} = 15$ sec.
Extrator:	Pendulor in Bottom Standing Caisson
Overall Efficiency:	0.5
Caisson:	Unit Length of 20 m
Rating Output per Unit:	$11.5 * 20 * 0.5 = 115$

(2) EXPENSE AND COST (Debt Financing Rate 6 % per Year)

A: Cost of Caisson =	$12 (M\text{¥}/m) * 100 = 1200 M\text{¥}$
B: Cost of Generating System =	$60 M\text{¥} * 5 = 300 M\text{¥}$
C: Total Construction Cost =	$1500 M\text{¥}$
D: Specific Cost = C/ Output =	$1500/575 = 2.6 M\text{¥}/kW$
E: Fixed Cost = Total Cost * Equivalent Coefficient	$= 1500 * 0.07581 = 114 M\text{¥}/Year$
F: Operation Cost = B * 0.05 =	$15 M\text{¥}/Yea$
G: Expenditure = E + F =	$129 M\text{¥}/Year$
H: Amount of Generated Electricity	$= \text{Output } 24hr * 365day * \text{Workig Rate}$
	$= 575 * 24 * 365 * 0.58 = 2.72 * 10^6 kWh/Year$

(3) MARKET COST

I: Cost of Electricity = G/H =	$44 \text{ ¥}/kWh$
--------------------------------	--------------------

The result of estimation is shown in Table 4 which reveals that Kantou area shows the lowest market cost, Pm of 44(¥/kWh). It is still about three times than that of oil-fired as of 1994. It is sensitive to the debt financing rate which is 6 % in present estimation. For the case of 2% rate, Pm decreases to 30(¥/kWh).

The total costs, Pt, however, becomes close to it at Kantou area (Table - 5). For the case of the debt ratio of 2 % it becomes less than that of oil-fired.

TABLE - 4 COST OF ELECRCITY FROM WAVE in ¥/kWh

LOCATION	Pm	Pe	Ps	Pt
HOKKAIDOU	62	(a) -18	1	45
	40	(b) - 5	1	58
TOUHOKU	59	(a) -16	1	44
	38	(b) -11	1	49
KANTOU	44	(a) -11	1	34
	30	(b) -13	1	32

In addition to the wave power, the other two ocean energies, namely current and tide, and wind are also investigated for the cost analysis at promising locations in Japan, the costs of which are considerably higher than those of wave power as shown in Table-5, except wind. -5.

TABLE - 5 COST OF ELECTRICITY BY RENEWABLE ENEGIES
IN ¥ /kWh (Ratio to Oil-Fired)

ENERGY	LOCATION	Pm	Pe	Ps	Pt
WAVE	KANTOU	44	-13	1	32 (1.3)
CURRENT	TSUGARU STRAIGHT	33	3	1	37 (1.5)
TIDE	ARIAKE BAY	73	3	2	78 (3.1)
WIND	MURORAN	48	-14	1	35 (1.4)
OIL - FIRED	KANTOU	12	12	1	25 (1)

CONCLUSIONS

The present study has revealed that wave power utilization at erosive coasts is found to be a promising way to get inexpensive clean energy in Japan and may be so for most coastal countries though the cost depends on heavily domestic natural and economical condition. The utilization will restore invaluable fossil fuels, and precious beaches for the future generation.

ACKNOWLEDGMENTS

The author would like to thank Dr. Tomiji WATABE, T-Wave Consulting Volunteer and Mr. Senji OSANAI, formerly Manager of Cold Region Port & Harbor Engineering Research Center for their constant support to the wave power study at Muroran Institute of Technology.

Thanks must go to Miss Hiromi HAMATSU, former student who had done a part of this study for her B. E. Thesis and Mr. Noriyuki OOTA, the technical staff who assisted for preparing the manuscript at Department of Civil Eng. & Architecture of the institute.

CHAPTER 357

FAESIBILITY TESTS OF NEW PENDULAR-TYPE WAVE ENERGY CONVERSION APPARATUS

Senji Osanai¹, Hideo Kondo², Yuzo Mizuno³ and Tomiji Watabe⁴

Abstract

In order to utilize natural energy, it is essential to develop a fully compatible system, instead of conventional power-generating systems.

The authors proposed a new pendular-type wave power generation device. Design criteria for a new rotary vane pump systems (NRVP) was studied for several years and a 5-kW-model test plant with a large displacement of 45.9 l/rev pump was established. This simplified pendular system was considered to limit the investment costs. This paper describes the new pendular-type converter and its components, and presents observation data obtained in field tests conducted at sea.

1. Introduction

As Japan is largely dependent on fossil fuels such as coal and petroleum for energy, transition to nuclear power and others non-fossil fuels is being undertaken. Efforts should be made to find energy-saving techniques or new energy sources in order to ensure future development while protecting the earth's environment. It is essential to switch to clean and natural energy sources such as solar radiation, wind power and wave power.

.....

3) Dr., Civil Engineering Research Institute, Hokkaido Development Bureau, 1-3 Hiragishi, Sapporo 062, Japan

4) Dr., T-Wave Consulting Volunteer, 5-23-3 Misono, Noboribetsu, 059, Japan

However, these sources have problems regarding cost and generation capacity limitations. The biggest obstacle to the practical use of clean and natural energy sources is their generating costs compared with those of fossil fuels.

To address this problem, a new, pendular-type wave energy conversion device, named Pendular by the authors, was developed.

In 1981, the first device^{1), 3)} (20 kW) was installed on a breakwater at the Port of Mashike in a collaborative development project involving the Town of Mashike, the Muroran Institute of Technology and Hitachi Zosen corp. Full-scale feasibility tests were conducted.

Following these tests, in 1983 a research group from the Muroran Institute of Technology made the first experimental test device by improving the existing one, and conducted test plant experiments. The tests achieved the expected results and the device was proved to be efficient in wave energy conversion. But it was absolutely necessary to further reduce the power generation costs. Therefore, based on the past research and development results, a new, remarkably improved wave energy conversion device was built under a new research plan. Field tests were conducted at sea.

2. Outline of new pendular device

Wave energy conversion devices can be largely classified into OWC(Oscillating-wave-column) and pendular-types. The principal of the device is shown Fig.1.

Horizontal standing wave motion is converted to motion of the pendular plate, which is then converted to reciprocating rotary motion of a vane-type rotary pump directly connected to the pendulum. This rotation feeds hydraulic oil to the hydraulic motor and drives the generator.

Figure 2 shows the original pendular device^{4), 8)} which had a cylinder pump. It was used to drive an oil motor-generated set.

Since the pendulum actuated the pump, both were fixed on a common bed lest the caisson suffer from the huge reaction of the pump. When the pump and pendulum were coupled together at sea, the system became dangerous because

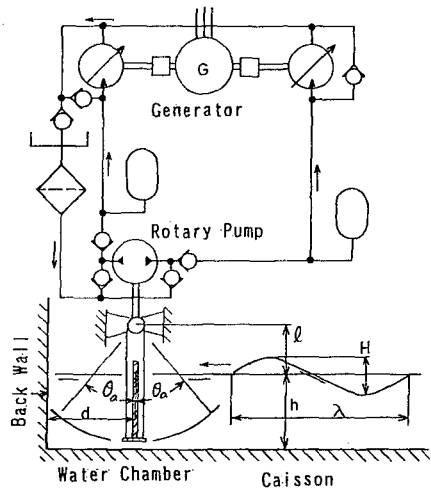

Fig. 1 Principle of the device

the pendulum moved whenever incident waves exited it. A water gate as illustrated as in the figure was required.

Fig.2 Original pendular device

Fig.3 New pendular device

In order to improve cost efficiency, simple combined feature was invented in which a rotary vane pump was coupled with the pendulum.

A long shaft was used to support both the pump rotor and the pendulum, having no coupling component. There were 3 bearings on the shaft, 2 of which were for the pendulum. This combination makes for easier installation work than with the previous model. This system was called a new pendular device^{2),5),6)} as seen in Fig.3.

This large-capacity vane -type pump offers the following advantages:

- 1) The features of the pendular system can be simplified through an integrated pendular plate and rotary vane-type pump.
- 2) Energy generation costs can be reduced through simplification of installation work at sea.
- 3) High-wave resistance of the pendular system is also improved.

3. Design of new rotary pump and pendulum

3.1. Rotary pump

Displacement D_p of the pump, which consists of 2 vanes, is described in the following equation, assuming it is the same as the previous pump.

where D_p displacement of the pump

$$D_p = \frac{\pi}{2} (d_1^2 - d_2^2) B = 2 \pi A_p r$$

d_1 vane tip diameter
 d_2 rotor cylinder diameter
 B vane width
 A_p piston area (cylinder pump) = $98.17 \times 10^{-4} \text{ m}^2$ r arm radius = 0.6 m

The leakage is prevented by the metal seals. As leakage is proportional to the total seal length L_p , a pump having greater value of D_p/L_p (displacement/total seal length) can operate more efficiently. D_p/L_p is shown in the next equation⁷⁾:

$$\frac{D_p}{L_s} = \frac{\pi ((d_1/d_2)^2 - 1) d_1^2}{4 \left(2 \frac{d_1}{d_2} + \frac{d_1}{W} \left(\pi + \frac{d_1}{d_2} - 1 \right) \right)}$$

where W vane width

Through the results of the research, the following equation was determined to provide the optimal profile of the pump⁷⁾:

$$\frac{d_1}{d_2} = \sqrt{\frac{(0.36 \sim 0.46) (d_2/W) \tau_s}{P_{\max}} + 1}$$

where $d_2/W = 1.0 \sim 1.2$, τ_s is shearing stress of the shaft, P_{\max} is maximum delivery pressure of the pump.

Applying the research results, the test pump shown in Fig.4 was designed.

Fig.4 New rotary pump

Its specifications are arranged in Table 1.

Table 1 Specification of the NRVP

Input: $\eta_1 E_1 = 16.6 \text{ kW}$	Displacement: $D_p = 0.0459 \text{ m}^3/\text{rev}$
Vane tip diameter: $d_1 = 0.45 \text{ m}$	Rotor cylinder diameter: $d_2 = 0.30 \text{ m}$
Vane Width: $W = 0.26 \text{ m}$	Shaft diameter: $d_s = 0.232 \text{ m}$
Movable angle: $\theta_{\text{max}} = 65^\circ$ (both sides)	
Pressure (mean/max.): $P_{\text{mean}}/P_{\text{max}} = 12.8/25 \text{ MPa}$	

3.2. Pendulum

The power E_1 produced by the pendulum can be determined with the following equation⁷⁾:

$$E_1 = 1/8 \times \rho \ g \ H^2 \ C_g \ B \ \eta_1$$

where H is wave height = 1.5m, ρ is density of water = 1,030kg/m³, g is acceleration of gravity = 9.81 m/sec², C_g is group speed of the incident waves = 3.46m/s (wave period 4s, water depth: $h = 2.75 \text{ m}$), B is width of the pendulum in water = 2m, η_1 is conversion ratio from wave power to pendular power = 80%.

In this case, these parameters were adopted in the design, and then it was decided that $E_1 = 16.6 \text{ kW}$.

In design, amplitude of pendular motion θ_a was established using the following values.

$$\theta_a = M / (\omega N) = 0.285 \text{ rad} (16.3^\circ) \text{ at no load operation}$$

$$\theta_a = 16.30^\circ \times 0.625 = 10.20^\circ \text{ at optimal load operation}$$

where M is amplitude of exiting moment = 370kNm, N is load factor by wave generation = 828kNms, ω is circular frequency of wave = 1.571rad/s ($T = 4 \text{ s}$).

As seen in the pendular device shown in Fig.5, the basic style was not changed significantly, though the pendulum is more durable in storms with its rubber tires of heavy track's, it can swing wider

Fig.5 Test pendular device

and more reliable to absorbing shock loads. It is expecting to be relatively maintenance free.

In order to prevent electro-chemical corrosion, the shaft was connected to the earth through brushes and zinc plate were fixed to the pendulum surface and incorporated into the vane- type rotary pump.

3.3. Installation

The device was installed using a large crane in August 1994, on the caisson of the Muroan Institute of Technology around the exterior of the south breakwater in the Etomo area of Muroan. The installation was completed within 2 hours, not included preparation of a gate.

Muroan is centrally located on the middle of Hokkaido and faces the Pacific Ocean. The water in front of the breakwater is approximately 4.0 m in depth. Because of the port's location in a bay, incoming waves are small. The largest significant wave was 2.7 m high and its period was 5.4 second. The mean wave direction was west northwest. Photo 1 shows the installation of the device. Fig. 6 shows the location of the port of Muroan.

Photo 1 Installation work

Fig. 6 Location of Muroan port

4. Measurement of the new pendular-type wave conversion device

Measurement were made at 8 points: ① Pump pressure (4 points). ② Motor

axis torque (1 point), ③ Motor axis rotation speed (1 point), ④ Pendulum gradient (1 point), ⑤ Wave recorder (1 point).

Eight patterns were successively measured, with load condition changed every 20 minutes. The data was stored on a CVS-type disk. Figure 7 shows the interior structure of the observation system.

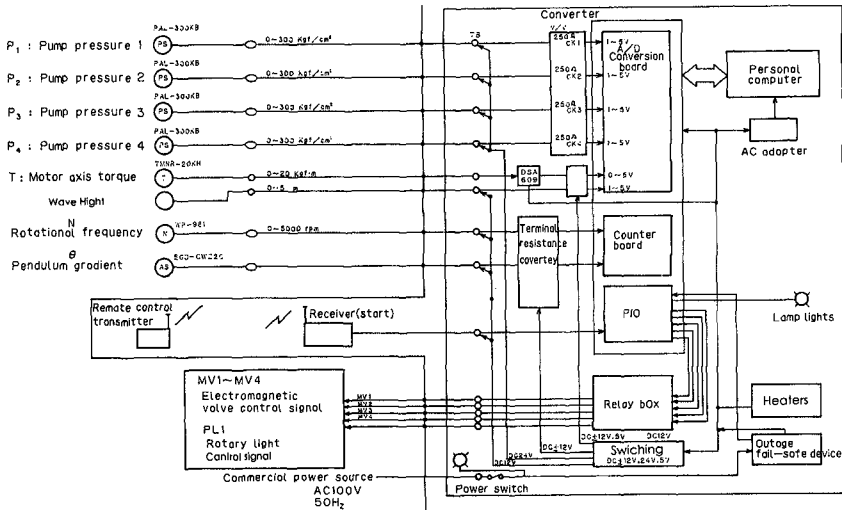

Fig.7 Observation instruments and wiring diagram

5. Observation of the new pendular-type wave energy conversion device

The new pendular-type wave energy conversion device was produced and tested in accordance with the development schedule shown in Fig.8.

The device was produced in 1993 and 1994. It was installed at the site, along with observation instruments, and ancillary electrical work was carried out before conducting observations.

Fig.8 Research and development schedule

The device was installed in August 1994 in front of the port of Muroran shown fig-6. Since then, tests have been conducted for 20 months. In order to analyze efficiency , measurements were conducted at 8 points during operation. The data is presented in Table1. Figure 9 shows spectrum response of the system . Two spectrums, wave and angular displacement of the pendulum, showed a close correlation.

Table 1 Observation data

Fig.9 Responsiveness of the system

Figure 10 shows the efficiency of the new pendulum. The efficiency η_1 is shown in relation to wave period, $T_{1,3}$. It can be seen that $\eta_1 = 0.5 \sim 0.9$, and it reaches peak value at approximately $T_{1,3} = 4.5 \sim 5.2$ second.

During the field test ,the pump operated without a breakdown, but pump effi-

ciency was only 27-37%.

No contamination of the oil has been observed, so it is presumed the cause of low efficiency may be malfunction of the seal .

Besides the power conversion test, remarkable durability of the pump has been proved .There were no troubles around the pendulum or the pump such as loosening of bolts , leaking of oil or wear of sliding parts.

Fig.10 Efficiency of the new pendulor

6. Conclusions

Through testing of the new pendular device , the following conclusions were obtained.

- 1) The new rotary-vane pump system proposed for the pendulor makes installation easier, without the need for a water gate. It can lower energy costs.
- 2) The new pendular system improves durability not only for the pump, but also for the pendulor.
- 3) Efficiency of the new pendular was approximately 50~70 % (It was the same as the old pendulor coupled with a cylinder pump.)
- 4) Pump efficiency did not achieve the predicted value, as derived in the indoor test.

Therefore, there is still the need to solve the problems regarding pump efficiency and the seals on the pump unit. Further research to this end is expected .

After a great deal of research and development, the new pendular system was realized. It employed unique technique developed in Hokkaido, and which must be further developed. To put the device to practical use, we must continue field tests. Observation data, particularly that for durability and efficiency versus load, will be collected for application in design.

Acknowledgments

The authors would like to express their sincere gratitude to Mr. Seino, Muroran works of Narasaki Co. Ltd., and the Port Authority of Muroran for their contributions in the installation of the measuring instruments and to the 1st Regional Marine Safety Headquarters for their cooperation in the use of a power source.

CHAPTER 358

Watertable Dynamics in Coastal Areas

Hong-Yoon Kang¹ and Peter Nielsen²

Abstract

Fresh water lens measured under the coastal barrier is much thinner than that predicted by the classical Ghyben-Herzberg theory. Landward downsloping watertable which is usually seen at coastal areas results in a landward flow of salty water or waste water released into aquifer. Comparison between the laboratory experiments with regular waves and no tides and the field data has revealed significant difference in magnitudes of the infiltration velocity. It is obvious that the tidal phase is very important. Infiltration velocities are large when the shoreline moves landward on a partially saturated beach on a rising tide. General magnitudes of U , are $0.08K$ for steady laboratory conditions to $0.45K$ for field conditions during the rising tides. A mathematical model of the watertable which includes the effects of runup infiltration is obtained in a steady state. A finite-difference numerical model of the watertable is also presented with the glassy/dry boundary as a boundary condition.

Introduction

Watertable dynamics in coastal areas are of obvious interest in relation to problems such as salt water intrusion to the aquifer and wastewater disposal from coastal developments, but research into these processes has been scarce. In addition, the modeling of swash zone sediment transport requires a better knowledge of the beach groundwater dynamics.

Extensive field studies along the east coast of Australia have revealed that the overheight in the coastal watertable due to wave runup and tidal action on the ocean side are sufficient to create a steady drift of salty ground water under narrow coastal islands

and barriers. Figure 1 details a typical situation showing the landward downsloping watertable and the very thin fresh water lens monitored at the narrow northern end of Bribie Island near Brisbane, Australia.

Figure 1. Field data showing the landward downsloping watertable and the thin fresh water lens (Bribie Island North, 14 July 1994).

In this case, the difference in groundwater level between the ocean side which is exposed to waves and the landward side which is relatively sheltered from waves is 0.4 meters. The magnitude of difference varies depending on the wave conditions, the slopes on the two sides and the landmass width. These features are important for understanding ecosystems in these areas and for pollution control. The difference in groundwater levels shown in Figure 1 is due to the combined effect of tides and waves.

The fresh water lens observed at the barrier island is seen to be much thinner than that predicted by the classical Ghyben-Herzberg (see Domenico and Schwartz, 1990) theory. The Ghyben-Herzberg result was obtained from simple hydrostatics with no consideration of the details of the wave runup infiltration near the high water mark. The measured fresh water lens under the barrier also shows an asymmetry, i.e. it opens up gradually on the ocean side, but closes abruptly on the landward side.

This paper outlines the recently developed theory for wave effects significantly affecting coastal watertable dynamics and presents comparison with field and laboratory measurements. Watertable modeling is also given mathematically and numerically.

Wave Induced Watertable Overheights

Ocean waves raise the coastal watertable through their lifting of the free mean water surface seaward of the shoreline, i.e. wave setup, and due to the infiltration from wave runup landward of the shoreline. See Figure 2.

Wave Setup

The phenomenon of wave setup has been treated extensively in the water wave

Figure 2. Definition sketch

literature. Extensive field data have been reported by Nielsen [1988] and Hanslow and Nielsen [1993]. They indicate that the shoreline setup $\bar{\eta}_s$

$$\bar{\eta}_s = 0.38H_{orms} \tag{1}$$

or

$$\bar{\eta}_s = 0.048\sqrt{H_{orms}L_o} \tag{2}$$

where H_{orms} is the root mean square deep water wave height and L_o the deep water wave length ($L_o = gT^2/2\pi$, where T is the wave period).

Regular Waves, No Tide

Experimental studies were undertaken in a wave flume with regular waves and no tide to gain insight into process of infiltration from wave runup and the resulting watertable overheight as reported by Kang et al. (1994). It was found from the flume experiments that the asymptotic inland overheight $\bar{\eta}_\infty$ depends on the beach profile, the wave height H_i and the wave period T , but not directly on the hydraulic conductivity K of the beach material. Kang et al. [1994] recommended the following formula in relation

to Hunt's [1959] formula for the runup of regular waves:

$$\bar{\eta}_\infty = 0.62(Z_R - SWL) = 0.62 \tan\beta_F \sqrt{H_i L_o} \tag{3}$$

where Z_R is the level of maximum runup, SWL the still water level and $\tan\beta$ the beachface slope. This indicates that the asymptotic inland overheight amounts to be 62% of the runup height irrespective of sand size. However, separate regression lines for coarse and fine sands, as seen in the relation between the inland overheight scaled on the wave height ($h_\infty - SWL/H_i$) and the surf similarity parameter $\xi (= \tan\beta_F (L_o/H_i)^{0.5})$ (see Figure 3), show a weak effect/correlation of sand size, indicating that the watertable overheight is larger for larger sands, in the range of wave conditions of $1.2 \text{sec} \leq T \leq 2.8 \text{sec}$ and $58 \text{mm} \leq H_i \leq 200 \text{mm}$ with aquifer depths ranging from 372mm to 436mm (regression coefficients: 0.64 with $r^2=0.73$ for coarse sands and 0.48 with $r^2=0.86$ for fine sands). This trend is consistent with Gourlay's [1985] data. The fact that the watertable overheight is larger for coarser sands may not be caused directly by different sand sizes, but by different beach profile shapes associated with different breaker types and different beach materials (see Rector, 1954; Gourlay, 1980; 1985). In general, finer sands form characteristically flatter foreshore beach profiles (with an outer bar formed at the breaking point of the waves), and more energy is dissipated through the surf zone than for beaches with coarse sands for the same wave conditions. The former results in less runup on the beach face than the latter. Smaller wave runup heights hence produce less watertable overheight.

Figure 3. The normalized inland overheight as a function of the surf similarity parameter $\xi (= \tan\beta_F (L_o/H_i)^{0.5})$.

On the other hand, the present result is not directly consistent with Gourlay's [1992] example for a flat wave ($H/L_o=0.007$) which shows that the elevation of the watertable increased as the hydraulic conductivity of the beach material decreased. Equation (3) may apply when the breaking waves are not surging (for $H/L_o > 0.01$: see Figure 4 of Gourlay [1985]) and the beach material is sand, but it may not hold for very flat waves ($H/L_o < 0.01$). The wave steepness is an important factor governing onshore or offshore movement of beach material which determines the beach profile and breaking point/characteristic. It thus influences the beach watertable elevation/profile.

Wave Runup Infiltration

Recently, the wave runup infiltration contributing to significant lifting of the coastal watertable was stressed by several researchers (e.g. Nielsen et al., 1988; Hegge and Masselink, 1991 and Kang et al., 1994). Figure 4 outlines the processes of wave runup/infiltration and the coastal watertable.

Figure 4. Relationships between wave runup, infiltration and the coastal watertable.

The top part of the figure shows the runup distribution (transgression statistics) of irregular waves, i.e. the fraction of the waves which transgressed certain points during the recording interval. The middle part shows the infiltration velocity distribution from wave runup, and the bottom part shows the corresponding elevated coastal watertable. With no sinks or sources landward of the runup limit the watertable will be horizontal landward of the runup limit.

Runup infiltration velocities indirectly determined from the watertable measurements and the parameters n and K of the porous medium, using the Finite

Difference approach, have maximum values roughly midway between the shoreline and the runup limit from both the field and laboratory data (see Kang et al., 1994 and Kang, 1996). General magnitudes of the infiltration velocity U_i are $0.08K$ for the steady laboratory conditions to $0.45K$ for field conditions during the rising tides. This difference is probably due to the fact that the field data were taken during rising tides where the beach is less saturated than in the steady state of the laboratory experiments. These magnitudes may vary according to characteristics of the porous medium.

Mathematical Modeling of the Coastal Watertable

Consider homogeneous sand body, with the specific yield n and the hydraulic conductivity K overlying a horizontal impermeable stratum at depth D . Under the Dupuit-Forchhermer assumption, the local height h of the watertable above the impermeable layer obeys the Boussinesq equation:

$$n \frac{\partial h}{\partial t} = K \frac{\partial}{\partial x} \left(h \frac{\partial h}{\partial x} \right) \quad (4)$$

In order to model the watertable in the zone of runup infiltration, the modified Boussinesq equation or the corresponding linearized equation (5) which includes the runup infiltration effect should be used as reported by Nielsen et al. (1988) and Kang et al. (1994):

$$n \frac{\partial h}{\partial t} = KD \frac{\partial^2 h}{\partial x^2} + U_f(x,t) \quad (5)$$

where $U_f(x,t)$ is the infiltration velocity averaged over numerous uprush-backwash cycles or the infiltration flow rate per unit area.

For steady flume condition (pure wave forcing, no tide), equation (2) leads to:

$$\frac{\partial^2 h}{\partial x^2} = -\frac{1}{KD} U_f(x) \quad (6)$$

The nature of $U_f(x)$ may reasonably be expected to be:

$$U_f(x) = \begin{cases} C_f K f(x) & \text{for } x_s \leq x \leq x_R \\ 0 & \text{for } x > x_R \end{cases} \quad (7)$$

where C is a dimensionless infiltration coefficient and $f(x)$ is a dimensionless function of x . x_s and x_R are the horizontal shoreline and the runup limit coordinates, respectively.

In order to define the solution for equation (6) under the steady laboratory

conditions, consider a simple situation where the infiltration velocity $U_f(x)$ is distributed evenly between the shoreline x_s and the runup limit x_R . That is

$$U_f(x) \equiv U_I \tag{8}$$

Then equation (8) is written as:

$$\frac{\partial^2 h}{\partial x^2} = -\frac{U_I}{KD} \tag{9}$$

The boundary condition at the runup limit ($x=x_R$) may be written as:

$$\frac{dh}{dx} \Big|_{x=x_R} = 0 \tag{10}$$

and the boundary condition at the shoreline can be stated as:

$$h_{x=x_s} = D + \bar{\eta}_s \tag{11}$$

The solution to equation (9) with the boundary conditions (10) and (11) is :

$$h(x) = D + \bar{\eta}_s + \frac{U_I(x_R-x_s)^2}{KD} \left[\frac{x-x_s}{x_R-x_s} - \frac{1}{2} \left(\frac{x-x_s}{x_R-x_s} \right)^2 \right], \quad x_s \leq x \leq x_R \tag{12}$$

and for $x=x_R$, the asymptotic inland overheight is obtained as:

$$h_\infty = h_{x=x_R} = D + \bar{\eta}_s + \frac{1}{2} \frac{U_I(x_R-x_s)^2}{KD} \tag{13}$$

Hence we see that the asymptotic inland overheight is proportional to $(x_R-x_s)^2/D$. If $U_f(x)$ is always distributed in the same way between x_s and x_R , i.e.

$$U_f = KF \left(\frac{x-x_s}{x_R-x_s} \right) \tag{14}$$

where F is a universal function, equation (13) can be written as:

$$h_w = D + \bar{\eta}_s + C \frac{(x_R - x_S)^2}{D} \quad (15)$$

where C is a constant. A universal function F would give a universal constant C .

Numerical Modeling of the Watertable

Model Formulation

The numerical technique used here is the finite-difference approach. Consider the typical four-node grid with node spacings of δ_x and δ_t in each coordinate direction. The dependent variable $h(x, t + \delta_t)$ will be obtained from the following equation, which is a Taylor series expansion about node $h(x, t)$:

$$h(x, t + \delta_t) = h(x, t) + \delta_t \left(\frac{\partial h}{\partial t} \right) \quad (16)$$

By substituting the watertable equation (4) into (16), we get the governing equation:

$$h(x, t) = h(x, t) + \delta_t \frac{K}{n} \frac{\partial}{\partial x} \left(h \frac{\partial h}{\partial x} \right) \quad (17)$$

for the groundwater surface level h . In this way one equation is obtained for each node, which can be used to find $h(x, t + \delta_t)$.

In order to get the solution for the most seaward and landward wells, we need two boundary conditions. The first of these can be obtained using the glassy/dry boundary (G/D) which corresponds to the watertable exit point, as the seaward watertable boundary condition (see Figure 5). Hence, since the G/D is moving horizontally as well as vertically, the spacing δ_x from the G/D to the first well is not constant, i.e.

$$\delta_{x1} = \delta_{x2}, \quad \text{for the first well landward of MSS} \quad (18)$$

where δ_{x1} is the distance between the glassy/dry boundary and the first well landward of MSS, δ_{x2} is the distance between the first and second well landward of MSS and MSS defines the intersection between the mean sea level (MSL) and the beachface (cf. Figure 5).

Figure 5. The moving glassy/dry boundary as the seaward watertable boundary condition

Secondly, at the landward boundary, a reflecting, no flux boundary condition is imposed. This is reasonably realistic since the watertable waves decay exponentially with distance from the shore. That is

$$h(x - \delta_x, t) = h(x + \delta_x, t) , \quad \text{for } x \rightarrow \infty \quad (19)$$

Numerical solution of equation (17) subject to the periodic boundary condition at the ocean and to (19) is then readily obtained by iteration. That is, in order to overcome the influence of the initial conditions, the model is run for several tidal cycles.

Comparison with Experiments

As an example, the watertable data measured for 25 hours from Kings Beach, Queensland are used because tides were approximately sinusoidal at the time of measurement.

Figures 6 and 7 show the time variations of simulated and measured watertables at 15m, 20m and 30m landward from the mean sea level shoreline with the variation of glassy/dry boundaries during two semidiurnal tidal cycles (25 hours period), respectively. The amplitudes of the watertable variation from the model give quite good agreement with those of the measured watertable. It is however seen that the simulated watertable levels always sit a bit higher than the measured watertable levels. This difference may be reduced by using the shoreline as a boundary condition because the shoreline always sits lower than the glassy/dry boundary level. Some improvement may also be obtained by varying hydraulic conductivity *K* and aquifer depth *D* at each well. The compactness of the beach sand body may vary in the shorenormal direction and hence hydraulic conductivity may vary shorenormally.

Figure 6. Simulated watertable variations during two semidiurnal tidal cycles at wells landward of the mean sea level shoreline. The numbers on the curves indicate distances landward from MSS.

Figure 7. Measured watertable variations at the wells landward of the mean sea level shoreline from Kings Beach (Nov. 24-25, 1991).

Conclusions

Field measurements of groundwater dynamics in coastal barriers show landward downsloping watertable which results in a landward flow of salt water or waste water released into aquifer. Fresh water lens under the barrier tends to be much thinner than that predicted by the classical Ghyben-Herzberg principle.

Comparison between the laboratory experiments with regular waves and no tides and the field data (see Kang, 1996) has revealed significant difference in magnitudes of the infiltration velocity. It is obvious that the tidal phase is very important. Infiltration velocities are large when the shoreline moves landward on a partially saturated beach on a rising tide. General magnitudes of U_f are $0.08K$ for the steady laboratory conditions and $0.45K$ for field conditions during the rising tides.

A mathematical model of the watertable which includes the effects of wave runup infiltration was obtained in a steady state. The development of the numerical watertable model was also attempted with the glassy/dry boundary as a boundary condition. However, the numerical model of the watertable in this study is based on tidal fluctuations with the use of the wave-influenced G/D boundary condition.

CHAPTER 359

LONG RANGE POSITIVE EFFECTS OF THE DELRAY BEACH NOURISHMENT PROGRAM

Kim E. Beachler, P.E.¹
and
Douglas W. Mann, P.E.²

INTRODUCTION

The success of beach nourishment projects is often questioned due to the observed losses of sand from the fill area and what appears to be a loss of benefits. Observations made by the authors indicate that there have been noticeable advances in the shoreline both to the north and the south of the Delray Beach, Florida beach nourishment project. The purpose of this evaluation is to show that much of the sand which moves out of the project can actually be accounted for and benefits the neighboring beaches.

The City of Delray Beach is located on the southeast coast of Florida approximately 80 kilometers north of Miami (Figure 1). A portion of the City encompasses about 4.8 km of the barrier island. The nourishment project is maintained over a distance of 4.3 km.

BACKGROUND HISTORY

In the 1960's, the Delray Beach shoreline was experiencing severe erosion. The public beach was almost non-existent and State Road A1A was damaged annually in winter storms (Figure 2). To combat this problem, the City constructed concrete and rock revetments along the public beach. In 1971, the concrete revetment failed and the City initiated a beach nourishment program.

The initial beach nourishment was completed in 1973. The project totaled 1,249,739 cubic meters of sand which was dredged from an offshore borrow area and placed in the project area. Subsequent to the initial nourishment the project area was renourished in 1978, 1984 and 1992 using sand volumes of 536,000, 994,000 and 770,000 cubic meters, respectively. The location of the various fill placements is shown in Figure 2.

The annualized cost of the beach nourishment program is approximately US\$980,000 (Coastal Planning & Engineering, Inc., 1991). The program is a Federally authorized shore protection project. As a result, the nourishments are designed consistent with Federal (U.S. Army Corps of Engineers) standards and are funded at both the federal, and local level.

The variation of fill volumes in this program (1973 to the present) is indicative of the expanded knowledge gained from both the monitoring of the beach fill and the advancement in beach nourishment design over this time period. A review of the initial 1973 fill placement has indicated that only enough material was placed to construct the design (storm protection) section of the beach. Virtually no sand was placed to account for end losses or background erosion losses (advanced nourishment). Subsequent nourishments have placed sufficient sand in an advanced nourishment section to maintain the design section through the nourishment interval. This design procedure is consistent with the National Research Council (NRC) recommendations (NRC, 1995).

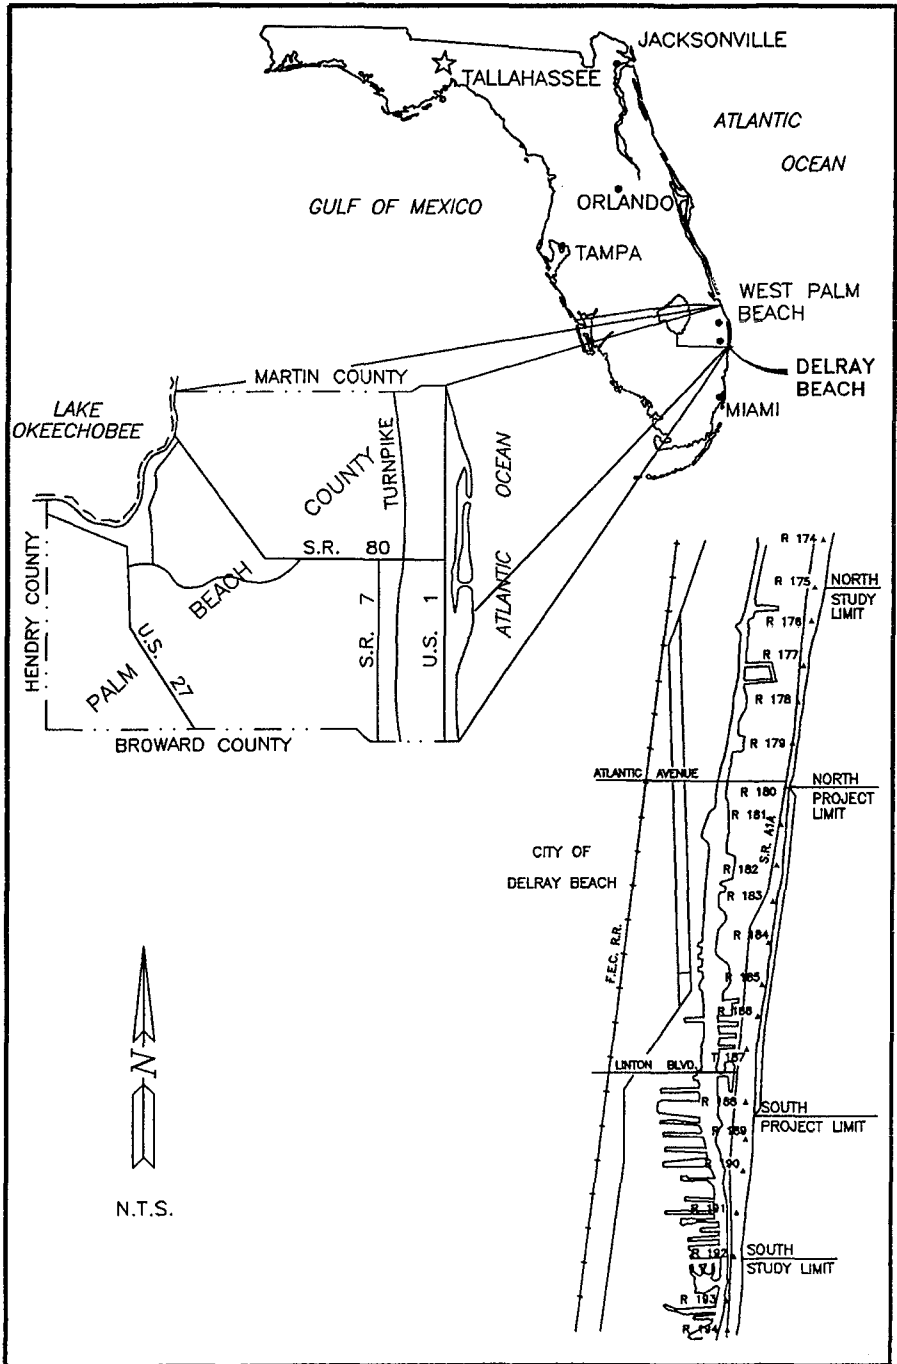

FIGURE 1

BEACH MONITORING, ANALYSIS, AND RESULTS

Annual monitoring studies have been conducted by the City of Delray Beach since the initial restoration, providing data for the performance assessment. Survey data from the State of Florida Department of Environmental Protection collected in 1974, 1990, and 1995 was used to evaluate changes outside of the project area. The State of Florida maintains a series of beach profiles which are spaced approximately every 330 meters along the sandy shoreline of the State. The profiles in the fill area are shown in Figure 2. All beach profiles are surveyed from the upland limit to the depth of closure (approximately -10 meters).

Figure 3 shows the mean high water shoreline changes from 1974 to 1995 both within the fill area and on the adjacent shorelines. While the initial fill project occurred in 1973, no beach profiles were measured on the adjacent shorelines until 1974. As a result, the shoreline response in Figure 3 is not complete; nevertheless, the survey comparison represents one of the few extended (spatially and temporally) monitorings of a beach nourishment program.

The beach fill plan form demonstrates end loss or diffusion characteristics which are similar to those predicted by Pelnard-Consideré (1956) though a direct comparison has not been made. Accretion outside of the fill area is highest immediately adjacent to the fill and tapers to lesser amounts further from the fill (Figure 3). The length of the taper to the south is longer than the taper to the north which is consistent with the net littoral transport to the south. There are distinct points to the north (R165) and south (R201) where the data showed no change or erosion over the 21-year comparison. These end points are used as the lateral limits of the impact of the beach fill on adjacent beaches. It is probable that the beach fill impacts beaches further to the south, but that the accretion due to the fill is less than the existing erosion. The north limit is in the vicinity of a large natural limestone rock outcrop which tends to act as a groin and divides the beach into small littoral cells.

The monitoring data indicates that some of the sand from the nourishment project has moved about 3 kilometers north and south of the fill limits. This movement results in an advancement of the shoreline as well as increased volumes of sand on the beaches within the neighboring towns of Gulfstream and Highland Beach. The nourishment program has placed about 3.5 million cubic meters of sand on Delray Beach between 1973 and 1992. The beach profiles indicate that a total of 43% of that sand, about 1.5 million cubic meters, has been eroded from the fill area; however, the analysis found that 1.3 million cubic meters (85%) of that sand could be located between 2.7 km north of the project to 3.5 km south of the project. The total volume accreted to the north is 629,000 cubic meters over 2.7 km and to the south the accretion is 673,000 cubic meters over 3.5 km. Therefore, the majority of the sand that has eroded from the project has not been "lost" but rather has been deposited on adjacent beaches.

Nourishment Interval

The nourishment interval for the Delray Beach nourishment project has increased from 5 years to the present 8 years (1984 to 1992). The design of the fill places an economically optimum amount of advanced nourishment on the beach. Currently, the advanced nourishment is designed to last 9 years (U. S. Army Corps of Engineers, 1992). The increase in the actual nourishment interval is a result of better estimation of end losses and the spreading of the beach fill. The diffusion theory indicates that a longer fill project will last longer than a shorter fill project. The accretion of sand on adjacent beaches has extended the "effective" length of the beach and has resulted in less diffusion loss and a longer nourishment interval.

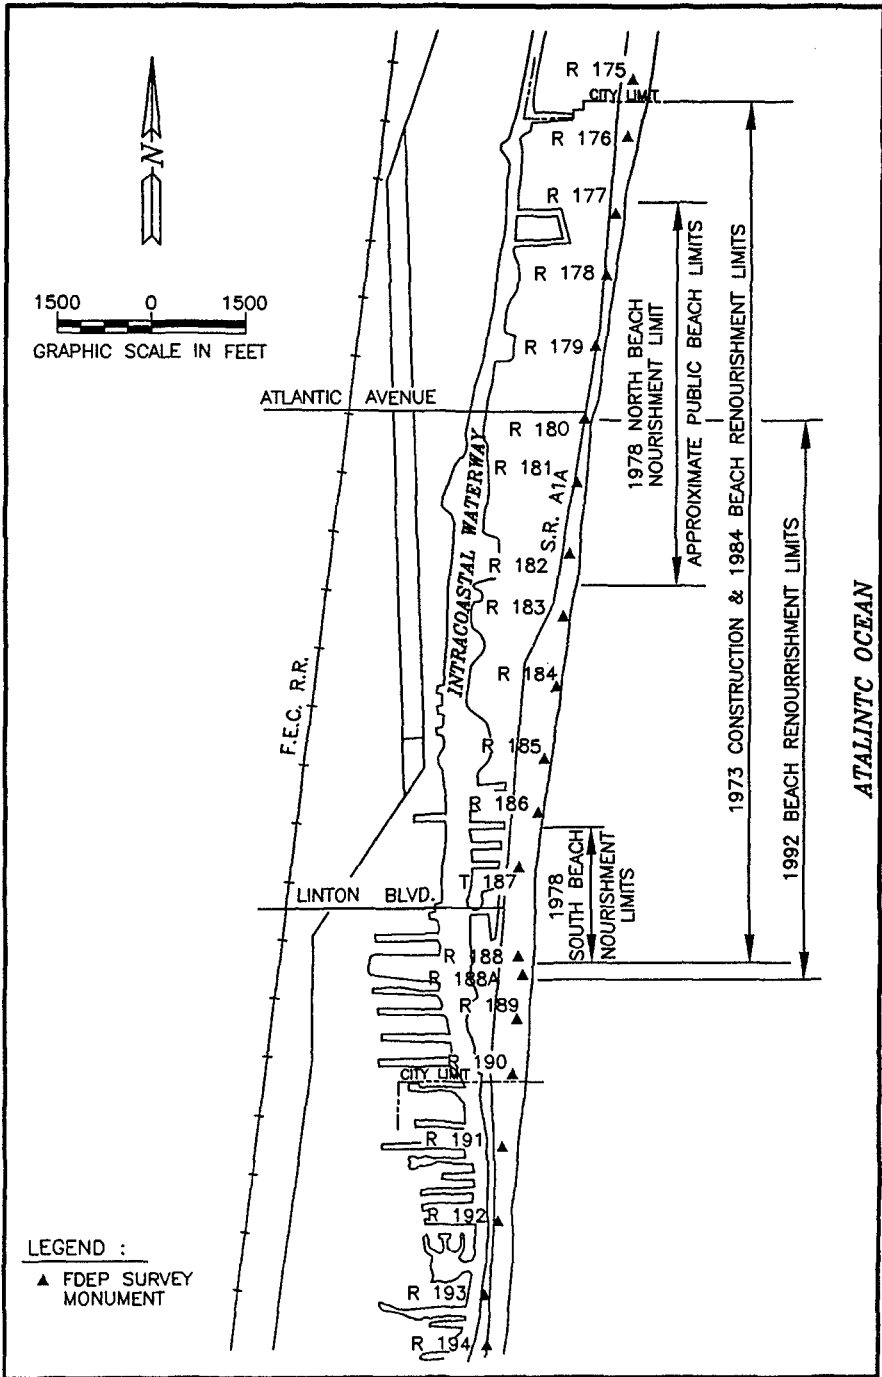

FIGURE 2

Figure 3

PROJECT BENEFITS

Benefits of a beach nourishment project are attained in several ways. The most important are the protection of upland properties from coastal storm damage, the improved recreational value of the maintained beaches and the resulting increase in property values. The City of Delray Beach, who manages its beach program, requested that these benefits be determined to understand the positive impact of the beach program on the local economy.

Storm Damage Reduction

Storm damage prevention benefits presented in this paper are limited to those that are recognized by the U.S. Army Corps of Engineers in their evaluation of Federal participation. Storm damage reduction benefits are estimated by comparing the with project damage to the with out project damage. Damages are limited to structural damage to upland structures and roads, the loss of fill from upland areas from extreme events, the loss of land from long term recession of the beach profile, and the damage to existing coastal armoring. In addition, the prevention of coastal armoring is also included as a benefit. The Florida coast is susceptible to large storm surge and wave events associated with tropical storms and hurricanes. As these storms are acknowledged to be random events, storm damages are calculated in a probabilistic method. The method of computing the storm damages is generally described by Bodge(1991). For this analysis, the computer program of Thomas(1990) was utilized. An interest rate of 7.625 percent was assumed for the economic calculations. While this interest rate is about twice the U.S. rate of inflation, it is the rate prescribed by the U.S. Army Corps of Engineers and results in conservative benefits estimates. All economic data is calculated in U.S. dollars.

The storm damage prevention benefits were calculated using land and property values from the 1995 tax appraisers roll. For the fill area only(R175 to R189), the storm damage reduction benefits are \$3,819,800 annually. The annual storm damage reduction benefit of the Delray Beach nourishment projects on the adjacent beaches is \$5,863,000. This can be further divided; \$2,552,500 for properties in Gulfstream to the north and \$3,310,500 for properties to the south in Highland Beach.

The storm damage reduction benefits are thus greater outside the fill area than inside the fill area. While this may appear counterintuitive since the fill material is placed only in Delray Beach, the benefits are higher due to the level of upland development in each area. The City of Delray Beach maintains a public beach which is accessed by a beach front road. The adjacent communities of Highland Beach and Gulfstream are heavily developed along the ocean with expensive private homes and multi-unit condominiums. In addition, the Town of Gulfstream was heavily eroded in the early 1970's. The accretion of sand on a heavily eroded and heavily developed beach generates significant storm damage reduction benefits.

Property Value Enhancement

Recent beach nourishments within the state of Florida have resulted in increased property values. This increase in property values results in beach front owners receiving higher profits from their real estate investments as well as increasing the local property tax. A recent analysis of the study area was performed by Regional Research Associates(1996). They compared the unit property values(\$/square meter) for similar properties located on the barrier island and on the mainland(Figure 1). The Delray Beach nourishment project has resulted in beachfront properties costing 15-20% more than mainland properties due to the maintained beach. This increase is \$109.6 million within the fill area, \$31.0 million and \$58.4 million in Gulfstream and Highland Beach, respectively. The property value increase results in annual local taxes

of \$2.8 million, \$1.1 million, and \$1.9 million for Delray Beach, Gulfstream and Highland Beach, respectively.

Recreation Benefits

Recreational benefits attributed to a beach nourishment project are due to the increase in available beach space. The Corps of Engineers limits the recreational benefits by the demand to go to the beach and by the availability of public parking. The maintenance of the beach nourishment results in the annual benefits of \$496,000 in Delray Beach (Coastal Planning & Engineering, Inc., 1991). Because there is no public parking or access within Gulfstream or Highland Beach, no recreational benefits accrue due to the project.

Benefit Summary

The Delray Beach beach maintenance program generates approximately \$10.2 million annually in storm damage reduction benefits and recreational benefits to the City of Delray Beach and the adjacent towns of Highland Beach and Gulfstream. A common economic decision making principle is the ratio of annual benefits to annual costs. For this project, the benefit to cost ratio is 10.4. This excludes the increase in annual tax revenues due to the effect of the beach on property values.

CONCLUSIONS

The Delray Beach nourishment program has had a positive effect on a total of 11.3 km of shoreline as a result of filling about 4.3 km on a periodic basis. The analysis showed average shoreline advances of 28.3 meters to the north of the fill and 23.1 monitoring to the south. This was confirmed by an analysis of total volume change over the 23-year life of this project. The study accounted for 85% of the sand lost from the nourishment project.

As a result of this accretion outside of the fill area in neighboring cities, it was found that storm damage prevention benefits amounted to \$3,819,800 within the fill area and \$5,863,000 outside of the fill area but as a direct result of sand moving from Delray Beach to neighboring shorelines. The fact that there is a beach in place within the fill area provides an increase of 15 to 20 percent in property values.

ACKNOWLEDGMENT

The property value analysis data from Regional Research Associates is appreciated.

CHAPTER 360

EFFECTIVENESS OF A COMBINED BEACH AND SHOREFACE NOURISHMENT ON THE ISLAND OF NORDERNEY/EAST FRISIA, GERMANY

Hanz D. Niemeyer¹, Ralf Kaiser¹ & Heiko Knaack¹

Abstract

In order to improve the effectiveness of artificial nourishments a replenishment outside of the beach itself was taken into consideration for a prototype test. Contradictory to the earlier six conventional beach nourishments the material was deposited both on the shoreface and on the beach. The fate of the combined shoreface and beach nourishment was as well as that of the preceding conventional beach replenishment intensively monitored including field investigations of bathymetry, hydro- and sediment dynamics. On the basis of these data and additional application of mathematical models the effectiveness of this new type of nourishment has been evaluated in comparison with a conventional beach replenishment.

Introduction

The East Frisian island of Norderney experiences structural erosion in its western parts since the beginning of last century which is caused primarily by large scale tidal inlet and ebb delta migration [LUCK 1977; NIEMEYER 1995] and secondary by a gradient in long shore transport in the generally west-eastern directed drift [KRAMER 1960; NIEMEYER 1991]. In addition to earlier erected solid structures eight beach nourishments have been executed here since 1951/52 [KRAMER 1960; KUNZ 1991; NIEMEYER et al. 1995a]. Hydro- and morphodynamical boundary conditions have already been described in earlier publications [NIEMEYER 1991].

In 1992 a combined beach and shoreface nourishment was chosen as an alternative to conventional beach nourishments (fig. 1) [NIEMEYER et al. 1995a]. In order to evaluate its effectiveness an intensive monitoring programme including sedimentological, morphological and hydrodynamical site

¹Coastal Research Station of the Lower Saxonian Central State Board for Ecology, P.O. Box 1221, 26534 Norderney/East Frisia, Germany

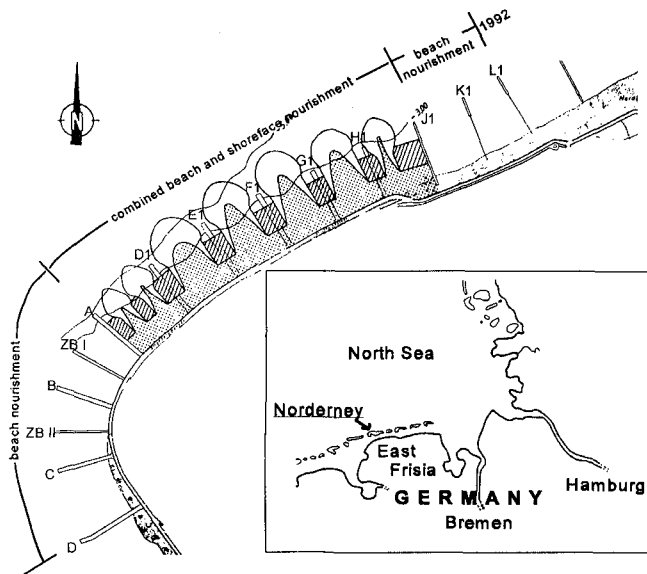

Figure 1. Island of Norderney/East Frisia in the southern North Sea; placements of the combined beach and shoreface nourishment in 1992 and of the preceding conventional beach replenishment in 1989

measurements has been carried out [KNAACK et al. 1996] as well as for the preceding conventional beach nourishment [KUNZ 1991; NIEMEYER 1991]. The investigations were carried out in cooperation with Danish and Dutch partners in the project "Innovative nourishment techniques evaluation (NOURTEC)" in the framework of the MAST II-programme of the European Communities and are additionally funded on a national basis. Results of the investigations carried out in respect to the combined shoreface and beach nourishment on the island of Norderney are subject of this paper focussing on its effectiveness by comparison with the preceding conventional one.

Design and initial behavior of the combined beach and shoreface nourishment

On the western and northwestern beaches of Norderney structural erosion is counterbalanced by artificial beach nourishments since 1951 [KRAMER 1960; KUNZ 1991; NIEMEYER 1991] though already between 1899 and 1909 dredging material has been dumped on the shoreface of the western beaches in order to improve beach stability [NIEMEYER et al. 1996]. In 1992

both nourishment techniques were combined for the replenishment of the northwestern beaches whereas on the western beaches only the beach was nourished (fig. 1). Basic idea of the deposition of material on the shoreface was to benefit from observed transport mechanisms explaining the pending of material between beach and shoreface [NIEMEYER 1991]. On the western beaches a deposition on the steep shoreface was considered as inconvenient; high initial irreversible losses into the close deep inlet channel were anticipated. A pure shoreface nourishment on the northwestern beaches was excluded because its execution by dumping or the rainbow-method on the shoreface between the groynes was regarded as dangerous for the executing vessels. Therefore the nourishment of the shoreface was carried out similar to that of the beach after finishing there the replenishment: the pipes were lengthened in the middle of the groyne fields and large humps were pumped into that area (fig. 2). It was anticipated that the local hydodynamical forces would create a dispersion of the sand stored in the artificial humps across the whole shoreface within a few weeks leading to its more or less uniform distribution.

Explanatory the reshaping of the hump in the groyne field E_1-F_1 is documented here by depth lines with reference to German datum = NN which is approximately equivalent to mean sea-level whereas mean high tide is about NN + 1,2 m and mean low tide about NN - 1,3 m (fig. 3): It is evident that the hump is lesser pronounced on the shoreface than on the beach. The highest initial losses occur therefore also on the intertidal beach and not on the shoreface which lower parts even benefit, but to a much lesser extent than the reduction of the hump's volume on the beach. A suitable explanation might be

Figure 2. Execution of the shoreface nourishment by pumping humps of sand from the shore

Figure 3. Reshaping of a sand hump after nourishment execution

that the geometry of the humps enforced the initialization of strong ripp currents evacuating large amounts of the nourished material from the beach across the shoreface directly offshore being there unavailable for the anticipated pending between beach and shoreface.

Behavior of the combined beach and shoreface nourishment

Behavior of the total nourishment

The analysis of the behavior of the nourished beaches is focussed on the areas where the replenishment has been carried out both on the beach and on the shoreface. For this area also the corresponding data of the preceding conventional nourishment are taken into consideration in order to compare the effectiveness of both replenishment techniques. A comparison for the relative volumes per m beach length of the two replenishments above certain levels with reference to NN across the whole stretch between the groynes A and J₁ (fig. 1) highlights again that in the case of the combined nourishment the volumes on the shoreface below NN -1,5 m are not significantly large in relation to that ones on the beach, particularly not if compared with volumes of the preceding conventional replenishment (fig. 4a). This fact is evidently confirmed by a comparison of the volumes between the chosen levels (fig. 4b): the relative volumes on the beach of the combined nourishment are higher than those of the conventional one. But nevertheless the data highlight also that a comparison of the two distinct nourishment on the basis of their lifetime will remain insufficient, because the remaining relative volumes of the combined beach and shoreface nourishments were at the end of its lifetime in 1994 higher than those of the preceding conventional one in its final stage.

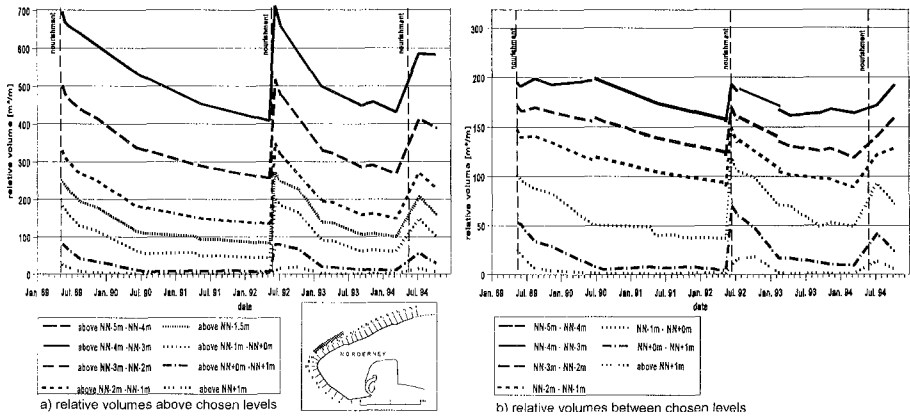

Fig. 4: Relative volumes per m beach length between the groynes A and J₁ after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

Behavior of the nourishment in specific groyne fields

In order to get a deeper insight into the behavior of the two nourishments the development of their volumes in specific groyne fields has been evaluated with reference to the differences of shape and relative volumes. In the groyne field A-D₁ (fig. 1) at the downdrift edge of the combined beach and shoreface nourishment the relative volumes become between nearly all levels continuously smaller after the conventional beach nourishment of 1989. Only a slight increase occurred in the lower part of the shoreface in the very beginning and on the intertidal beach after a lifetime of more than two years (fig. 5). Contradictory the relative volumes of the lower shoreface increase during the whole lifetime of the combined nourishment and there is after initial erosion accretion on the upper part of the beach above mean sea-level during the first autumn and winter after implementation of the nourishment.

In the updrift succeeding groyne field D₁-E₁ (fig. 1) the intertidal beach loses relative volume immediately after the conventional beach replenishment in 1989 (fig. 6). After the first winter following the implementation of the nourishment here the relative volumes have again the same order of magnitude as before. They remain on the lower part of the intertidal beach then rather stable and decrease slightly in the final stage of the lifetime. The relative volumes on the shoreface increased during the first stage of the lifetime or experienced even a transient increase. After a period of about one year in coincidence with reduction of the relative volumes on the beach to the pre-nourishment level a continuous erosion of the shoreface started. It is itself suggesting that probable losses on the shoreface might have been compensated by eroded material from the beach as long as this source was available.

Fig. 5: Relative volumes per m beach length between the groynes A and D₁ between distinct levels after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

Fig. 6: Relative volumes per m beach length between the groynes D₁ and E₁ between distinct levels after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

Fig. 7: Relative volumes per m beach length between the groynes E₁ and F₁ between distinct levels after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

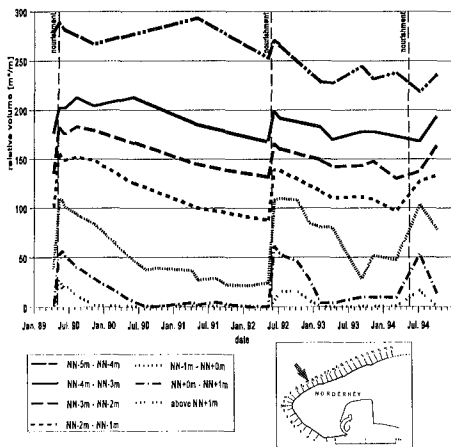

Fig. 8: Relative volumes per m beach length between the groynes F₁ and G₁ between distinct levels after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

The nourished volumes in this groyne field have been larger for the subsequent combined nourishment leading to remarkable initial losses beside a slight increase on the highest part of the beach during the following five months. But after more than one year of lifetime a stabilization occurred on a

Fig. 9: Relative volumes per m beach length between the groynes G_1 and H_1 between distinct levels after the conventional beach replenishment in 1989 and the combined beach and shoreface nourishment in 1992

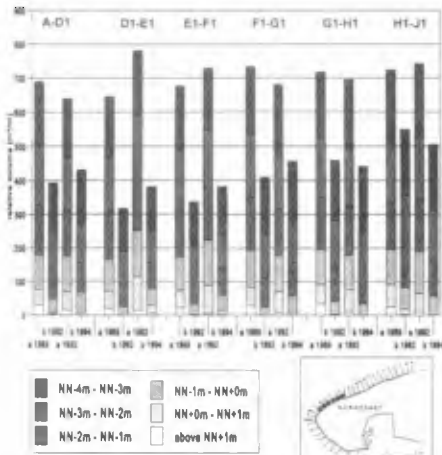

level significantly higher than the one before the implementation of the nourishment. Moreover the higher parts of the beaches recovered where the material is in respect of the primary aim to reduce wave loads more effective than anywhere else in the profile. This highlights once more that the morphological situation did not demand for the subsequent nourishment in 1994.

Similar results are gained for the next two groyne fields in updrift direction $E_1 - F_1$ and $F_1 - G_1$ (fig. 1) though less pronounced than for $D_1 - E_1$: There are both on the upper part of the beach as well as on the lower shoreface transient phases with accretion after initial erosion (fig. 7 + 8). Particularly on the lower part of the beach the relative volumes are significant larger at the final stage of the combined beach and shoreface nourishment than before.

Contradictory the relative volumes after the combined nourishment in the groyne field $G_1 - H_1$ follow another tendency. Whereas their values remain rather stable or increase even on the lower shoreface those on the beach reflect continuous erosion. Particularly there the preceding conventional beach replenishment has not experienced a higher amount of erosion though its lifetime lasted longer (fig. 9). This effect requires further explanation, because the behavior of the nourished beach and foreshore in this area has changed in comparison with preceding nourishments. Erosion has become relatively higher with respect to the rates in the groyne fields being located updrift.

Total balance

For all groyne fields the relative volumes between certain levels have been determined as well for the combined beach and shoreface nourishment in 1992 as for the preceding conventional beach replenishment in 1989 on the following basis: total amount before and after execution (fig. 10.1 + 10.2), losses and nourished volume (fig. 11.1 + 10.2). The relative volumes after the execution of the combined nourishment are higher than after the implementation of the preceding conventional one in the groyne field $E_1 - F_1$, $H_1 - J_1$ and particularly in $D_1 - E_1$. According to the relative volumes before

10.1 Groyne fields A-D1 to H1-J1 above NN -4m

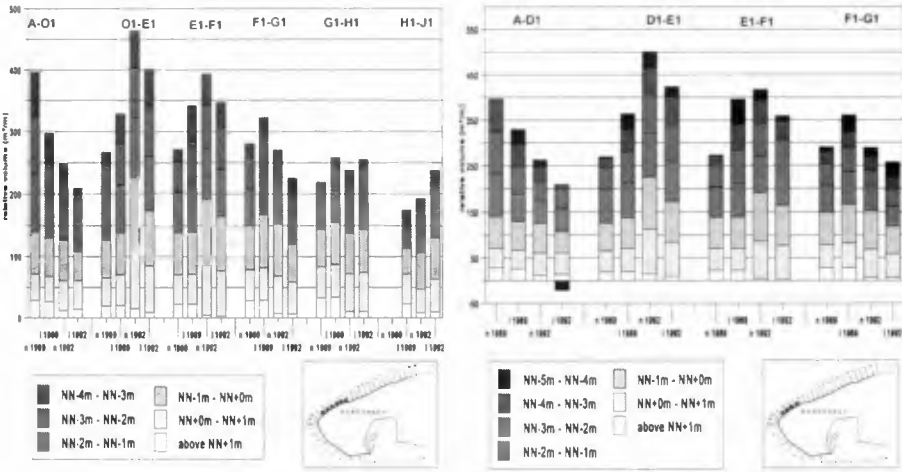

10.2 Groyne fields A-D1 to F1-G1 above NN -5m

Fig. 10: Relative volumes per m beach length between distinct levels after implementation (a) and at the end of the lifetime (b) for the nourishments in 1989 and 1992

implementation this was aimed at counterbalancing an anticipated higher rate of erosion in these areas (fig. 10.1 + 10.2). The same design procedure has been applied for the replenishment in 1989 (fig. 11.1) for the groyne field A-D₁ which has been rather successful if the remaining relative volumes in total are taken into consideration. In the groyne fields A-D₁, F₁-G₁ and G₁-H₁ the total relative volumes have been smaller for the combined nourishment in comparison to that one in 1989. The remaining relative volumes at the end of the lifetime of the combined nourishment are higher at that of the conventional replenishment between the groynes A and G₁ and smaller in the two following groyne fields G₁-H₁ and H₁-J₁ (fig. 10). Of high importance with respect to the primary aim to reduce wave attack at the seawall are the significantly higher remaining relative volumes on the beach and there particularly in the upper part above mean sea-level in the area between the groynes A and F₁ and to a lesser extent in the groyne field F₁-G₁. With respect to the necessity of a subsequent nourishment a comparison of the remaining relative volumes at the end of the lifetime of both nourishments makes evident that the minimum values existing before the combined beach and shoreface nourishment were still by about 25% and more exceeded in any place at the end of its lifetime (fig. 10)

Beside the groyne field A-D₁ the losses after the conventional beach nourishment exceed the nourished relative volumes (fig. 11). Though the losses in A-D₁ were not compensated by the combined nourishment it delivered on overish of which is particularly evident for the lower shoreface where instead of losses a net win has taken place (fig. 11.2). The comparison

11.1 Groyne fields A-D1 to H1-J1 above NN -4m

11.2 Groyne fields A-D1 to F1-G1 above NN -5m

Fig. 11: Relative nourished volumes (n) and afterward losses (l) per m beach length between distinct levels for the nourishments in 1989 and 1992

between nourished relative volumes and subsequent losses makes evident that particular for the stretch between the groynes A and G_1 where for both nourishments the highest losses occur the combined beach and nourishment left over an overshot of material at the end of its lifetime. In the groyne fields A-D₁, F₁-G₁, G₁-H₁ (fig. 11) and if the lower part of the shoreface is included even in the groyne field E₁-F₁ the total losses after the implementation of the combined nourishment have been remarkably smaller than for the preceding conventional beach replenishment. Only in the groyne fields D₁-E₁ and H₁-J₁ the total losses after the execution of the combined nourishment have been larger than those of the preceding one (fig. 11.1). The difference decreases by about 50 % for the groyne field D₁-E₁ if the lower shoreface is taken into consideration (fig. 11.2). With respect to of the major purpose of artificial nourishments in this place to reduce wave attack on the seawall it is of high importance to check the losses on the upper part of the beach. The behavior of combined beach and shoreface nourishment in the area with the largest losses makes evident that particularly there the relation between nourished and lost relative volumes above mean sea-level is favourable in comparison to that of the preceding conventional beach replenishment (fig. 11).

Impacts of changing local wave climate

measurements in the offshore area and on the shoreface of the island of Norderney highlighted enormous changes in wave damping on the ebb delta of the tidal inlet. In comparison to results from earlier investigations [NIEMEYER 1987] waves are lesser attenuated when propagating across the ebb delta, even for conditions with no remarkable set-up on mean high tide the

Fig. 12: Topography for the area seaward of the tidal inlet and the northwestern shore of the island of Norderney according to surveys in 1960, 1975, 1990 and 1995

shelter effect of the ebb delta for the northwestern beaches of the island of Norderney was remarkably reduced. In order to get a deeper and more systematic insight into background on these processes runs with the mathematical wave model HISWA [HOLTHUIJSEN & BOOIJ 1987; BOOIJ & HOLTHUIJSEN 1992] have been carried out for four distinct morphological situations of the area seaward of the tidal inlet and the northwestern shore of the island of Norderney (fig. 12): the bathymetries of 1960, 1975, 1990 and 1995 were used as a basis for model topography. The model HISWA has already been successfully applied to this specific area and similar ones and is regarded as a suitable tool for the anticipated purpose [DEN ADEL et al. 1991; NIEMEYER et al. 1995b].

Already the simple comparison of the topography for the distinct four situations makes significant morphological changes evident (fig. 12): Whereas the ebb delta is becoming even more pronounced after 1960 with a climax in 1975 the later surveys in 1990 and 1995 make a reduction of the shallows with heights above NN - m evident. Accompanied is this process by a migration and seaward directed deepening of the main channel of the inlet between 1990 and 1995: Both morphological changes enhance onshore wave penetration in direction of the island's northwestern shores.

Fig. 13: Significant wave heights for the area seaward of the tidal inlet and the northwestern shore of the island of Norderney according to the bathymetry in 1960, 1975, 1990 and 1995 (computed with HISWA)

The model runs confirm this first estimate with respect to penetration of higher waves into the northwestern shoreface of the island of Norderney (fig. 13): For the situations of 1960 and 1975 no significant changes occur. But already for the topography of 1990 higher waves with $1,75 \text{ m} \leq H_s \leq 2,00 \text{ m}$ propagate across the ebb delta though not appearing nearshore. For the topography of 1995 waves with heights with this order of magnitude occur on a large part of the shoreface. This increase in nearshore wave energy is not only confirmed by prototype data; the measured wave heights on the shoreface are even higher than those being computed with the model for the same offshore conditions. Additional investigations have shown that this effect does not increase for storm surges with higher set-up and higher waves. The higher waves enforce also a more intensive wave energy dissipation due to breaking in the ebb delta area.

In order to make the effect of this change in local wave climate for the dynamics on the northwestern shoreface and beaches of the island of Norderney more evident the computed significant wave heights for all four morphological situations are compared at 26 selected points at the edge of shoreface and beach parallel to the island's northwestern shore (fig. 14). For the situations of 1960 and 1975 there are no remarkable changes in wave climate. The significant wave heights are of the same order of magnitude on

Fig. 14: Significant wave heights at the edge of shoreface and beach parallel to the northwestern shore of the island of Norderney according to the bathymetry in 1960, 1975, 1990 and 1995 (computed with HISWA)

Fig. 15: Differences of significant wave heights at the edge of shoreface and beach parallel to the northwestern shore of the island of Norderney according to the bathymetry in 1990 and 1995 (computed with HISWA)

the whole stretch of the northwestern shoreface. In 1990 there is an increase of wave heights particularly in the stretch between the groynes A and F₁ but they decrease further downdrift. In 1995 wave height have increased in all places downdrift of groyne A (fig. 15). This comparison highlights that the combined nourishment experience for the same offshore conditions higher wave loads with stronger driving forces than the preceding conventional one. This unfavorable boundary conditions are another indication for the superior effectiveness of the combined nourishment. The change in wave climate explains also the higher losses occurring after the implementation of the combined beach and shoreface nourishment in the area downdrift of groyne H₁.

Conclusions

The comparison between the combined beach and shoreface nourishment and the preceding conventional replenishment with respect to their effectiveness has lead to the following conclusions:

1. Lifetime is in this case no suitable measure for comparing the effectiveness because the remaining relative volumes are for the combined nourishment in any place larger than the accepted minimum values for the preceding conventional for which no damages of the seawall occurred.
2. High initial losses of the combined nourishment might be credited to the chosen execution method with the deposition of humps which might have provoked strong ripp currents in the groyne fields. A less concentrated dumping of supply material on the shoreface could improve the measure.
3. Relatively higher losses in the downdrift part of the combined nourishment in comparison to the preceding conventional one do not occur due to the changes in the execution method. They are enforced by changes in local wave climate due to migration of the ebb delta leading to an increase of the driving forces for longshore currents and littoral drift.
4. The application of reliable mathematical wave models in combination with available actual bathymetries is suitable to make changing wave loads evident allowing an optimized adaption of the spatial distribution of relative nourished volumes in distinct groyne fields.
5. Particularly in the area with high rates of erosion the behavior of the combined nourishment delivered indications for the anticipated pending of the sand between shoreface and beach leading there to a recovery of the upper part of the beach which is beneficial with respect to the major aim of these nourishments to enforce wave energy dissipation in front of the landward placed seawall.

6. An further optimization of artificial nourishments on the northwestern shore of the island of Norderney requires a definition of acceptable wave loads for the existing seawall in order to evaluate the ultimately necessary minimum of relative volumes on the beach for sufficient wave energy dissipation.

Acknowledgement

This investigations have been carried out in the framework of the NOURTEC project of THE COMMISSION OF THE EUROPEAN COMMUNITIES (Contract MAS-CT93-0049) and additionally benefitted from national funds of the GERMAN FEDERAL MINISTRY FOR EDUCATION AND RESEARCH and the LOWER SAXONIAN MINISTRY FOR THE ENVIRONMENT. The authors have substantially benefitted from the joint cooperation in this European project with their Danish and Dutch partners. CHAPTER 361

Nearshore Berm Performance at Newport Beach, California, USA

Chuck Mesa¹

Abstract

In 1992, approximately 1,276,000 cubic yards of littoral material was hydraulically placed into a berm configuration in nearshore water depths at Newport Beach, California, USA. A monitoring program conducted included directional wave measurements, beach and bathymetric profiles, surficial sediment sampling, and controlled aerial photography. Analysis of the bathymetric profiles collectively indicate the berm is experiencing a shoreward-directed dispersal; there is no evidence suggesting offshore or alongshore directed berm movement. Sediment physical characteristics and grain size distribution indicating the berm effects on the seabed are discussed. Recently proposed models for berm stable/active categorization and migration rate are examined. Surfing at the site was significantly enhanced; the berm created breaking wave conditions never before experienced at this location.

Introduction

This paper describes a nearshore disposal monitoring project at Newport Beach, California, USA. The nearshore placement activity was conducted during the period Jan-Nov 1992. Approximately 1,276,000 cubic

1

U.S. Army Corps of Engineers, Los Angeles District, P.O. Box 2711, Los Angeles, CA, 90053, USA

yards of suitable littoral material was hydraulically placed into a berm configuration in water depths ranging from -5 ft to -30 ft MLLW (Note: All elevations and/or depths cited herein are in feet referred to Mean Lower Low Water (MLLW)). These depths are both within and outside the day-to-day surf zone. The purpose of the monitoring plan was to determine the fate of the disposal berm by providing a quantitative and qualitative description of the movement of disposal material in the cross-shore and alongshore directions. The material was obtained as the result of the Lower Santa Ana River flood control channel expansion project.

The project site is located in the City of Newport Beach, California, USA. The shoreline immediately landward of the disposal area is a mixed use area of recreation and residential development. Coastal structures in the project area include three shore perpendicular jetties at the mouth of the Santa Ana River, and a field of eight groins. The disposal site was selected to confine the material between the river mouth system and the groin field.

Monitoring Plan

The monitoring program conducted during the period Dec 91 - May 95 included directional wave measurements, beach and bathymetric profiles, surficial sediment sampling, and controlled aerial photography of the project area (Fig 1).

The nearshore directional wave climate was monitored by installation of a S_{xy} slope array wave recording instrument during the period 3/92 - present. The slope array was placed offshore of Huntington Beach approximately 1.5 miles northwest of the project site at a water depth of 33 ft.

The 24 beach and bathymetric profile lines were established as follows: 8 lines placed throughout the groin field system; 11 higher spatial resolution lines placed at 300 ft intervals over the disposal area; 1 line placed over the Santa Ana River delta; 3 lines spaced at even intervals; 1 line (control) placed

approximately 1.5 miles northwest of the project area. The control line is not expected to be influenced by movements of the nearshore disposal material, and acts as an indicator for seasonal or gross shoreline movements. Profiles were measured from a fixed point on the backshore to depths of greater than -40 ft. Profile survey dates were: 12/91 pre-construction; 5/92 1st interim; 7/92 2nd interim; 11/92 1st post-construction; 3/93 2nd post-construction; 5/93 3rd post-construction; 1/94 4th post-construction; 11/94 5th post-construction; and 5/95 6th post-construction.

Sediment samples were obtained by surficial grab sampling techniques along 6 profile lines (Line 1, Line 5, Line 9, Line 14, Line 19, Line 24) at 8 elevations corresponding to +6 ft, 0 ft, -6 ft, -12 ft, -18 ft, -24 ft, -30 ft, and -36 ft.

Controlled aerial photography flown over the project area included: 12/91, 6/92, 11/92, 12/92, 3/93, and 5/93.

Wave Climate Description

Directional wave measurements indicate a multi-directional, seasonally dependent, sea/swell climate is experienced at the project site. The nearshore slope array recorded 6905 observations during the measurement period. The sample histogram of wave heights included a maximum measured wave of 10.6 ft; the mean, mode, and standard deviation are given as 2.7 ft, 2.5 ft and 0.9 ft respectively. The sample histogram of spectral peak period indicates double peaks at $T=7$ sec and $T=15$ sec. In southern California this is typically associated with sea and swell respectively (not withstanding the respective classical definitions dependent on the point of origin). The combined sea/swell climate was assumed a priori; a double peaked distribution of wave climate was expected.

Profile Comparison

Repeated bathymetric mapping of the cross-shore profiles indicates the nearshore disposal material

formed a significant clearly distinguishable feature on the local seabed relative to the pre-project profile.

Fig 2 illustrates a time series of the cross-shore distribution of berm material at Line 19 (located at the disposal area northwestern boundary). Fig 2 indicates the berm is distributed along the profile approximately between depths of -2 ft and -32 ft. The berm toe appears located at the -32 ft contour; the berm indicates a relatively sharp relief on the seaward side and is diffused gradually towards shallower water. The berm maximum vertical relief (e.g. "centroid") appears located at a depth of -29 ft.

Fig 3 is a time series comparison of the profile *differences* developed by subtraction of the pre-project profile from the post-construction profiles. Inspection of Fig 3 clearly illustrates the berm cross-shore behavior. The berm centroid is located 1900 ft from the survey baseline, or about 1200 ft from the beach. The berm had a maximum vertical relief of 14.5 ft from the pre-project seabed, diminishing successively to 11.5 ft, 9.0 ft, 8.5 ft, and finally diminishing to 8.0 ft by the sixth survey episode (31 months). Thus, the berm vertical relief appears to diminish rapidly initially, with the deflation rate decreasing over time. Close inspection of Fig 3 indicates as the berm crest erodes, the crest material is sheared off in the *landward* direction. The survey data indicates there is significant accretion of material throughout the region between the berm and the foreshore. This landward directed movement is particularly indicated by the accretion of material in a bar formation as indicated in the 5/93 survey episode. Further inspection of Fig 3 indicates the berm centroid location is stationary, and not migratory as the berm erodes. There is no indication the berm migrates as a solitary feature; migration is measured as a function of the crest material dispersal. This observation is relevant to the following discussion of berm migration rate.

There is no evidence in the data to suggest offshore or alongshore directed movement of the berm material. Analysis of all measured profiles indicates

no signal within the resolution of the survey data which substantiates seaward berm movement. There is little or no indication of significant alongshore movement of the berm. Due to the prevailing wave climate, net sediment transport is a priori expected to be in the southeasterly direction. Analysis of the profile closest to the disposal area southeastern boundary (Line 8 within the groin field) indicates no signal to substantiate southeasterly alongshore movement. Likewise, there is no significant indication of berm migration in the northwesterly direction. This is unambiguously no movement across the northwesterly control line. The profile closet to the northwestern boundary exhibits some accretionary signal, however, that was determined to be remnant storm flow material from the Santa Ana River.

Sediment Physical Characteristics and Distribution

The sediment characteristics of the nearshore disposal material are known from pre-project geotechnical analyses. The material was approximately 83% sand and 17% fines (defined as passing the #200 U.S. Std sieve), with a d_{50} median diameter of approximately 0.27 mm which is classified as fine sand under the Unified Soils Classification.

Fig 4 illustrates a time series comparison of sediment grain size distribution along a selected profile (Line 19) and depth (-24 ft). The pre-project (12/91) sediment distribution is a poorly graded fine sand material, approximately 17% fines, with a d_{50} median diameter of 0.09 mm. Fig 4 indicates a well behaved coarsening of the grain size distribution between the 1st, 2nd, and 5th survey episodes. At the 5th survey episode (11/94) the sediment achieved its coarsest distribution, a poorly graded fine sand, 1% fines, with a d_{50} median diameter of 0.22 mm. There appears to be a rebound of the grain size distribution at the 6th survey episode.

Fig 5 illustrates a cross-shore time series comparison of d_{50} median diameters at Line 19. The data is fairly well behaved and indicates the coarsest

fraction is located on the upper portions of the profile while the fine grained fraction is dispersed towards deeper water. The berm material is coarser than the pre-project seabed and appears to be maintaining its position on the seabed.

Fig 6 illustrates a cross-shore time series comparison of percent fines at Line 19. The data clearly shows the percent fines is significantly higher in water depths greater than -24 ft. Over time the percent fines remain less than or approximately equal to the pre-project seabed condition.

Berm Categorization

Hands & Allison (1991) present a empirically based method to categorize stable or active nearshore berms. The method calculates the long-term distribution of wave-induced, near-bed velocities as an appropriate criterion to discriminate between stable and active behavior. Used conjunctively with the Hallermeier proposed inner and outer limits of profile zonation, the method successfully discriminates between stable and active berms in the "buffer" zone bounded by the inner and outer limits.

The results of the present analysis, shown in Fig 7, delineates the regions of berm stability or activity based on the wave-induced near-bed velocities. The berm in the present analysis is classified as *stable*, particularly at the 75-95 percentile which Hands & Allison describe as possessing the best correlation with berm behavior. It is worth noting that the present berm velocity distribution crosses the boundary delineating the stable-active regions, and also tends to converge towards the active classification near the 99-percentile (indicating a tendency for berm movement during extreme events).

The results using the Hallermeier profile zonation limits, shown in Fig 8, indicate the berm falls in the "buffer" zone. Hands & Allison further showed that berms stable in the buffer zone were less than 50% below the outer limit, while active berms were more than 50%

above the outer limit. Thus, with this methodology the Newport Beach berm gains an active classification. This directly contradicts the previously determined *stable* classification based on near-bed velocities. However, it should be noted that the berm could be considered weakly active based on its relative position as slightly greater than the 50% outer limit within the buffer zone.

Berm Migration Rate

Douglass (1995) proposed a model for landward migration rate estimation of nearshore sand berms. The model is formulated on the assumption that net shoreward sediment transport is due primarily to the velocity asymmetry characteristics of finite amplitude waves. The model parameters can be estimated using a joint probability density function (height-period, direction is assumed onshore) of site-specific wave climate data. The "expected value" of berm migration rate can be estimated as a function of depth.

The results estimate the berm migration rate to be approximately 100 ft/yr (Fig 9). Douglass provides no guidelines for choosing a depth from the functional relationship to use for berm migration estimation. An observation made during this analysis indicates that the results are critically dependent on the depth chosen. The depth used in the current study is the depth at the berm center of mass. However, this depth no longer exists after berm placement. Since the method is based on the velocity asymmetry of finite amplitude waves, the depth used should be the depth at the berm crest. This appears to be an inherent inconsistency, yet still the model appears to produce results that are in reasonable agreement with observed values and are the correct order of magnitude. The decaying semi-logarithmic function of depth appears intuitively correct. However, with decreasing depths at the shore, the model expected value approaches unrealistically high values. The model also assumes landward migration only and does not consider offshore movement.

Surfing

The nearshore berm disposal project temporarily significantly enhanced conditions for the recreational sport of surfing. This study photographically recorded breaking waves never before experienced at this location. The pre-project wave-breaking condition typically consisted of long crested swell waves propagating over straight and parallel contours with wave breaking occurring relatively close to shore. Typical pre-project surfing can be described as beach-break resulting in short, fast spilling/plunging "lefts" and "rights".

The hydraulic placement techniques employed by the construction contractor resulted in a series of small mounds constructed throughout the disposal area footprint. These disposal mounds were dispersed cross-shore throughout the nearshore zone, from near the typical breaker line to upwards of 1,200 feet offshore. Refraction effects focused the wave energy directly onto the individual mounds, which were effectively a severe perturbation to the straight and parallel bathymetric contours, tending to scatter the local wave field (Photo 1). The result was many wave "peaks" throughout the nearshore zone. Due to the extremely sharp relief of the mounds, waves tended to shoal extremely quick, increasing the local wave steepness, and creating a very "fast", "hollow" surfing wave (Photo 2). The surf lasted throughout the period of nearshore disposal, and several months thereafter. The surf was best at lower tidal levels with longer period swell.

Conclusions

In 1992, approximately 1,276,000 cubic yards of littoral material was hydraulically placed into a nearshore berm configuration at Newport Beach, California, USA. The monitoring program established included directional wave measurements, beach and bathymetric profiles, surficial sediment sampling, and controlled aerial photography. Bathymetry measurements indicate the berm is eroding by undergoing dispersal of the crest material shoreward. The berm base appears

stable. There is no evidence suggesting either offshore or alongshore movement of the berm material. Sediment physical characteristics indicate the coarser sediments are remaining within the active littoral system, while the berm is not adversely affecting the percentage of fines. Results using recently proposed models for berm stable/active categorization and migration rate are mixed. The berm gained both a stable and active classification. A calculated migration rate of 100 ft/yr appears correct in order of magnitude, but some question remains on functional application based on selection of appropriate water depth. Surfing at the site was significantly improved. Berm influence on the local wave field created shoaling and breaking conditions never before experienced at this location.

Acknowledgments

The author wishes to acknowledge the Commander, U.S. Army Corps of Engineers Los Angeles District, for authorizing publication of this paper. It was prepared as a result of the Lower Santa Ana River Flood Control Improvement study. I would like to thank the following individuals for their assistance and participation in this project: Dr. Scott L. Douglass at the University of South Alabama and Mr. Edward B. Hands at the Coastal Engineering Research Center. A special thanks is expressed to the boys at The Frog House Surf Shop.

CHAPTER 362

San Gabriel River to Newport Bay Erosion Control Project Orange County, California 30 Years of Periodic Beach Replenishment

Arthur T. Shak, P.E.¹, M. ASCE and Joseph A. Ryan, P.E.²

Abstract: Monitoring of a Beach Erosion Control project consisting of a protective and feeder beach with periodic beach nourishment in Orange County, California is assisted with Computer Aided Design and Drafting technology. Time series of depth changes and profile volumes are analyzed, and predicted renourishment requirements compared to 31 years of project history.

Introduction

The U.S. Congress authorized an erosion control project in 1962, recognizing the impacts of flood works, coastal harbors and other factors in causing beach erosion along the northern Orange County, California shoreline. With legislatively established cost-sharing between the State and federal government, an initial beachfill was constructed in 1964, with periodic nourishment in 1971, 1979, 1984, 1989-90 and 1996-97. Future beachfills are projected to be needed on a 5 year cycle, indefinitely.

The construction of the project was modified from the originally formulated plan with the use of sand sources of opportunity, the addition of a groin field, and deferring a detached breakwater/sand trap feature. A comprehensive analysis was performed of available profile data to compute the shoreline and volumetric history from pre- and post project to the present. This analysis was compiled by meticulously reconstructing historic data from the 1960's to the present to create controlled digital terrain maps which can easily be analyzed with CADD software.

2) Civil Engineer, U.S. Army Corps of Engineers, Los Angeles District, Los Angeles, California 90053.

Project History

The erosion control project formulated in the 1960's consisted of a protective and feeder beach to be located at the updrift end of the littoral cell at Surfside and Sunset Beach, with periodic beach nourishment by back-passing from the downdrift end of the cell near the Santa Ana River. The project area of approximately 20 km alongshore had a planned fill volume of three million cubic yards (mcy) for the initial protective beach, and a projected periodic renourishment rate of 1.75 mcy every five years. A detached offshore breakwater was also planned as a sand trap to be located at the downdrift location. The overall project plan is shown on Figure 1.

The initial protective and feeder beach was built in 1964 with four mcy of material from the adjacent Anaheim Bay/Seal Beach Naval Weapons Station (NWS). Between the initial fill and 1995, four renourishment cycles and three dredging projects of the NWS placed 8.6 mcy of dredge material - measured at the dredge site - at the feeder beach, as listed in Table 1. Of dredge material, 5.0 mcy were borrowed from offshore dredge pits. Photos 1 and 2 show typical pre and post beachfill conditions.

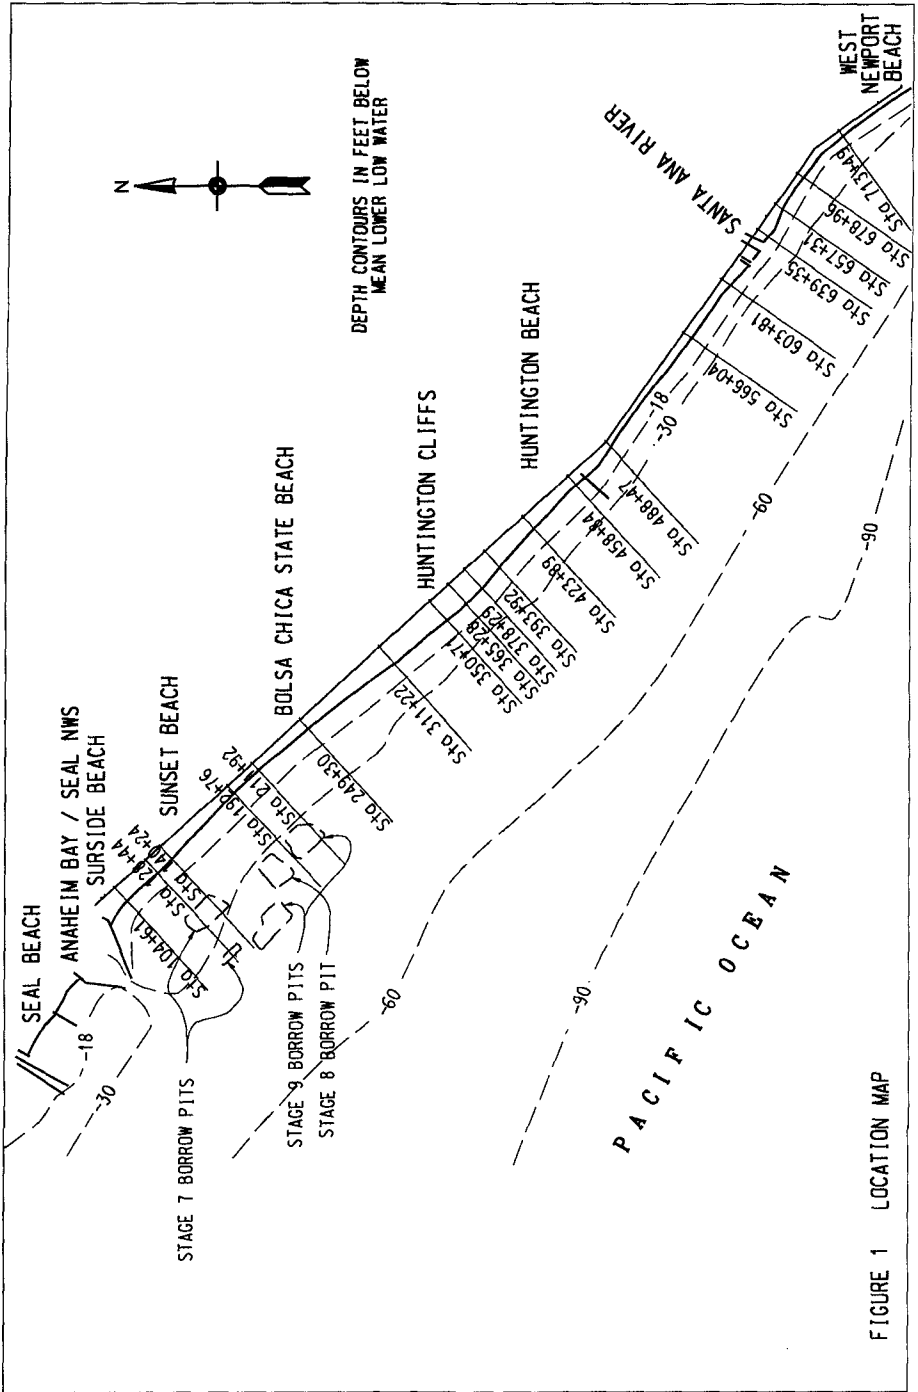

Construction of the detached breakwater/sand trap is deferred pending a demonstration of need, and no backpassing from the downdrift beach area has been performed. A groin field and beachfill at west Newport Beach was added to the project and constructed between 1969 and 1973. Eight groins were constructed and their cells filled with about 1.5 mcy of beachfill from the Santa Ana River or the adjacent Balboa peninsula.

Sep 1990	522,000	12,589,000	Stage 9/Offshore Borrow Pit

Analysis Methodology

Commercial Computer Aided Drafting and Design (CADD) software, MicroStation and InXpress from Bentley Systems, Inc., were utilized in creating digital terrain models (DTM) of the beach and nearshore hydrography. The CADD design files (.dgn) and digital terrain models (.dtm) are full scale models referenced to the California State Plane Coordinate System (SPCS27, Zone 6) as described in Stem(1989). The coordinate system was chosen for compatibility with an existing Geographic Information System (GIS) database made

**PHOTO 1 Feeder Beach Area - Post Stage 7 Beachfill

**PHOTO 2 Feeder Beach Area - Pre Stage 8 Beachfill
(April 16, 1982)**

available by Orange County, California, allowing overlays of the beach profile data to map data having property line resolution and orthogonally rectified aerial photography. Programs, such as CORPSCON developed by the U.S. Army Corps of Engineers Topographic Engineering Center, are available for conversion to any of the common horizontal datums with an accuracy as good as the original positioning data. The vertical datum used for all of the analysis is mean lower low water.

Available surveys used to construct DTM models, also referred to as Triangulated Irregular Network (TIN) models, include condition surveys, and pre- and post construction surveys of the San Gabriel River to Newport Bay Beach Erosion Control project; dredging of the Seal Beach NWS; the Santa Ana River Mainstem (SAR) project; the Coast of California Storm and Tidal Wave Study (CCSTWS); and surveys of the National Ocean Survey (NOS) conducted along the coasts in 1934 and 1975-77. Surveys were performed with varying degrees of spatial coverage and resolution, as well as duration. The recent profile surveys (1990's) were collected in time periods as short as a week while the 1960's surveys were collected over several months and the NOS surveys collected over multiple years. A tabulation of surveys utilized are listed in Tables 2 and 3.

After the tedium of reconstructing survey notes to the SPCS27 datum and data input into the DTM models, analysis alignments or baselines and control volumes were established. Volume estimates can be made with three different computational methods: 1) surface to surface comparisons between each facet of TIN models, 2) comparison of gridded surfaces fit to the TIN models, and 3) the traditional average-end area method applied to cross-sections of an alongshore alignment. The surface to surface approach provides the most numerically precise computation of the available data, however, the most useable volumetric comparisons were provided by the average-end area method with carefully selected sections located near surveyed profile lines. The reason that the surface to surface or gridded model computed erroneous results were due to differences in alongshore spacing of profiles between the different surveys resulting in the comparison of measured to interpolated surfaces. Interpolation of the beach profile across even slight embayments can result in large errors. The location of the selected sections used are shown on Figure 1. Sample cross-sections generated from the TIN model are shown on Figure 2.

Closure Depth and Profile Control Volume

The depth of closure, "pinch-out" depth, or location where measurable depth changes do not occur could not be readily found in the profile comparisons. Some reasons why the profiles have significant depth changes in deeper than typical depth of closure water depths are the dredge borrow pits, nearshore dredge material disposal, and subsidence associated with mineral extraction, besides natural sediment transport occurring on the nearshore shelf. The depth of closure concept defined as the seaward limit of significant sediment transport is a misnomer since near-bottom wave induced currents do mobilize large volumes of sediment, and small depth changes on the nearshore shelf result in large volume changes in comparison to the volumes contained on the beach and within the limits of the surf zone. Utilizing a depth of closure concept as a control volume boundary in plan, with its location determined from an abrupt change in the standard deviation of a time series of elevation is a more useful definition along this coastline. This boundary approximates the seaward limit of "significant" wave generated longshore currents and is numerically more consistent with

FIGURE 2 PROFILES

Offset in Feet

values estimated from formulae and wave statistics, ie. the 12-hour annual wave at Huntington Beach of 233 cm based on four years of observation results in a computed depth of closure of 16 feet (Hallermier, 1981). It also does not have to assume a priori insignificant sediment transport across the boundary.

Figure 3 shows the mean, range and standard deviation of elevation along a profile through the feeder beach at Surfside Beach. Elevation statistics were computed separately for the Feb 1992 to May 1995 time period and the 1963 to 1983 time period because of the differences in collection methodology and sampling interval between the two data sequences

**FIGURE 3 MEAN, RANGE and STANDARD DEVIATION
of PROFILE DEPTH**

-- ie. multiple surveys per year compared to multiple years per survey. For the recent 3-year period, a depth of closure boundary is at approximately -16 feet, while for the 20-year period it is at approximately -20 feet. This depth of closure also coincides with the boundary between the shoreface and nearshore shelf. Alongshore variation of depth of closure ranges from about -16 to -28 feet, the deepest being located offshore of Huntington Cliffs and Huntington Beach.

A control plan area was defined for profile volume computation. This area is bounded by the landward limit of overlapping survey coverage on the back beach, but below the toe of the coastal cliffs, and the location of the 20-foot depth contour of the 1963 survey -- although a seaward boundary that varies with depth by alongshore location could have also been applied.

Profile Volume and Volumetric Changes

Profile volumes, contained within the control volume plan limits defined by the survey limit along the beach backshore and the -20 foot contour, are averaged with ranges and deviations computed as shown on Figure 4 by alongshore stationing. These profile volumes, in cubic yards per alongshore foot of beach, have a zero mean over the available surveys. Relatively large standard deviations in profile volume occurs for sections through the Surfside-Sunset feeder beach (Sta 100 to Sta 140) and south of the Santa Ana River Mouth (Sta 630) with values of about 190 cy/ft and 110 cy/ft, respectively. These large variations are due primarily to beach nourishment, groin field and nearshore berm construction (see Mesa, Paper No. 330). Along the remainder of the shoreline, where natural transport processes predominate, the standard deviation of profile volume averages approximately 60 cy/ft.

End-area volumes contained in the control volume described above and relative to the 1963 survey are shown in the format of a mass-haul diagram in Figure 5. Volumes, by date, are cumulative alongshore starting at Anaheim Bay (Sta 97+71) progressing southeasterly to West Newport Beach and the Newport submarine canyon (Sta 757+74). A positive, flat or negative slope of the diagram indicates an accreted, stable or eroded profile volume, respectively, relative to pre-project condition in 1963. The effects of the initial 4 mcy beachfill can be seen in the July 1964 survey, which shows a profile volume gain of about 3 mcy along Surfside-Sunset Beach (Sta 100 to Sta 200). Other general observations from this diagram are that the total profile volume accreted between Anaheim Bay and the Santa Ana River (Sta 100 to 630) for all surveys compared to 1963; a slight erosional trend is observed in the Huntington Cliffs area (Sta 350 to 410); and with the exception of Dec 78 and Jan 83, both abnormally severe storm years in addition to being surveys before renourishment stages, the profile volume along most of the shoreline has been stable or accretional. The sharp increase in alongshore volume at the Santa Ana River mouth in 1969 is the result of a broad delta created by the flood flows earlier that year. A similar increase shown in the 1992 through 1995 surveys are due to construction of a 1.3 mcy nearshore berm (1992), and groin field and beachfill (1970's) at West Newport Beach.

Other control volumes were defined such as the area bounded by the back beach and the MLLW datum plane (dry beach volume), and the nearshore shelf area bound by the -20 and -30 foot contour in 1963. The dry beach volume follows similar trends to that of the profile

FIGURE 4 PROFILE VOLUMES

FIGURE 5 CUMULATIVE PROFILE VOLUMES

volume of the -20 foot depth, whereas, the nearshore shelf (-20 to -30 ft) has experienced deepening over a large portion of this coastal segment. Some of this deepening is the direct result of sand mining for beach replenishment while other deepened areas appear to be directly related to subsidence associated with mineral extraction. The latter has been documented through differential leveling along the coast highway and is most evident in comparison of the 1934 to 1975 NOS nearshore hydrography.

Conclusions

Available surveys for the northern Orange County coastal segment have been analyzed with the use of CADD and triangulated irregular network models. Historic surveys with U.S. Coast and Geodetic Survey control can be reduced and used to build a shoreline and profile history database accessible to GIS systems. State Plane Coordinate Systems can be easily related to geodetic coordinates allowing utilization of data from multiple historic sources. Once the TIN models are created, time series of depths, volumes and shoreline positions can be queried for analysis.

As for the San Gabriel River to Newport Bay Erosion Control Project, monitoring over 30 years of beach nourishment has shown a transport rate from the feeder beach to be remarkably close to the originally projected beachfill requirements published by the U.S. Army Engineer District, Los Angeles(1962). Comparison of profiles generally show wider beaches and a deepening of the nearshore. By comparison to the pre-project condition, artificial beach fills have created a protective and feeder beach such that the profile volume has always been above that which existed in 1963, except during the severe winter seasons of 1978 and 1982-83. At the feeder beach location, 772,000 more cubic yards existed on the beach above MLLW datum in May 1995 than in 1963, and 1.39 million cubic yards more existed within the profile volume bound by the beach and historic -20 foot contour. The initial beach construction, NWS channel deepening and four nourishment cycles placed dredge material totaling 12.6 mcy on the feeder beach. Assuming 15 percent of the dredge prism to be composed of fine grain sediments which would quickly wash away, a beach nourishment volume of 10.8 mcy can be estimated. Only 1.4 mcy remain within the profile volume of the feeder beach after 31 years, yielding an average loss rate of 303,000 cy/year. The predicted periodic renourishment volume of 1.75 mcy about every five years in the 1962 study was based on an annual loss of 350,000 cy/year, consisting of 300,000 cy/yr loss from the littoral cell and 50,000 cy/yr loss to the offshore, wind and other causes.

While periodic beach nourishment has maintained profile volumes above pre-project levels, protective beach widths are not always provided for all locations. This is particularly true for about 3,000 feet adjacent to the Anaheim Bay East Jetty (sta 100+00 to 130+00) which appears to have a component of southeasterly directed longshore transport from westerly swells and reflected southerly swell as can be seen in the approaching wave fronts of Photos 3 and 4.

CHAPTER 363

A Ten-Year History of Dolos Monitoring at Crescent City

William S. Appleton¹, Thomas Kendall¹, M. ASCE,
and Jeffrey A. Melby², M. ASCE

ABSTRACT

Ten years of monitoring data are now available from the Crescent City dolos monitoring program. This extensive field data collection program was initiated in 1986, following the rehabilitation of the dolos section of the main stem of the Crescent City Outer Breakwater. The rehabilitation involved the placement of 680, fiber-reinforced, 38-tonne dolosse. Unique field monitoring techniques have been employed to collect data at Crescent City: movement data have been collected with ground-truthed, low-altitude (helicopter) photogrammetric survey techniques and stress data have been derived from strain gages mounted internally in select dolosse grouped together near the center of the dolos field. Results presented in this paper include 10 year histories on: wave climate, dolos movement/breakage, stress build up within dolosse, and concrete strength and fatigue. In addition, internal strain gage instrumentation verification test results are presented.

INTRODUCTION

The hydraulic stability of dolos armor units has been a large factor in their success as an armor unit. For this reason, the use of dolos armor units has helped to allow for the construction and long-term stability of shore and navigation protection structures sited in extremely energetic wave environments. The use of dolos armor units has been extensive and in most cases these armor units have performed well; however, due to the slender nature of the dolos design, these units are susceptible to breakage especially as the size of the units increases. To gain further insight into the mechanisms which govern the design life of these

¹USACE, San Francisco District, 333 Market Street, San Francisco, CA 94105-2197, USA

²USACE, Waterways Experiment Station, 3909 Halls Ferry Road, Vicksburg, MS 39180-199, USA

breakwater armor units, the Corps has collected an extensive data set from the dolos armor layer located on the Crescent City, California Outer Breakwater.

There are now 10 years worth of monitoring data available addressing the role of dolos movement, breakage, fatigue, and static stress build-up which provide insight into mechanisms affecting the life of these armor units.

BACKGROUND

The Crescent City Outer Breakwater has had a history of being badly damaged since it was lengthened in 1930 to include the section which now contains dolos armoring. In particular, the last 100 meters of the structure's main stem have been especially difficult to maintain and, consequently, dolosse have been used in this section for the past 22 years. The most recent round of extensive maintenance work came in 1986 when, following years of wave damage from winter storms, the dolos section of the breakwater was rehabilitated. The rehabilitation work involved the placement of 680, 38-tonne fiber-reinforced dolosse on the seaward slope of the structure (Figure 1) and 80 on the lee side slope for future use. Placement of the armor units was aimed at recreating, to the extent possible, the design tested in physical model studies which included the use of trenching and buttressing (with stone) along the dolosse southern perimeter for increased stability at the dolosse-stone transition. A thorough background description of the project site can be found in Kendall (1988) and Kendall and Melby (1989).

Figure 1: Typical cross-section through the dolos section of the Crescent City Outer Breakwater.

MONITORING TECHNIQUES

Displacement and Breakage Monitoring

Dolos displacements and breakage have been monitored since the completion of the rehabilitation project. Targeted and non-targeted dolos displacements have been detected and assessed using photogrammetric techniques. A helicopter continues to be used as the platform for mapping photography work; this technique allows for the measurement of targeted dolos displacements to be reported with an accuracy of ± 2 cm and non-targeted dolos displacements with an accuracy of ± 15 cm. This work has been previously reported by Kendall (1988) and Kendall and Melby (1992). Changes in the subsurface slope and toe of the structure are monitored using both side scan sonar and diving inspections. However, given the conditions under which this work is conducted, only gross estimates of subsurface displacements can be made.

Dolos breakage counts are monitored through walk-over inspections of the dolos field as well as by helicopter reconnaissance. To date, no techniques have been identified which would allow for determining subsurface breakage.

Static Stress Monitoring

As part of the 1986 rehabilitation work, 20 of the dolosse were instrumented with internal strain gauges mounted on rebar rosettes. An internal microprocessor allowed for data to be digitized within the dolos. The instrumentation measures two moments and a torque, which are then used to compute stresses at the shank-fluke interface. The data stream from the internal microprocessors is sampled at a rate of 1 Hz for six minutes and only data that has passed a series of reliability tests is retained for analysis. Instrumented units that repeatedly fail the reliability tests are removed from the sampling rotation and are no longer retained as part of the sample set. Further details of the data acquisition system and summary of the static stress monitoring program are provided by Kendall and Melby (1992) and Melby and Turk (1995).

Of the 20 instrumented dolosse, 17 were found to be functioning properly during the first round of sampling in 1987. Since then, the number of instrumented dolosse returning data which passes the reliability tests has dwindled to three, all of which are located in the top of the armor layer.

Artificial Loading of Dolos

Upon reviewing the time history of average static stress in the instrumented dolosse through 1994, it was anticipated that future stress readings might begin to fall outside of a range which could be explained through observed boundary conditions. Therefore, a testing method was developed and implemented in 1995 on one dolos (dolos C), to determine if the instrumentation was giving false readings. Dolos C was selected because it had a low RMS error on the data channels, the magnitude of the recorded displacements were not very reasonable and the dolos was resting on the top layer with the upper surface of the shank nearly horizontal.

A steel load frame was bolted onto the shank of the dolos and designed to allow for the placement of a load on the extreme end of the dolos fluke equivalent to the full weight of another dolos. A 90.6-tonne (100-ton) hydraulic jack was used to apply the load, which was done in increments of 6.9 MPa (1000psi) corresponding to a force of 8,858 kg (19,511 lbs).

Fatigue and Concrete Strength

Given the constant cyclical loadings experienced by concrete armor units placed in the near-shore wave environment, the question of what role, if any, fatigue plays in the life of concrete armor units, was asked. In the most recent round of monitoring activities, this question was addressed.

Although fatigue testing in its formal sense, strength versus number of blows and destructive testing, was not carried out on the armor units, 7.6 cm (3 in) diameter core samples were taken from dolosse placed in both 1974 and 1986 to determine changes in the concrete strength over time. If the armor units were experiencing significant fatigue, it was expected that the compressive and flexural-tensile strength of the samples would reflect it. Both of the armor units were located near the cap since heavy sampling equipment presented a significant mobility limitation.

WAVE CLIMATE

Presented in Figure 2 is a time history of wave power off of Crescent City. Buoy data, taken primarily from the Point St. George buoy #46026 (41.9° latitude, 124.4° longitude, 60 m of water), was used to generate the plot shown. Nearby buoys were used to fill in gaps in the Point St. George Buoy data set. The extreme local wave energetics that the structure is subjected to annually are clearly evidenced in Figure 2.

Hales (1985) provides a thorough description of depth-limited waves at the outer breakwater at Crescent City. Hales applied RCPWAVE, a numerical model which calculates the combined wave refraction/diffraction/shoaling effects in shallow water, using the bathymetry off Crescent City and tidal stages of -0.3 m (-1 ft) mean lower low water (MLLW) and +3.04 m (+10 ft) to obtain the design wave criteria for the 1986 rehabilitation. Based on Hales work, a depth-limited breaking wave of approximately 10.5 m was determined to be the design wave for the structure. Hale's work as well as comparison with a small data set from a buoy placed just offshore of the structure in 12 m of water, indicated that wave transformation coefficients are on the order of unity or greater for typical storm events out of the west to west-southwest directions.

Approximately 10 years of buoy data (buoy # 46014) were analyzed to determine whether the structure has in fact seen its design wave. Presented in Table 1 are the probabilities of exceedence for wave heights (H) greater than 5 m for measured significant wave heights (H_s) equal to or exceeding 5m. It was assumed that the wave heights were Rayleigh distributed. The buoy data set was filtered for events generating significant wave heights greater than 5m, of which 29 were found for a total of 80 hours. Given the near unity wave transformation

coefficients, deep water wave heights were likely to have existed just seaward of the structure as well. The maximum tidal stage was then found for each of the events using standard tide tables. Presented in Figure 3 is a plot of the results of this analysis.

Figure 2: Time history of wave power off Crescent City, California.

Table 1: Probability of exceedence for wave heights for a Rayleigh distribution.

Significant Wave Height (H_s), meters	Wave Height (H)					
	5 m	6 m	7 m	8 m	9 m	10 m
5 m	13.5 %	5.6 %	1.9 %	0.6 %	0.15 %	0.03 %
6 m	24.9 %	13.5 %	6.6 %	2.9 %	1.1 %	0.39 %
7 m	36.0 %	23.0 %	13.5 %	7.3 %	3.7 %	1.7 %
8 m	45.8 %	32.5 %	21.6 %	13.5 %	8.0 %	4.4 %
9 m	53.9 %	41.1 %	29.8 %	20.6 %	13.5 %	8.5 %
10 m	60.7 %	48.7 %	37.5 %	27.8 %	19.8 %	13.5 %

Of the 29 extreme events identified, 9 of them, or approximately 30%, occurred during peak tidal stages that equaled or exceeded +1.8 m (6 ft), giving a minimum water depth at the toe of the repair section of 10.6 m (35 ft). The storm setup contribution to the water depth at the structure during the events is not known since measured tidal records at Crescent City have not yet been analyzed, however, it is reasonable to assume that the storm setup contribution would be on the order of at least a half meter. Therefore, there have been at least 9 events to-

date which may have generated waves equaling and possibly exceeding the design wave in water depths that would have allowed these waves to reach the structure prior to breaking. Generally speaking, the above events correspond with wave power readings in excess of $800 \text{ m}^2\text{s}$ in Figure 2.

Figure 3: Number of significant wave events and corresponding tidal stage.

MONITORING RESULTS THROUGH THE TENTH YEAR

Evidence of Long-term Nesting

The history of average cumulative dolos displacement is shown in Figure 4. Kendall and Melby (1992) reported that for those units having undergone translation, the dominant direction of movement was up-slope. For those units having experienced rotation, the dominant axis about which rotation occurred was the z axis (yaw). Since 1992, significant displacements have occurred for four units, one in 1994 and three in 1996. In all four cases, translation up-slope was observed, however there did not appear to be an indication that rotation about the z axis was more prevalent than rotation about any of the other axes. It is interesting to note that while the curve describing average cumulative translations continues to behave as one might expect for a fully nested structure, the jump in the cumulative rotation curve is not as intuitive. It would appear that as equilibrium nesting conditions are approached, significant rotations are more likely to occur than significant translations. In other words, a nested quasi-equilibrium state is more apt to allow for rotations than translations of the armor units. A similar jump in the cumulative rotation curve corresponding with a relatively flat translation curve was seen in the 1992-1993 data as well. Considering that translation requires that the centroid of the unit be displaced, while rotations can occur via a pivot point, it is understandable that rotations should be more likely to occur under nested conditions. Results appear to indicate that despite near equilibrium nesting conditions, movements, especially

rotations, will continue to occur although they seem to be small enough not to be considered significant.

Side scan sonar records as well as dive inspections indicate that there were no significant changes in the position of the toe or slope of the dolos rehabilitation section.

Breakage

Prior to 1993, the last year in which any new broken dolosse were found was in 1988 (one unit was found). However, as presented in Figure 5, a comparatively large number of broken units were found in 1993. But, as also shown in Figure 5, it is uncertain when these units actually were broken, and it is thought, given the appearance of the breaks, that they could have occurred much earlier, but were simply not visible from the helicopter surveys used almost exclusively up until 1993.

Figure 4: Time history of cumulative dolos displacement.

Figure 5: Dolos breakage results.

Static Stress History

Burcharth (1988) defined the various loads on armor units, the three primary loads being static loads, impact loads and pulsating loads. The history of average static stress measured within the dolosse is presented in Figure 6. Each data point represents an average of all of the reporting units on that date. Also shown in Figure 6 is the dwindling sample set from which these readings were taken. Initial measurements, made in 1987, were taken from 17 units, 3 in the lower armor layer and 14 in the top layer. 1995 measurements were taken from 3 units, all of which were located in the top layer. The average static stress for the three (3) reporting units was found to be approximately 3 MPa (434 psi). The trend in this curve is not an artifact of the dwindling sample size as the history of the three remaining units reflects the same trend exhibited.

The newest data point appears to be consistent with the trend apparent in the data from prior years, showing a linear increase in static stress. However, the continuing linear increase in static stress levels within the dolosse is cause for concern, since boundary conditions leading to such stress levels are not at all apparent. Therefore a check was made to determine if the static stress levels being reported by the instrumentation were reasonable. An extreme boundary condition was considered, one where a dolos was assumed to be loaded at the extreme end of a fluke by the weight of another 38-tonne unit. Simple beam theory was applied to obtain an approximation of the normal stress at the section A - A shown in Figure 7. This simple calculation showed that the maximum normal stress (located at the extreme fibers of the cross section) for the boundary condition shown is approximately 2.5 MPa (358 psi). Hence, the latest stress reading has exceeded the estimated "full dolos loading" level.

If the post nesting growth of static stress within the dolosse is to be believed, then the flexural-tensile strength of the concrete is rapidly being approached. The slope of the plot in Figure 6 indicates that the reserve concrete strength is being consumed at a rate of approximately 3% per year. However, if this was in fact

true, given the wave events that these units are being subjected to, one would

Figure 6: Time history of average static stress levels

Figure 7: Caricature of dolos loading

expect a much higher rate of breakage in recent years than what has been observed. In order for the instrumentation to be functioning properly while still returning data that indicates a continuing rise in static stress, the concrete must be relaxing while the strain gauges continue to deform. Shrinkage, thermal contraction/expansion and creep were considered as mechanisms that may be

responsible for creating permanent strains on the instrumentation, while at the same time allowing the concrete to recover via plastic deformations. Creep or some form of plastic deformation within the concrete is the only plausible explanation. However, as pointed out by Neville and Brooks (1987), the effectiveness of stress relaxation by creep is reduced with time. Most stress that is relieved via creep is done so in the very early stages of concrete curing. Shrinkage, swelling and thermal expansions/contractions may have influenced the static stress trend during the first year, but after that they would play a very minimal role in any static stress buildup. Therefore, material properties of concrete and boundary conditions are unable to fully explain the recorded high measurements of static stress.

Artificial Load Testing

Results from the artificial load testing showed that the recorded strain was of the correct order of magnitude given the load, but half what one would expect from an analytical check using simple beam theory. Since the actual moment arm length is difficult to quantify due to unknown boundary conditions and since the dolos is not a slender beam, the difference between the analytical check and the measured value is considered to be within reason (Melby and Turk, 1995).

Fatigue and Concrete Strength

Core samples that were returned to the lab for testing were subjected to traditional compressive and tensile testing methods. The compressive tests were done in accordance with American Standard for Testing Materials (ASTM) C 39, the splitting in accordance with ASTM 496 and the flexure in accordance with ASTM C 293. Shown in Table 2 are the concrete strength test results.

Table 2: Concrete strength test results from core samples taken in 1995.

Dolos/Core Number	Compressive Strength (MPa)	Flexural Tensile Strength (MPa)	Splitting Tensile Strength (MPa)
559 / N1	-	9.79	4.31
559 / N2	53.24	8.55	2.14
559 / N3	56.41	-	4.59
752 / N1	70.69	-	4.48
752 / N2a	-	11.93	3.48
752 / N2b	-	-	3.03
752 / N4	60.00	10.03	3.48
752 / N6	73.45	-	-
236 / N1	52.34	-	4.17
236 / N2	-	8.76	-
236 / N3	62.83	7.55	4.14
236 / N4	-	-	2.93

Non-shaded area contains data obtained from 1986 dolosse and the shaded area is data obtained from 1974 dolosse.

Lab results indicated that on average, the flexural-tensile strength of the

concrete samples from the 1986 dolosse had increased 48% and the compressive strength had increased 70%. These increases in concrete strength are based upon a 28-day compressive strength of 36.4 MPa (5,280 psi) reported by Bevins (1989) and a 28-day flexural-tensile strength of 6.8 MPa (984 psi) reported by Gutsehow (1989). For standard type II cement, a 50% increase in 28-day compressive strength after five years can be expected. Therefore, although the concrete used in the dolos is steel-fiber reinforced, the 70% increase over 10 years is significant considering that most of the changes within concrete occur in the first five years.

Conclusions regarding the compressive and flexural-tensile strength of the concrete used in the 1974 dolos could not be made due to a lack of data prior to 1995. However, the compressive strength of the cores tested was within 2% of the average compressive strength obtained from the 1986 dolos concrete samples while the average flexural-tensile strength was within 20% of the 1986 values.

CONCLUSIONS

- It is highly likely that the dolos section of the Crescent City Outer Breakwater has been subjected to its design wave and possible that it has experienced design wave conditions as many as nine time.
- While the time history of dolos displacements does continue to show some rotational displacements, the dolos field is believed to have reached a relatively nested state following the first storm season.
- Strain gages in the tested dolos were shown to be functional within acceptable parameters. Moments measured were on the same order as those predicted by simple linear beam theory.
- Although the internal instrumentation within dolos C was found to be functional and recorded strain readings brought about by artificial loading were within reason, static stress readings still need to be questioned. The material properties of concrete, i.e. creep, shrinkage/swelling, thermal expansion/contraction, do not appear to explain the observed measurements.
- Both compressive and flexural-tensile concrete strengths measured in 1995 on the 1986 dolosse, were found to be significantly higher than design strengths (28-day); 70% and 48%, respectively.
- Fatigue weakening within dolosse does not appear to be significant.

RECOMMENDATIONS

- Conduct aerial photogrammetric work every 2 years. Exceptions would be made following extremely energetic winters having repeated events during which there is a greater than 1% chance of the design wave occurring (approximately when $H_s^2 T > 800 \text{ m}^2\text{s}$).

- Investigate the possibility of picking up a dolos and measuring static stress rebound as an additional step in verifying internal instrumentation measurements.

ACKNOWLEDGEMENTS

The work described in this paper has been conducted as part of the Operations and Maintenance program of the U.S. Army Corps of Engineers (USACE) San Francisco District.

CHAPTER 364

BREAKWATER DAMAGE IN OKUSHIRI PORT DUE TO THE HOKKAIDO NANSEI-OKI EARTHQUAKE TSUNAMI

Katsutoshi KIMURA¹
Yuzo MIZUNO¹
Hiroichi TSURUYA²
Yasuyuki NAKAGAWA²

Abstract

A tsunami caused by the Hokkaido-Nansei-oki earthquake struck Okushiri Island and the southwest coast of Hokkaido damaging many port facilities. This paper describes typical breakwater damage at Okushiri Port and the applicability of Tanimoto's formula for tsunami wave forces on vertical walls based on prototype failure analyses and the result of numerical simulations. The armor stability and the rubble mound scourings were examined from the results of 3-D model tests at a scale of 1/15. The damage patterns at the narrow opening of breakwaters were reproduced by the tests. The necessary weight of armor blocks and foot-protection blocks for breakwater heads were calculated by the C.E.R.C. formula using averaged flow speed at the peak of tsunami.

Introduction

The Hokkaido Nansei-oki earthquake of July 12, 1993, had a Richter scale magnitude of 7.8, and generated a huge tsunami. Okushiri Island, 70 km from the seismic center, was struck by the tsunami. In addition to a death toll exceeding 200, the tsunami damaged many public facilities in the coastal areas and port facilities, mainly breakwaters.

In general, breakwater damage from tsunamis are classified into the following two patterns;

- Sliding of caissons by tsunami wave forces
- Scouring of rubble mound foundations at breakwater heads by the strong tsunami flows

The caissons of the Kawaragi breakwaters in Hachinohe Port were damaged along a total length of 328m in the 1968 Tokachi-oki Earthquake. Ito et al. (1968) analyzed the tsunami height by numerical simulations and confirmed that the difference in the water level between the inside and outside of the breakwater led to the damage. In Noshiro Port, the offshore seawalls of a power plant were heavily damaged by the 1983 Nihonkai-Chubu earthquake tsunami. Tanimoto et al. (1983) analyzed the tsunami wave forces based on the field survey and model tests. In Okushiri Port at the eastern side of Okushiri Island, similar damage patterns appeared in the north breakwater. In this paper, the relationship between the sliding distances and tsunami height is examined from the results of numerical simulations

The armor stability at the breakwater head is a very important factor for the design of tsunami protection breakwaters. Tanimoto et al. (1988) made the three-dimensional (3-D) model tests for the offshore breakwaters in Kamaishi Port, and proposed armor stability coefficients for practical design. A remarkable aspect of tsunami damage appeared at the narrow opening between the outer east breakwater and the east breakwater in Okushiri Port. The head caissons of both breakwaters

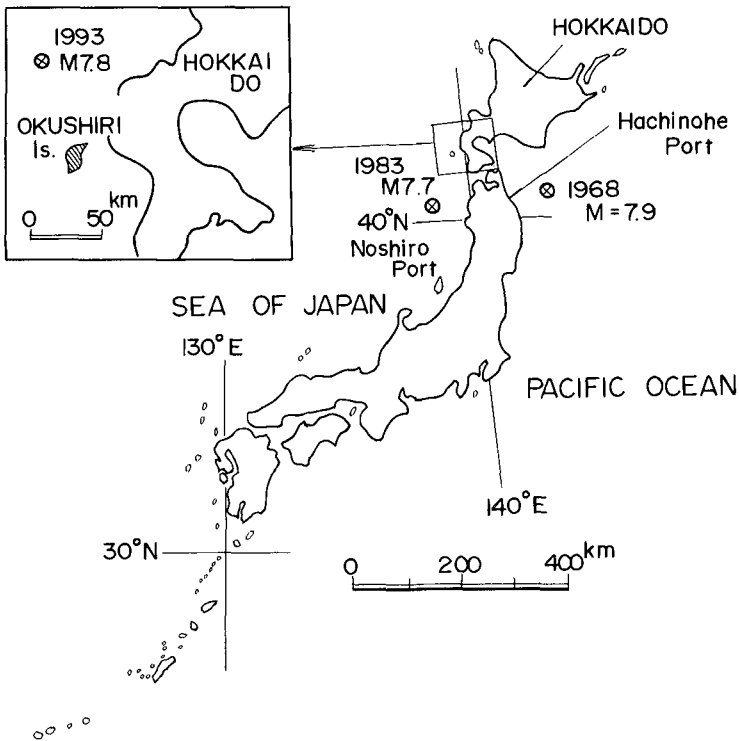

Figure 1. Location of Epicenter

collapsed due to scourings of rubble mound covered with armor blocks by the strong tsunami flow. To reproduce the damage pattern, large-scale 3-D hydraulic model tests were made at a model scale of 1/15. In this paper, the relationship between the flow speed and the damage ratio is examined from test results, and the applicability of armor stability coefficients is confirmed for the practical design of breakwaters against tsunamis.

Outline of breakwater damages

On 12 July 1993, a tsunami, caused by seismic disturbance at latitude $42^{\circ} 47'$ and longitude $139^{\circ} 12'$ struck Okushiri Island and along the southwest coast of Hokkaido. Figure 1 shows the location of the epicenter and Okushiri Island.

Okushiri Port on the eastern side of Okushiri Island is the only port of the island, and includes the ferry terminal to mainland Hokkaido. Figure 2 shows the breakwaters and port facilities in Okushiri port. The outer east breakwater and the east breakwater are the main barriers against wind waves. The opening between the outer east breakwater and the north breakwater is used for the main waterway, and a narrow opening between the outer east breakwater and the east breakwater is also used for a waterway for small craft.

Figure 3 shows the damage pattern of the north breakwater. Sections A, B, C, and D are caisson-type composite breakwaters, and section E is a concrete block type. According to the eyewitnesses, the tsunami waves propagated parallel to the shore line and attacked vertically against sections, C, D, and E of the north breakwater. In contrast, caissons slid little in sections A and B near the head of the breakwater.

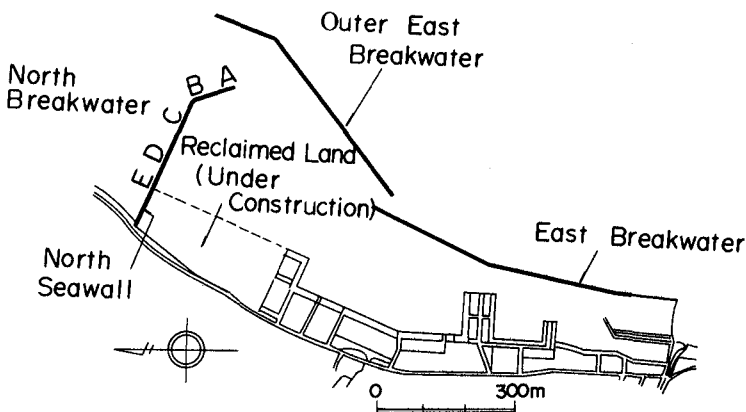

Figure 2. Breakwaters in Okushiri Port

Figure 3. Caisson Sliding at the North Breakwater

Figure 4. Damage Patterns of Section C of the North Breakwater

Figure 4 (upper diagram) shows a standard cross section of section C. The depth was 7.6m and the caisson was settled at a depth of 5.0m. Figure 4 (lower diagrams) shows typical damage patterns. At the position of X=180 m, the caissons slid 20m and pushed foot-protection blocks (3.0m long, 2.5m wide and 1.0m thick) and concrete blocks (6tf beehive). The scouring of rubble stones (30~300kg)

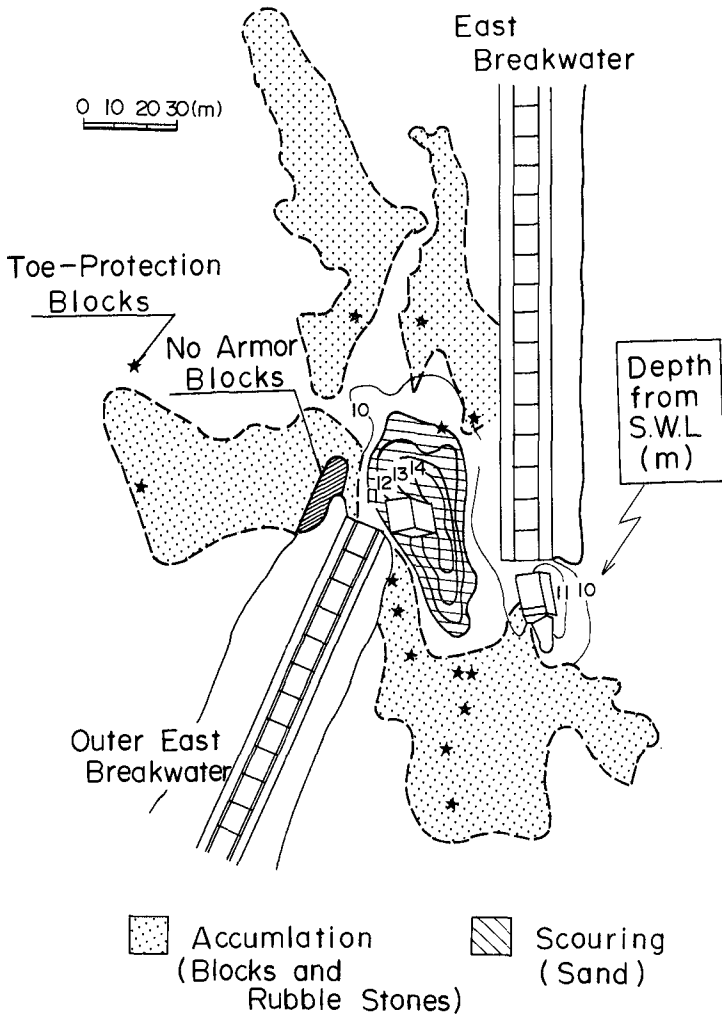

Figure 5. Scouring at the Narrow Opening

progressed along with the action of tsunami waves even after the caissons had slid, and mound rubble collected at $X = 160$ m.

Figure 5 shows the scouring at the narrow opening between the east and the outer east breakwaters. The width of the opening is 35m and the depth was 10m. Rubble mounds of both breakwaters were covered by concrete blocks (1 tf beehive) and foot-protection blocks (1.5m wide, 2.5m long and 1.5m thick). These armor

blocks were moved and scattered as shown in Fig. 5. The maximum scouring depth was 4 m from the original sea bed, and the head caissons at both breakwaters collapsed.

Tsunami forces on vertical walls

The lower part of Fig.6 shows the sliding distance S of each section in the north breakwater. The upright structures of Section E (seawalls for reclaimed land) were heavily damaged, because the sand fillings were not completed when the tsunami struck. Other sections were caisson breakwaters with depths of 5~11 m, and widths of 7.5~9.0 m.

Tanimoto (1983) proposed tsunami wave pressure distributions (Fig.7). The pressure intensity under the still water level p_1 and the crest tsunami height η^* can be calculated as follows:

$$p_1 = 2.2w_0a_I \quad \text{-----(1)}$$

$$\eta^* = 3.0a_I \quad \text{-----(2)}$$

Figure 6. Tsunami Heights and Sliding Distances of the North Breakwater

Figure 7. Tsunami Wave Pressure Distribution

where a_I is the incident tsunami height and w_0 is the unit weight of water. h_1 and h_2 are the depth at the offshore side and the harbor side, respectively.

The upper part of Fig.6 shows the critical tsunami heights a_c (horizontal lines) calculated by Tanimoto's formula, and the incident tsunami heights a_I (solid circles) estimated by 3-D numerical simulations. The sliding distances S increase when $a_I \geq a_c$, which confirms the applicability of Tanimoto's formula for prototype failures.

The distance between Okushiri Port and mainland Hokkaido is about 30km. Because the wind fetch is short, the design wave height for the breakwater H_{\max} was 3.5 ~ 5.1 m. However, the design wave height in most ports and harbors facing the Sea of Japan exceeds H_{\max} of 10 m. The small design wave height for Okushiri Port seems to have contributed to the extensive damages.

Experiments on scouring by strong tsunami flows

Large-scale hydraulic model tests with a scale of 1/15 were also made in the 3-D basin (50 m long, 20 m wide and 3.5 m deep) at the Port and Harbour Research Institute (Fig.8). Four axial flow pumps were installed in the basin so that tsunami waves could be reproduced by the action of the flow. By changing the rotation direction and cycles of the axial pumps, the flow direction and speed could be changed according to the analog signals.

The breakwater models were placed in the center of the basin (Fig.9). The scourings of rubble mounds and successive caisson failures at the narrow opening were reproduced. The depth was 66cm, the average depth of this area considering the tidal conditions. The upright section of breakwaters were made of reinforced concrete box (66.7cm long, 56.7cm wide and 73.3cm high) and their weights were adjusted by the filling materials. Concrete blocks (296gf beehive) and foot protection blocks (10cm wide, 16.7cm long and 6.7cm thick) were produced to scale. To facilitate the observations, concrete blocks were classified into four areas (Fig.9) and painted different colors.

Figure 8. 3-D Basin with Flow Generators

Figure 9. Breakwater Model in the 3-D Basin

Figure 10. Flow and Water Level at the Center of Opening

Tsunami waves were simulated by generating oscillatory flows with the observed tsunami period of 10 minutes (prototype scale). The forward direction is defined as flow coming into the harbor. The flow speed was monitored at the center of the opening (Fig. 8) with a 2-D electromagnetic flow meter at the depth of 10 cm above the still water level. The peak flow speed of the tsunami (U_0) was defined as the square root of each flow components. The water level was also measured at the same point by a wave gauge.

Five kinds of tsunami flow with different peak speeds ($U_0 = 112, 151, 169, 180$ and 196 cm/s) were used for stability tests. How many tsunami waves attacked this area is not clear, but at least three waves are certain to have covered this area from information given by witnesses. In this experiment, tsunami waves corresponding to a duration of 6.5 times as long as the wave period were created to observe the displacement of the armor blocks and caissons. Figure 10 shows the flow and water level changes at $U_0 = 196$ cm/s.

Damage patterns around breakwater heads

Armor damage was found first at area No.3 in the outer east breakwater at a flow rate $U_0 = 151$ cm/s. The number of blocks moved was 18, and the damage ratio in this area was 20 %. The damage of foot-protection blocks was not observed at this flow rate. Tanimoto et al. (1988) examined the flow patterns at the mouth of tsunami protection breakwaters in 3-D model tests. They pointed out that the armor damage was heavier at the projecting head for the flow direction. In our experiment, the damage pattern for the forward flow was the same as for the experiments of Tanimoto. However, for the backward flow, no damage was observed at the area of No.7 of the east breakwater, probably because the opening ratio of our experiment was much lower than usual for tsunami protection breakwaters

Photo 1. Damaged Caisson and Mound of the Outer East Breakwater

At the flow rate $U_0=169$ cm/s (6.5 m/s in prototype), all armor blocks were damaged at the outer east breakwater and rubble stones were also scattered. At the east breakwater, 80% of the armor blocks were damaged. The damage of foot protection blocks was observed as 80% at the head of the outer east breakwater.

At the flow rate $U_0=196$ cm/s (7.6 m/s in prototype), the first tsunami wave scoured most of rubble stones around the head caissons, and the head caissons of both breakwaters tilted due to the scouring of the rubble mound. In the outer east breakwater, the damage progressed further to the head caisson failure by the second tsunami wave. The maximum flow rate at the failure was recorded to be 2.3 m/s (8.9 m/s in prototype). Photo 1 shows the damaged caisson and mound of the outer east breakwater after the experiment. The prototype damage around the breakwater heads as shown in Fig. 5 was successfully reproduced by these model tests.

Necessary weight of Armors

The weight required to withstand the flow can be calculated by the following Coastal Engineering Research Center (C.E.R.C.:1984) formula;

$$W = \frac{\pi w U_0^6}{48y^6 g^3 (w/w_0 - 1)^3 (\cos \theta - \sin \theta)^3} \quad (3)$$

where W is the weight of armor unit, U_0 is the flow speed, w_0 is the unit weight of fluid, w is the unit weight of armor units, g is the acceleration of gravity and θ is the angle of mound slope. This equation (3) is commonly accepted as giving the

Figure 11. Damage Ratios of Armor Blocks and Foot-Protection Blocks

necessary weight of stones and armor blocks to withstand steady flows. Tanimoto et al.(1988) carried out the armor stability tests of tsunami protection breakwaters, and showed the applicability of this formula for tsunami flows.

Tsuruya et. al. (1994) recommended that the Isbash parameter γ for beehive blocks should be 1.2 in the actual settled condition, and 0.967 for individual blocks separately settled on the sea bottom. Kimura(1995) proposed that $\gamma=0.6\sim 0.7$ can be used based on the previous tsunami damage for foot-protection blocks.

In the 3-D model test for breakwater heads, damage ratios were also observed for each tsunami flows. Figure 11 shows the damage ratio of beehive and foot-protection blocks for $U_0=151, 169, 180$ and 196 cm/s. The critical flow speed $(U_0)_{cri}$ is calculated from Eq.(3) for beehive ($\gamma = 1.2$) and foot-protection block ($\gamma = 0.65$). Damage starts from $U_0/(U_0)_{cri} = 1.0$, and therefore the applicability of these coefficients is proved.

Conclusions

The damage analyses of breakwaters in Okushiri Port due to the 1993 Hokkaido Nansei-oki earthquake tsunami gave the following results and conclusions;

- The caisson breakwaters, whose design wave height due to storm waves were small, were damaged by the tsunami attack.
- The applicability of Tanimoto's formulae for tsunami forces on vertical walls was confirmed by the prototype failure analyses of the north breakwaters in Okushiri Port.

- The failure at breakwaters heads was reproduced by the 3-D model tests. The maximum flow speed of the tsunami was estimated as 8.9 m/s in the prototype.
- The necessary weight of armors around the head of breakwaters can be estimated by the C.E.R.C. formula using the Izbash parameter of previous model tests.

The 3-D experiment in this report did not reproduce the scouring of sandy sea beds. The sea bed was possibly scoured at a smaller flow velocity than indicated in this report, which resulted in the destruction of mounds and in turn led to the collapse of caissons at the breakwater head. Future studies should consider the influence of sediment movement.

Acknowledgments

The field survey on breakwater damages was made by the Port and Harbor Division of Hokkaido Development Bureau and the Cold Region Port and Harbor Engineering Research Center. The authors would like to express their gratitude to Professor N. Shuto at Tohoku University for advice on the numerical calculations on tsunami height.

CHAPTER 365

RICHARDS BAY NORTH BREAKWATER - REPAIR OF A ROUNDHEAD: MONITORING, MODEL TESTING, DESIGN AND CONSTRUCTION

D Phelp¹ , A M^cClarty² and A Bartels³

ABSTRACT

The head section of the north breakwater, at the entrance to the Port of Richards Bay, has suffered some damage since its construction in 1973. This paper briefly discusses the changes in the design conditions, the first unsuccessful repair in 1986/87, using 15t dolosse, the annual photographic monitoring results showing the rates of damage to the roundhead since then, and the model testing of various repair options, using available spare 20t and 30t dolosse. Finally the construction of the optimal repair, carried out in 1996, using a heavy duty mobile crane (with 48m boom reach) and DGPS positioning, is described. Construction was still in progress at the time of publishing this paper.

INTRODUCTION

The Port of Richards Bay, on the east coast of South Africa, has two dolos breakwaters, a shorter straight breakwater on the northern side of the harbour entrance channel and a longer curved breakwater on the southern side. The north breakwater consists of a straight rubble mound structure, constructed in 1973, which stretches for approximately 600m perpendicular to the coastline. The original armouring on this breakwater consists mainly of 5t dolosse on both sides of the trunk, but includes 15t dolosse on the roundhead (Figure 1). Like many similar breakwaters, the neck of the roundhead was found to have experienced the worst damage to the armour layer.

² Portnet, Port of Richards Bay, P O Box 464, Richards Bay 3600 (SA)

³ Entech Consultants (Pty) Ltd, P O Box 752, Stellenbosch 7600 (SA)

Annual photographic monitoring of the north breakwater showed an increase in damage in localised areas on the head, particularly on the southern side (Figures 1 and 2), despite temporary repairs using 15t dolosse, carried out by Portnet in 1986/87. A previous model study (CSIR, 1992a) indicated that the spare 20t and 30t dolosse, available from a stockpile of spare dolosse at the root of the south breakwater, would be suitable for the repairs. It was therefore decided to test various repair options using 20t and 30t dolosse.

In June 1994 the CSIR was commissioned by Portnet to carry out a physical model study to determine the most cost effective design for the repair work. These included repair solutions in which a toe of anchored 30t dolosse was constructed around the head and 20t dolosse were placed in the cusps and over the anchor chains. After an initial calibration run, a total of four different repair options were tested. Due to delays in the commissioning of a suitable crane, the construction of the final repair was delayed to the end of 1996. This paper does however include construction details of a temporary repair using 5t dolosse (placed using an available smaller crane) and the start of the final repair, using the 20t and 30t dolosse.

FIGURE 1: View of North Breakwater and Cross-Section through head.

MONITORING RESULTS

The crane/helicopter photographic survey method (Phelp *et al*, 1994) was used to annually monitor the breakwater. The photographic survey stations are spaced at 25m intervals, and both sides of the breakwater are monitored; the breakwater was however already 13 years old before annual photographic monitoring was commenced. The areas with the highest damage (over 25% breakage) continued to

deteriorate the fastest. At stations P2 and P3 on the round-head, the damage was mostly localized in cusps, which are visible in Figure 1. A sharp increase in the rate of damage in the worst areas, since 1992 (72 months), can be seen in Figure 2. This damage has mainly been attributed to bottom scour resulting in increased wave heights reaching the breakwater, ie. increased depth limited wave heights. Station P1 also lies at the transition between the 5t and 15t dolosse, which is at an inherent weak point in the armouring.

FIGURE 2: Rates of Damage to the Dolos Armouring Since 1987.

FACTORS CONTRIBUTING TO THE HIGH DAMAGE

The occurrence of low pressure cyclonic storms (cyclones Demoina and Emboa in 1984) subjected the breakwater to wave heights exceeding the 7,9m 1:50 year design H_{mo} . Storm wave and low atmospheric pressure set-up associated with these storms also had the effect of raising the water level, thereby raising the depth limited wave heights reaching the breakwater. A previous model study on wave penetration in the entrance channel (CSIR 1974) also showed, based on wave refraction that wave conditions between SE and S (deep sea) result in the worst conditions opposite the north breakwater head.

Bathometric surveys carried out regularly by Portnet revealed a general erosion of sand, of up to 2m, around the head and seawards of the breakwater, especially between 1989 and 1994. This would have resulted in further increasing the depth limited heights of the waves reaching the breakwater. Besides the scour at the toe (seismic surveys carried out by CSIR in August 1993 confirmed the toe erosion) the breakwater was also subjected to severe storms in October 1990 (max H_{mo} of 6.1m) and moderate storms since then, resulting in accelerated damage to the dolos armouring behind the weakened toe.

Like many similar breakwaters, both sides of the neck of the roundhead were found to have experienced the worst damage to the armour layer. Jensen (Jensen, 1984) found that for tetrapods, relative to the stability coefficients for the breakwater trunk, the roundhead area at 135° from the wave direction showed the lowest stability. This indicates that some of the damage found on the southern side of the north breakwater could also have been caused by more northerly waves. Model tests also showed evidence of eddies on the lee-side of the roundhead where toe dolosse were pulled off the slope.

Repairs which were carried out in 1986/87 using 200 additional 15t dolosse have proved unsuccessful, mainly due to the toe damage and sea-bed erosion mentioned above. No model tests were done for these initial repairs. The area where the 15t dolosse on the roundhead meet the 5t dolos trunk (Figure 1) has also been a focus of damage, likely as a result of poor interlocking between the different sized units.

RESULTS OF MODEL TESTS

Constraints to the Repair Design

Model tests were carried out in an existing 3D model of Richards Bay (CSIR, 1995), to save both time and costs. This available model was built at a scale of 1:110 and covered the harbour entrance and part of the inner channel. The model test options were restricted to using available 200 20t and 100 30t dolosse, which have been brought across the harbour from a stockpile near the southern breakwater. The proposed repair consists of a double row of 30t dolosse at the toe, with a double layer of 20t dolosse behind. 5t dolosse were also available to wedge into the gaps behind the 20t repair and between the existing 5t slope where the repair overlapped the breakwater trunk section.

The removal of rubble and pre-repair slope preparation was limited to the removal of only large broken dolos pieces (assisted by divers), and the filling of holes at the toe of the armour slope. The crane reach was limited to 45m for a 30t dolos, which was achieved by using a specially designed crane which could fit onto the 6m wide mass-concrete capping of the north breakwater.

Choice of Model Scale

The scale of 1:110 used for the tests gives a Reynolds number of approximately 1×10^4 , which is just within the minimum range recommended by Van der Meer (Van der Meer, 1988) but less than the

value recommended by CERC. Some scale effects should therefore be expected, especially on the 5t dolosse, but these scale effects have been found (Oumeraci, 1984) to make the model results conservative. The scale effects, being similar for all the test runs, still allowed the comparisons made between the options tested. The results were however interpreted as giving an indication rather than an exact prediction of the possible damage. The calibration test showed that the hindcast of the damage which occurred in the 1990 storm is in qualitative agreement with the observed prototype damage confirming the validity of the physical model. A plan of the model is shown in Figure 3 and the "as-built" cross-section through the head in Figure 1.

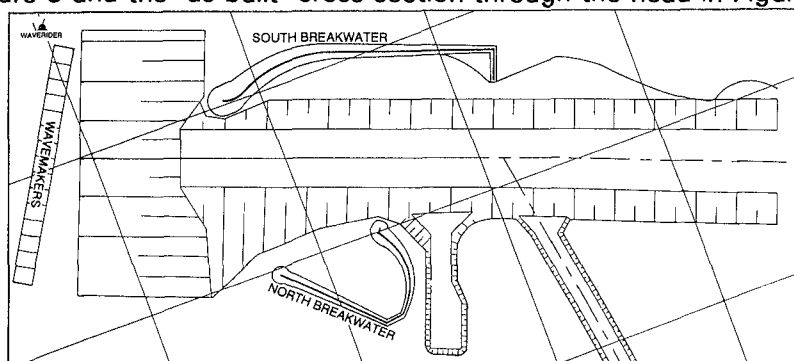

FIGURE 3: Plan showing Model Layout

Wave Generation and Measurement

Eight standard wire resistance wave probes were used which were coupled so that measurements could be carried out over prescribed areas. The wave generator bank was 9,75 m long situated at the 1 km mark (Figure 3). The direction of the generators was 30° N, ie: waves coming perpendicularly out of the wave boxes have a direction of 120° . Based on a review of existing data, the following main test conditions:

- Wave direction, entrance area (12s) 145°
- Storm input, Richards Bay Spectrum, $\gamma = 2,74$ with the following approximate steps $H_{mo} = 4, 5, 6, 8$ m with following wave per respectively: $T_p = 10, 12, 13, 15,5$ s
- Water level for main test MHWS = 2,0 m CD

DESCRIPTION OF THE TESTS

Test procedure

In order to calibrate the physical model, a calibration test was carried out in which the prototype damage resulting from the 1990

storm was reproduced in the model. A number of repair options were then investigated, starting with the simplest option and then extending the repair until a stable solution was found. Before each repair option was constructed, the original damage (after the 1990 storm) was replicated in the model. The repaired breakwater was then exposed to the five different wave conditions described above. After each test, the repair dolosse were removed and the 1990 damage reconstructed, after which the next repair option was implemented.

Measurement of Damage

Movements of Dolosse

The number of dolos movements was determined by comparing the photographs taken before and after each run. A number of swing tests were carried out on full-scale 9t dolosse to determine the degree of movement these dolosse could sustain without breakage (Zwamborn and Phelp, 1989). Based on the results of these tests it was recommended that all movements greater than half the height of a dolos be included as damage. The number of dolosse which moved was determined separately for a number of zones located at the head of the breakwater. The damage was then expressed as a percentage of the number of dolosse placed in each zone.

Rocking Dolosse

In addition to determining the movements, the number of dolosse which were rocking was estimated visually during each test. However due to the difficulty in observing these movements over the whole test area, it was decided to use the small movements (less than $h/2$), which were measured from the photographs, as an estimation of rocking dolosse. In (CSIR, 1992b) this alternative approach was also adopted, where it was found that dividing the movements less than $h/2$ by nine, would give a reliable estimation of the number of rocking dolosse.

DETAILS OF THE REPAIR OPTIONS TESTED

Discussion on the Repair Strategy Followed

The strategy of placing 20t or 30t dolosse on top of the damaged 5t and 15t dolosse was originally tested and found to be feasible in previous model tests (CSIR, 1992a and 1992b). Static tests on dolosse have shown that a dolos can carry 4 to 6 times its own weight without breaking; this implies that a number of layers can be constructed without breakage under static load. Thus it was considered feasible to place a 1 to 2 layer thick 20t dolos strengthening layer, safely on top of the

existing damaged 15t dolosse. Although the quality of the underlying 15t dolosse is questionable, the dynamic loading over the past 8 years has caused the weaker dolosse to break, and careful placing of new dolosse should not result in significant further breakages. However, since most parts of the repair sections will consist of already broken units, the repair itself was designed as well interlocked armour, finished to a uniform slope, which should be able to stand on its own.

Although stresses cannot be modelled, extensive prototype observations and structural tests on full size dolosse support the above conclusions. For example the main breakwater at Gansbaai, on the South African southern coast, consists of an original layer of 4.5t dolosse covered by one layer of 12.4t units, covered by one layer of 17.1t dolosse overlapped with a double layer of 25t dolosse. This repair has thus far proved to be successful.

Repair Option 1

The first repair option tested involved the filling of the cusps with the minimum number of dolosse, ie. starting with the simplest option and then extending the repair until a stable solution was found. This was a temporary (intermediate) repair solution to protect the breakwater core from further damage, but would also eventually form part of a more permanent repair. The number of repair dolosse per hole was approximately 10 30t and 20 to 30 20t dolosse. The total number of dolosse needed to repair all the cusps (northern and southern sides) was approximately 40 30t and 150 20t. The 30t dolosse were used to construct a toe at the bottom in front of the cusps to anchor the 20t dolosse filling up the cusps behind.

Repair Option 2

After repair option 1 had shown extensive damage to the edges of the repaired areas, it was decided to extend the repaired area to provide a more uniform profile. The second repair option was similar to the first repair option but with a more continuous row of 30t dolosse at the toe around the whole breakwater head. The construction of a toe with a double layer of 30t dolosse was an attempt to increase the stability of the repaired slope. The 20t repair layer was then placed on top of the 15t dolosse. The shape of the head was modified slightly to have a slightly flatter slope. Approximately 80 30t and 200 20t dolosse were used.

Repair Option 3

In this repair option the cusps were also filled with 20t dolosse, but the 30t dolosse on the southern-side of the breakwater were fixed

using anchor chains (scrap, ship's anchor chains). First, a double row of 30t dolosse were placed to construct the toe, after which the 20t dolosse were used to repair the cusps and to cover the chains. This method proved to be very successful in the construction of the Port of Cape Town breakwater where similar conditions exist at the toe (CSIR, 1985 and Zwamborn *et al*, 1990). As was done in Cape Town, the end of the chains should be connected to a piece of scrap rail to provide improved anchorage. Approximately the same number of dolosse were used as for the temporary repair option (option 1). The chains used to fix the 30t dolosse can be clearly seen. Figure 4 shows the anchor chains in the model and as used in prototype.

FIGURE 4: Anchor Chains used to Secure 30t Toe Dolosse

Repair Option 4

In this repair option, a double row of anchored 30t dolosse was used to construct the toe around a slightly wider head. The 20t dolosse were then placed in the cusps and over the chains. Also, before the 20t dolosse were placed on top of the 15t dolosse, the damaged slope beneath the repair was reprofiled to allow for a double layer of 20t dolosse, to provide a more uniform repair slope. In this last repair option all the 30t dolosse were fixed by anchor chains.

INTERPRETATION OF RESULTS

Comparison of Damage to the Repair Options Tested

A comparison of the damage at the end of each run is shown graphically in Figure 5. The x-axis presents the section of the breakwater which starts at the northern-side of the breakwater, around the head to the southern side of the breakwater. These location numbers are given in Figure 5. Repair Option 4 is clearly the best option.

FIGURE 5: Comparison of Damage to the Repair Options Tested

For all the repair options, the existing 15t dolosse were well protected by the additional dolosse. For repair options 1 and 2 it was clear that again, similar to the prototype, the highest damage could be observed just behind the head at the southern side of the breakwater. The eddies caused by the waves passing around the head were responsible for rolling the toe dolosse along the surface of the rubble. Once a dolos had been extracted from the slope it was easily rolled along by big waves.

The 30t dolosse, which were fixed by anchor chains, reduced the damage in that specific area considerably. Repair Option 4 showed acceptable damage levels for all the repair dolosse, apart from the area on the northern side of the head where the 20t dolosse showed higher damage - poor interlocking of this section may have been the cause. The damaged 15 t dolosse on this side were not reprofiled as was done on the southern side, which meant that the 20t repair dolosse were not interlocked properly in a double layer. Although the original prototype damage (CSIR, 1994) on the northern side of the head is less than one third of that on the southern side, it is felt that the repairs would have been more effective if the whole northern side had also been properly prepared (reprofiled) before the repair.

Based on the results of the model study and from previous experience, the following recommendations for the repair works were made:

- a) Before any repairs, as many as possible of the broken pieces of dolosse should be removed without disturbing adjacent dolosse.
- b) Crane and ball surveys should be used to identify all underwater depressions, both before and during construction of the repair.
- c) Particular care should be taken when placing the dolosse to ensure that dolosse interlock as well as possible with the

underlying dolosse. Re-slinging of a newly placed dolos is worth the effort if a better interlocking is obtained.

- d) For the placing of dolosse, both above and below water, a predetermined grid pattern should be developed with angles and distances for the crane, or x,y references for DGPS positioning.
- e) The 30t toe dolosse should be anchored by chains.

CONSTRUCTION OF THE OPTIMUM REPAIR

Construction Methods

Based on the results of the model tests, 20t and chained 30t dolosse were to be used for the repair. The 20t and 30t dolosse were brought across from the south side of the entrance channel to a stockpile at the root of the north breakwater, while the 5t dolosse were also already available from a part of the root of the original breakwater which was now covered with sand. Three double direction trailers were then used to transport the dolosse onto the breakwater. These trailers could only pass when unloaded, which meant that only one 20t or 30t dolos could be brought onto the breakwater at any one time (Figure 6).

Initial crane and ball surveys were done with 5m profile intervals over the damaged areas. A certain amount of reprofiling was then carried out to remove irregularities in the overall profile. Broken pieces of dolosse were removed and placed in erosion holes. Another crane and ball survey was then carried out to get the underlayer profile, from which the repair dolos placing grid could be calculated. The smoother the underlayer profile, the easier it was to set a placing grid with uniform packing density.

The repair dolosse were then placed, starting with the double row of chained 30t dolosse at the toe. The chains, which were lifted on a separate hook were laid at an angle of 45° seawards along the toe of

the slope, later to be covered with 20t dolosse. The crane hook was fitted with a 15m sling (to ensure the hook and pulley remained out of the seawater), a quick release hook (Figure 6) and a double cable sling. The double slings which support the dolosse were hand spliced (instead of swage joined) to allow easy removal of the slings once the dolos was in position. The quick release hook was hung from a swivel and fitted with two torque bars, which allowed easy rotation of the dolosse to ensure good interlocking. The torque bars were attached to 10mm nylon (light and water resistant) ropes, which were pulled perpendicularly from the mass capping to orientate the dolosse.

It was found that to ensure correct packing density, the dolos placing must be kept as close as possible to the grid coordinates. The final orientation and positioning of the dolos is then done by eye to ensure good interlocking. Dolosse are placed with a minimum of three contact points to reduce the change of rocking under wave action. After all the grid positions were full, it was found that up to 10% additional dolosse had to be placed "in holes" to ensure a well interlocked uniform profile. To identify these "holes" it is advisable to get an aerial view of the slope from a helicopter, or from a basket hung from the crane.

DGPS for Crane Positioning

For both the crane and ball surveys of the slope profiles, and the correct placing of the dolosse, there was a need to accurately position the hook of the crane. The original method used was triangulation from two theodolites, but this proved labourious and time consuming. Another method was to fit the crane with a pendulum boom angle indicator and a horizontal slew protractor whereby the horizontal and vertical angles of the boom could be measured and converted from polar to x,y grid coordinates.

Recently a differential GPS system has been introduced using satellite positioning linked to a portable computer onboard the crane (Figure 7). The satellite receiver is positioned on top of the crane boom, directly above the position of the hook. The pre-determined positions are entered into AutoCAD software on the computer, and standard survey software enters the real time navigation parameters which indicate the position of the boom. By entering the standing position of the crane along the breakwater, the boom reach and safety circle can also be indicated on the screen. The crane operator can then immediately see which dolosse can be placed from the present position of the crane. The AutoCAD dolos placing grid is shown in Figure 8.

The positioning software includes the following useful features:

- Zoom in and out, and centring the cranes position on the screen.
- The entry of up to 20 predetermined crane standing positions on the breakwater, including facility to orientate and offset.
- The entry of up to 500 top and 500 bottom layer dolosse, including an indication of size and numbering (colour options)
- The facility to import and editing of an AutoCAD or other CAD drawing of the breakwater eg: the "as-built" layout.
- Indication and editing of the safe radius of the cranes reach.
- The input and storage of the placed positions of the dolosse.
- A backup system where the polar coordinates can be entered to position the crane, should the DGPS signal fail.

FIGURE 8: Example of DGPS AutoCAD Dolos Placing Grid

Emergency Temporary Repair and Final Repair

Planning for the repair was well underway by mid 1996, when a breakdown of the special crane (the only crane which could fit onto the breakwater and have sufficient reach for placing the 30t dolos toe) resulted in having to delay the final repair to the end of 1996. As the localised damage on the southern side of the roundhead was starting to

expose the underlayer rock, it was decided to carry out emergency temporary repairs. These took the form of filling the cusps with 5t dolosse (which could be placed with a smaller mobile crane). This repair was not extended further than the original slope profile so that it would form part of the underlayer of the final repair. The same construction method was used as described above. Figure 9 shows this section before and after the emergency repair. Figure 10 shows the chained 30t dolosse at the start of the final repair in December 1996.

ACKNOWLEDGEMENTS

The first author would like to thank Mr M^cClarty of Portnet and Mr Bartels of Entech for their contributions to this paper and for the team spirit which prevailed between Portnet, the Client/Port Authority, Entech, the Coastal Consulting Engineers and the CSIR Research Laboratory.

CHAPTER 366

THYBORØN COASTAL INVESTIGATIONS 1995: NEW LESSONS FROM AN OLD COASTAL PROBLEM

by
I. Brøker¹, J.A. Zyserman² and Per Roed Jakobsen³

INTRODUCTION AND BACKGROUND

Thyborøn channel is located on the West coast of Jutland, Denmark, and connects the Limfjord with the North Sea, see figure 1. The channel was naturally opened following a major storm event in 1862. In the years after the opening of the channel, the neighbouring coasts experienced substantial erosion, which put the town of Thyborøn at risk. For historical background and previous investigations and analysis, please see References.

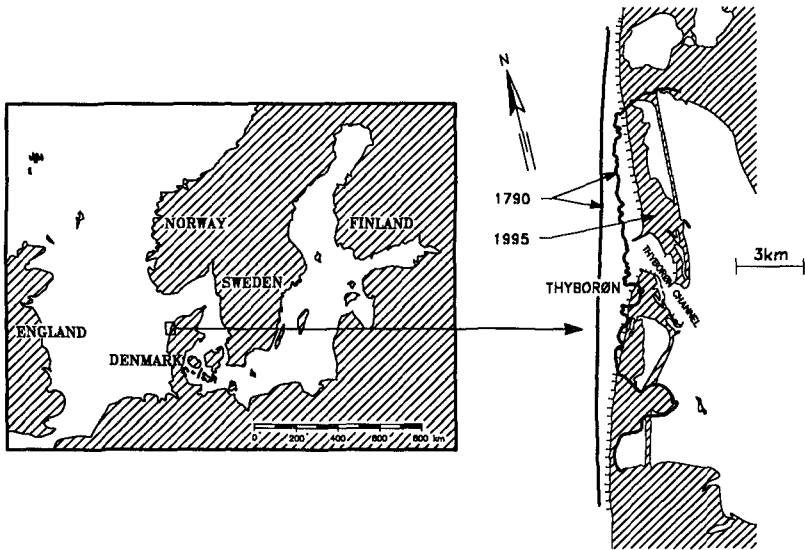

Figure 1 Location map, including indication of development over 205 years

¹ Chief Engineer, Danish Hydraulic Institute (DHI), Agern Allé 5, DK-2970 Hørsholm, Denmark

² Coastal Engineer, Danish Hydraulic Institute (DHI), Agern Allé 5, DK-2970 Hørsholm, Denmark

³ Director, Danish Coastal Authority, Højbovej 1, DK-7620 Lemvig, Denmark

The geology in the area can be briefly described as postglacial sediments, mostly fine to medium sand, overlaying hard clay in depths of 10 to 12 m below seabed level. The area is exposed to severe storms from directions between southwest and northwest. Along the coast the conditions are influenced by a northgoing sea current. In the inlet area the currents are determined by the differences in water level across the peninsula of Jutland. The tidal variations are small, with a maximum tidal range of ~ 40 cm. The yearly net sediment transport along the narrow barrier beaches is directed towards the inlet from both sides. The undisturbed net transport rates are of the order of magnitude of 1 million m^3/year . A dense groyne system reduces the longshore sediment transport rates to about 2-300,000 m^3/year from each side; the sediment transported into the channel ends up on large shoals inside the Limfjord, giving a yearly deposition of approximately 0.5 mill m^3 .

The groynes along the coast have decreased the rate of shoreline retreat to about 50% of the natural erosion. This means that the land ends of the groynes have to be extended inland in pace with the erosion. The tips of the groynes experience continuous deterioration due to severe pressure arising from the wave action. The submerged groyne elements are left on the seabed as they are still considered as active parts of the coastal system.

NUMERICAL MODELLING STUDIES

As a part of the study of the processes around this inlet numerical models were established, both for the quantification of the overall sediment budget along the barrier beaches, and for the study of the details of the morphological evolution under storm conditions inside and around the inlet.

Sediment budget along the barrier beaches

The sediment budget along the barrier beaches has been studied by the LITPACK model, and the details around the inlet by a morphological model constructed from various modules of MIKE 21. **LITPACK** is a model complex for calculation of waves, wave-driven currents (possibly coupled with a general sea current) and longshore sediment transport on an arbitrary coastal profile. A basic assumption of quasi-uniform conditions in the longshore direction allows for simulation of all combinations of waves, water levels and sea currents and establishment of a complete sediment budget. The calculated budget is illustrated in figure 2. The budget was validated through comparisons with the transport rates derived from measured erosion/deposition during 15 years.

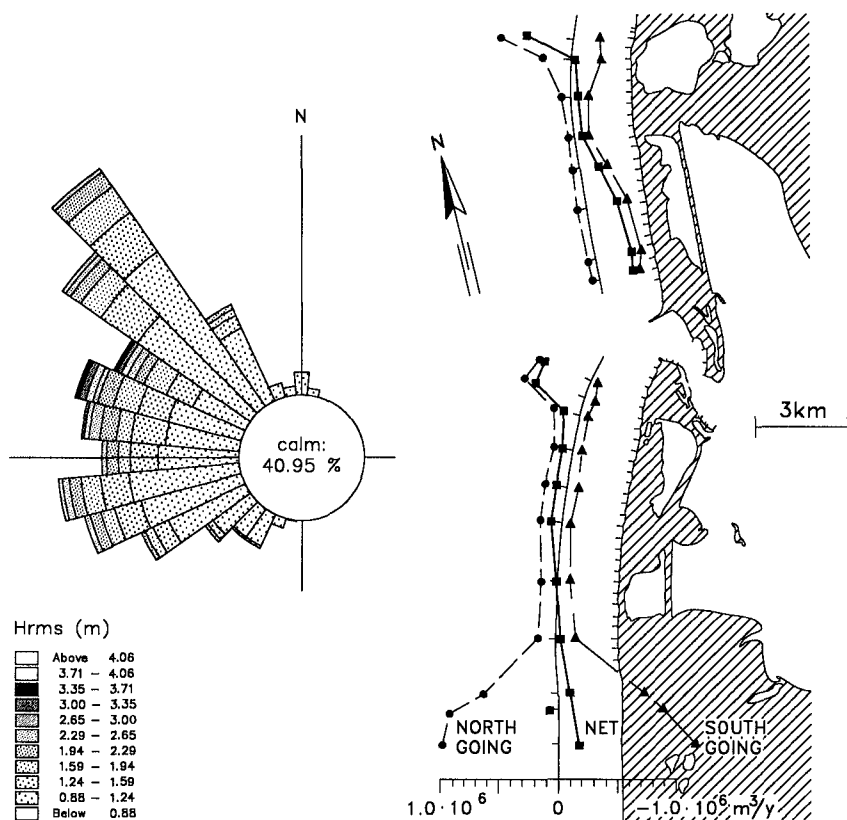

Figure 2 Left: Illustration of wave statistics
 Right: Sediment budget along the barrier beaches

Wave level, wind and directional wave data were available for a three-year period. Two characteristic storms (Storm 1 and Storm 3) were selected for detailed studies of sediment transport and morphological evolution in the area around the inlet. Furthermore, the littoral transport along the barrier islands during each storm was calculated using LITPACK to give an indication of the representativeness of the two storms. The distributions of the littoral drift in the longshore direction and along a selected profile are shown in figure 3. The comparison showed that the storms represented approx. 20 % and 15 % of the southgoing and northgoing yearly transport, respectively. The distribution along the coastal profile is, however, more concentrated over the bars under storm conditions than in average over the year.

Detailed studies around the inlet

Model setup and boundary conditions for the morphological model

A comprehensive set of models was established in order to transfer measured data into boundary conditions for a morphological model covering the area of interest. The measured data comprised: directional wave measurements at Fjaltring, water levels at Thorsminde, Thyborøn, Aalborg and Hanstholm, wind at Thyborøn and Aalborg, see figure 4. Current speed and direction were measured in the channel during one month for calibration purposes. The model areas and the positions of measurements are indicated in figure 4. It

must be noted that the fluxes across the eastern boundary of the general hydrodynamic model are calculated from a 1D river model, MIKE 11, which covers the entire Limfjord from Thyborøn to Aalborg, see Figure 4.

The general and the regional hydrodynamic models have a resolution of 400 m and 100 m respectively. The model is MIKE 21 HD, which is depth-integrated. In the general model the driving forces are wind and variations in tidal levels and fluxes along the boundaries. The effect of Coriolis force is included.

The regional wave model is a parameterised, spectral wind wave model, MIKE 21 NSW.

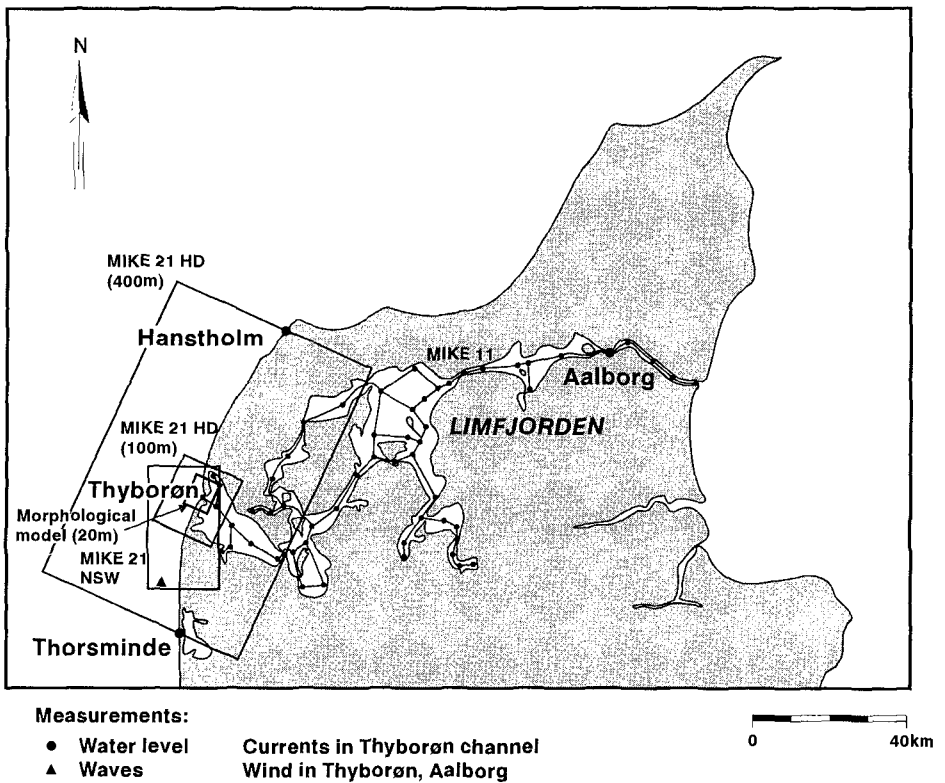

Figure 4 Areas covered by the general and regional hydrodynamic model
 Area covered by the regional wave model
 Area covered by the morphological model
 Locations of measured water levels, wind, waves, currents

The regional models give boundary conditions to the morphological model, see figure 4 for the extent of this model. In the morphological model, wave-, current- and sediment transport modules are coupled as described below. A mild-slope wave model, based on the parabolic approach, was applied in the morphological model complex. Inside the morphological model area, the time- and space-varying radiation stresses were included as an extra forcing term for the hydrodynamic model. The resolution within the morphological model area is 20 m.

Brief description of the morphological modelling complex

DHI's morphological modelling complex is centred around the hydrodynamic model. A morphological simulation is 'warmed up' by calculation of initial wave and current fields on a fixed bed. After the 'warm-up period' the sediment transport field and the corresponding rates of bed level change rates, $\partial z/\partial t$, are calculated. $\partial z/\partial t$ is incorporated in the continuity equation of the hydrodynamic model, and the hydrodynamic simulation proceeds for a period of time corresponding to a so-called 'morphological timestep', which is determined so that the maximum Courant number for the migration of bed forms is less than 1. At the end of this (typically short) period of time the sediment transport field is recalculated using the bathymetry evolved within the morphological timestep. The wave field is recalculated every k'th morphological timestep, where k is an arbitrary integer. (In the present simulation k equals 3). A second-order accurate finite-difference method is used for the calculation of $\partial z/\partial t$ and the truncation errors are eliminated by a modified Lax-Wendroff scheme.

This setup meets the requirements of offering the capability of running with time-varying boundary conditions, and of minimizing the computational effort by avoiding recalculation in the hydrodynamic model. A block flow chart of the morphological model complex is shown in Figure 5.

Three different types of **wave models** are presently built into the morphological complex: an elliptic mild slope model, MIKE 21 EMS, a parabolic mild slope model, MIKE 21 PMS, and a spectral nearshore wind wave model, MIKE 21 NSW. The second one was used in the simulations described here.

The **hydrodynamic module** in the morphological modelling complex is MIKE 21 HD, which solves the vertically integrated equations of conservation of mass and momentum in two horizontal dimensions. The hydrodynamic model operates with a space- and time-varying hydraulic roughness, accounting for the apparent bed resistance in combined waves and current. This apparent roughness is updated every morphological time step.

The deterministic intra-wave period model for **transport of non-cohesive sediment**, STP, is applied. The model covers the range from pure current to combined current and waves (breaking or non-breaking), see Deigaard et al (1986). It is a basic assumption in the present model complex that the transport capacity is a function of the local conditions.

The hard-clay layer described in the Introduction section was included in the model as a non-erodible surface over which transport was allowed to take place.

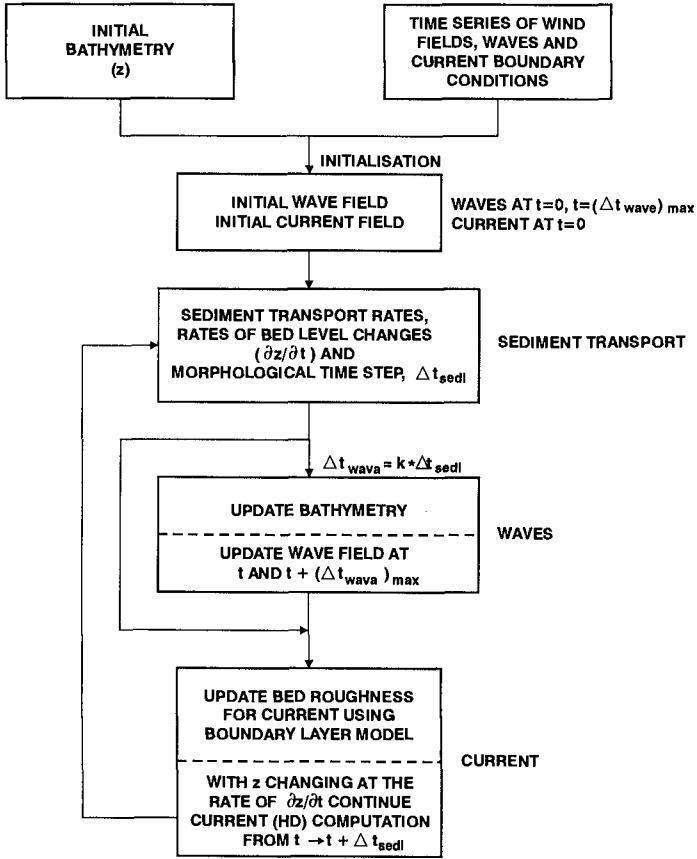

Figure 5 Block flow chart for the morphological modelling complex

Examples of results from the morphological modelling

As mentioned above, two historical storms, each of a duration of 4 days, were modelled in detail. The two storms represented typical storms from the two dominant directions, namely southwest and northwest.

Results from one of the storms, covering the period 20/1/1993 0:00 - 24/1/1993 0:00, are presented in figures 7 and 8. Figure 6 gives a brief overview of some of the important parameters, i.e. water levels at 3 stations, wind speed and direction and wave height and direction. Figure 7 shows wave-, current and sediment transport patterns at the peak of the storm, 22/1/1993 12:00. Figure 8 shows the bed level changes after 1 day, 2 days, 3 days and 4 days. The results show that sediment is 'sucked' out of the cells between the groynes, some of it is deposited off the groyne system in this storm, but most of it, as well as littoral drift which enters the model area, is trapped in the inlet area.

- b) From 20/1 1993 0:00 to 22/1 1993 0:00
- c) From 20/1 1993 0:00 to 23/1 1993 0:00
- d) From 20/1 1993 0:00 to 24/1 1993 0:00

New understanding of the complicated processes in the area was gained from the modelling work. Examples of details which were learned from the simulations are given below.

One example is the fact that the inlet over the last years has started to erode more severely on the opposite side, (the east side) to that where erosion previously occurred. It was clearly seen from the modelling that storms from southwest were responsible for this development, and over the last years the intensity of these storms has actually increased.

This effect becomes more clear if the model is run without any non-erodible clay layer. Figure 9 shows the comparison of the accumulated bed level changes over 4 days with and without the clay layer. It appears that a potential for erosion at the east side exists. (It should be mentioned that erosion does take place in the clay, just at a much slower pace than for sand. Erosion in the clay is therefore not included in the present model.) One effect of the clay layer on the sediment transport is seen from figure 10, where the accumulated transport across the western limit of Thyborøn channel, defined by the tips of the breakwaters, is compared for Storm 3 with and without the clay layer. It appears that the transport capacity is larger when the clay layer is included than when this is not the case. This is connected to the fact that the transport capacity decreases for increasing depth for constant flux.

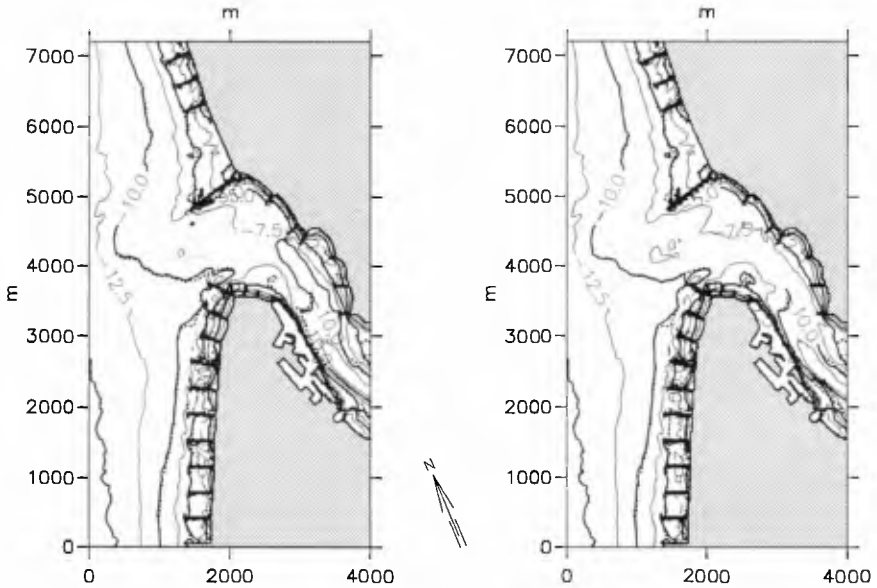

Figure 9 Comparison of accumulated bed level changes over 4 days.
 Left: without clay layer
 Right: with clay layer

Figure 10 Comparison of sediment transport through the inlet with and without the clay layer

Another example was the observed tendency for more severe wave overtopping along the harbour protection works, which has moved further inside the channel than earlier observed. This could now be explained by the deposition and erosion patterns related to the predominant southwesterly storms which permitted the waves from northwesterly directions to penetrate further into the channel.

Sensitivity to the length of the groynes

The groyne system at Thyborøn was constructed about 100 years ago. Due to the ongoing erosion, the coastal profiles have steepened off the tips of the groynes with the result that the ends of the groynes have collapsed, and rocks from the old structures have been left at the sea bottom. The length of today's groyne system and the way in which its submerged part influences the littoral transport are therefore not known. The effect of the groynes on the morphological evolution has consequently been investigated for the two extremes: the original length of the groynes and today's length, as determined from the overwater part of the groynes.

Figure 11 shows the sediment transport on 22/1/1993 15:00 and the morphological response in the vicinity of some of the groynes in the two cases: original length of the groynes, and present length of the groynes. It appears that the flow and the sediment transport patterns and thereby the morphological response are very different for the two configurations. The example demonstrates the capability of the modelling complex to represent the interaction between the longshore current that is generated within the cells and forms a rip current along the updrift side of each groyne and the eddies generated in the lee of each groyne.

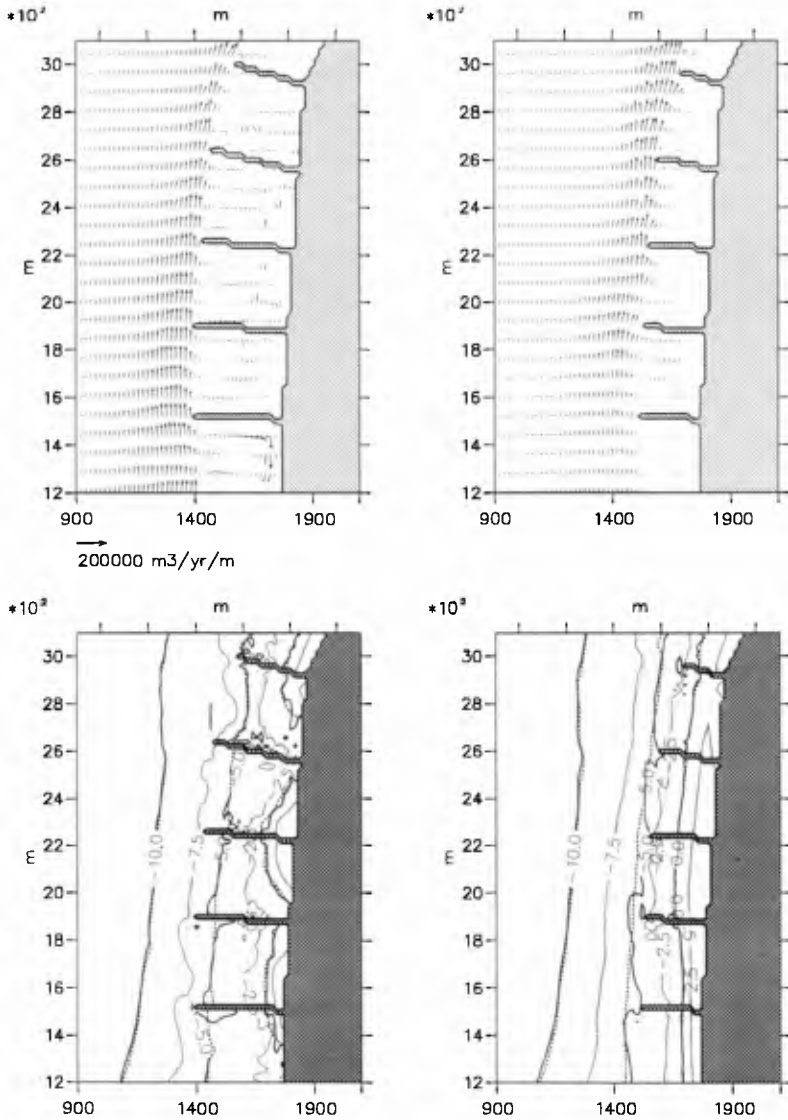

Figure 11 Sediment transport (instantaneous) and morphological response (20/1/1993 0:00 - 22/1/1993 15:00) in a groyne field during a storm. Two different lengths of the groynes are tested

CONCLUSIONS AND FUTURE PROSPECTS OF THE STUDY

Use of mathematical coastal models has cast new light on well-known coastal problems in the area and has allowed to quantify important parameters such as transport rates, spatial distributions of wave heights and current speeds, etc.

The results from the models have been useful in understanding some of the observed processes, cf. changes in erosion patterns in the channel and increased wave overtopping along the harbour structures.

Numerical models have proved to be an important tool for the analysis of different situations such as length of the groynes, existence of a non-erodible surface underlying the sandy bottom, etc.

The work around Thyborøn is still in progress, November 1996.

More historical storms are planned to be modelled. The intention is to simulate a large enough number of different storms to reproduce both the observed sediment transport through the inlet and the development along the barrier beaches through a suitable combination of the storm events. At the present stage, only very scarce information is available on the current statistics in the inlet. A measuring campaign has been planned based on the model results, and this has now been initiated.

The model complex will be used to guide the design of possible coastal protection structures and to evaluate the effect of different nourishment schemes.

CHAPTER 367

Probabilistic Risk Assessment of Beach Erosion at Pevensey Bay in England

Ping Dong¹ and Keith J Riddell²

Abstract

This paper presents a comprehensive case study in which probabilistic methods were applied to assess the risk of damage to properties protected by a shingle beach on the south coast of England. Both the short term storm response and longer-term longshore drift effects were considered. The mathematical model was calibrated against data from an extensive series of physical model tests and was used to predict the shoreline evolution for a number of beach management design options. A full cost-benefit analysis was carried out based on the predicted damage probabilities. The general methodology developed is believed to be applicable to other situations with different beach material types and various design options.

Introduction

In recent years, the limitations of a conventional semi-probabilistic approach in coastline studies and scheme development have become more widely recognised. In studying beach processes, hydraulic parameters such as extreme waves, tides and surges are usually specified in terms of single parameter return periods or joint return periods. The safety of the structure, or the level of protection it provides, is ensured by selecting design conditions (generally waves and water levels) which, individually and/or in combination, have a sufficiently remote chance of occurring. No explicit reliability calculations are undertaken and the precise level of damages over the design life, due to overtopping, breaching and erosion, is unknown. Consequently, the standard of protection that coastal defence schemes may be expected to achieve

¹ Formerly Principal Engineer, Babbie Group Ltd, now Lecturer, Department of Civil Engineering, University of Dundee, Dundee DD1 4HN, United Kingdom

² Divisional Director, Babbie Group Ltd, Simpson House, 6 Cherry Orchard Road, Croydon, Surrey, CR9 6BE, United Kingdom

can only be given in terms of the return periods of these input parameters rather than the damages which may be expected to occur. The success of such an approach would require that the return period of any damages is not lower than the return periods of the corresponding input parameters, a condition that can not be guaranteed *a priori* in a non-linear multi-parameter dynamic system such as a beach. By comparison with traditional methods, a direct technique which aims at evaluating the probabilities of occurrence of the beach processes that are actually responsible for the flood damages gives more meaningful design conditions. It also enables the evaluation of the variabilities and uncertainties in the damage estimates and provides a rational basis for cost-benefit assessment to be used as an integral part of scheme development.

The probabilistic design concept in coastal engineering is not new. It has been used in the design of breakwaters, seawalls and sand dunes as shown in a recent review on probabilistic design of flood defences by Vrijling (1990). Nearly all of the previous applications were restricted to dealing with the short term response of coastal defence structures under extreme forcing conditions, and the methodology used was largely based upon standard theories and techniques developed for the reliability of structures. Only very recently has some attention been paid to longshore processes. Vrijling and Swart (1992) presented a probability Level II method for berm breakwater design to evaluate the cumulative damage to the breakwater as the result of the longshore transport of rocks under extreme angular wave attack. Both Level II and Level III methods were employed by Vrijling and Meijer (1992) to assess long term shoreline evolution using a one-line shoreline model as the transfer function. Both the practical value of such approaches in engineering assessment and the uncertainties involved were highlighted by these workers.

The advantages of adopting a probabilistic approach and some important practical issues concerning its application in scheme development were presented by Riddell (1993). Probably, due to the lack of quality long term data and the perceived complexity of probability methods, the coastal engineering community are still showing signs of reluctance in adopting such methods in the design of beach management schemes. However, this situation is about to change in the UK with the introduction of new design guidelines from the Government which emphasise the need for rational cost-benefit analysis, the long term sustainability of engineering works and the need for all coastal works to be carefully evaluated in the light of global considerations.

The paper presents a comprehensive case study in which a probabilistic methodology was applied to assess the risk of damage to properties protected by a shingle beach on the south coast of England. Both the short term storm response and longer-term longshore drift effects were considered. The mathematical model was calibrated against data from an extensive series of physical model tests and was used to predict the shoreline evolution for a number of beach management design options. A full cost-benefit analysis was carried out based on the predicted damage

probabilities. The general methodology developed is believed to be applicable to other situations with different beach material types and various design options.

Figure 1 - Site Plan of Pevensey Bay

Site characteristics and design objectives

Pevensey Bay (Figure 1) has a shoreline 9km in length curving from a north/south alignment to east/west in a fairly classical bay configuration. Its beach is formed by shingle material above the mean water level grading rapidly to sand below this point. The shingle ridges, which are generally low and narrow, stand as a fragile

Figure 2

line of defence to the moderately well-developed low lying areas immediately behind the beach crest. Along several sections of the frontage, the beach has suffered from severe depletion of the mobile material and a large part of the existing timber groyne system has also been badly damaged, being, effectively, near the end of its useful life. Over the last twenty years extreme storms, combined with high tides, have, on a number of occasions, resulted in overtopping, beach crest recession and even small-scale breaching. These events have brought about considerable damages, not least of which were the costs of mobilising emergency services and carrying out rehabilitation measures to ensure some continued standard of protection. This situation can be best illustrated by an aerial view and a land-based photograph (Figure 2) of one of many critical locations showing the close proximity of housing to the crest of the shingle beach.

The threat of much larger breaching of the defences in the near future led the former National Rivers Authority (now part of the Environment Agency) to engage Babbie Group to carry out a comprehensive study of the Pevensy frontage lasting for a period of well over four years (1991-1995). During the first phase of this project, extensive data (both contemporary and historic) were collected and analysed with regard to waves, currents, sediment characteristics, beach profiles and past damages. Deterministic mathematical models were used to predict the beach response during extreme storm attack and the long term shoreline evolution over many years of average wave climate. These field data and predictions were used in an approximate cost-benefit analysis and for the preliminary design of a range of management options. During the second phase of the project, a detailed assessment of a limited number of potential scheme options was carried out, involving an extensive physical modelling programme and numerical model predictions.

Having realised the deficiencies of the deterministic methods that were used in the first phase, the decision was made to apply probabilistic techniques for both beach recession predictions and cost-benefit analysis. In this paper some of the work carried out in the second phase of the project is presented, with special emphasis on the use and validation of the probabilistic methods for beach recession predictions and cost-benefit analysis.

Methodology

General approach

The study methodology identified storm beach response as the primary process to be assessed in order to determine the type and severity of erosion, breach and levels of flooding. The probabilistic approach used for crest recession and overtopping was a simplified version of a full Level III approach with the erosion due to long-term longshore drift gradient being treated as an independent addition to the short-term crest recession.

Extensive physical model tests were carried out in the random wave flume and wave basin at HR Wallingford. The purpose of these tests was to assess the beach response under selected design storm waves and average morphological conditions over a period of 5 years. For the flume tests, 9 conditions were tested having estimated joint wave and water level return periods ranging from 1 in 1 year to 1 in 250 years. These tests were carried out on three profiles and two different gradings of beach material. Beach profile development for each test condition was recorded and used to calibrate a mathematical model. In the basin tests, one morphological condition and three (two for some cases) storm conditions were used. The full wave climate was represented by four equivalent wave spectra with increasing energy but decreasing probability of occurrence. The water levels were controlled to follow a predetermined tidal cycle. The data from the physical model tests were used to adjust the predictions made by the mathematical models. The return periods of overtopping and crest recession were calculated using a twenty year hindcast joint wave and water level time series, both including and excluding an allowance for long term sea level rise.

From wave refraction analysis and inshore monitoring results, it was found that the inshore wave climate exhibits considerable change from one end of the frontage to the other. In order to account for this variation, the use of different design wave conditions at different sections of frontage, for the purpose of cross-shore process analysis, was necessary. Due to these longshore changes of wave climate, as well as the change in shoreline orientation, large gradients in littoral drift exist at a number of sections of the shoreline. The effect of this was confirmed by observations that these beaches were known to be prone to erosion and required continuous maintenance. Therefore, longshore structural erosion was included in the overall risk analysis.

In developing design options, the probability of various levels of damage was determined for each beach management scenario, and these probabilities were then used to carry out a comprehensive cost-benefit analysis. This methodology is summarised in Box 1.

Transfer functions

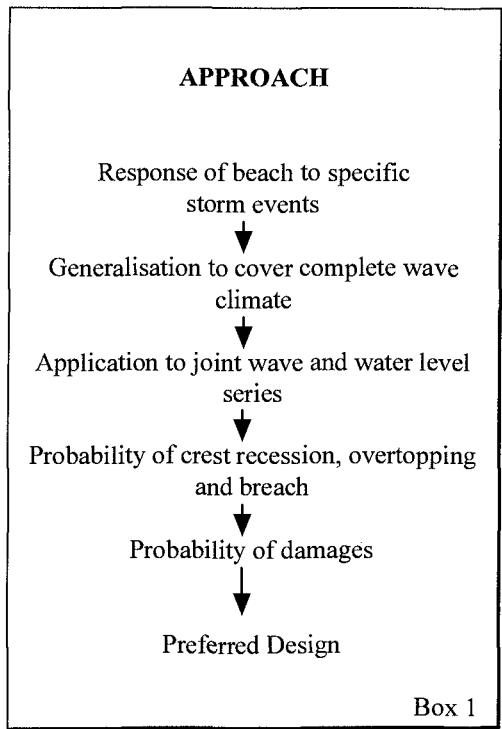

A key element in the design methodology is the transfer function which determines the response of the system for a given set of input parameters. In coastal engineering, the transfer functions are usually in the form of empirical equations or models or process-based mathematical models. Deterministic beach profile responses during storms have been parameterised by Dean (1972), Van der Meer (1991) and Powell (1991). Among these models the **Beach Profile Prediction Model** by Powell was developed specifically for shingle beaches based on extensive physical model tests and validated against a certain amount of (mainly UK) field data. This was therefore selected for the present work.

In order to limit the number of random variables that have to be considered, the model parameters were treated as deterministic and adjustable to give the best fit to the site specific data from the flume tests. In the case of Pevensey Bay such adjustments were required for only one of the three profiles considered. This was largely due to the influence of the limited thickness of the shingle layer at the location of this profile. It should be pointed out that the relationship as described by the BPPM model, between the equilibrium profile shapes and the input wave and water-level parameters, is highly non-linear and dependent upon the characteristics of the initial profile. Therefore, the predicted probability distribution of crest recession for different profiles could be quite different not just in terms of numeric values but also in the shape of the overall distribution.

Input Data

The input data can be classified into two main types: hydraulic data and morphological data. The hydraulic data consisted of a twenty year inshore joint wave and high water level time series, obtained by transferring a hindcast offshore time series to a number of inshore locations using a spectral back-tracking model (OUTRAY by HR Wallingford). The hindcasting model was calibrated against one year of offshore directional wave data obtained at the site during the study period. The refraction model was calibrated against simultaneous inshore records obtained at two locations.

The morphological data consists of surveyed beach profiles, sediment sizes and shoreline positions. Cross-sections at 150m intervals of this and adjacent frontages had been taken annually for a period of twenty years and were used for the detailed assessment of recent shoreline evolution and sediment budget considerations. For simplicity of modelling, the morphological inputs were treated as deterministic. The appropriate mean values and variations for these morphological input data were derived using historical charts and the long term beach survey data.

Prediction procedures

When considering cross-shore processes, it is important to preserve the essential correlation in the wave and water time series. This rules out a probability Level II method which assumes the parameters to be independent and to follow Gaussian distributions. All the wave and water level records in the time series, apart from some small waves deemed to be insignificant, were directly input into the calibrated BPPM model to obtain a single time series for the beach crest movement. The predicted beach movements were then ranked and fitted with appropriate logarithmic distributions. The same calculations were performed for each of the three profiles, taken as being representative of sections of frontage, using the appropriate time series for different inshore points.

Longshore processes are more difficult to deal with, because they essentially have two time scales; one for long-term average movements of sediment and the other for short-term storm effects. Although the techniques of Vrijling and Swart (1992) could, at least in principle, be adopted for predicting the probability of long term average shoreline changes, difficulties arise when trying to combine the two sets of recession probabilities from cross-shore and alongshore calculations. The short-term effects due to oblique storm waves on the coastline development would also need to be determined separately.

Short of using a 3D or quasi-3D model as a transfer function, further assumptions on the potential correlation between short- and long-term processes and between cross-shore and longshore effects have to be made. Due to the lack of research concerning the above problems, longshore processes were treated as deterministic. As a result, the crest recession probabilities would be invariant although the reference shoreline position would change with time as predicted by a one-line model. The corrections to the reference shoreline position were introduced in the design assessment based on the basin test results.

Predictions of crest recession

Model calibration

In order to ensure that the transfer function used was reliable the numerical model (BPPM) was firstly calibrated against the crest recession data from the flume tests. It was found that the model predictions agreed well with the measurements from Profiles 2 and 3 but some adjustment was necessary for Profile 1 in order to achieve best overall fit. Similarly the one-line model predictions were also compared with the actual shoreline positions determined from the annual surveys for the same data period (20 years). To achieve best agreement, it was found that the transport parameter in the CERC formula 'K' should be about 0.04 assuming the existing groynes are virtually ineffective.

Cross-shore beach crest recession

Assuming that an equilibrium beach profile can be established over the period of one tidal cycle, under given wave and water level conditions, the time series of crest recession and overtopping rates can be calculated for a given beach configuration. The exceedance probability and the return periods of crest recession can then be determined using ranking statistics. Some of the results are shown in Figures 3 and 4. It can be seen that the active crest tends to establish seaward of the initial crest for most wave conditions during the twenty year record period whilst

crest retreat takes place during only a small number of severe events. In order to determine the extreme crest recession, a logarithmic curve was fitted to the computational data. The crest recessions for the more extreme events such as 1 in 250 year, can be obtained by extrapolation of the fitted recession curves.

Figure 3

the joint probability density of wave and water level and then calculating the overtopping and crest recession for the extended records. This is due to the fact that the joint probability density function is very irregular at small values, and it is difficult to find a sensible surface to fit to these values. Whatever probability distributions is assumed, large errors are unavoidable in extrapolation.

In general, the accuracy of the simpler method has been shown to depend on the data length, regularity of crest movement and the transfer functions adopted. From the model tests it was found that the

Figure 4

beach can be 'washed off' by overtopping when its crest is very thin. This means that extrapolation of the predicted recession probability can not be extended indefinitely because the crest movement can change from progressive erosion to wash-out with only a very small change of input hydraulic conditions. A minimum crest width has been assumed on the basis of the model tests which represents this change of mode of beach damage. A 250 year return period was determined to be the upper cut-off limit for the extrapolation of beach processes at the study frontage.

Figures 3 and 4 also show the observed recession ranges during previous observed storms. Although the data are rather limited, and the quality of these data is far from ideal, it was quite satisfying to note that the predictions were consistent with the field data on all three profiles. Since the numerical model was only calibrated against data from the physical model, and for only a limited number of extreme storm conditions, the predictions obtained are considered to be remarkably good.

Effects Of Long Term Shoreline Evolution

Although the storm response of the beach is dominant in the determination of the level of risk at any particular point in time, the long-term shoreline evolution trend must be taken into account if the true risk level of a particular section of the

Figure 5, Strongpoint Basin Test in Progress

coastline, over a significant length of time, is to be established. For an open beach, the long term erosion due to the longshore transport gradient is usually fairly regular at a given site, depending, primarily, on the average wave climate, the supply of material and local shoreline orientation. The mean erosion rates for the Pevensey Bay frontage were calculated using a standard one-line model. In order to account for variability in the predictions of wave climate and sediment supply, the average shoreline position was determined for 5, 10, 20 and 50 year periods. The storm wave

response probability was assumed to be invariant at any time within the design life of the defence. Although it is possible to introduce a higher level of probabilistic representation for the shoreline position than that used, such an approach was rejected on the grounds that the transfer function would have become too complicated to be practicable and no suitable method was found which was capable of dealing with the correlation between longshore and cross-shore processes in a consistent and robust way.

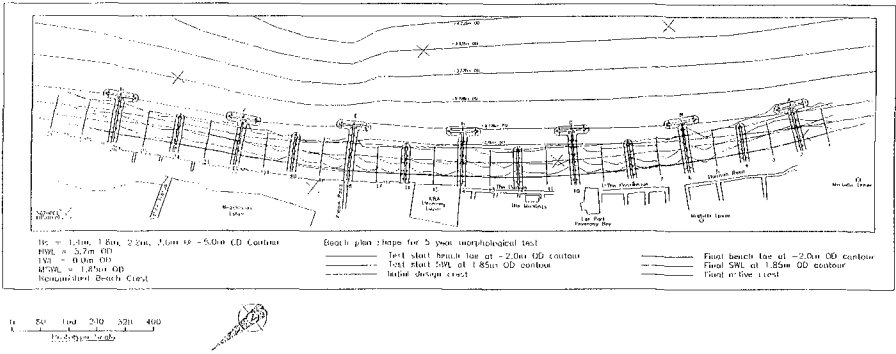

Figure 6 - Basin Test Results for mixed Rock T-head and Groyne Scheme

In developing the scheme options a number of beach management scenarios, ranging from timber groynes to large shore-attached rock structures, were tested in the wave basin. The crest movements under morphological and extreme storm conditions were obtained. Using similar techniques as described for the open beach case, the crest recession probabilities for each of the beach management options were estimated, taking into account the effects of the longshore gradient of drift rates during storm events. An example of a test in progress is shown in Figure 5 and an example of scheme test results in Figure 6. A comparison of the effect of different

Figure 7 - Crest Recessions for various schemes

management options on the probability distribution of crest recession is shown in Figure 7.

Cost Benefit Analysis

The ultimate aim of all the preceding analyses is to generate damage probability graphs for all kinds of damage/loss considered. A typical graph for an open beach 'do-nothing' option is shown in Figure 8. In developing various design options, losses due to erosion, overtopping and breaching were all included wherever appropriate. The damage cost was assessed for each year during a nominal 50 year design life using appropriate discount factors. Since the total loss for any area is not always the simple sum of all probable losses, depending on the physical characteristics and economic values of the shoreline and hinterlands, and the interaction between them, care must be taken in deriving the total losses/damages.

Figure 8 - Damage / Probability Profile

Discussion And Conclusions

A probabilistic design methodology has been developed which can be applied to shoreline studies, scheme design and the selection of management options. It provides a rational basis for the assessment of flooding risk and the standard of protection.

As long as the joint time series of wave and water level can be made available, it is straightforward to calculate the probability of run-up, overtopping and breaching using either empirical formulae or mathematical models. Physical modelling significant confidence to the results of the above and is essential for the consideration of non-standard situations.

Beach response is not just dependent on waves and water levels. Many other parameters are important such as the initial beach profile, material variability and storm duration and sequencing. A true probabilistic design methodology needs to take into account all of these parameters on a physical basis including systematic sensitivity assessments.

The transfer functions which provide the link between hydraulic parameters and beach processes are dependent on the configuration of the beach and detailed material properties. Great care must be taken when applying a transfer function developed for one type of beach condition to another.

Based on this study the following conclusions can be drawn

1. Predicted erosion probabilities are consistent with experimental data and some limited field observations.
2. The probabilistic method is no more difficult to apply than a conventional method, although it does require more long-term data and is therefore more time consuming.
3. Predictions are site dependent and sensitive to changes in the parameters characterising the beach and within the numerical model transfer function.
4. The damage modes treated in this study were limited and many other damage modes such as scouring, abrasion and offshore loss of beach material could be important at other beaches. Hence, design decisions made at one site should not be transferred to another site despite apparently similar features.
5. It has been found to be virtually impossible to deal with both long term and short term processes using the same high level of probabilistic techniques and within the prediction framework adopted. Research in this area is urgently required.

CHAPTER 368

BEACH NOURISHMENT IN ALTAFULLA, SPAIN: VERIFICATION OF THEORETICAL MODELS

J. Galofré¹, F. J. Montoya² and R. Medina³

ABSTRACT

This paper describes the comparison between results from theoretical methods and field data measurements on a beach nourishment project, in Altafulla beach, Spain. A brief review of the processes involved in the behaviour of beach nourishment projects are made in order to analyse beach evolution after filling it. Theoretical results can be obtained applying theoretical methods. A monitoring program was carried out after nourishment works and field data measurements were taken in order to verify theoretical models. Capability, application and validity of models to the prediction of a project performance are discussed comparing with field data results.

The conclusion of the comparison is made for the Altafulla case study and a discussion of the results is included in order to understand beach evolution method by field data results.

1.- INTRODUCTION

Beach nourishment works, as an integrated coastal zone management plan, are used as a coastal engineering tool in order to guarantee the functions of a beach. The most important functions of a beach are: - Energy dissipation mechanism and Useful free space for every one.

Theoretical, technical-empirical and numerical methods are needed in order to design the solution and optimize nourishment efficiency. They must be calibrated in order to know the right beach parameters and analyze their behaviour.

Analysis of beach behaviour has received considerable attention during the last decades. Although the sediment processes involved in the changes of a beach are non linear and have great variability both in space and time, the comparative analysis of beach evolution with theoretical models and field data is necessary in order to know how powerful the predictive models are. These models can be used to assist in the determination of project design and/or beach evolution. Furthermore, models describing the response of beaches to different coastal forcings have become increasingly numerous and sophisticated in recent years (see Work and Dean 1995, as a general reference). At present, however, there is no model that can be used to solve all the spatial and temporal scales of variability involved in beach nourishment evolution and, consequently, different models must be used. Monitoring field data are needed in order to calibrate and verify the models. It is necessary to know how well every model works and when it can be used.

The goal of this paper is to analyse the theoretical and real behaviour of Altafulla beach, comparing monitoring field data to technical-empirical and numerical model results. Various types of models are used, they are classified by their spatial and temporal domains of applicability.

2.- ANALYSIS METHOD

The analysis of processes, scales and tools is necessary in order to advance the knowledge of beach behaviour.

In order to understand beach performance it is necessary to analyse the beach forcings that are acting on the beach, these are the cause of all the processes.

The beach responses are the consequence of the beach forcings, they are the phenomena that appear along the coast. Beach behaviour analysis implies many methods working with the forcings and responses give a comprehension of beach performance.

Erosion, accretion and beach change in offshore bottom topography are controlled by beach forcings described in table 1. They are divided into three time scales of variability: Short term (less than 15 days), middle term (15 days to 6 months) and long term (years). The space scale considered is the meso scale that has a range from 100 m to 10 km shoreline. There are others spatial scales like microscale, less than 100 m shoreline, and macroscale, more than 10 km shoreline. This case study involves the mesoscale. The responses of beaches to these perturbations and variable forcings can be found in a wide range of time scales, see table 2.

Besides the wide range of temporal and spatial scales of variability, coastal evolution processes are often three-dimensional. In spite of this, important aspects of the coastal behaviour can be understood and prediction on the bases of lower-

dimensional models. These models take advantage of the circumstance that the response of a beach often exhibits a different behaviour with essentially different length scales in three mutually orthogonal space directions (vertical, cross-shore and longshore), De Vriend, (1992).

The next point is to define the models that it is possible to use for the analysis of the forcings and responses. Table 3 shows a wide range of different models.

To improve predictive models for beach responses, an accurate description of the forcings is necessary. From table 3, it can be seen that existing hydrodynamic models (wave, tide propagation and wave induced currents) can be used for solving the forcings at almost all spatial scales of interest. The choice of a particular model should be made in relation to the response model to be used.

When selecting a response model, several physical facts must be taken into account. Cross-shore transport is very important just after the fill. A nourishment beach reaches its equilibrium profile within the first year after the fill (Kamphuis and Moir 1977). Several existing models can describe the post-fill evolution of the profile (usually neglecting longshore transport). However, cross-shore transport at greater time scales (months to years) remains a challenging problem that has not received a great deal of attention (Work and Dean 1995).

Longshore sediment transport is found to be important near the shoulders of the fill in the beginning. The effects of the longshore gradients propagate afterwards into the nourished region. N-line models can represent these coastline changes in the mid-long term. The one-line approach imposes limitations by neglecting the influence of cross-shore transport. However, this can be overcome if the model is calibrated adequately (Hanson and Kraus 1977). Technical empirical models can be useful in order to know beach equilibrium planform (Hsu et al, 1989) and profile equilibrium form (Dean, 1995). For the long term evolution prediction, parametric models (e.g. equilibrium profile-coast line models) and statistical models (e.g. P.C.A. models) can help N-line models.

The next step is to analyse this wide range of models and select the most interesting in order to know the beach behavior. In beach analysis from input data with the analysis method, must be obtained the output data. In table 4 an analysis model is proposed for it.

The case study will compare the models propounded in table 4 with the field data obtained from the monitoring program.

3.- FIELD SITE AND DATA COLLECTION

The site of the field study is Altafulla (Fig.1), a sandy beach located 10 km north of Tarragona and 80 km south of Barcelona, in Catalonia, on the Mediterranean Coast of Spain. Altafulla is a half-opened beach 2.3 km long located between two capes, "Els Munts" to the east and "Tamarit" to the west. A small river flows during storms in the middle of the beach.

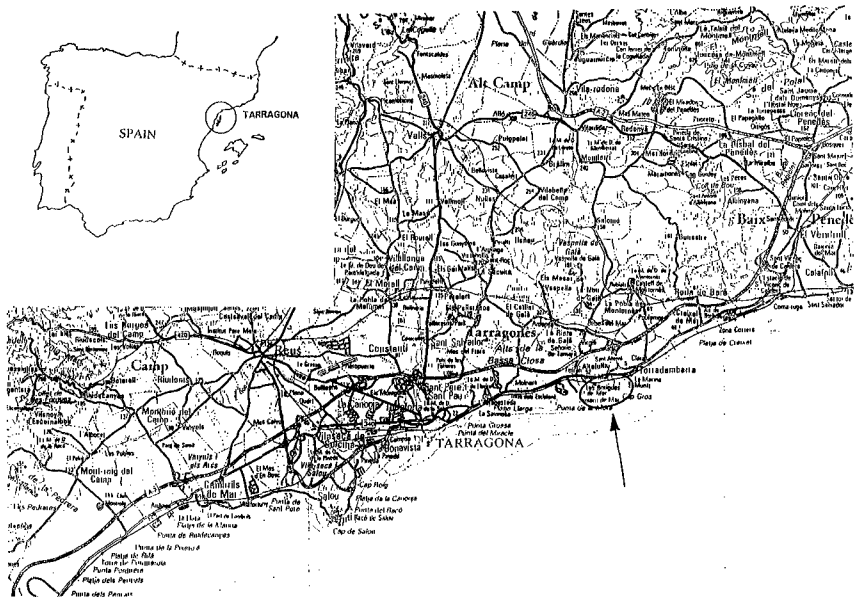

FIGURE 1 SITE LOCATION MAP

There are two predominant directions of wave approach: SW and E. More than three quarters of deep water waves approach Altafulla from those sectors. The annual average significant wave height is about 0.5 m with typical winter storm waves of H_s of about 3.0 meters. Tides at Altafulla are negligible. In figure 3 a visual wave distribution is made and the affected area is shown, sea and swell limits are defined.

The native beach sand had a mean diameter between $D_{50} = 0.12$ to 0.2 mm and the beach profile slope changed from 1.2 % to 2.0 % from shoreline to bathymetric -5 meters. This value contour is considered the profile closure depth at Altafulla. The bottom of the sea is sandy up to the 10 m bathymetric contour line.

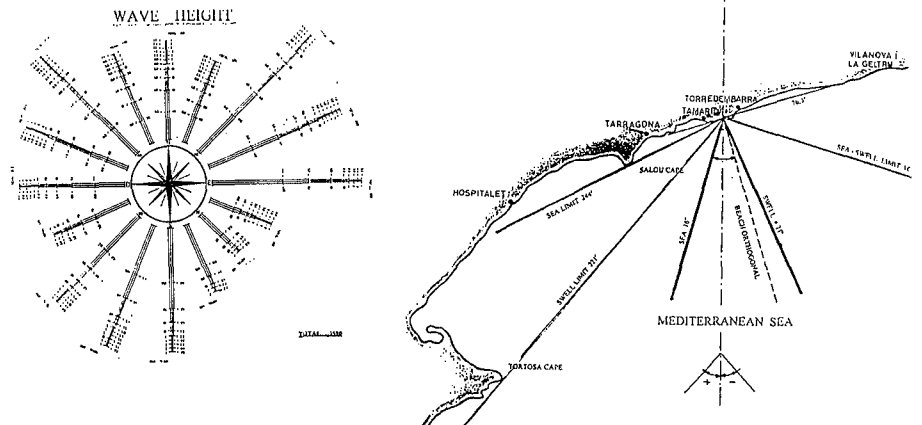

FIGURE 2) WAVE CLIMATE. SEA AND SWELL LIMITS

4.- BEACH NOURISHMENT AND MONITORING PROGRAM

In figure 3, a bathymetric map is shown in order to present beach problems and their solution.

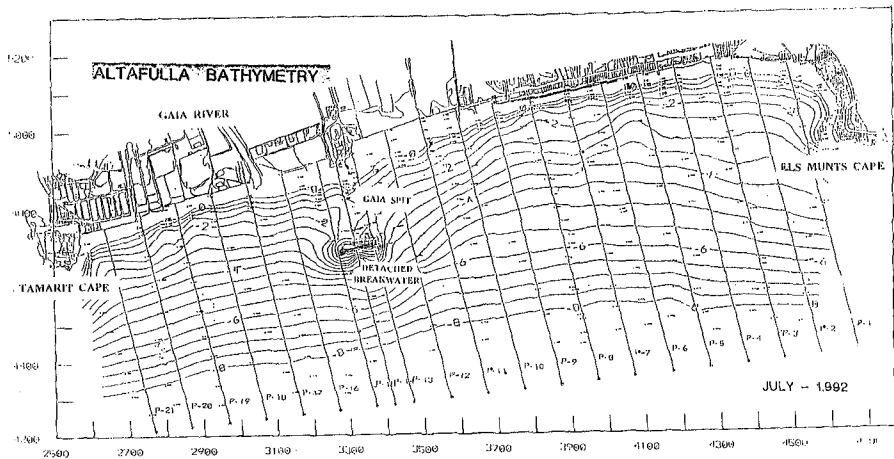

FIGURE 3 MORPHOLOGICAL AND BATHYMETRIC MAP

Several erosion problems occurred in the northern part of the beach. A seawall was built to prevent backshore building damage. Southward littoral drift reduction of sediment appeared because of the construction of a dam 8 km up to the Gaià river and sand extraction during the 50's and 60's for construction works and filling the surrounding marsh. These have been theorized as major factors in the erosion that has been witnessed in Altafulla. A beach nourishment project was undertaken in 1989. Beach nourishment started in late 1990 and was completed in 1991. The beach nourishment works consisted of 160.000 m³ of borrowed sand volume. The borrowed sand had a median diameter averaging $D_{50} = 0.6$ mm. A detached breakwater was also built in the middle of the beach, see figure 3. The breakwater was 110 m long and was placed at the -5 m bathymetric contour line.

A monitoring project was carried out to evaluate the evolution of the fill. The monitoring program started in July 1991, at the conclusion of the fill, and finished in December 1993, before renourishment works. The field program includes bathymetric beach profile every survey and sediment samples on some surveys. Six profile surveys were taken in this period. Each profile was surveyed from permanent monuments landward to a depth of approximately 10 meters. Sediment samples were taken in the last survey and samples were collected along three profiles simultaneous with beach equilibrium planform and profile survey.

Historical aerial pictures and visual maritime climate data are used with monitoring data in the comparison with the models.

5.- MODEL VERIFICATION

In table 3 a wide range of models which affect forcings and responses have been described. In table 4, a selection of these models have been chosen in order to define the analysis method to study beach nourishment evolution. Beach planform, beach profile form and grain size distribution can be obtained from historical analysis, maritime climate data, topobatymetric and granulometric data using the analysis methods.

The field data are needed in order to validate the models, some data are input, some are used to calibrate the models and others are output data. A planform and profile form are analysed in order to know their equilibrium. Grain size distribution is evaluated.

Qualitative and quantitative verification have been made. Qualitative results have been obtained studying beach dynamics and comparing with aerial pictures and topobatymetrics. Beach dynamics were computed by means of the numerical models.

Computations were carried out for conditions before and after the fill and construction of the detached breakwater. Different wave heights, wave periods and wave approach directions were used applying the REFDIF program, from Kirby and Dalrymple (1983-1986) computed by the parabolic wave propagation model.

Different wave heights were composed, the refraction and diffraction phenomena were combined. By analysing aerial pictures, the protected areas behaviour, predicted by the models, can be observed. Figure 4 shows the wave induced currents determined from the wave field, as shown in the last figure. It can be seen that the breaking waves currents direction, induced by different wave height, change near the capes and the breakwater by diffracting phenomena. Aerial pictures

FIGURE 4.a) WAVE INDICED CURRENTS $H=0.5$ m; $\alpha = +45^\circ$; $T = 10$ s.

FIGURE 4.b) WAVE INDUCED CURRENTS $H = 3.0$ m; $\alpha = +45^\circ$; $T = 10$ s.

confirm these results showing sand accumulation in the calm areas. The spit formation landward of the breakwater can be explained with these results as is shown in the monitoring bathymetry.

Quantitative verification can be made in order to analyse beach behaviour. Beach profile, planform and prediction methods are verified.

Beach field data profiles were compared with theoretical profiles before and after nourishment works. The Dean profile was used and compared with field data. The beach profile before nourishment can be approached by $y = A \cdot X^{2/3}$, with the corresponding A according with $D_{50} = 0.16$ mm., the average of D_{50} in the native beach. After nourishment the beach profile can be approached by the same formula with A corresponding with $D_{50} = 0.35$ mm., the average of D_{50} in the nourished beach in the last topobathymetry field data.

Closure depth profile is calculated by the Birkermeier formula and compared with monitoring field data. Bathymetric -5 m. contour is considered the closure depth at Altafulla. This value was determined from the monitoring profiles and by technical-empirical model.

Planform was analysed by technical-empirical and numerical models and the results have been compared with monitoring field data results. The technical-empirical Hsu and Silvester method was used for analysing planform on the east part of the beach. Figure 5 shows the results with a great similarity with theoretical and field data results. The spit formed landward of the detached breakwater built in the middle of the beach is analysed using the method proposed by Gonzalez (1995), to calculate spits and tombolos. Figure 6 shows the application of this method and the conclusion is compared with the results of the monitoring field data results.

Numerical models can be used in order to understand beach performance and beach evolution. The basic procedures followed in this case study to analyse the beach nourishment evolution were the one-line model and statistical model. Field data are needed in order to calibrate and verify the one-line model and as input data for statistical models that can show theoretical tendencies from field data.

The one-line model used was GENESIS, (Hanson and Krauss, 1991). The model was calibrated with the profile evolution data following the procedure by Hanson and Krauss (1989). The climate waves were taken from visual data and calibrated from Tarragona harbour buoy data. Figure 7 shows the results of the shoreline position obtained from the model. The field data used for the calibration was 92 - 02 - 28 to 93 - 10 - 17.

The one-line model is a powerful tool that must be used carefully. To model the reality means to simplify the problem in order to reach some logical results that represent because two capes exist at the ends of the beach. These capes are not very long but it is not know if sand bypassed them.

In the model the capes are represented by two diffracting groings 550 m long. This hypothesis works well in a small and mesotime scale. It was calibrated and verified using two years monitoring field data and the results were quite reasonable. But if we apply long-term scales, more than 10 years, the results must be discussed more accurately. The boundary conditions are critical, especially for the evaluation of the sand beach losing outside the study stretch. Extra data are needed in order to calibrate the program better. Length, sand bypassing and sand transmission must be discussed in order to apply long term.

Wave climate is another data that must be chosen carefully. In this case visual data, calibrated with Tarragona harbour buoy data, were used. During the monitoring period not many storms occurred. This means that the medium wave climate that visual data represent was not absolutley according to real wave climate.

Sand granulometry is another aspect to consider. In the GENESIS model and program homogeneous sand is used, in this case it was supposed that all the sand had $D_{50} = 0,35$ mm. Before restoration $D_{50} = 0,2$ mm and in the mouth os the Gaià river a lot of rocks and gravel existed. This phenomena was not considered in the GENESIS program. In the places where gravel exists erosion problems are less than in sandy areas. In long term analysis these aspects have importance and the results must be taken carefully.

Combined phenomena, boundary conditions, wave climate and sand granulometry have incidences in the prediction results in long term scale and it is difficult to plan long term future by this kind of program in this case.

EQUILIBRIUM PLANFORM

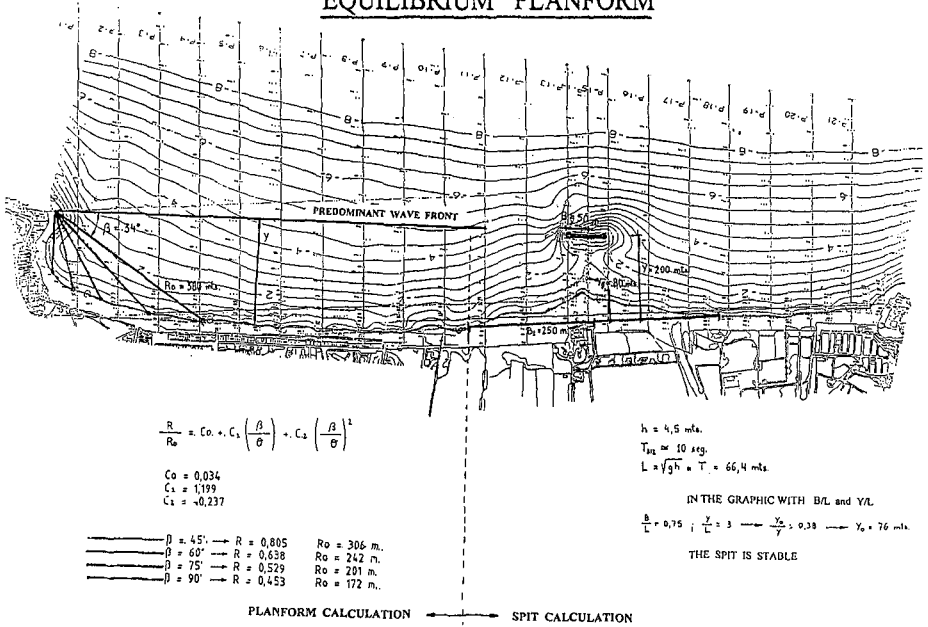

FIGURE 5 THECNICAL-EMPIRICAL METHODS INPLANFORM EVALUATION

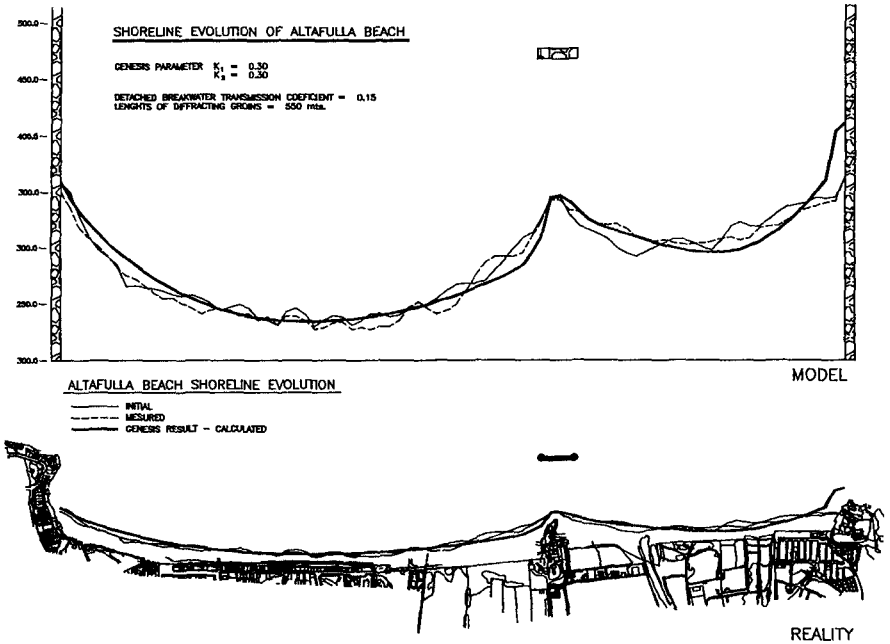

FIGURE 6 NUMERICAL METHOD, GENESIS, FOR SHORELINE EVOLUTION ANALYSIS

In order to understand beach behaviour, after the analysis of beach profiles and planform, a brief study of longshore transport was made. Theoretical formulas can be used, some of them only consider oblique wave incidence: CERC, KOMAR, etc. In this case height wave gradient, because of diffraction phenomena, are also important. That is why it is necessary to use models that consider both phenomena. The GENESIS program also calculates longshore transport ratios along the shoreline and the average transport ratio considering obliquity wave incidence and height wave gradient. In this calculation initial and final shoreline data were used to calibrate the model. The average of long shore transport is about 5.000-9.000 m³/year, this result agrees with some theoretical studies made near this area.

A statistical model was used computing the monitoring topobathymetry field data in order to find the tendencies of beach behaviour. The statistical model used was Principal Component Analysis (three way PCA). The method was used to objectively separate the spatial and temporal variability of the beach profile, planform and the sediment grain size data, as described by Medina et al 1994. The results show a seasonal variability in the beach profile data and a long-term trend. The bases of these statistical methods are the concentration of all topobathymetric information and to find some intrinsic information that can explain the trend of the beach evolution.

Three-way PCA is a statistical tool that can be used in the knowledge of beach behaviour. In Figure 7 the first, second and third cross-shore components, eigenvector are shown. The first one defines the mean of the variable, in this case representing the medium average profile. The second cross-shore eigenvector is very important in the upper part of the profile and it will play an important role in determining the upper profile slope. The third cross-shore eigenvector shows a berm-bar variability. In our case the second and third eigenvectors have influence on the detached breakwater comparing COMPL Ø and COMPL 1. A similar analysis can be made for long-shore eigenvectors.

The shows temporal eigenvectors, have been calculated the first one represents medium average temporal variation. The second one represents a seasonal dependence. Both of these are constant, and in the case of a two-year monitoring program, the temporal variability is not important. This means that the beach is in a quite equilibrium position with this wave climate. The combination of these eigenvectors explains most of the variability of the evolution of the beach. In order to combine them we will use the corresponding Bartussek core matrix values and the percentage of variation explained. This matrix shows how to combine eigenvectors. In order to better interpret the variability they account for, it is useful to examine the profile or the bathymetry that is obtained by the product or one alongshore eigenvector with one cross-shore eigenvector, and use the corresponding temporal function to determine how the obtained profile or bathymetry evolves in time.

FIGURE 7 b) CROSS-SHORE EIGENVECTORS BEFORE NOURISHMENT WORKS

6.- CONCLUSION AND DISCUSSION

1.- Good data is needed in order to know the beach behaviour. It is the most important aspect for Coastal Engineers.

1.1 Wave climate must be obtained from:, Directional buoy, Non directional bouy with the direction data, Non directional buoy, Visual climate data.

This is the classification from the most valuable data to the least. Also, it depends on the range of information that it is possible to use. It is necessary to check different data information, if possible, and analyse it carefully before choosing the calculation data.

1.2 Topobathymetry data are the physical suport of Coastal Engineers. Accurate data is necessary for all kind of model. It is necessary to control: Study are limits, Profile distance, Profile length, Points per profile, Position system and errors, Bathymetric and althymetric measurement system and errors, Working weather conditions, Technical and worker personnel, Data analysis and computation, Topobathymetry frequency.

1.3 Sand sampling is needed as a basic component of beach performance. It is necessary to control: Study area limits, Sampling points, Sampling system, Sampling analysis and computation, Sampling frequency.

2.- Technical empirical models are easy to use and give important qualitative and some quantitative results. Data errors can be detected.

3.- Numerical models are more complicated to use than technical-empirical and sometimes can take data errors obtaining results with more errors.

4.- No model, technical-empirical or numerical, gives good results with bad data.

- 5.- Numerical models need a lot of data, a calibration step and a verification step. The whole process requires a lot of time and money. For this reason, it is necessary to be rigorous choosing them on quantity and quality.
- 6.- Statistical models must be studied in depth in order to find the beach trends.
- 7.- Altafulla beach has been studied comparing monitoring field data and theoretical models. It is a quite stable beach with a sand drift of 5.000 m³/year, from east to west. Sand is accumulated in calm areas and eroded in open areas.

CHAPTER 369

ALTERNATIVES TO BEACH STABILIZATION: CAMBRILS COAST CASE STUDY (SPAIN)

Nuria Lupón⁽¹⁾, Alfonso Vidaor⁽²⁾, Jordi Galofré⁽³⁾ and F. Javier Escartín⁽⁴⁾

ABSTRACT

A study of alternatives including a shoreline evolution numerical modelization has been carried out in order to both diagnose the erosion problem at the beaches located between Cambrils Harbour and Pixerota delta (Tarragona, Spain) and select nourishment alternatives.

INTRODUCTION

Cambrils and Montroig are two villages located in a zone of big tourism growth in the Tarragona coast (northeast of Spain) 35 km from Tarragona and 125 km from Barcelona, very well communicated by road, motorway and railway (see figure 1).

Due to the importance of this tourist zone the Spanish Ministry planned a beach nourishment project for the area, including six beaches (6,000 meter long): Verge del Camí, Llosa, Torrent d'en Gené, Ardiaca, Riudecanyes and Pixerota.

The Cambrils Harbour construction in the thirties with a breakwater reaching the active depth, acting as a sediment transport barrier, strongly modified the littoral dynamics on beaches located southwest, suffering a severe regression only partially controlled by stabilization works carried out, which consisted basically in the construction of detached breakwaters and sand contribution. The efficiency of those works wasn't completely satisfactory, and the coastal zone between Cambrils Harbour and Pixerota delta presents nowadays a clear lack of stability with a general trend to regression.

Figure 1: Location plan

MARITIME CLIMATE

The wave data used were:

- Cap Tortosa directional buoy, belonging to the General Directorate of Ports and Coasts of the Catalonia Autonomous Government during the interval 90/6 to 93/6, located at $0^{\circ}58'6''$ E, $40^{\circ}44'6''$ N coordinates in a depth of 45 m.
- Visual data registered at Casablanca oil platform during the interval 1983-1988, located at $1^{\circ}21'30''$ E, $40^{\circ}43'3''$ N coordinates in a depth of 170 m.
- Visual data registered by ships in the zone $0^{\circ}-2^{\circ}20'$ E, $40^{\circ}-41^{\circ}30'$ N and treated by the National Oceanic and Atmospheric Administration in Asheville.

The three data are valid though each of them presents some inconvenients:

- The Cap Tortosa buoy data have great reliability for being instrumental registers, but encompass a period of only three years.
- The ship visual data present a longer temporal interval, enough to represent the average zonal climate, but they have lesser reliability because of their origin.
- The Casablanca visual data present an intermediate reliability compared to other data.

NATIVE SAND GRANULOMETRIC ANALYSIS

A complete topographic and bathymetric survey of the studied zone was made including from dry beach to depth -13, deeper than active depth. At the same time a native seabed sand sampling campaign was performed: sixty sand samples in twelve profiles at five depths (+2.5, ± 0.0 , -3.0, -5.0 and -8.0) were analyzed obtaining the results shown in table 1.

Sample	D ₁₆ (mm)	D ₅₀ (mm)	D ₈₄ (mm)
+2.5	1.568	0.549	0.290
±0.0	1.684	0.553	0.296
-3.0	0.453	0.299	0.180
-5.0	0.439	0.312	0.221
-8.0	0.439	0.311	0.212
Total	0.859	0.390	0.232

Table 1: Native sand granulometry

BORROW SAND GRANULOMETRIC ANALYSIS

Studies performed in the last years verified the existence of submarine sand banks close to the project area, capable of being used for beach nourishment (as in the L'Hospitalet de l'Infant beach regeneration).

Another possible source for borrow sand was the material originated by the granite meteorization, locally known as "sauló". There existed four quarries near the project area that had been already used by the Ministry with satisfactory results.

The representative mixture granulometric characteristics for the two borrow sand types are shown in the table 2

	D ₁₆ (mm)	D ₅₀ (mm)	D ₈₄ (mm)
"Sauló"	1.568	0.549	0.290
Seabed sand	1.684	0.553	0.296

Table 2: Borrow sand granulometry

REGENERATION CHARACTERISTICS

There isn't a general rule that relates submerged beach slope with sand granulometry. However it's known that the slope proportionally increases with the average sand grain size.

R. Silvester in his classical publication "Coastal Engineering" showed relationships between the beach slope and the sand size for three types of beaches: protected, semi-exposed and exposed.

For the different native sand samples the relation between beach slope and grain size was analyzed, obtaining figure 2, in which the three theoretical curves before mentioned were drawn, too. The values measured in Cambrils and Montroig beaches were located on the curves, representing exposed beaches. The borrow sand average size (0.42 or 0.92 mm) was located in the upper zone of the figure, where an additional dotted line representing Cambrils and Montroig beaches was drawn.

Figure 2: Submerged beach slope vs. Average grain size

In 1984 Garau and Friedman suggested a beach profile model for the case of sand classified by littoral processes for open beaches in the Mediterranean. The beach slope could be calculated using the average diameter D_{50} by means of the expression

$$m = 0.075 + 0.035 \cdot \ln D_{50}$$

Finally, from eroded profiles analysis Vellinga (1984) got a relationship between beach slope (with a certain granulometry) and slope (with another grain size):

$$m_1 = m_2 \left(\frac{w_1}{w_2} \right)^{0,56}$$

where w is the grain fall velocity. Once known the Cambrils and Montroig beaches grain sizes ($D_{50} = 0.39$ mm) and slopes (between 1V:30H and 1V:57H) and borrow sand sizes ($D_{50} = 0.42$ or 0.92 mm) the design beach slope could be calculated. The Ministry finally chose the seabed sand option with 1V:50H as submerged slope.

The estimation of longshore sediment transport rate induced by breaking wave action was used to obtain the zero transport direction, that is the shoreline orientation for which the average sand movement is zero.

A first estimation using the Komar's formulation was made in the assumption of straight uniform beach. The calculations were made for different shoreline orientations between 10°N and 115°N and for the three wave data (see figure 3). It can be noticed that the differences between the ship and Casablanca visual data curves are relatively little whereas the Tortosa buoy data curve differs much more (this is probably due to

that the differences between the ship and Casablanca visual data curves are relatively little whereas the Tortosa buoy data curve differs much more (this is probably due to the shorter time interval which could be not completely representative of average local climate). It can be observed too, that for the real shoreline orientation (around 60° N) the transport direction is NE-SW, as it could be deduced from sand accumulation north of Cambrils Harbour (that acts as total barrier to sediment transport). A further analysis indicated that sediment transport values estimated with the ship visual data seemed to be overestimated, specially gross transport, so the most representative data appeared to be those obtained from the Casablanca data. In this case the zero transport orientation was approximately 38° N.

The average incident wave direction was also estimated according to

$$D_{av} = \frac{\sum_i D_i \cdot p_i}{\sum_i p_i}$$

where p_i is the presentation probability, obtaining a value $D_{av} = 135,1^\circ$ N, very close to the zero net transport direction. Therefore this was considered as the average wave direction, value very similar to the perpendicular to the shoreline orientation north of Cambrils Harbour, were there is no sand movement.

Figure 3: Net sediment transport

HISTORICAL EVOLUTION

A previous step to alternatives study was the shoreline historical evolution analysis in order to know the situation in the area between Cambrils Harbour and Pixierota delta, and how the existing beaches were formed. Five aerial photographs restitutions corresponding to 1947 (February), 1957 (June), 1965 (August), 1973 (June) and 1977 (March), two aerial photographs (not restituted, for qualitative estimation, June of 1983 and May of 1990) and May 1994 bathymetry were used for the analysis.

Historically the Cambrils and Montroig coast presented a continuous beach nourished by the sand transported by littoral drift in NE-SW direction. The Cambrils Harbour, built in the late thirties, became the main artificial barrier to sediment transport.

The main local sedimentary sources are the existing streams (Alforja, Verge del Camí, Torrent d'en Gené, Riudecanyes and Pixierota) characterized by a discontinuous flow, only important during storms periods. Some of them have created small deltaic formations with coarser material (gravels).

The correspondence between the beaches located south of the harbour and its distance or kilometric point (KP) is

Verge del Camí (V)	100 to 900	L'Ardiaca (A)	2300 to 2800
Llosa (L)	900 to 1800	Riudecanyes (R)	2800 to 3400
Torrent d'en Gené (T)	1800 to 2300	Pixierota (P)	3400 to 5400

The 1947 shoreline included the Cambrils Harbour presence and became the comparison base for the study. In the period 1947-1957 the V, L, T and A beaches eroded in average 2.7, 2.8, 1.8 and 2.1 meters/year respectively, although the first 200 meters of V beach advanced 0.8 m/year. The first 400 meters of R beach eroded 1 m/year whereas its last 200 meters advanced 0.4 m/year. P beach eroded an average of 0.9 m/year. The cause of this behaviour was the interruption of sediment transport by Cambrils Harbour that in the zone had the NE-SW direction: therefore beaches located SW of the port became the main nourish source for the littoral current, so its erosion process started.

Between 1957 and 1965 the generalized erosion process continued with an absolute lower value in the northern half. The average regressions were 0.7, 1.4, 1.1, 1.1 and 1.1 m/year respectively, though the first 350 meters of V beach advanced 1.5 m/year. The first 200 meters of P beach advanced 0.4 m/year whereas the rest eroded in average 1.1 m/year.

In the period 1965-1973 the V, L, T, A and R beaches eroded an average of 1.4, 1.9, 1.9, 1.3 and 0.2 m/year respectively, although the first 300 meters of R beach advanced 0.3 m/year. The first 200 meters of P beach advanced 0.5 m/year whereas the rest eroded 1.0 m/year.

This means that in 1973 the average shoreline erosion for the sector was between 20 and 55 meters in comparison to 1947 (with extreme values of 70 meters). So in 1976 the first stabilization project was performed, consisting in the construction of four detached breakwaters, the enlargement of an existing breakwater and the nourishment of sand to generate tombolos behind the detached breakwaters that stabilized the V, L, and T beaches. Nevertheless the lack of sediment proceeding from the three first beaches which in the past had nourished partially the littoral current accelerated the

erosion process in the rest of beaches: the **A**, **R** and **P** beaches eroded in average 1.7, 3.6 and 1.9 m/year.

Thus, in 1985 a second stabilization project was carried out, with the construction of two additional detached breakwaters to protect the **A** and **R** beaches and six artificial islands between the detached breakwaters and the coastline to optimize its behaviour that had caused important erosions at the center of the protected beaches. Since then the northern beaches shoreline position hasn't varied substantially, indicating its stability, while the Riudecanyes delta and **P** beach have continued to erode with an average of 0.6 and 1.6 meters/year.

All this values are summarised in table 3 whereas all the shoreline evolution is represented in figure 4.

Beach	Verge del Camí		Llosa	Torrent d'en Gené	L'Ardiaca	Riudecanyes		Pixerota
1947-57	+0.8	-2.7	-2.8	-1.8	-2.1	-1.0	+0.4	-0.9

Table 3: Average annual accretion and erosion summary

Figure 4: Shoreline evolution between Cambrils Harbour and Pixerota delta

From shoreline variations the volume of sand mobilized by wave action between Cambrils Harbour and Pixerota delta was estimated in 35,000 m³/year with a direction NE-SW.

ALTERNATIVES STUDY

In the study carried out nine stabilization alternatives were analysed, taking into account flexible solutions (just sand nourishment) and rigid ones (new breakwaters). All of them included the demolition of the existing detached groins until the depth -2.0 and considered a minimum dry beach width of 60 meters (see figure 5). The quarry and sand volumes required and budgets for each alternative are presented in table 4.

- *Alternative 0*: It consisted exclusively in sand contribution between Cambrils Harbour and Pixerota delta. From the historical shoreline evolution study it was estimated that 8 years after nourishment the erosion in the northern beach would be important enough (about 20 m) to consider a periodical sand contribution south of the harbour at a rate of 35,000 m³/year.
- *Alternative 1*: Compared to alternative 0 it included a 142 m long groin at the Pixerota delta to ensure a beach support. The groin was designed short enough to let the sediment pass (and nourish southern beaches as Rifà and Porquerola), so the same periodical contributions that in alternative 0 were necessary.
- *Alternatives 1a, 2, 2a*: Compared to option 1, they incorporated one, two and three groins respectively with the same purpose, being also permeables to sand movement.
- *Alternative 2b*: In this case the groins position was very similar to alternative 2a, but they were much longer and included submerged toes in order to stabilize completely the new three northern beaches (until Riudecanyes delta), as littoral transport was completely interrupted. The southern groin (at Pixerota delta) was the same than in alternatives 0 to 2a. From historical shoreline evolution study it was estimated that 17,500 sand m³/year would be mobilized in direction NE-SW between Riudecanyes and Pixerota deltas and would cross the last groin to nourish partially the southern beaches (Rifà, Porquerola...). Therefore there would exist in those beaches an insufficiency of 17,500 m³/year that should be added periodically south of Pixerota delta to avoid its erosion. Moreover, the sand mobilized along the new Pixerota beach would produce important erosions in the northern part, so it was estimated that 8 years after the regeneration periodical sand contributions (17,500 m³/year) south of Riudecanyes delta would be necessary.

Alternative	0	1	1a	2	2a	2b	3	4	5

Alternative 2b

Alternative 3

Alternative 4

Alternative 5

Figure 5b: Suggested regeneration alternatives

- *Alternatives 3, 4 and 5:* They had the same purpose than the previous alternative but the complete stabilization of the northern beaches was obtained respectively by means of: *a)* two long detached groins and one transversal groin with a submerged toe, *b)* seven detached groins and *c)* six transversal groins between 157 and 214 meters long with submerged toes respectively. In the Pixerotha delta the same groin than in alternative 2b was designed.

SHORELINE EVOLUTION NUMERICAL MODELIZATION

After having presented the nourishment alternatives, the shoreline evolution numerical modelization for three of them (1, 1a and 5) was carried out with the GENESIS v 3.0 program.

A thorough calibration process was done in order to obtain transport coefficients for the area, necessary for long term coastal evolution predictions of the alternatives selected. For calibration the 1947 and 1957 shorelines were used. Different simulations were made by varying the formulation parameters until obtaining a proper adjustment between the numerical values of the longitudinal transport and shoreline evolution in comparison with measured values. This adjustment was obtained for $K_1 = 0.40$ and $K_2 = 0.20$

Long term simulations (10 years) were made in order to estimate the beach evolutive trend for the three alternatives. In figure 6 results for the alternative 1 modelization are presented. It can be noticed the main problem is that the shoreline erodes half of the beach amplitude (won with the nourishment) five years after the regeneration at certain points. Therefore a second prediction including periodical sand contributions was made (figure 7). After some tests it was estimated that a 38,000 m³/year contribution stabilized the beach. This value was very similar to that estimated in the alternatives study. At Riudecanyes and Pixerotha deltas the maximum erosion was limited due to its granulometric characteristics (gravels and boulders). This methodology was repeated for the 1a and 5 alternatives.

CONCLUSIONS

The alternative 1a was selected by the Ministry and a construction detailed design was developed in order to prepare the tendency of the works. Main quantities and budget for the project are:

Tn of quarry demolished from existing groins:	193,000
Tn of quarry for new groins:	81,000
m ³ of sand for initial beach nourishment:	2,616,000
Total budget (M\$):	15.6
Length of beach stabilized:	5.2 km

Figure 7: Alternative 1 shoreline evolution prediction with periodical sand contributions

CHAPTER 370

THE EFFECT OF GRAIN SORTING ON PROFILE STABILITY OF NOURISHED BEACHES

Ram K. Mohan, Ph.D., P.E.¹ and Timothy W. Kana, Ph.D., P.G.²

Abstract

Dean's (1983) model is often used to predict the profile shape and berm width after nourishment. Ideally, if the borrow sediment is identical to native sediment, the adjusted profile will take on the same shape as the existing profile. But, if the borrow sediment is coarser than native, the nourished profile will adjust to a steeper configuration, producing a wider dry beach. If borrow sediments are finer, the fill will adjust to a gentler slope, producing a narrow dry beach. A conceptual model of the effect of grain sorting on nourished profile stability is presented in this paper and verified by comparison with actual beach measurements. The results indicate that the post-nourishment performance can be improved measurably by minor variations in grain size distribution, specifically where a coarse fraction is present (i.e., negative skewness). Fill placement technique and other environmental factors, of course, also impact performance.

Introduction

Numerous researchers have developed empirical models for beach profile stability and equilibrium slopes (Brunn, 1954; Dean, 1983 and 1991; Hands, 1981; and Krumbein and James, 1965). However, these models relate primarily to environmental factors such as wave steepness, wave energy, tide levels, and sea-level changes. Historical data from numerous beaches indicate a trend of increasing slope with grain size and decreasing slope with increasing wave energy (Wiegel, 1964). The general relationship of wave energy, grain size, and beach face slope on sand beaches is illustrated in Figure 1. Empirical data from numerous beaches confirm the trend of increasing slope with grain size and decreasing slope with

increasing wave energy (Wiegel, 1964). Larger grain sizes allow increased percolation of wave uprush and a corresponding decrease in backrush volumes (Waddell, 1973). This results in steeper beach face slopes with increasing grain size.

Intense mixing under breaking waves will further affect the distribution of grain sizes over the shore face. Coarsest material is common at the breakpoint ("step" at the toe of the beach face), and fining will occur in either direction: toward the foredunes and back shore (Mason and Folk, 1958; Fox et al., 1966) and toward the lower foreshore (Swift et al., 1971). Multimodal size distributions across the beach occur in some areas [e.g., Duck, North Carolina (Kana et al., 1980)], but more commonly, a single mode distribution occurs. Data from Swift et al. (1971) revised by Swift (1976) show variations in the modal grain size from the berm to the lower shoreface (Figure 2). Sediment coarsening near the breaker line is reflected in the size distribution in Swift's transect B, as well as by coarse-skewed distributions for this zone of profile in transects A and C. As Swift's data show, sorting is generally good across the shoreface. Dean (1983; 1991) performed extensive work in modeling equilibrium profiles, assuming a uniform grain size distribution across the active profile.

Work and Dean (1991) suggest that varying the grain size across the profile within limited size ranges typical for beaches does not significantly improve the simpler, and often used, profile model (Brunn, 1954; Dean, 1983):

$$h(y) = Ay^{0.667}$$

where h is the water depth at a distance y offshore of the mean water line and A is a scale parameter dependent on sediment characteristics.

Dean's model (Dean, 1983; 1991) has been used to predict the resulting profile shape and berm width (dry beach width) after nourishment. In simple terms, if borrow sediment is identical to the native size distribution, the adjusted profile will take on the same shape as the existing profile. But if the borrow sediment is coarser than native, the nourishment profile will adjust to a steeper configuration, leaving more sand along the back shore (and producing a wider dry beach). If borrow sediments are finer, the fill will adjust to a gentler slope with more material shifting offshore (producing a narrow dry beach) as shown in Figure 3. As a result of these important relationships, the Shore Protection Manual (USACE, 1984) and common practice recommends use of the same or slightly coarser size distribution for nourishment purposes. The authors followed these guidelines for selecting the borrow area for the 1991 Hunting Island nourishment project (CSE, 1991). The borrow area sediments for this project contained slightly coarser sands and the grain size distributions confirmed the negative skewness of the samples produced by the presence of broken shells. Overfill ratios for this project were

favorable in the range 1.10 to 1.20 and the percentage mud was relatively low at 5 percent. Based on these results and the findings of other investigators just outlined, some changes in the profile shape and slope after nourishment would be expected. This change would be due to a general coarsening of the beach sediment, or due to a change in the grain size distributions across the shoreface after nourishment.

A conceptual model of the grain size distribution shift for hydraulic nourishment projects will be presented in this paper and verified by comparison with actual beach measurements taken after the fifth Hunting Island beach nourishment project.

Effect of Method of Placement on Profile Stability

Given a different size distribution of borrow sediments compared to the native sediments, the method of placement would affect the size distribution across the profile. Fill by trucks along intertidal and dry beach is likely to produce uniform admixtures which are gradually eroded along the seaward margin. Back shore fill in this case may initially contain the same distribution of fines as the borrow area. In fact, a legitimate concern with such projects is the possibility of creating hard pan because of the binding effect of muddy sediment in the mixture (Siah et al., 1985; Kana and Jones, 1988). These fines may not erode until large storms occur or more seaward material has shifted downslope through profile adjustment.

For projects built by pipeline dredge, the response will be different. Studies on dredged material disposal (Montgomery, 1978; Palermo et al., 1978) show that coarse material settles closest to the discharge point, whereas the fine material moves further away in the slurry. If the pipeline is placed along the back shore, this leads to sorting down-profile, with coarse material concentrating along the berm and finer material settling downslope. The result will be a systematic shift in the grain size distributions from the back shore to the lower foreshore.

Conceptual Model of Nourished Beach Profile Stability

A conceptual model of the grain size distribution shift for hydraulic nourishment projects is presented in Figure 4. As the material is discharged onto the beach, the coarser fraction settles in the upper beach face. This modifies the pre-nourished grain size frequency curve by shifting it to the left, thereby indicating that the coarser fraction has increased (Figure 4a). The mid-sized fraction moves further down the beach profile and settles along the beach face. Since the grain size distribution of this section of the beach is very similar to the modal size fraction, the pre-nourished grain size frequency curve retains its shape more or less (Figure 4b). The finer fraction moves further down the profile and eventually settles at the lower foreshore. This modifies the pre-nourished

grain size frequency curve by shifting it right, thereby indicating that the finer fraction has increased (Figure 4c).

An important consequence of this is that the upper beach face and berm becomes more stable and wider than would occur if the borrow area sediments matched the native beach. This means that the recreational life may be longer as well because dry-beach width often defines recreational benefits. A negative consequence of such a shift in the grain size distributions is the possibility of accelerated erosion of the lower shoreface.

Comparison with Actual Beach Observations

Comparison of pre-nourished (1990) and post-nourished (1993) grain size distribution curves for the fifth Hunting Island beach nourishment project (Figure 5) show a clear trend of the sediments at the berm becoming coarser after nourishment while those along the beach face becoming finer after nourishment. The 1993 beach samples retained a coarse tail but the proportion of coarse material decreases with distance offshore. The bulk of the sample population is seen to shift toward finer sized down profile and has a smaller modal size than native in the lower shoreface.

Two schemes of statistical analysis were used to compare the native beach (1990) and nourished beach (1993) sediments (Krishna Mohan et al., 1993). In the first method (Method A), coarse sand, very coarse sand and gravel were grouped together to form percent coarse material (i.e., <1.0 Phi). Similarly, very fine sand, silt, and clay were grouped together to form percent fine material (i.e., >3.0 Phi). According to this scheme, the total sediment volume of the borrow area (757,644 cy) consisted of 15.35 percent (116,298 cy) coarse material and 19.17 percent (145,240 cy) fines. While the results of this analysis (see Table 1) show the expected trend of increased coarsening in the berm and increased fines in the lower beach, they do not include a large portion of the fill represented by size classes 1.0 Phi to 3.0 Phi. Therefore, the authors prepared a second analysis whereby the entire sediment grain size range was divided into two broad subdivisions comprising of coarse and fine groups.

In the second method of analysis (Method B), materials with grain sizes less than 2.5 Phi were classified as coarse and those with grain sizes greater than 2.5 Phi were classified as fines. Accordingly, most fine sands, medium sands, coarse sands, very coarse sands and gravel fall into the "coarse" category. Similarly, some fine sands, very fine sands, silts and clays fall into the "fine" category. According to this scheme, the total sediment volume of the borrow area (757,644 cy) is comprised of about 51.44 percent (389,732 cy) coarse material and about 48.56 percent (367,912 cy) fines. Table 2 summarizes the results obtained by this method which clearly supports the propositions of the conceptual model. A close

examination of Table 2 indicates that coarse sediments in the berm increased from 36 percent to about 78 percent of the sample population after nourishment, whereas those at the beach face decreased from 56 percent to about 42 percent of the sample population. These trends correspond to the leftward shift of the upper beach sediments and the rightward shift of the lower beach sediments as predicted by the conceptual model. The grain size statistics in Tables 1 and 2 confirm these trends but also show that two years after nourishment the fill retains a coarse tail and is more graded. Sorting decreased significantly between 1990 prefill and 1993 postfill conditions (about 0.4 Phi to 1.0 Phi, respectively); and skewness became more negative in the 1993 samples. Skewness after nourishment was higher on the beach face than on the berm or lower foreshore.

Table 1. Comparison of native beach (1990) versus nourished beach (1993) composite samples. [Coarse <1.0 ϕ ; fine >3.0 ϕ]

Kana and Andrassy (1993) conducted a volume change analysis for the postnourished beach profile which showed that there has been a rapid loss of sand in the project area. By April 1993, north beach had lost 50 percent of the fill, and south beach had lost almost 80 percent of its fill. The central project area compartment lost about 45 percent of the fill by April 1993. Figure 6 (lower) illustrates the average unit volume beach change since nourishment (February 1991) as a function of contour interval within the project area. The dry beach to MHW (+10 ft to +3.2 ft NGVD) within the project area retained 70 percent of the fill through April 1993. The intertidal beach (MHW to MLW; ie., +3.2 ft to -2.2 ft NGVD) retained about 45 percent of the fill two years later. In contrast, the underwater lenses (-2.2 ft to -12.0 ft NGVD) retained only 27 percent of the fill by April 1993. A close review of these results reveals an interesting factor: the loss rate for the upper beach lenses was much lower. These results support the predictions of the conceptual model that more fill is retained at the berm than on the lower beach.

Table 2. Comparison of native beach (1990) versus nourished beach (1993) composite samples. [Coarse 2.5ϕ; fine >math>2.5\phi</math>]

Location	Mean Grain Size		%Coarse		%Fine

Note:UBF=Upper Beach Face; LBF=Lower Beach Face; LSF=Lower Shore Face.

Comparison with Previous Projects

Unpublished profile data following the December 1968 and December 1971 federal projects at Hunting Island were used to develop an estimate of the average fill volumes remaining (Figure 6 top and middle). The reported mean grain sizes prior to nourishment are given in Tabel 3.

Table 3. Mean Grain Size of Native Beach and Borrow Area Sediments.

Project Year	Native Beach Grain Size (mm)	Borrow Area Grain Size (mm)
1968	0.16	0.18
1971	0.16-0.21	0.18
1975	--	--
1980	0.14-0.20	--
1991	0.20	0.20-0.23

A review of Figure 6 indicates that fill losses have been exceedingly rapid after all projects. However, the proportion of fill remaining above low water has been many times higher following the 1991 nourishment. In fact, upwards of 75% of the fill remaining following the 1991 project has been situated above the low water contour. In contrast, most of the fill above low water was lost soon after the 1968 and 1971 projects.

Conclusions

A conceptual model of profile stability for beach nourishment projects was presented in this paper. The model predicts a trend of sediments in the upper beach becoming coarser by means of selective sorting at the discharge point (hydraulic nourishment) along the back shore, while those at the lower beach become finer after nourishment. While the conceptual model of nourished profile stability is not quantitative, it can be used as a basis for predicting trends and formulating alternatives. Comparison with actual beach observations support this prediction since the actual (observed) data showed the berm sediments becoming measurably coarser in both mean grain size and degree of grading (i.e., poor sorting). Comparative profiles and a detailed volume change analysis revealed that the dry beach retained 70 percent of its fill whereas the underwater lenses retained only 27 percent of their fill after two years. This further supports the idea that use of coarser borrow material will improve longevity of the upper beach. Profiles, in this case, became steeper after nourishment. In conclusion, three factors become important in controlling the postnourishment grain size distribution and profile stability (in order): (i) *Grain size distribution*: This fundamentally controls the overall slope and distribution as predicted by equilibrium profile theory. Basic engineering logic suggests increasing coarse material tends to improve beach profile stability. The finer fraction washes out faster, thereby decreasing longevity and, hence, should be kept to a bare minimum whenever possible; (ii) *Placement of fill material*: The most common method of placement of fill material in a nourishment project is by the use of pipelines. If discharge is along the back shore, coarse material will settle near the berm and fines will shift downslope with the slurry. This type of placement improves berm longevity. If the discharge point is along the lower foreshore (i.e., profile nourishment, Brunn, 1988), coarse material will have less chance of concentrating on the berm; and, (iii) *Environmental factors*: These include the magnitude and interrelationship of the following variables: background erosion rates, shoreline morphology, waves, currents, tides, and storm frequency. These factors produce site-specific responses and are independent variables in nourishment design.

CHAPTER 371

The Use of Data Assimilation to Improve Wave Hindcast Results

Jon M. Hubertz¹

Abstract

A sequential data assimilation scheme was used to assimilate wind speed and direction measured at land and buoy platforms into a modeled wind field over the Gulf of Mexico during January 1996. The resulting wind field is more accurate than the modeled field alone for locations near the coast where winds are affected locally by transition from land to water. The assimilated winds result in improved hindcasts of wave height over modeled winds alone when compared to wave measurements from buoys.

Introduction

Data assimilation is the process of incorporating observations of a dynamic system into a model of the system. In the context of wave modeling, this is the process of incorporating observed wind and/or wave information into a wave model or the results from a wave model. At this stage of wave model development, the most significant and timely improvement in the accuracy of model results lies in the combination of measurements and model results.

The Wave Information Study (WIS) at the Coastal and Hydraulics Laboratory (CHL) has developed and is applying a WIS Data Assimilation System (WDAS) to make optimal use of data collected under the Coastal Field Data Collection Program at CHL. The objective is to improve the accuracy of hindcast results, especially in high energy events where available wind fields and/or present wave models are sometimes not sufficiently accurate.

¹Coastal and Hydraulics Laboratory, U.S. Army Engineer Waterways Experiment Station, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199

Accuracy of Present Wave Models

Cardone et al. (1996) conclude that first, second, and third generation wave models presently in use give equivalent results when used to hindcast extreme wave heights in two severe storms off the U.S. East Coast. Their conclusion is based on comparison of model results to measurements from nine buoys. They also note that all models underestimate the highest waves over 12 m. Tracy and Cialone (1996) provide statistics from comparison of results from the same second generation model used by Cardone et al. to 16 buoys off the U.S. East Coast for one year, 1994. They conclude there is little bias in wave height and peak period results from the model compared to measurements, and root mean square differences are about 0.5 m and 2 sec, respectively. Until a significant improvement in wave modeling emerges, the most expedient approach to improved accuracy is the use of data assimilation in wave hindcasting.

Assimilation Techniques

All data assimilation techniques attempt to improve the results of a model by using some method to minimize the difference between model results and a set of observations of model variables, spaced closely in location and time to model values and considered more accurate than model values. Data assimilation approaches can be grouped into two general categories. One is referred to as sequential and the other variational.

Sequential techniques use observations to improve model results only at the time the observations occur; that is, current observations are discarded as soon as assimilated. Their success increases with the number of observations in space each time data are assimilated. A number of different approaches are included in the sequential method. These are, in ascending order of complexity, direct insertion, blending, nudging, optimal interpolation, successive corrections, and Kalman filtering.

The adjoint method is a commonly used variational approach. It considers a set of observations in space over a certain time interval which by ergodicity is equivalent to a distribution in probability space. Again, the objective is to minimize the difference between model results and observations or a cost function. This is done by solving a set of equations consisting of the model equations and adjoint equations. The adjoint equations are formed by differentiating the cost functions with respect to a control variable and setting the result equal to zero. This differentiation can be very difficult due to the dynamical coupling between state variables in the cost function and control variables, for example, wave height and wind speed, respectively.

Hubertz, Thompson, and Wang (1996) provide a summary of recent studies which employed these techniques to improve wind, wave, and water level/current model results. The WDAS employs a sequential technique similar to optimal interpolation which allows assimilation of vector or scalar measurements from random points on a

latitude, longitude grid with model data and interpolation to a target grid using minimization of a quadratic form to provide fit and smoothness.

WIS Data Assimilation System

Application of the system consists of three steps. First, available measurements pass through a quality control filter to ensure only valid data are used and they are consistent in characteristics, e.g., units, conventions, elevation, etc. Second, a target grid is specified upon which the results of the assimilation process will be available for use. Randomly spaced measurements and/or data from a model are interpolated to this target grid. Finally, a set of equations (one for each target grid point) is solved which minimizes the difference between input data and final values on the target grid. The equations allow a weight for data type if one type of data is considered more important, and a smoothing weight on a derivative constraint to control smoothness of the final field. The equations to be solved have the form

$$w_d(F_d - F)^2 + \beta^2[(\delta F/\delta x)^2 + (\delta F/\delta y)^2] = \text{Minimum}$$

where F refers to a vector or scalar variable, d to input data, w a weight, β a smoothing parameter, δ the derivative operator, and x , y the longitudinal and latitudinal directions, respectively. The equations are solved with a Gauss-Seidel iteration scheme. Details of the system are provided by Oceanweather Inc. (1996).

Results - Time Series at a Point

Wind speed and direction from buoys and coastal land stations in the Gulf of Mexico were assimilated into an approximate 1 degree latitude, longitude background wind field from the National Meteorological Center (NMC) during January 1996. Figure 1 shows the locations of measured and modeled wind data. Measured data locations are indicated by either the alphabetic Coastal-Marine Automated Network (CMAN) designation or the National Data Buoy Center (NDBC) numeric identifier. Modeled National Center for Environmental Prediction (NCEP) wind results are indicated by the meteorological wind barb symbols.

Measured data are available every hour while NCEP data are available at a 6-hour interval. The NCEP data are interpolated in time to every hour. NCEP values are removed within a specified radius of measured values to give added influence to the measured data. Figure 2 provides an example of the difference between modeled NCEP data, measured data from the buoy and the assimilation product WDAS using both NCEP modeled and buoy data at the grid point closest to the buoy. The WDAS and buoy data are almost identical reflecting the influence of the assimilation process at the grid point closest to the buoy. The NCEP model data depart from the other two most

notably at times of higher wind speeds, which in these cases are due to fronts moving offshore. These are at approximately hours 175, 275, 450, and 650 in Figure 2.

Figure 1. Locations of Measured and Modeled Wind Data

Wind fields from NCEP and from the assimilation process were input to the WISWAVE model to hindcast wave conditions over the Gulf of Mexico during January 1996. The hindcast results were then compared to wave measurements made at the buoys shown in Figure 1. Hindcast wave height results at the grid point closest to the buoy and measured values at the buoy are compared in Figure 3. Wave heights are overestimated at the same times wind speeds are overestimated, the NCEP winds being higher with respect to hindcast values using assimilation with measurements at the buoy. The first 50-75 hours in Figure 3 represent the “spin-up” of the model and should not be used to compare differences in wind input. At other times there is little difference between using NCEP winds and the assimilated wind product.

In general there was little improvement in hindcast wave height and peak period using the assimilated winds over using the NCEP winds alone, as measured by monthly values of bias and root mean square differences at the eight buoys recording wave information during January 1996. However, these monthly statistics mask cases where

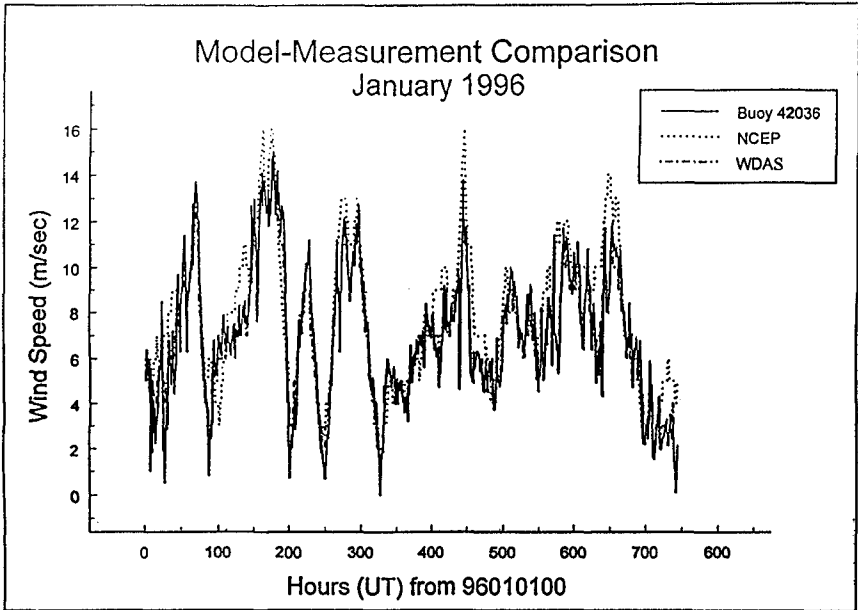

Figure 2. Wind Speed Versus Time at Buoy 42036 for Measured, Modeled, and Assimilated Data

Figure 3. Wave Height Versus Time from WISWAVE Model Using Wind Input from NCEP Model and Winds from WDAS Compared to Measurements from Buoy

the NCEP winds did not accurately represent local wind speeds and directions. In these cases, improved hindcast values of wave height and peak period were obtained.

Results - Wave Height on Grid at One Time

Next, differences in hindcast wave heights over the entire grid at one time are shown for the case of using NCEP winds alone and using the product of the assimilation process. Figure 4 shows the winds over the Gulf of Mexico at 0100 UT on January 28, 1996. This corresponds to hour 650 on the previous time series plots. The contour interval is 1 m/s. Wind speed is relatively high (10 m/s) and offshore along the northwest coast of Florida. It was in this area assimilated winds were lower than NCEP winds (Figure 2) and resulted in lower wave heights of about 1 m (Figure 3).

Figure 4. NCEP Wind Field Over Gulf of Mexico at 0100 UT, January 28, 1996

The difference in hindcast wave height using NCEP winds as input and using the assimilated winds as input over the whole Gulf at hour 650 is shown in Figure 5. The contour interval is 0.4 m. Most of the difference is in the northeast Gulf where the land/water boundary has an influence on offshore winds. These differences illustrate the spatial effect of assimilating data when the NCEP winds do not accurately model local

conditions. Note, that in other areas differences are small indicating there is little effect of using assimilation. In these areas at this time, the NCEP winds provide accurate wave results.

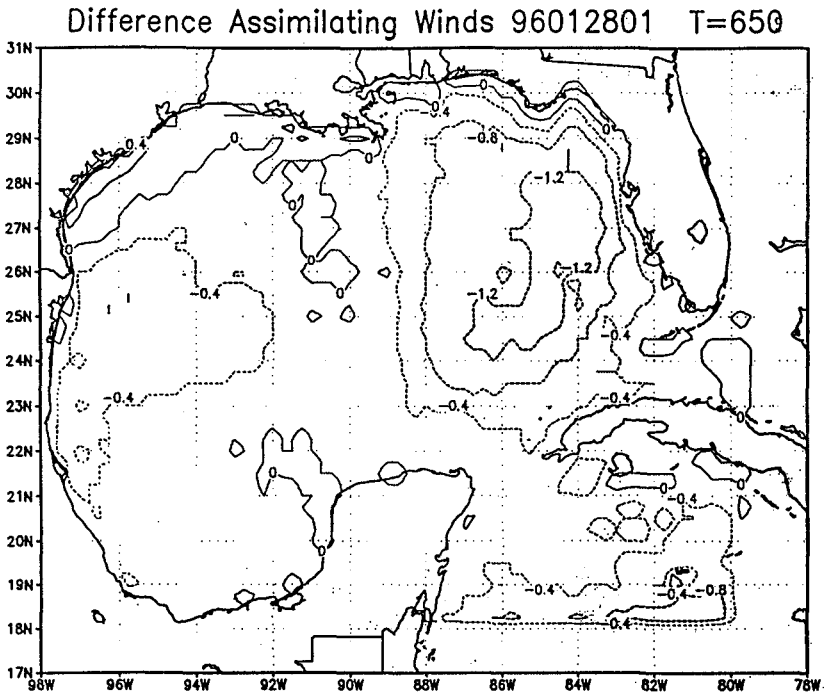

Figure 5. Hindcast Wave Heights Using NCEP Winds as Input Minus Hindcast Wave Heights Using Assimilation Winds as Input (Contour Interval 0.4)

The above applications assume correcting a wind field will lead to acceptable wave model results. If this is not the case, then the wave model is deficient, and accurate hindcast results can only be obtained by fixing the model or modifying the results by assimilating measured wave data. The WIS system can also be used in this mode using either scalar input such as wave height and peak period or vector input from wave height and direction values.

This approach can also be extended to modifying wave spectra. Typically, a WIS hindcast spectra has 20 frequency bands. For a given wave model grid over a geographic region at a given time, one has 20 stacked grids of energy densities representing the energy spectrum at each grid point. Measured energy density corresponding to model bands can be assimilated over the grid at each frequency level. This amounts to applying the system 20 times in a scalar mode using energy density. The resulting volume of data

accurately reproduces the measured spectrum near the measurement point and spreads to surrounding points based on the value of a smoothing parameter.

Conclusions

At this time, first, second, and third generation wave models in use give equally good or bad results. Until advances in the theories of wave models are made, the most expedient improvement in the accuracy of wave hindcast results lies in the use of available measurements to either improve wind input or modeled wave results through data assimilation. Since accurate wave hindcast results are critically dependent on accurate winds, a system has been developed to improve hindcast wind input. The system was tested in the Gulf of Mexico using one month of modeled hindcast winds and available wind measurements from land and buoy platforms.

The system was successful in improving hindcast wave heights for certain times and locations dependent on the land/water boundary and weather systems. Improvements of up to 1 m in wave height were realized. The system will be implemented in the WIS nowcast procedure in a test mode in 1997.

CHAPTER 372

Grain-size influence on sand transport in oscillatory sheet flow

C. Marjolein Janssen¹, Jan S. Ribberink²

Abstract

Experimental investigations (Ribberink & Chen, 1993; Ribberink & Al-Salem, 1994; Katopodi et al., 1994) indicated that the grain diameter is an important parameter for the prediction of the *net* (time-averaged) transport rates in oscillatory sheet flow. As only little is known about the influence of the grain diameter on the net transport rates and the transport mechanisms, new experiments with fine sand ($D_{50} = 0.13$ mm) were carried out in the Large Oscillating Water Tunnel (LOWT) of Delft Hydraulics. Since 1992 the LOWT is equipped with a recirculation system, such that experiments with combined wave-current flow can be performed at full scale (1:1).

Several existing transport models are based on the assumption that the transport can be described in a quasi-steady way (see Janssen, 1995). In order to investigate whether or not this assumption is valid, both a 'quasi-steady' (Baillard, 1981) and a 'semi-unsteady' (Dibajnia & Watanabe, 1992) transport model are verified with existing and new experimental data.

Description of two existing sand transport models

a) Baillard (1981)

The first model described here, is the one developed by Baillard (1981), which is one of the 'quasi-steady' models. These models are based on the assumption that the transport rates under oscillatory flow can be described in a quasi-steady

e-mail: j.s.ribberink@sms.utwente.nl

way, which means that it is assumed that the sand transport reacts immediately to changes in flow condition. Therefore a direct relation exists between the instantaneous near-bed free stream velocity or instantaneous bed shear stress and the instantaneous transport rate. The assumption of quasi-steadiness is often applied in sheet flow conditions, where the majority of the sand transport takes place in a thin layer close to the bed and a quick sediment response to the oscillatory flow can be expected (see Ribberink et al., 1994).

The model of Bailard consists of a bed-load and a suspended-load part. Both parts contain a term which depends on the bed slope. Because the model is compared with measurements of sand transport above a horizontal bed, these terms become zero. In order to calculate the *net* sand transport rate, the equation is averaged over the wave-period, resulting in:

$$\langle q_s \rangle = \frac{\rho_w c_f}{(\rho_s - \rho_w) g} \frac{\varepsilon_b}{\tan\varphi} \langle u^3 \rangle + \frac{\rho_w c_f}{(\rho_s - \rho_w) g} \frac{\varepsilon_s}{w_s} \langle |u|^3 u \rangle \quad (1)$$

Where $\langle \dots \rangle$ means time-averaging over the wave period, q_s is the sand transport rate per unit width (m^2/s), ρ_w and ρ_s are the density of the water and the sediment (kg/m^3), c_f is a friction coefficient (-), g is the gravity acceleration (m/s^2), ε_b and ε_s are efficiency factors for the bed-load and the suspended-load transport (-), $\tan\varphi$ is the tangent of the dynamic friction angle (-), w_s is the settling velocity of the sediment (m/s) and u is the horizontal near-bed velocity, directly above the wave boundary layer (m/s).

Because of the assumption of quasi-steadiness *and* the fact that q_s is related to the third- and fourth-power velocity moment, the *net* sand transport rate, predicted by this model, will always be in the direction of the largest velocity, i.e. under real asymmetric waves, generally this will be in the onshore direction.

b) Dibajnia & Watanabe (1992)

Dibajnia & Watanabe developed a 'semi-unsteady' model, which is able to take into account unsteady effects, like the time-lag between velocity and concentration, although it does not contain fully unsteady equations. Considering the amount of sand which is entrained during a positive half wave cycle, the model determines the part which will be transported directly by the positive half cycle and the part that will still be in suspension as the flow reverses and will therefore be transported by the negative velocity, during the successive half cycle. The relative magnitude of these parameters depends on the ratio of the fall time of the particles (determined by their settling velocity and the height to which the particles are suspended) and the period of the positive half wave cycle. Of course the same is valid for the negative half cycle. The net sediment transport rate is the difference between the two contributions in positive and the two contributions in negative direction. For the exact formulations, the reader is referred to the original paper.

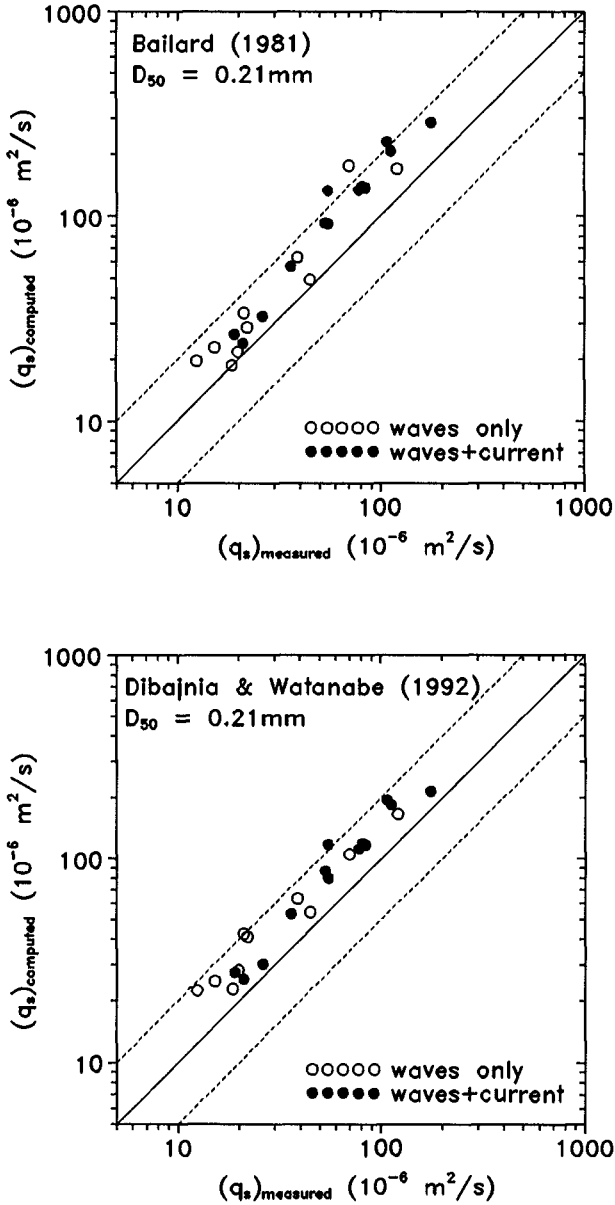

Figure 1: Comparison between measured and calculated net transport rates for sand with $D_{50} = 0.21 \text{ mm}$. Model results of Bailard (1981) and Dibajnia & Watanabe (1992).

Comparison between two models and existing data

In order to verify the two transport models and to check whether the assumption of quasi-steadiness is always valid in sheet flow conditions, predicted net transport rates were compared with measurements, performed in the Large Oscillating Water Tunnel (LOWT) of Delft Hydraulics. This facility enables experiments to be performed at full scale and is able to generate oscillatory flows with net currents superimposed. Net transport rates are derived from a mass-conservation technique by measuring the bed level before and after a test and determining the weight of sand collected during the test in the sand traps. (For a more detailed description see the following pages).

Fig.1 shows the measured and calculated transport rates on log-log scale for the models of Bailard and Dibajnia & Watanabe, respectively. All data are for sand with a mean diameter $D_{50} = 0.21$ mm (settling velocity $w_s = 0.026$ m/s) and both experiments with purely oscillatory flow (Ribberink & Al-Salem, 1994) and combined wave-current flow (Ribberink et al., 1994) are included. All conditions were in the sheet-flow regime. For the model of Bailard the following values of the input parameters are used: $\varepsilon_b = 0.1$, $\varepsilon_s = 0.02$, $\tan\varphi = 0.625$. For the case of purely oscillatory flow c_f is calculated as the friction factor of Jonsson, slightly modified by Swart (1974) with $k_s = D_{50}$. For the case of combined wave-current flow, c_f is calculated as a combined wave-current flow friction factor, developed by Ribberink & Van Rijn and described by Koelewijn (1994). The model of Dibajnia & Watanabe does not require any further input parameters. The solid lines represent perfect agreement between the predicted and the measured transport rates, while the dashed lines represent a factor two difference. It is clear that both models perform similarly, with almost all predictions within a factor two of the measurements. Apparently, the assumption of quasi-steadiness is reasonable in this case of sheet flow conditions and relatively coarse sand.

However, the situation is completely different for transport rates of sand with a mean grain diameter D_{50} of 0.13 mm. Fig.2 shows a comparison between the experimental data (Ribberink & Chen, 1993) and the predictions by the two models. The test conditions of these experiments concerned purely oscillatory, asymmetric (2nd-order Stokes) flow. It must be emphasized that again all test conditions were in the sheet-flow regime. The experiments show the surprising behaviour of a negative net transport rate for increasing root-mean-square velocity (U_{rms}), corresponding to increasing oscillatory velocities. This means that for large oscillatory velocities the *net* sand transport rate is opposite to the direction of the largest velocity (i.e. in 'offshore' direction). Because of the assumption of quasi-steadiness, the model of Bailard is not capable to predict this behaviour and apparently, the assumption of quasi-steadiness is not valid for this fine sand.

In contrast to the model of Bailard, the model of Dibajnia & Watanabe predicts decreasing and even negative net transport rates for increasing oscillatory velocities. This is caused by the part of the entrained sand which remains in suspension and is transported in opposite direction. Due to the asymmetry of the

flow this results in negative net transport rates. Although the trend shown in the data is followed much better by the model of Dibajnia & Watanabe, the magnitudes are still different.

Figure 2: Net transport rates as a function of the root-mean-square velocity (U_{rms}). Measurements by Ribberink & Chen (1993), model results of Bailard (1981) and Dibajnia & Watanabe (1992)

New experiments

From the previous section it is clear that the grain diameter is an important parameter in the prediction of the net transport rate. Apparently, the assumption of quasi-steadiness is not valid in the case of sand transport of very fine sand in purely oscillatory sheet flow conditions. In order to investigate the influence of the grain diameter on the net transport rates and the transport mechanisms in *combined wave-current flow*, a new set of experiments with fine sand ($D_{50} = 0.13$ mm) was performed in the LOWT of Delft Hydraulics. The experimental research was carried out between October 1995 and January 1996 and consisted of two parts. In the first part, net sand transport rates were measured and in the second part, detailed time-dependent measurements of velocity and concentration were performed. This paper focuses on the first part of the experiments, i.e. the net transport measurements.

i) The Large Oscillating Water Tunnel

Figure 3: General outline of the Large Oscillating Water Tunnel of Delft Hydraulics.

Fig.3 shows a general outline of the LOWT. The tunnel has the shape of a vertical U-tube with a rectangular horizontal test section and two cylindrical risers on either end. The desired oscillatory water motion inside the test section is imposed by a steel piston in one of the risers. The other riser is open to the atmosphere. The test section is 14 m long, 1.1 m high and 0.3 m wide and is provided with flow straighteners on either end. A 0.3 m thick sand bed can be brought into the test section, leaving 0.8 m height for the flow above the bed. Two sand traps are located underneath the cylindrical risers.

The maximum piston amplitude is 0.75 m, which means a maximum semi-ex-cursion length of the water particles in the test section of 2.45 m. The range of velocity amplitudes is 0.2 - 1.8 m/s and the range of oscillation periods is 4 - 15 seconds. It is possible to generate purely sinusoidal, regular asymmetric and irregular oscillatory motions with the piston.

In 1992 the tunnel was extended with a recirculating flow system connected to the cylindrical risers, so that a steady current can be superimposed onto the oscillatory motion. The maximum superimposed current velocity in the test section of the tunnel is 0.5 m/s. The recirculating flow system is also provided with a sand trap, consisting of a 12 m long pipe with a diameter of 1.2 m. The trap was designed for trapping 90% of the suspended sediments (minimum grain size 100 microns) at maximum flow discharge.

ii) Measurement procedure

During these experiments net transport rates as well as near-bed velocities were measured. The velocities were measured at 10 cm above the bed, using a 2D forward scatter Laser-Doppler system, developed by Delft Hydraulics.

Net transport rates were derived from a mass-conservation technique. Therefore the bed level along the test section is measured before and after the test and the weight of sand, collected in the traps during the test, is determined.

The bed levels in earlier experiments were measured by hand. However, for the present experiments a bed level profiling system (BLPS) was built. The BLPS consists of three bed profilers, mounted on a measurement carriage, which can be moved along the test section. The bed level measurement technique is based on a conductivity measurement. The profilers measure the bed level every cm along the test section, accurate to about 0.4 mm in the vertical. From the difference between the bed level before and after a test, the total volume of sand, eroded from the test section (including pores), can be determined. This sand is collected in the three sandtraps and weighed under water, giving the total volume (without pores).

The transport rate in the middle undisturbed part of the test section can now be calculated by solving the continuity equation for the sediment over the test section, starting either from the left- or from the right-hand side, resulting in two estimates of the net transport rates.

iii) Test conditions

Table 1 Test conditions present experiments

Condition	T (s)	U_m (m/s)	U_a (m/s)
H2	7.2	0.23	0.70
H3	7.2	0.23	0.95
H4	7.2	0.23	1.10
H5	7.2	0.23	1.30
H6	7.2	0.23	1.47
H7	7.2	0.44	0.50
H8	7.2	0.44	0.70
H9	7.2	0.44	0.95
H24	4.0	0.23	0.70
H4S	4.0	0.23	1.10
H12	12.0	0.23	0.70
H12S	12.0	0.23	1.10

The test conditions of the present experiments consisted of combinations of sinusoidal oscillatory flow, with varying amplitudes of the velocity (U_a) and varying oscillation periods (T), superimposed onto varying net current velocities (U_m). Again all test conditions are in the sheet-flow regime. The test conditions

are summarized in Table 1, where the italic typed conditions represent the two test conditions which are equal to the test conditions of earlier experiments with coarser sand (Katopodi et al., 1994).

Results of new experiments in comparison with model predictions

Fig.4 shows the measured net transport rates of the new experiments ($D_{50} = 0.13$ mm) in comparison with the predictions of the two models. The results for a constant net current velocity (U_m) of 0.23 m/s and a constant wave period (T) of 7.2 s are shown as a function of the amplitude of the oscillatory velocity (U_a).

Because of the assumption of quasi-steadiness in the model of Bailard, this model predicts strongly increasing net transport rates for increasing oscillatory velocities. The measured net transport rates have much smaller values and show a weaker increase for increasing oscillatory velocities. The predictions of the model of Dibajnia & Watanabe are much closer to the measured values. However, a more detailed comparison (Fig.4b) shows that this model predicts *decreasing* transport rates for amplitudes of the oscillatory velocity larger than about 1.1 m/s. This is again caused by the unsteady effects. Although the increase in the measured net transport rates is much smaller than predicted by the quasi-steady model, the measurements do not yet show a decrease in transport rate. Thus apparently the unsteady effects are smaller than predicted by the model of Dibajnia & Watanabe. This is opposite to the situation for purely oscillatory flow, where the measurements showed a larger unsteady effect, than predicted by the model of Dibajnia & Watanabe (see Fig.2).

Fig.5 shows a comparison between the measured and calculated net transport rates as a function of the wave period (T), for a constant amplitude of the oscillatory velocity (U_a) of 1.1 m/s and a constant net current velocity (U_m) of 0.23 m/s. In the quasi-steady model of Bailard the wave period only has an effect on the friction factor. Increasing wave periods lead to decreasing friction factors, resulting in decreasing sand transport rates, as shown in Fig.5. However, the measurements show decreasing net transport rates for *decreasing* oscillation periods. The same trend is predicted by the model of Dibajnia & Watanabe. It is caused by the fact that the unsteady effects become relatively more important for decreasing wave periods.

Grain-size influence on net sand transport rates in sheet flow conditions.

The influence of the grain size can be analyzed by just comparing the experimental data and by analyzing the performance of both models for all data of fine and coarser sand. In Fig.6 the net sand transport rates are plotted as a function of the third power velocity moment for all experiments in combined wave-current flow (Ribberink et al., 1994 and present tests). From this figure it is clear that the net transport rates of fine sand are smaller than those of coarser sand. This is completely opposite to the behaviour in uni-directional steady flow, where finer sediments would result in larger transport rates. The decrease in net transport rate

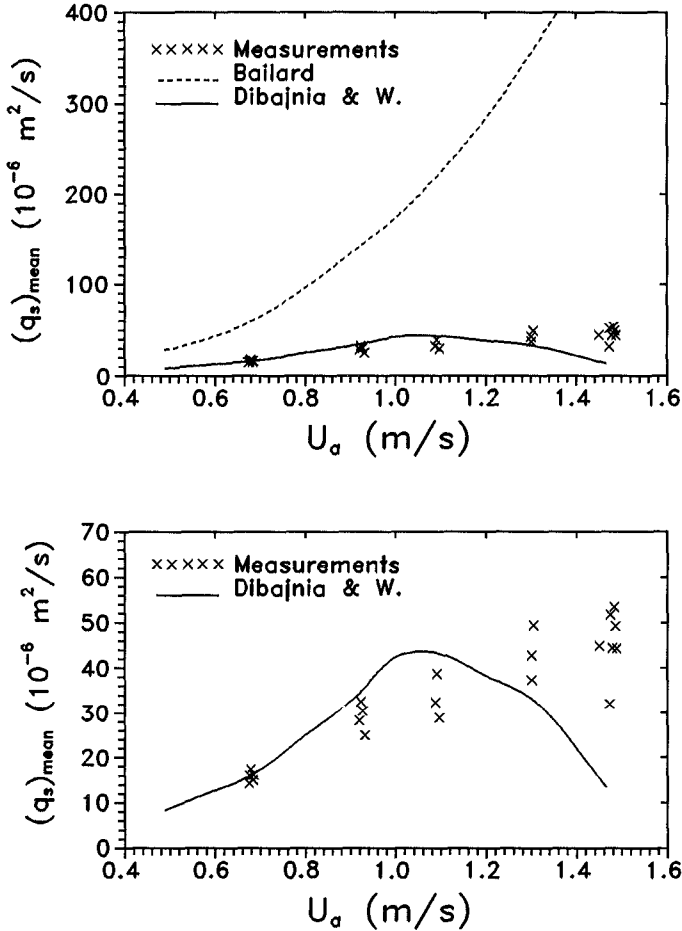

Figure 4: Net transport rates as a function of the amplitude of the oscillatory velocity U_a , for $U_m = 0.23$ m/s and $T = 7.2$ s. Present tests compared with model results of Bailard (1981) and Dibajnia & Watanabe (1992).

is caused by the unsteadiness, as the amount of sand in motion (or gross transport rate) will be larger for the finer sand. However, part of the sand remains suspended and is transported in opposite direction, resulting in smaller net transport rates.

Fig.7 is similar to Fig.1, but now also includes the data for fine sand. The two tests with negative transport rates in purely oscillatory flow (see Fig.2) are left out, because they cannot be plotted on a log scale. As observed before, both

Figure 5: Net transport rates as a function of the oscillation period T, for $U_m = 0.23$ m/s and $U_a = 1.08$ m/s. Present tests compared with model results of Bailard (1981) and Dibajnia & Watanabe (1992).

models show a similar kind of agreement with the experimental data for sand with a mean grain diameter of 0.21 mm. However, the 'quasi-steady' model of Bailard largely overpredicts the measured transport rates of fine sand. Due to the inclusion of unsteady effects in the model of Dibajnia & Watanabe, predictions by the latter model for fine sand are much better. This confirms the fact, already observed for the purely oscillatory flow data, that even in sheet flow conditions the assumption of quasi-steadiness of the transport rates is not always valid for fine sand.

Analysis of unsteady behaviour of net transport rate of fine sand

In order to analyze the unsteady behaviour of the transport rate of fine sand, use is made of the results from the second part of the experiments (time-dependent measurements of velocity and concentration). The net sand transport rate can be calculated from:

$$\langle q_s \rangle = \int_0^h \langle u(z,t) * c(z,t) \rangle dz = \int_0^h \langle \phi(z,t) \rangle dz \tag{2}$$

Figure 6: Measured net transport rates for fine ($D_{50} = 0.13$ mm) and coarse ($D_{50} = 0.21$ mm) sand as a function of the third-power velocity moment.

Where c is the sediment concentration (m^3/m^3), φ is the sediment flux (m/s), z is the height above the bed (m), t is time (s) and h is the water depth (m).

Because both the velocity and concentration consist of a time-averaged ($\langle \dots \rangle$) and an oscillatory (\sim) component, the time-averaged sediment flux $\langle \varphi(z) \rangle$ can be split up into a current-related $\langle \varphi_c(z) \rangle$ and a wave-related $\langle \varphi_w(z) \rangle$ contribution, as follows:

$$\langle \mathbf{u}(z, t) * c(z, t) \rangle = \langle \mathbf{u}(z) \rangle * \langle c(z) \rangle + \langle \tilde{\mathbf{u}}(z, t) * \tilde{c}(z, t) \rangle = \langle \varphi_c \rangle + \langle \varphi_w \rangle \quad (3)$$

The vertical distributions of these two contributions, as well as the total (time-averaged) flux profile, are shown in Fig.8 (for more detail about the time-dependent measurements, see Janssen et al., 1996). The results are for test condition H6 (see Table 1). It is clear that the total net transport rate (derived by integrating the total flux profile over the height), will be positive (i.e. in the direction of the net current). Of course the current-related contribution is positive everywhere, because it is just the product of the time-averaged velocity (which is positive by definition, because it is the velocity of the net current) and the time-averaged concentration. However, the wave-related contribution has a value which is of the same order of magnitude, but in opposite direction (against the net current). This must be caused by a time-lag effect between the oscillatory component of the concentration and the oscillatory velocity. Because of this negative wave-related transport rate, the total net transport rate will be much smaller than

Figure 7: Comparison between measured and calculated net transport rates for fine sand ($D_{50} = 0.13$ mm) and coarse sand ($D_{50} = 0.21$ mm). Model results of Bailard (1981) and Dibajnia & Watanabe (1992).

predicted by the 'quasi-steady' model, which does not include this effect. Additionally, the total net transport rate will be smaller than in the case of coarser sand, where the larger particles result in a smaller time-lag between concentration and velocity and therefore less negative wave-related transport rates. So apparently, the behaviour, as present in the concept of the model of Dibajnia & Watanabe is not only occurring in rippled bed conditions, but also occurs in sheet flow conditions with fine sand.

Conclusions

Modelling the sand transport in a quasi-steady way leads to the following predictions for net sand transport rates: i) increasing net transport rates for decreasing grain diameter, ii) largely increasing net transport rates for increasing oscillatory velocities and iii) increasing net transport rates for decreasing wave periods. However, experimental data of net transport rates in oscillatory sheet flow show the following results:

- *Smaller* net transport rates for 0.13 mm sand than for 0.21 mm sand.
- A much *weaker increase* in net transport rates for 0.13 mm sand than for 0.21 mm sand, with increasing oscillatory velocities.
- *Decreasing* net transport rates with decreasing wave periods for sand with $D_{50} = 0.13$ mm and conditions with sufficiently large oscillatory velocities.

Figure 8: Vertical distribution of time-averaged total, current- and wave-related sediment flux, determined from time-dependent velocity and concentration measurements (experiment H6).

All these 'unsteady effects' are caused by a time-lag between velocity and concentration, resulting in negative wave-related transport rates and therefore smaller total net transport rates than without these effects. Apparently, even in sheet flow conditions, the net sand transport rate cannot always be described in a quasi-steady way. Obviously, the quasi-steady model of Bailard (1981) is not able to predict these phenomena. The 'semi-unsteady' model of Dibajnia & Watanabe (1992) is at least able to predict the behaviour qualitatively. However, this model underpredicts the unsteady effects in purely oscillatory asymmetric flow and overpredicts the unsteady effects in the case of combined wave-current flow (compare Fig.2 and Fig.4b).

Acknowledgements

The authors want to thank the Dutch Ministry of Transport and Public Works (RIKZ), for the financial support to perform the experiments. The help of Mr. W.N. Hassan and Mr. R.J. v.d. Wal during the experiments and the data-processing is greatly appreciated. The first author also wants to thank the Technology Foundation (STW) for their financial support during the complete research project.

CHAPTER 373

Cross-shore sediment transport mechanisms in the surfzone on a timescale of months to years

Klaas T. Houwman¹ and Gerben Ruessink¹

Abstract

The relevance of several cross-shore sediment transport mechanisms on a timescale of months to years was studied. Data from a large measuring campaign carried out in the outer surfzone of a barred surfzone was used to calculate sediment fluxes. The transport rates were calculated using the measured near bed velocities and sediment concentrations, and two sediment transport models. Both fluxes and the transport rates are only significant during breaking waves. The high-frequency fluxes/transportations are onshore directed, the mean fluxes/transportations are offshore directed, and the low frequency waves also give offshore directed fluxes/transportations. Taking into account the frequency of occurrence of the conditions, the breaking wave conditions turned out to be the most important for the cross-shore sediment transport on a timescale of a year. The cross-shore sediment transport is a delicate balance between the onshore directed high frequency term and the offshore directed mean term. Therefore the smaller terms, like the low frequency term and the bedload term, may still be of importance to the net sediment transport.

Introduction

In the surfzone mean currents and high- and low frequency waves are responsible for sediment transport. Most field experiments presented in literature have focussed a typical time scale of a single storm-event. It is therefore unknown whether sediment transport on the scale of months to years is dominated by infrequent high energy conditions or by the often occurring calm to moderate conditions. In the frame work of the NOURTEC-project (Hoekstra et al., 1994) a shoreface nourishment was carried out in the multiple bar system of the Dutch island of Terschelling. A large-scale field measuring program, started to monitor this nourishment, offered an opportunity to determine the most important sediment

¹ Institute for Marine and Atmospheric Research, Utrecht University, Department of Physical Geography, P.O.Box 80.115, 3508 TC Utrecht, The Netherlands.

transport mechanisms at different locations in a barred surfzone and to evaluate the relevance of these mechanisms on a time scale of months to years. The sediment transport mechanisms were evaluated in the following way. Firstly, sediment fluxes were calculated using the measured velocity and sediment concentrations to determine the importance of mean currents, and high- and low-frequency waves to the *suspended* sediment transport on a time scale of a few weeks. These fluxes were related to the ratio of the local wave height and the local waterdepth (H_{m0}/h), incorporating both changes in wave conditions and tidal water levels. Secondly, the Bailard (1981)-approach was used to evaluate the relative importance of currents, high- and low frequency waves to the suspended sediment transport. The calculated contributions of the currents and waves were combined with a probability density function of H_{m0}/h to obtain insight in the effects on a timescale of years. Finally, a convection-diffusion sediment transport model (Van Rijn, 1993) was used, again in combination with probability density functions to evaluate the influence of waves and currents.

The Terschelling field site and data acquisition

The field experiment site is fully exposed to the North Sea with an annual mean significant offshore wave height of 1.1m (Van Beek, 1995). The tide is semidiurnal with a range of 1.5 and 2.5m during neap and spring tide, respectively. The nearshore area can be described as very dissipative with a very mild overall slope (1:200) and is characterized by the presence of several breaker bars (Hoekstra et al., 1994). In the period May 1994 to November 1995 three measuring campaigns were carried out: T2- (May and June 1994), T3- (October and November 1994), and the T4- (October and November 1995) campaign of five weeks each. The offshore significant wave height during the whole period ranged from 0.2 to 5m. During these campaigns four tripods (F2 to F5) were positioned in a cross-shore array (see Figure 1). Each tripod was equipped with two electro-magnetic flow meters (EMF) at an initial height of 0.25 and 1.2m above the bed and with a pressure sensor at 2.2m above the bed. On the tripods F3, F4 and F5 also two optical back scatter sensors (OBS) at 0.15m and 0.25m above the bed were installed. Timeseries were acquired with a sampling frequency of 2 Hz for 2048 seconds per hour. During the whole period from May 1994 to November 1995 the tripod F3 operated continuously (however without OBSs). At a waterdepth of 15m a wave directional buoy (WAVEC) was operational during the same period. The morphology landward of F4 evolved from a more or less alongshore uniform bar-trough system during the T2 and T3 campaigns to a three dimensional bar system during the T4 campaign. Seaward of F4 no large morphological changes were observed.

Figure 1. Instrumented positions and cross-shore profile of June 1994

Field observations of suspended sediment fluxes

Method

Fluxes were calculated from the measured timeseries of the cross-shore velocity u and concentration c . These timeseries were divided into a mean- and a high and low frequency oscillating term.

$$\langle u.c \rangle = \langle \bar{u}.\bar{c} \rangle + \langle \tilde{u}_h.\tilde{c}_h \rangle + \langle \tilde{u}_l.\tilde{c}_l \rangle \quad (1)$$

The left-hand side of (1) is the net suspended sediment flux; the first term on the right-hand side is the mean flux and the second and the third one are the high frequency and low frequency oscillating flux, respectively. The brackets denote time-averaged values. A positive flux is directed onshore. The separation frequency between high- and low-frequency waves was set to 0.04 Hz. Because of the different height at which u and c were measured, a correction for \bar{u} had to be applied. Here, a simple engineering rule was used (Van Rijn, 1991), which reads as

$$\bar{u}_1 = \bar{u}_2 \left(\frac{z_1}{z_2} \right)^{0.25} \quad (2)$$

As a result, \bar{u} at $z = 0.15$ m was about 88% of that at $z = 0.25$ m. Very small offsets in \bar{c} ($< 1 \text{ kgm}^{-3}$) were encountered and corrected for. For this reason, the background concentration equaled 0 kgm^{-3} .

Results

Burst-averaged values of the high- and low-frequency oscillating fluxes at $z = 0.15$ m at F3 (T2 and T4-), F4 (T2 +T3-) and F5 (T2 campaign) are plotted in Figure 2 as a function of the local relative wave height (spectral wave height based on short wave

band) H_{m0}/h . A study of Van Enckevort and Reincke (1996) made in the intertidal zone of the same cross-shore transect showed that initial wave breaking starts at $H_{m0}/h = 0.33$. In other words, the highest wave in a wavegroup is breaking at this local relative wave height. Assuming that this relationship holds for the deeper parts of the nearshore zone, a distinction can be made between transport under breaking and nonbreaking wave conditions.

F3: At F3 non-zero fluxes only occurred for H_{m0}/h values larger than about 0.3 - 0.35 at the lower sensor (Figure 2) and 0.35 - 0.4 at the upper one (not shown). In other words; when wave breaking occurs at that location. High-frequency fluxes were onshore directed and were associated with the horizontal asymmetry of the incident short waves, i.e. the difference in magnitude between onshore and offshore orbital motion. Low-frequency fluxes were rather small and seaward directed and were likely related to bound long waves.

For $H_{m0}/h < 0.3$ sediment was not resuspended on the time scale of individual short waves nor on that of wave groups. The negligible oscillating fluxes for $H_{m0}/h < 0.3$ thus seemed to be mainly due to a lack of coherence between u and c for almost all frequencies. In addition, the variance in c was very low at both sensors compared to more energetic events.

For $H_{m0}/h > 0.3$ sediment was stirred on both the individual short-wave and wavegroup time scale. The co-spectrum between u and c showed the 'classic' shape of a large positive (onshore) peak at the peak frequency of the short waves and a broad negative (offshore) peak at infragravity frequencies (cf. Huntley and Hanes, 1987). The phases at the peak frequency were between -45 and 0 degrees, which indicates that c lagged u slightly. Phase lags between both sensors were, in general, negligible at both high and low frequencies.

The oscillating fluxes at $z = 0.25$ m were considerably smaller than at $z = 0.15$ m. The sediment fluxes at the upper OBS were about 29 % and 4 % of that at the lower OBS for the high- and low-frequency sediment flux, respectively.

Time-averaged values of the mean flux at $z = 0.15$ m are also shown in Figure 2 as a function of H_{m0}/h . The largest fluxes, which were in a seaward direction, occurred for conditions with H_{m0}/h above 0.3 to 0.35. This indicates that these negative fluxes were associated with wave-driven undertows.

F4: The same pattern for the oscillating fluxes and the mean fluxes were also found at F4. However, during one wave event offshore directed high frequency fluxes occurred as well, caused by phase lags between \tilde{u}_h and \tilde{c}_h larger than 90 degrees. The reason for these large phase lags is not fully understood. In general, phase lags are ascribed to the presence of ripples (e.g., Vincent and Green, 1990), though they have also been observed in the sheetflow regime (e.g., Ribberink and Al-Salem, 1995). Why such large phase lags developed during this particular storm (presumably sheet flow conditions) and not during other ones or at other positions is unknown. The mean fluxes at F4 were not only offshore directed due to undertows, but also onshore directed velocities and fluxes were observed (Figure 2). The origin of these onshore currents is not clear. On average, the mean fluxes were offshore directed and the averaged high-frequency fluxes onshore.

F5: In the trough at F5, no breaking wave conditions occurred ($H_{m0}/h < 0.3$). Although some scatter is present at the high frequency fluxes (Figure 2), no systematic contribution of this term was found. The scatter at the mean fluxes was not the result of enhanced cross-shore currents, but was caused by high sediment concentrations unrelated to the cross-shore velocity signal. These high sediment concentrations were probably the result of the tidal longshore currents in combination with bedforms.

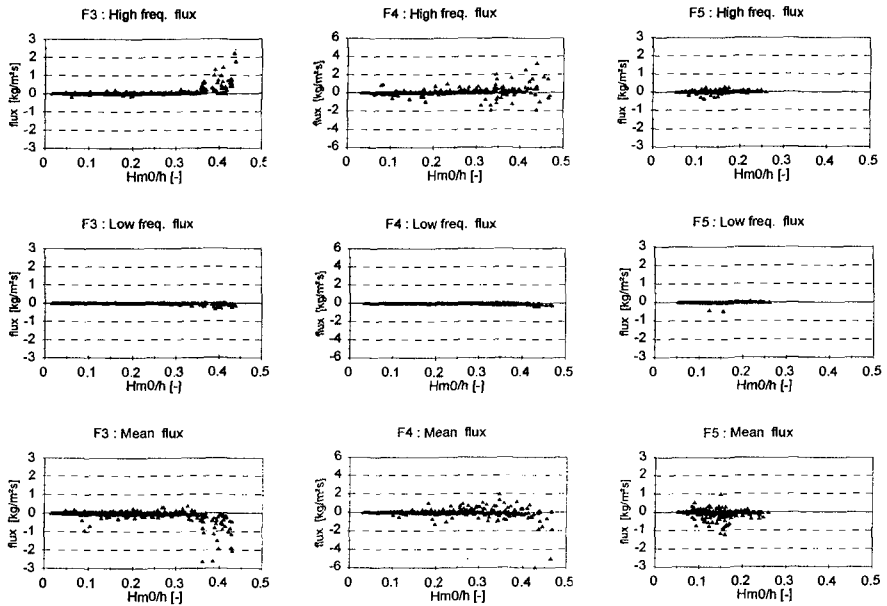

Figure 2. Measured fluxes at 15 cm above the bed at F3, F4 and F5

Long-term suspended sediment transport: an energetics approach

Introduction

The analysis of the suspended sediment fluxes at a height z above the bed has given important insight into the magnitude, direction and relative importance of different processes to the total suspended sediment transport. However, the findings strictly apply to the height z and are, therefore, not necessarily representative for the depth-averaged fluxes. Furthermore, the analysis presented so far has not taken the long-term distribution of the hydrodynamical conditions into account. The magnitude of the fluxes increased with H_{m0}/h , but this does not necessarily mean that on a time scale of months to years the sediment transport is limited to conditions which occurrence in time is only infrequent. The cumulative effect of small, but often

occurring transports may outweigh that of large, but rarely present ones. The cross-shore transport rate under mean and oscillating flows can relatively simple be modelled with a formulation in which the sediment transport rate is assumed to respond instantaneously to fluctuations in velocity above the bed (Bowen, 1980; Bailard, 1981). This rate is then expressed as a linear combination of terms containing products of the three different velocity components \bar{u} , \bar{u}_h and \bar{u}_l . These terms, referred to as 'velocity moments', represent the depth-averaged sediment fluxes.

Roelvink and Stive (1989) showed that the most important contributions to the magnitude and the direction of suspended load transport is given by the term $\langle |u(t)|^3 u(t) \rangle$. This term can be expanded in several terms after replacing the instantaneous velocity $u(t)$ by a sum of the mean, high and the low frequency oscillating velocity. The most important terms (Roelvink and Stive, 1989) are:

$$\langle |u|^3 u \rangle = 4 \langle |\bar{u}_h|^3 \bar{u} \rangle + \langle |\bar{u}_h|^3 \bar{u}_h \rangle + 4 \langle |\bar{u}_h|^3 \bar{u}_l \rangle \quad (3)$$

In these terms the stirring of sand is proportional to $|\bar{u}_h|^3$. The sediment is then transported by any mean current, by high-frequency (HF) and low-frequency (LF) oscillations. Under breaking wave conditions in shallow water other velocity moments, such as those related to the stirring of sediment by long waves ($|\bar{u}_l|^3$), may become of importance as well (Foote et al., 1994; Kroon, 1994), but these terms are neglected in the present analysis. The velocity moments were scaled with the inverse of the fall velocity w to investigate their cross-shore variability. The drag - and the efficiency coefficient (Roelvink and Stive, 1989) were assumed to be constant over the profile. The median sediment fall velocity at F2, F3, F4 and F5 were 15.1, 17.7, 27.6 and 20.5 mm/s, respectively (Guillén and Hoekstra, 1996). The velocities of the lower EMF were used to calculate the velocity moments. It should be emphasized that the energetics approach is only applied to investigate trends; quantitative information on the time-averaged transport rates is not a subject of this section.

Results

The w^{-1} -scaled velocity moments are shown in Figure 3 as a function of H_{m0}/h . The lines shown in Figure 3 are based on the average values of a particular H_{m0}/h -class (width = 0.02). At each position the w^{-1} -scaled velocity moments were clearly related to H_{m0}/h , and the growth of the velocity moments start at $H_{m0}/h=0.3$. In general, the contribution of $\langle |\bar{u}_h|^3 \bar{u}_h \rangle$ (HF) and $\langle |\bar{u}_h|^3 \bar{u} \rangle$ (mean) to the total fourth-order velocity moment were about equal, but of opposite sign. Consequently, the LF-term $\langle |\bar{u}_h|^3 \bar{u}_l \rangle$, which had a negative sign and was smaller than both $\langle |\bar{u}_h|^3 \bar{u}_h \rangle$ and $\langle |\bar{u}_h|^3 \bar{u} \rangle$, often strongly influenced the size and the direction of the net fourth-order velocity moment. The fourth-order velocity moments at F5 were minimal compared to those at the other positions indicating negligible suspended sediment transport in the middle trough.

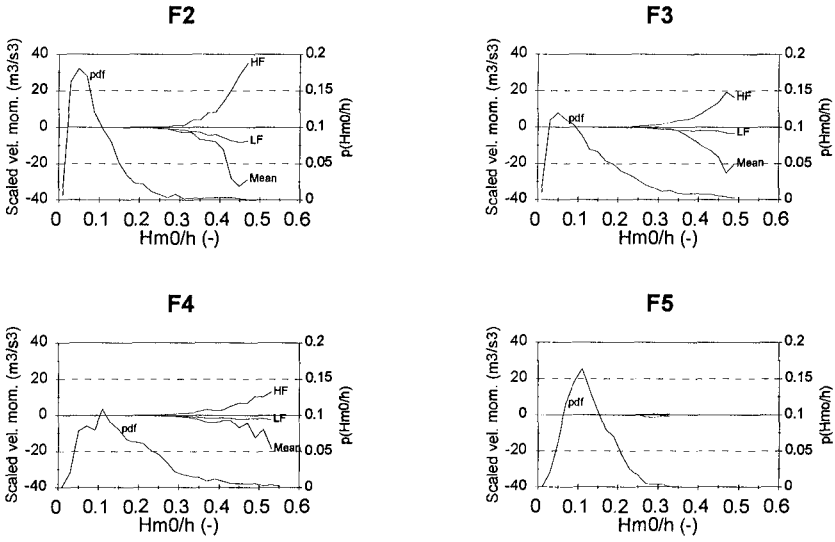

Figure 3. Measured scaled velocity moments and probability density function of ($Hm0/h$)

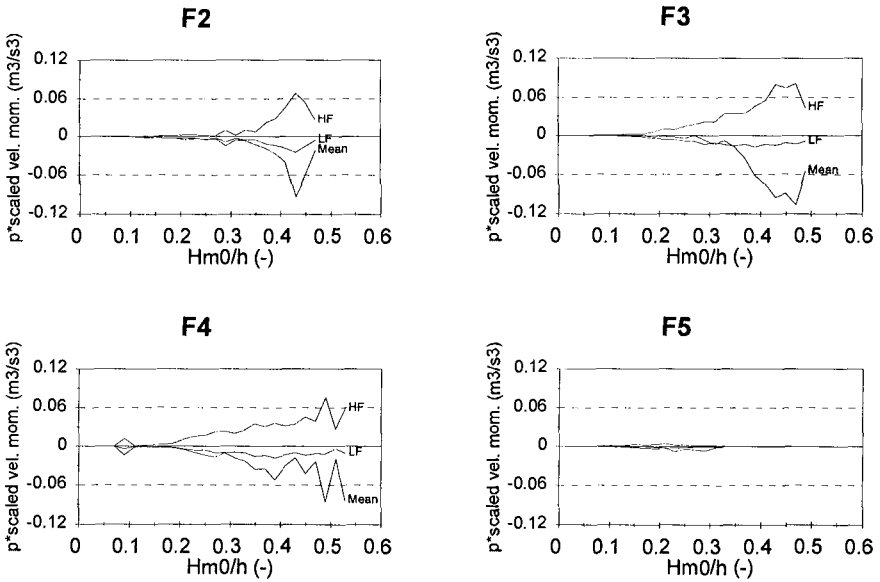

Figure 4. Long term transport rates weighted for the frequency of occurrence

An impression of the long-term effect, i.e. on the time scale of months to a few years, can be obtained by multiplying the H_{m0}/h -dependence of the velocity moments with the probability density function of H_{m0}/h at that location. At each location the frequency of occurrence of H_{m0}/h is known from the measurements. Figure 3 also shows the probability density function (pdf) of H_{m0}/h ($p(H_{m0}/h)$) at each position. The pdf of F2, F3, F4 and F5 are determined based on measured data of 2682, 9220, 1551 and 1541 hours, respectively.

The product of the pdf and the w^{-1} -scaled velocity moments is shown in Figure 4. Significant contributions of the separate processes to the long-term suspended sediment transport started from a value of $H_{m0}/h = 0.25$ at F2, and of $H_{m0}/h = 0.15$ at F3 and F4, which means that the suspended sediment transport was restricted to 3.4%, 32% and 51% in time at F2, F3 and F4, respectively. The majority of the suspended sediment transport (about 70 to 90 %) took place, however, when wave breaking occurred at that location ($H_{m0}/h > 0.33$) and as a consequence, was limited to a much smaller amount in time (1.8, 5.6 and 8.5% in time respectively). This does not imply that the long-term suspended sediment transport is restricted to truly extreme events, except perhaps at F2. For decreasing water depths the occurrence of the long-term suspended sediment transport shifts towards more common conditions, although it remains largely restricted to conditions with breaking waves.

The products of the pdf and the velocity moments are in the same order at F2, F3 and F4 and much smaller at F5. The approximately equal net long-term suspended sediment transports at F2, F3 and F4 are caused by the fact that the two largest contributions, viz. the high-frequency oscillating and current-related one, are nearly the same and, therefore, cancel out. This implies that the cross-shore suspended sediment transport is a delicate balance between contributions by mean currents, and by high- and low-frequency waves. The present results have also indicated that the long-term suspended sediment transport in the middle trough is very small.

Long-term sediment transport: the Van Rijn/Ribberink model

Method

The Van Rijn/Ribberink model (Van Rijn, 1993) was used to calculate the sediment transport. This model is a combination of two different submodels: a suspended load (Van Rijn, a convection-diffusion model) and a bedload one (Ribberink). In the suspended load model the stirring of the sediment is the result of both waves and currents. However, the suspended sediment is only transported by mean currents; oscillating suspended load transport is not included. The bedload model, however, is an instantaneous model. As a result, the sediment can be transported due to both waves (short and long waves) and currents. The model has been modified in such a way that timeseries of measured velocities and waterlevels can be used as input instead of the vertical mean velocity and wave height (Houwman and Hoekstra, 1994). Timeseries of the T2- and T4-campaigns at position F2, F3, F4 and F5 were

used to calculate the sediment transport. The measured timeseries of velocities u and v (at 0.25 m above the bed) and the measured waterlevels (measured by the pressure sensor at 2.2 m above bed) were used as input into the model. From these velocity signals the near bed velocity distribution was constructed assuming a logarithmic velocity profile for the mean current and a constant orbital velocity distribution in the vertical. Only measured velocity signals were used, therefore the effect of the wave induced near bed velocity ('Longuet-Higgins streaming') was not included in the computations. For the computations the local median grain size was used (d_{50} is 154, 163, 172 and 178 μm for F2, F3, F4 and F5 respectively) and a constant bed roughness height $k_s = 0.3$ cm.

The previous analysis of the fluxes and the velocity moments showed that the high-frequency suspended load transport cannot be neglected. To get insight in contribution of this term to the net transport, the Van Rijn model is modified in the following way. The model produces a time-averaged sediment concentration distribution over the vertical. At a certain height above the bed this mean sediment concentration is thought to be the time averaged value of two sediment concentration peaks per wave cycle, one during the onshore directed wave motion and the other during the offshore directed peak. According to the velocity moments approach the shape of the sediment concentration peaks can be assumed to be equal to the shape of $|u(t)|^3$. If one also assumes that each half wave cycle can be described with linear wave theory with different amplitudes but with equal duration, equation (4) is derived.

$$\begin{aligned} \bar{c}(z) &= k \left[\left| \frac{2}{T} \int_0^{T/2} U_{on}^3 \sin^3 \omega t dt \right| + \left| \frac{2}{T} \int_{T/2}^T U_{off}^3 \sin^3 \omega t dt \right| \right] \\ &= k * [U_{on}^3 + U_{off}^3] * \left[\frac{2}{T} \int_0^{T/2} \sin^3 \omega t dt \right] \end{aligned} \quad (4)$$

In equation (4), the left term is the time averaged sediment concentration at height z above the bed, U_{on} and U_{off} refer to the onshore and offshore peak orbital velocity, T and ω are the wave period and angular frequency, respectively and k is a constant. The oscillating suspended flux at a certain height z above the bed can be related to the fourth order moment $u^*|u^3|$. The wave averaged oscillating sediment transport rate $S(z)$ through a layer dz is then described by (5):

$$S(z) = \frac{1}{T} \int_0^T k * u(t) |u(t)^3| dt dz = k [U_{on}^4 - U_{off}^4] dz * \frac{1}{T} \int_0^T \sin^4 \omega t dt \quad (5)$$

$$S(z) = k' * \bar{c}(z) * \frac{U_{on}^4 - U_{off}^4}{U_{on}^3 + U_{off}^3} * dz$$

$$with : k' = \frac{1}{2} \int_0^T \sin^4 \omega t dt * \left[\int_0^{T/2} \sin^3 \omega t dt \right]^{-1} \approx 0.884$$

After integration over the vertical the oscillating suspended sediment transport can be obtained. The mean concentration at height z above the bed is calculated with the Van Rijn/Ribberink model, and the measured significant onshore and offshore orbital motions can be used.

This approach gives an upper limit for the suspended oscillating sediment transport, because one assumes that there are no phase lags present between $u(t)$ and $c(t)$ and that the sediment always responds instantaneously to the third power of the orbital velocity. However, the measurements have shown that phase lags were present and it is unclear if the sediment always responded to $u(t)^3$. Therefore, the parameter k' in (5) is replaced by a new parameter, the "efficiency coefficient" (eff) which incorporates these effects. This parameter was determined from the OBS data.

The measured fluxes were divided by the mean concentration for both OBSs at F3 and were related to the significant orbital velocity. The relative (to the mean) response of the sediment is important, because the mean concentration $c(z)$ is obtained from the model. The values are averaged for an orbital velocity class (width of 0.1m/s), based on data of the T2, T3 and T4 campaigns. A comparison between the measured values and the values of the fourth-order moment show that no fixed k' values can be taken. Based on the two lines from both OBSs the efficiency coefficient was determined as:

$$eff(U_{on}, z) = [(2.5 * z - 0.292) * U_{on}^{-3} * z + 0.42] * \tanh(6.5(z_{max} - z)) \quad (6)$$

$$IF \quad eff(U_{on}, z) < 0 \rightarrow eff(U_{on}, z) = 0$$

To prevent that large oscillating fluxes are calculated far away from the bottom, a tanh function was used to force the efficiency coefficient down to zero again at a particular height (z_{max}) above the bed. The model outcomes were not very sensitive for the values of z_{max} . In the calculations a value of 0.6 m was chosen for z_{max} . A comparison between the 'theoretical' efficiency coefficient k' and the 'observed' efficiency coefficient makes clear that the theoretical one is significantly higher than the observed one. At a height of 0.25 m above the bed the observed efficiency coefficient ranges from 0 to 0.2 (at $U_{on} = 1.6$ m/s) instead of having a fixed value of

0.884. The oscillating suspended load sediment transport was also calculated at F4 using the same formulation for the efficiency coefficient. The observed values were described reasonably by the model. Therefore the approach described above was used for all tripods.

Results

From the calculated cross-shore transport rates an average sediment transport can be calculated for a particular relative wave height class (H_{m0}/h). Figure 5 shows the transport rates calculated at four locations and split up into the contribution of the three transport mechanisms: bed(load), mean- and osc(illating suspended load) transport. The $p(H_{m0}/h)$ for each position are also given. At F2, F3 and F4 the mean and oscillating suspended load transport increased rapidly for situations with a relative wave height larger than 0.3.

The 'yearly-averaged' transport rates shown in Figure 6 were created in a similar way with the pdfs as for the velocity moments. For both F2 and F3 the oscillating and mean suspended load sediment transport were very high during breaking wave conditions ($H_{m0}/h > 0.33$). The yearly net sediment transport is a sensitive balance between the offshore directed mean suspended load transport and the onshore directed oscillating suspended load transport, the contribution of the bedload transport at these positions is only small. However, the difference between the relative large contributions of the suspended load terms may also be very small and, consequently the influence of the bedload transport on the net transport is not clear yet. Again at location F4 the mean suspended load is neutralized by the oscillating suspended load component. The magnitudes of the different yearly averaged transport rates at F2, F3 and F4 were of the same order of magnitude.

In the trough at the position F5 the cross-shore sediment transport rates were much lower and offshore directed. The lack of any onshore transport mechanism in the trough region indicates that no large onshore exchange of sediment across the trough may be expected.

Discussion and conclusions

The field measurements at Terschelling have shown that high- and low-frequency waves, as well as mean currents, contribute to the net suspended sediment transport. In general, the high-frequency oscillating transport is onshore directed and is caused by the positive skewness of the short waves. The low-frequency oscillating transport is in a seaward direction owing to the dominance of bound long waves in the total long wave field and the stirring of sediment on the wave-group time scale. The current-related flux is in an offshore direction in most cases and is caused by wave-driven undertows.

The "measured" fluxes start to increase at a relative wave height $H_{m0}/h > 0.33$, which coincides with breaking wave conditions. The velocity moments are increasing at a lower H_{m0}/h ratio (0.15 - 0.25) but also here the highest transport rates were found during breaking wave conditions. The suspended load transport rates calculated with

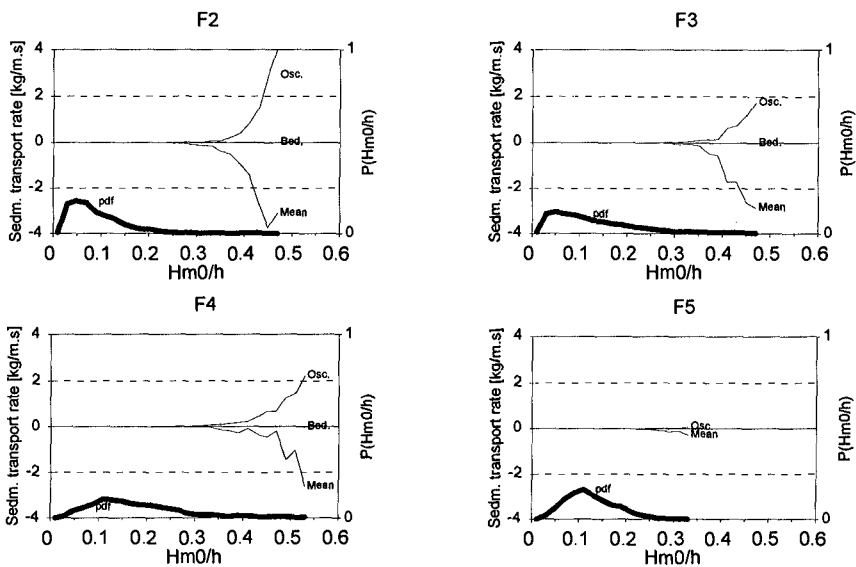

Figure 5. Modelled transport rates with pdf

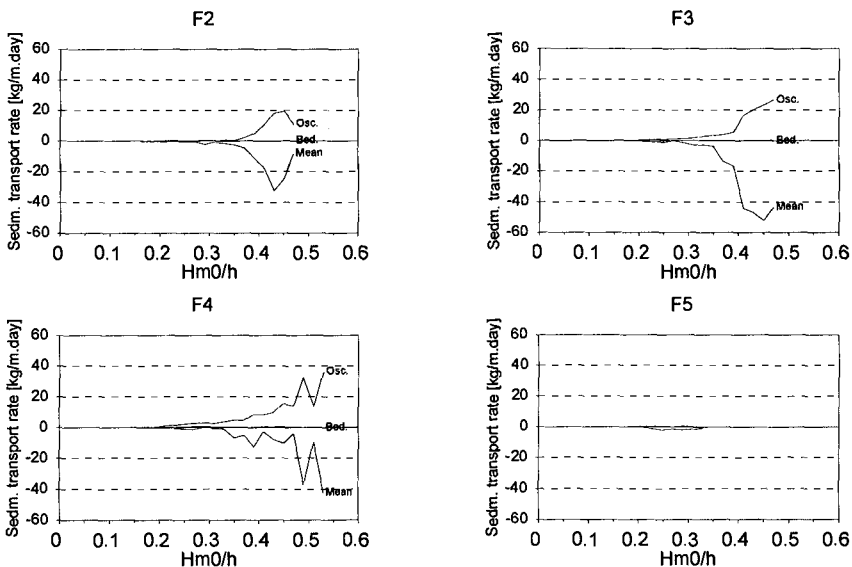

Figure 6. Long term transport rates weighted for the frequency of occurrence

the Van Rijn model were only non-zero during these conditions ($H_{m0}/h > 0.33$) as well. In general, the suspended load transport rates are well related to the relative wave heights H_{m0}/h .

All three applied methods show that the contributions of the onshore directed oscillating suspended load transport or flux is more or less balanced by the offshore directed mean transport/flux.

The combination of a local probability density function (pdf) and the calculated velocity moments and transport rates gives insight in the long term contributions of different transport mechanisms. The yearly averaged suspended load transport rates obtained in this way, start to increase at $H_{m0}/h > 0.33$ for F2, F3 and F4. This indicates that on the long run only breaking wave conditions are important at these positions. But again, at this time scale the suspended sediment transport is a delicate balance between the onshore directed (short wave) oscillating transport and the offshore directed mean transport.

The contribution of the low frequency suspended load transport is rather small compared to the high frequency and mean transport but is systematic and therefore still significant. The calculations of the bedload transport have shown that this contribution is very small compared to the other terms. Although the contributions of the low frequency suspended transport and the bedload transport are small their importance will increase when the mean suspended transport is neutralized by the oscillating high frequency transport.

The results obtained from the calculated long term transport rates are not in agreement with the beach-shoreface exchange mechanism proposed by Niederoda et al. (1984). They found an offshore directed sediment transport from the beach/inner surfzone to the upper shoreface ($h > 4\text{m}$) during a storm and a slow return of this sediment during low energetic conditions in response of asymmetric waves propagating to the coast. If this mechanism is also valid for the Terschelling coast one expects a large contribution of the short wave transport during non-breaking wave conditions ($H_{m0}/h < 0.33$) and a clear dominance of the mean transport during breaking wave conditions. However, for the whole range of H_{m0}/h values the terms are in balance and no clear dominance of a term at a particular H_{m0}/h value has been found. In addition, the morphological observations do not support the theory of such a systematic exchange mechanism between beach and deeper water.

The lack of significant sediment transport in the trough at location F5 also prevents a large exchange between the shallow water and deep water region. In the trough no waves break, and the calculated transport rates are very low. It seems that the landward-located trough acts as a barrier against cross-shore sediment transport.

CHAPTER 374

NUMERICAL PREDICTION OF BREAKING WAVES AND CURRENTS WITH A BOUSSINESQ MODEL

Okey George Nwogu¹

ABSTRACT

This paper describes the extension of a comprehensive numerical model for simulating the propagation and transformation of ocean waves in coastal regions and harbours to include wave breaking, runup and breaking-induced currents. The numerical model is based on a time-domain solution of a fully nonlinear set of Boussinesq-type equations for wave propagation in intermediate and shallow water depths. The equations are able to describe most of the phenomena of interest in the nearshore zone including shoaling, refraction, diffraction, reflection, wave directionality and nonlinear wave-wave interactions. The Boussinesq model is extended to the surf and swash zones by coupling the mass and momentum equations with a one-equation model for the temporal and spatial evolution of the turbulent kinetic energy produced by wave breaking. The waves are assumed to start breaking when the horizontal component of the orbital velocity at the wave crest exceeds the phase velocity of the waves. Numerical and experimental results are presented for the shoaling and runup of regular and irregular waves on a constant slope beach and wave-induced currents behind a detached breakwater.

1. INTRODUCTION

The processes of wave breaking, runup, setdown and setup of the mean water level, turbulent energy production, generation of nearshore currents and generation of infragravity waves are important driving mechanisms for the transport of sediments and pollutants in coastal regions. A full mathematical description of the complex hydrodynamics in the surf and swash zones is difficult due to the highly nonlinear and turbulent nature of flow. By making different simplifying assumptions, however, numerous mathematical models have been developed which reproduce with varying degrees of success the different hydrodynamic phenomena that occur in the surf and swash zones.

For waves propagating over simple bathymetries where shoaling, refraction and breaking are the dominant wave transformation processes, models based on the conservation of energy flux with an appropriate energy dissipation term have successfully been used to model the wave height variation in the surf zone (e.g. Battjes and Janssen 1978, Dally et al. 1985). Battjes and Janssen (1978) used a hydraulic jump analogy to derive

¹Canadian Hydraulics Centre, National Research Council, Ottawa, Canada K1A 0R6

the form of dissipation term while Dally et al. (1985) assumed that the dissipation rate was proportional to the difference between the local energy flux and a stable energy flux. Similar energy dissipation terms have also been incorporated into the mild-slope equation (e.g. Isobe 1987, Özkan and Kirby 1993).

Most surf zone wave transformation models are based on time-averaged integral wave properties and do not follow the breaking process in a time dependent manner. For applications such as irregular wave propagation and sediment transport over barred beaches, time domain modeling provides a more accurate description of the breaking and reformation process. A time-dependent breaking model is also able to simulate the transition region after the onset of wave breaking, where there is a rapid decay in wave energy with almost no change in the setdown of the mean water level. The transition zone plays an important role in the prediction of wave-induced currents and sediment transport in the surf zone (Nairn et al., 1990).

Time-dependent numerical models based Boussinesq-type equations have successfully been used to simulate the nonlinear transformation of multidirectional ocean waves in intermediate and shallow water depths (e.g. Nwogu, 1994). Boussinesq equations can accurately describe most wave transformation processes outside the surf zone including shoaling, refraction, diffraction, reflection and nonlinear wave-wave interactions. Recently, several authors have extended Boussinesq models to simulate wave breaking in the surf zone including Zelt (1991), Karambas and Koutitas (1992), Schäffer et al. (1993), and Sato and Kabiling (1994). The models essentially incorporate a dissipative term due to turbulence stresses or the presence of a surface roller into the momentum equation. The models differ on how they treat the onset of breaking and the rate of wave energy dissipation.

In this paper, we employ a one-equation turbulence model to describe the temporal and spatial evolution of the turbulent kinetic energy produced by wave breaking. The waves are assumed to start breaking when the horizontal component of the orbital velocity at the wave crest exceeds the phase velocity of the waves. The rate of production of turbulent kinetic energy is assumed to be proportional to the vertical gradient of the horizontal water particle velocity at the wave crest. The time-dependent model is applicable to both periodic and non-periodic unidirectional and multidirectional waves.

One advantage of extending Boussinesq-type models to the surf zone is the ability to implicitly model interactions between hydrodynamic processes occurring at different time scales. Wave-induced currents and mean water level fluctuations are implicitly included in the wave propagation model and are derived from a time-average of the predicted velocities and surface elevation respectively, without having to explicitly calculate radiation stresses and separately solve a time-averaged hydrodynamic model.

2. THEORETICAL MODEL

2.1 Fully Nonlinear Boussinesq Equations

Boussinesq equations represent the depth-integrated equations for the conservation of mass and momentum for nonlinear dispersive waves, propagating in water of variable depth. The velocity potential, ϕ , can be expanded as power series in the vertical coordinate, z . An approximation is introduced for frequency dispersion by truncating the series at second-order, resulting in a quadratic variation for the horizontal velocity over depth, and a linear variation for the vertical velocity:

$$\begin{aligned} \mathbf{u}(z) = & \mathbf{u}_\alpha + (z_\alpha - z)[\nabla(\mathbf{u}_\alpha \cdot \nabla h) + (\nabla \cdot \mathbf{u}_\alpha)\nabla h] \\ & + \left[\frac{(z_\alpha + h)^2}{2} - \frac{(z + h)^2}{2} \right] \nabla(\nabla \cdot \mathbf{u}_\alpha) \end{aligned} \quad (1)$$

$$w(z) = -[\mathbf{u}_\alpha \cdot \nabla h + (z + h)\nabla \cdot \mathbf{u}_\alpha] \quad (2)$$

where $\nabla = (\partial/\partial x, \partial/\partial y)$, $h(\mathbf{x})$ is the water depth and $\mathbf{u}_\alpha = \nabla\phi|_{z=z_\alpha}$. Given a vertical profile for the flow field (Eqns. 1 & 2), the governing equations of fluid motion can be integrated over depth, reducing the three-dimensional problem to a two-dimensional one. The depth-integrated mass conservation equation can be written as:

$$\eta_t + \nabla \cdot \int_{-h}^{\eta} \mathbf{u} dz = 0, \quad (3)$$

where $\eta(\mathbf{x}, t)$ is the free surface elevation. Although Boussinesq equations were originally derived for weakly nonlinear waves, a fully nonlinear variant of the equations was recently derived by Wei et al. (1995). The momentum equation, fully nonlinear up to the order of truncation of the dispersive terms, is derived from the dynamic boundary condition at the free surface as:

$$\begin{aligned} & \mathbf{u}_{\alpha t} + g\nabla\eta + (z_\alpha - \eta)[\nabla(\mathbf{u}_{\alpha t} \cdot \nabla h) + (\nabla \cdot \mathbf{u}_{\alpha t})\nabla h] \\ & + \left[\frac{(z_\alpha + h)^2}{2} - \frac{(h + \eta)^2}{2} \right] \nabla(\nabla \cdot \mathbf{u}_{\alpha t}) + \frac{1}{2}\nabla(\mathbf{u}_s \cdot \mathbf{u}_s + w_s^2) \\ & - [(\mathbf{u}_{\alpha t} \cdot \nabla h) + (h + \eta)(\nabla \cdot \mathbf{u}_{\alpha t})]\nabla\eta + \frac{f_w}{(h + \eta)}\mathbf{u}_b|\mathbf{u}_b| + \frac{\partial}{\partial z}(\overline{\mathbf{u}'w'}) = 0 \end{aligned} \quad (4)$$

where g is the gravitational acceleration, $\mathbf{u}_b = \mathbf{u}(-h)$, $\mathbf{u}_s = \mathbf{u}(\eta)$ and $w_s = w(\eta)$. Two additional terms have been introduced into the momentum equation to simulate the dissipation of wave energy due to bottom friction and wave breaking. f_w is an empirical bottom friction factor while $\overline{\mathbf{u}'w'}$ represents the shear stress due to breaking-induced turbulent velocity fluctuations (u', v', w'). A semi-empirical turbulence closure model (Section 2.2) is used to relate the turbulence stresses to the wave orbital velocities.

The elevation of the velocity variable z_α is a free parameter and is chosen to minimize the differences between the linear dispersion characteristics of the Boussinesq model and linear theory. An optimum depth for the velocity variable, $z_\alpha = -0.53h$, gives errors of less than 2% in the phase speed from shallow water depths up to the deep water depth limit.

2.2 Turbulence Model

Several turbulence models have been proposed for fluid flow problems (see review by Rodi, 1980). In this paper, the standard one-equation turbulence model is used to describe the spatial and temporal evolution of the turbulent kinetic energy, k , produced by wave breaking. We do not attempt to model details of the turbulent motion, but rather, investigate the effect of turbulence on the wave field.

The key assumptions made in developing the model are:

1. the breaking process is assumed to be "spilling"
2. turbulence is initiated in the wave crest region due to large vertical gradients of the horizontal velocity, $\partial \mathbf{u} / \partial z$
3. turbulence is produced only when the horizontal velocity at the wave crest exceeds the phase velocity of the waves
4. the rate of production of turbulent kinetic energy is proportional to the vertical gradient of the horizontal velocity at the wave crest
5. turbulence is primarily convected in the crest front region with the horizontal component of the orbital velocity at the crest

The Boussinesq eddy viscosity concept can be used to relate the turbulence shear stresses to the velocity gradients:

$$\overline{\mathbf{u}'w'} = -\nu_t \frac{\partial \mathbf{u}}{\partial z} \quad (5)$$

where ν_t is the eddy viscosity. By substituting the expression for $\mathbf{u}(z)$ given in equation (1), the dissipative term in the momentum equation (Eqn. 4) becomes:

$$\frac{\partial}{\partial z} (\overline{\mathbf{u}'w'}) = -\frac{\partial}{\partial z} \left(\nu_t \frac{\partial \mathbf{u}}{\partial z} \right) = \nu_t \nabla (\nabla \cdot \mathbf{u}_\alpha) \quad (6)$$

The rate of wave energy dissipation is thus governed by the magnitude of the eddy viscosity which is related to the turbulent kinetic energy, k , and a turbulence length scale, ℓ_t , by:

$$\nu_t = \sqrt{k} \ell_t \quad (7)$$

The turbulent kinetic energy is determined from a semi-empirical transport equation with a source term for turbulent kinetic energy production by wave breaking:

$$k_t + \mathbf{u}_s \cdot \nabla k = \nu_k \nabla^2 k + B \nu_t \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right]_{z=\eta} - C_D \frac{k^{3/2}}{\ell_t} \quad (8)$$

The first term on the right hand side represents the horizontal diffusion of turbulent kinetic energy. This term is usually much smaller than the convective term, $\mathbf{u}_s \cdot \nabla k$. The second term represents the production of turbulent kinetic energy due to wave breaking. The parameter B is introduced to ensure that turbulence is produced only when horizontal velocity at the wave crest, u_s , exceeds the phase velocity of the waves, C , i.e.

$$B = \begin{cases} 0 & |u_s| < C \\ 1 & |u_s| \geq C \end{cases} \quad (9)$$

This criterion is valid for progressive waves and has been found to accurately predict the breaker location observed in experiments with regular waves shoaling on a constant slope beach. For irregular waves, an approximate phase velocity can be calculated using the average zero-crossing period, although an instantaneous phase velocity can also be determined using $C = -\eta_t / |\nabla \eta|$.

The last term on the right hand side of the transport equation (8) represents the dissipation of turbulent kinetic energy into heat. C_D is an empirical constant with a representative value of 0.08 for most turbulent shear flows (Rodi, 1980).

The rate of production of turbulent kinetic energy depends on ν_t which initially is unknown. Using the mixing length hypothesis which assumes a local balance between production and dissipation of turbulent kinetic energy, the value of ν_t for the production term is determined as:

$$\nu_t = \frac{\ell_t^2}{\sqrt{C_D}} \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right]_{z=\eta}^{1/2} \quad (10)$$

By choosing an arbitrary value for C_D , the turbulence length scale ℓ_t becomes the only free parameter in the turbulence model which governs the rate of wave energy dissipation and turbulent kinetic energy production. ℓ_t is expected to be of the order of the wave height and is determined from comparisons of the numerical model results with experimental results.

2.3 Numerical Solution

The governing Boussinesq equations have been solved with an iterative Crank-Nicolson finite difference method, with a predictor-corrector scheme used to provide the initial estimate. The computational domain is discretized using a rectangular grid, with the dependent variables η , u_α and v_α defined at the grid points in a staggered

manner. The numerical solution procedure consists of solving an algebraic expression for η at all grid points, tridiagonal matrices for u_α along lines in the x direction and tridiagonal matrices for v_α along lines in the y direction at every time step. An explicit second-order scheme is used for the turbulence transport equation. Details of the numerical solution technique can be found in Nwogu (1996).

The boundaries of the computational domain may be specified as wave input boundaries or solid walls. Along external or internal wave generation boundaries, time histories of $(u_\alpha, u_{\alpha,xx}, v_{\alpha,xy})$ or $(v_\alpha, v_{\alpha,yy}, u_{\alpha,xy})$, corresponding to periodic or non-periodic unidirectional or multidirectional sea states are input. Waves propagating out of the domain are artificially absorbed in damping regions placed next to solid wall boundaries. Artificial damping of wave energy is accomplished by introducing terms out of phase with the surface velocity and fluid acceleration into the continuity and momentum equations respectively.

A simple extrapolation scheme is used to simulate wave runup. Consider the one-dimensional case where the shoreline boundary condition is given by zero mass flux, or equivalently, $\eta_x = 0$. When the water surface elevation η_i at grid point i exceeds the elevation of an adjacent land point, h_{i+1} , we assume that the land point will be flooded at the next time step. The initial value of the water level on the the land point for the next time step is then extrapolated from the surface elevation at adjacent water points:

$$\eta_{i+1} = 4\eta_i - 3\eta_{i-1} \quad \text{if } \eta_i > -h_{i+1} \quad (11)$$

Outputs of the numerical model are time histories of the surface elevation and two components of the horizontal velocity at desired grid points in the computational domain, corresponding frequency and directional wave spectra at those locations, the instantaneous water surface elevation at specified time steps, and the significant wave height distribution and time-averaged horizontal velocities over the entire computational domain.

3. NUMERICAL AND EXPERIMENTAL RESULTS

The numerical model was initially evaluated using data obtained from experiments carried out by Nwogu (1993) in the three-dimensional wave basin of the Canadian Hydraulics Center. A 1:25 constant slope concrete beach was constructed in the 30 m \times 20 m \times 3 m basin, equipped with a 60-segment directional wave generator. The toe of the slope was located 4.6 m away from the wave boards. The water depth in the constant depth portion of the basin was 0.56 m. Tests were carried out for a wide variety of regular and irregular, unidirectional and multidirectional waves. The water surface elevation along the centerline of the basin was measured with a linear array of 23 water level gauges. The experimental setup is described in greater detail by Nwogu (1993).

Figure 1. Breaking and runup of a regular wave ($T = 2$ s) on a 1:25 beach.

3.1 Shoaling of Regular Waves

The numerical model was used to investigate the shoaling and breaking of a regular wave with period, $T = 2$ s, and height, $H = 0.09$ m, on a 1:25 beach. The computations were carried out using a grid size $\Delta x = 0.1$ m and time step size $\Delta t = 0.04$ s. A bottom friction coefficient, $f_w = 0.01$, was used for all the computations. Figure 1 shows the spatial profile of the water surface elevation at an instant of time and the corresponding turbulent kinetic energy distribution. The turbulent kinetic energy is maximum close to the breaker location and decreases towards the shoreline. The turbulent kinetic energy exhibits an oscillatory behaviour in space due to the periodic nature of the production of turbulence from each breaking wave event.

Figure 2 shows a comparison of the measured and predicted time histories of the surface elevation at four water depths, both outside and inside the breaker zone. The numerical model is able to reproduce the highly asymmetric wave profile in the surf zone. The spatial variation of the average zero-crossing wave height and mean water level are plotted in Figure 3. Fairly good agreement is obtained between the numerical and experimental results. A turbulence length scale $l_t = 0.35$ m with $C_D = 0.08$ gave the best match of rate of wave energy decay through the surf zone. The solution is not unique, however, as other combinations of C_D , l_t , and the breaking criterion also give reasonable matches of the wave height decay. An extensive investigation is presently being carried out to recommend optimum values of the turbulence model parameters as a function of incident wave parameters.

Figure 2. Measured and predicted time histories for a regular wave ($T = 2$ s) shoaling on a 1:25 beach.

Figure 3. Measured and predicted spatial variation in wave height for a regular wave ($T = 2$ s) shoaling on a 1:25 beach.

Figure 4. Measured and predicted water surface elevations for an irregular wave with $T_p = 1.5$ s shoaling on a 1:25 beach.

3.2 Shoaling of Irregular Waves

The numerical model was applied to the shoaling of an irregular wave train on the 1:25 beach. A sea state with a duration of 819.2 s was synthesized from a JONSWAP spectrum with significant wave height, $H_{mo} = 0.09$ m, peak period, $T_p = 1.5$ s, and peak enhancement factor, $\gamma = 3.3$, using the random phase method. The computations were carried out using $\Delta x = 0.075$ m, $\Delta t = 0.025$ s and $l_t = 0.1$ m. Figure 4 shows a comparison of the measured and predicted water surface elevations at two shallow water depths. The numerical model is able to reproduce reasonably well the time-domain characteristics of individual wave breaking in an irregular wave train.

The spectral densities of the measured and predicted water surface elevation time histories at different water depths are compared in Figure 5. The spectral estimates were averaged over 0.04 Hz frequency bands. Fairly good agreement is obtained between the measured and predicted wave spectra. The numerical model is able to accurately describe the cross-spectral transfer of energy due to nonlinear wave-wave interactions as well as the decrease in wave energy through the surf zone.

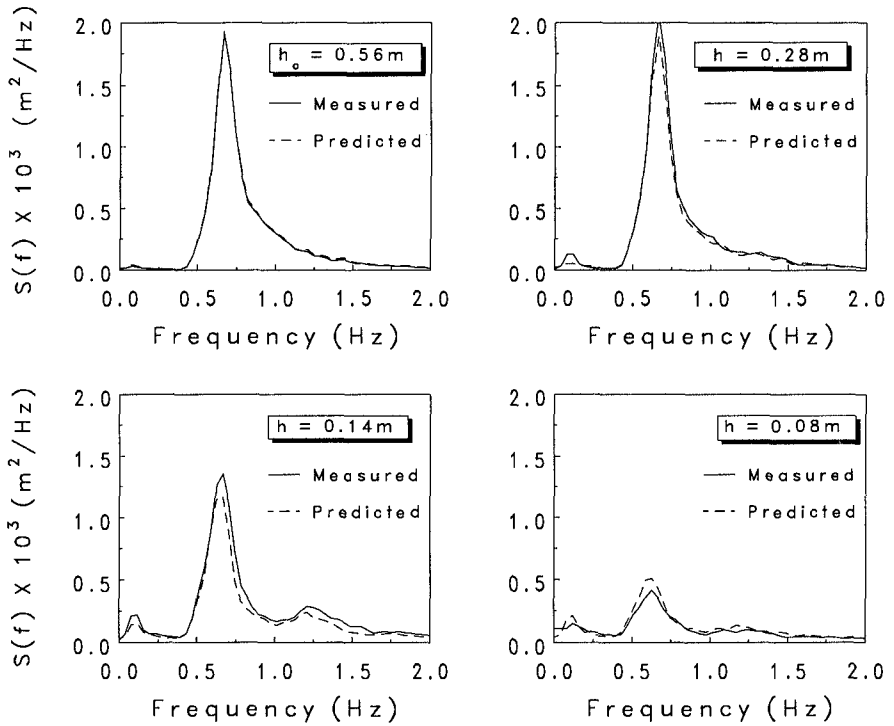

Figure 5. Spectral densities of surface elevation for an irregular wave with $T_p = 1.5$ s shoaling on a 1:25 beach.

Figure 6. Three-dimensional view of the instantaneous water surface elevation around an offshore breakwater a 1:50 beach.

3.3 Wave-Induced Currents behind a Detached Breakwater

The calculation of currents induced by breaking waves is important in modeling the transport of sediments and pollutants in the surf zone. The two-dimensional Boussinesq model was used to investigate the generation of currents behind an offshore breakwater on a constant slope beach by shoaling and breaking waves. A generic example was used with a 400 m long breakwater placed 350 m from the shoreline on a 1:50 beach. A normally incident regular wave with period $T = 10$ s and height $H = 2$ m was generated at the 10 m depth. The computations were carried out with $\Delta x = \Delta y = 5$ m, $\Delta t = 0.2$ s, and $f_w = 0.01$.

Figure 6 shows a three-dimensional view of the instantaneous water surface elevation around the offshore breakwater. Regions of the crest front with turbulent kinetic energy present have been highlighted in white. The predicted wave height distribution is shown in Figure 7 while the time and depth-averaged velocity pattern is shown in Figure 8. Two circulation cells are observed behind the detached breakwater. This pattern is qualitatively consistent with known observations of wave-induced currents and the formation of tombolos behind offshore breakwaters.

Figure 7. Average wave height distribution behind an offshore breakwater for a regular wave ($T = 10$ s, $H = 2$ m) shoaling on a 1:50 beach.

Figure 8. Predicted time and depth-averaged velocity behind an offshore breakwater for a regular wave ($T = 10$ s, $H = 2$ m) shoaling on a 1:50 beach.

4. CONCLUSIONS

A fully nonlinear Boussinesq wave propagation model has been extended to the surf and swash zones by coupling the mass and momentum equations with a one-equation turbulent kinetic energy transport model. The waves are assumed to start breaking when the horizontal velocity at the wave crest exceeds the phase velocity of the waves. The rate of production of turbulent kinetic energy is assumed to be proportional to the vertical gradient of the horizontal velocity at the wave crest. The numerical model has been compared to experimental data for the shoaling of regular and irregular waves on 1:25 beach. The model is able to reproduce reasonably well the frequency and time domain characteristics of waves in the surf zone. The results presented in this paper are of preliminary nature and further work is being carried to compare the numerical model with measured data on the spatial and temporal evolution of turbulence induced by wave breaking, the vertical distribution of currents in the surf zone, wave runup and nearshore circulation patterns.

Abstract

Experiments in flumes (i.e., Kemp and Simons, 1982, 1983, and Klopman, 1994) have shown that the mean current profile for following waves is more uniformly distributed than the corresponding current-only case, whereas the case of an opposing current leads to a more straight profile. This paper is concerned with proving that inclusion of the so-called Craik-Leibovich (CL) vortex force in the mean-current equation gives, at least for a part, an explanation of this phenomenon.

Introduction

For coastal dynamics applications it is essential to have an accurate prediction of the vertical structure of the mean current. The mean current, however, is strongly influenced by the free surface wave motion. Experiments in flumes (i.e., Kemp and Simons, 1982, 1983, and Klopman, 1994) have shown that the mean-current profile for following waves is more uniformly distributed than the corresponding current-only case, whereas the case of an opposing current leads to a more straight profile (see Figure 1). The purpose of this paper is to give a possible explanation of this behaviour. Hereto we consider the so-called Craik-Leibovich (CL) equation, derived by Craik and Leibovich (1976) in which a vortex force is present. The effect of this vortex force on the underlying flow is studied.

First we consider the CL-equation. As it is essential to have shear in the velocity profile, the used turbulence-closure model is subsequently described. Because the CL-equation is also used to describe the formation of Langmuir circulation cells, some properties of these are succinctly described next. For numerical evaluations the treatment of the vertical momentum equation is possible in a number

Figure 1: Mean current profiles, after Klopman (1994).

of ways. The most accurate one is described next. Finally the results of some numerical experiments are shown and compared with Klopman's measurements.

The CL equation

When deriving the mean-current equations in so-called Generalised Lagrangian Mean (GLM) coordinates, the following equation is obtained (see Andrews and McIntyre, 1978, Eq. (3.8)):

$$\overline{D}^L(\overline{u}_i^L) + \frac{1}{\rho_0} \frac{\partial \overline{p}^L}{\partial x_i} - \frac{\overline{\rho}^L}{\rho_0} g_i = \overline{D}^L(\overline{P}_i^L) + \frac{\partial}{\partial x_i} \left(\frac{1}{2} \overline{(u_m^L u_m^L)} \right) + \overline{P}_k^L \frac{\partial \overline{u}_k^L}{\partial x_i}, \quad (1)$$

where \overline{P}_i^L is the pseudo-momentum and $\overline{(\)}^L$ is the Generalised Lagrangian mean, i.e. the mean over the perturbed position. Summation over repeated indices is used, i.e., the Einstein convention is applied.

Leibovich (1980) has shown that under mild conditions, Eq. (1) reduces to the so-called Craik-Leibovich equation in Eulerian coordinates, which can be written as

$$\frac{\partial \overline{\mathbf{u}}}{\partial t} + (\overline{\mathbf{u}} \cdot \text{grad}) \overline{\mathbf{u}} + \text{grad} \overline{\pi} = \overline{\mathbf{u}}^S \wedge \text{curl} \overline{\mathbf{u}}, \quad (2)$$

where the pressure term $\overline{\pi}$ is given by $\overline{\pi} = \frac{\overline{p}}{\rho} + gz + \left\langle \frac{1}{2} \tilde{\mathbf{u}} \cdot \tilde{\mathbf{u}} \right\rangle$, $\overline{\mathbf{u}}$ is the (Eulerian) mean velocity and $\tilde{\mathbf{u}}$ is the wave part of the velocity. The so-called mild conditions for which the approximations are valid, amount to the condition that the waves are primarily dominated by their irrotational part. This implies that either the mean shear or the mean current is relatively weak and we thus have to impose the condition that the current is small with respect to the orbital velocity.

Notice that with $\overline{\mathbf{u}}^S = (\overline{u}^S, \overline{v}^S, 0)^T$ and $\overline{\mathbf{u}} = (\overline{u}, \overline{v}, \overline{w})^T$ we have, writing $\overline{\boldsymbol{\omega}} = \text{curl} \overline{\mathbf{u}}$,

$$\overline{\mathbf{T}} = \overline{\mathbf{u}}^S \wedge \overline{\boldsymbol{\omega}} =$$

$$\begin{aligned}
&= \left(\bar{v}^S \left(\frac{\partial \bar{v}}{\partial x} - \frac{\partial \bar{u}}{\partial y} \right), -\bar{u}^S \left(\frac{\partial \bar{v}}{\partial x} - \frac{\partial \bar{u}}{\partial y} \right), \bar{u}^S \left(\frac{\partial \bar{u}}{\partial z} - \frac{\partial \bar{w}}{\partial x} \right) - \bar{v}^S \left(\frac{\partial \bar{w}}{\partial y} - \frac{\partial \bar{v}}{\partial z} \right) \right)^T \\
&\cong \left(0, \bar{u}^S \frac{\partial \bar{u}}{\partial y}, \bar{u}^S \frac{\partial \bar{u}}{\partial z} \right)^T \equiv \bar{\mathbf{T}}_0, \quad (3)
\end{aligned}$$

where the latter approximations are those of Craik (1982), valid for a flume with x directed along the flume.

Although the inclusion of viscosity is not directly needed, it is needed in an indirect way, otherwise no shear would be present in the mean-current profile. Moreover, once generated vortices should remain bounded in magnitude and this is achieved by taking viscosity into account. Also in view of the application to a wave flume, where the lateral boundary conditions play an important role, we include the viscous stress tensor in the description. Equation (2) then is extended to

$$\frac{\partial \bar{\mathbf{u}}}{\partial t} + (\bar{\mathbf{u}} \cdot \text{grad}) \bar{\mathbf{u}} + \text{grad} \left(gz + \frac{\bar{p}}{\rho} + \left\langle \frac{1}{2} \tilde{\mathbf{u}} \cdot \tilde{\mathbf{u}} \right\rangle \right) = \bar{\mathbf{u}}^S \wedge \bar{\boldsymbol{\omega}} + \frac{1}{\rho} \text{div} \bar{\boldsymbol{\sigma}}', \quad (4)$$

where $\text{div} \bar{\boldsymbol{\sigma}}' \equiv \partial \bar{\sigma}'_{ki} / \partial x_k$ and $\bar{\sigma}'_{ki}$ is given by $\bar{\sigma}'_{ki} = (\eta^{(i)} \partial u_k / \partial x_i + \eta^{(k)} \partial u_i / \partial x_k)$, while no summation over the indices on η should be performed and the viscosity is usually non-isentropic. However, we take the (eddy) viscosity coefficient to be isentropic because of the scales on which the flow occurs here and the directions. Applying the Boussinesq-hypothesis, the stresses $\bar{\sigma}'_{ki}$ are approximated as

$$\bar{\sigma}'_{ki} = \nu_T \left(\frac{\partial \bar{u}_i}{\partial x_k} + \frac{\partial \bar{u}_k}{\partial x_i} \right), \quad (5)$$

while the eddy viscosity ν_T has still to be determined. In the present case we consider a cross section of the flume, i.e., we take $\partial_{x_1} \equiv 0$.

The turbulence-closure model

For the specification of the eddy-viscosity coefficient ν_T three possibilities were considered.

1. For a constant eddy-viscosity coefficient the velocity profiles near the bottom and the side walls are parabolic. This is physically not correct as for such situations the profiles should be logarithmic; ν_T should be flow-dependent.
2. Prandtl mixing-length model.

In the Prandtl mixing-length model, the mixing length ℓ is prescribed as a function of the geometry. Because in our case the lateral boundaries are

also of importance, the following variation of Bakhmetev's (1932) choice for shallow-water models is used for the mixing length:

$$\ell = \kappa y (b - y) (z + h) \left(1 - \frac{z + h}{h + \zeta} \right)^{1/2}, \quad (6)$$

where b is the width of the flume, h is the still-water depth, ζ is the free-surface elevation and κ is von Karman's constant. This choice for ℓ yields a parabolic profile near the boundaries. As ℓ only depends on the distance to the boundaries, it is independent of the secondary circulations induced by the CL vortex force \overline{T}_0 . No results from this model are shown.

3. $k - \epsilon$ model.

In our application of the $k - \epsilon$ model the advection and dissipation terms in the direction of the flume (the x -direction) have been neglected. The transport equations for the kinetic energy k and the dissipation ϵ are then given by

$$\frac{Dk}{Dt} = \nabla \cdot \left[\left(\nu + \frac{\nu_T}{\sigma_k} \right) \nabla k \right] + P_k - \epsilon \quad (7a)$$

$$\frac{D\epsilon}{Dt} = \nabla \cdot \left[\left(\nu + \frac{\nu_T}{\sigma_\epsilon} \right) \nabla \epsilon \right] + P_\epsilon - c_{2\epsilon} \frac{\epsilon^2}{k}, \quad (7b)$$

where

$$D/Dt \equiv \partial/\partial t + \mathbf{v} \cdot \nabla, \quad \nabla = (0, \partial_y, \partial_z)^T, \quad \mathbf{v} = (0, v, w)^T, \quad (7c)$$

$$P_k = \frac{1}{2} \nu_T \left| \frac{\partial \overline{u}_k}{\partial x_j} + \frac{\partial \overline{u}_i}{\partial x_k} \right|^2 \quad \text{with} \quad \partial_{x_1} \equiv 0, \quad (7d)$$

$$P_\epsilon = c_{1\epsilon} \frac{\epsilon}{k} P_k \quad \text{and} \quad \nu_T = c_\mu \frac{k^2}{\epsilon} \quad (7e)$$

and the constants are given by the standard setting:

$$c_\mu = 0.09, \quad c_{1\epsilon} = 1.44, \quad c_{2\epsilon} = 1.92, \quad \sigma_k = 1 \quad \text{and} \quad \sigma_\epsilon = 1.3. \quad (7f)$$

Boundary conditions for the $k - \epsilon$ model

The turbulent kinetic energy is imposed both at the side walls and the bed. The pertinent value is obtained by applying local equilibrium between production and dissipation of kinetic energy. This leads to the Dirichlet boundary conditions

$$k|_{y=0} = k|_{y=b} = (u_*^s)^2 / \sqrt{c_\mu} \quad \text{and} \quad k|_{z=-h} = (u_*^b)^2 / \sqrt{c_\mu} \quad (8a)$$

with u_*^s and u_*^b the shear-stress velocity at the sidewalls and the bottom respectively. The shear-stress velocity u_* is obtained by applying the logarithmic

boundary law for the velocity point nearest to the boundary. With δ half the grid size near the side walls and the bed and z_0 the roughness length, the following relations hold

$$\frac{\bar{u}(\delta)}{u_*} = \frac{1}{\kappa} \log \left(\frac{\delta}{z_0} \right) \quad \text{for a rough wall} \quad (8b)$$

and

$$\frac{\bar{u}(\delta)}{u_*} = \frac{1}{\kappa} \log \left(\frac{\delta u_*}{\nu} \right) + 5.2 \quad \text{for a smooth wall,} \quad (8c)$$

where \log is the natural logarithm. In the latter case the value u_* is found by iteration. Because a staggered grid is used, the velocity $\bar{u}(\delta)$ is indeed known at the previous time step. At the free surface we take $k = 0$.

For the transport equation for dissipation rate ϵ we take the following Neumann-type boundary condition:

$$\frac{\partial \epsilon}{\partial z} \Big|_{\delta} = -\frac{u_*^3}{\kappa \delta^2}, \quad (8d)$$

and at the free surface is taken $\epsilon = 0$.

Langmuir circulations

Equation (4) is basic to the generation of Langmuir circulations by an instability mechanism (Leibovich, 1983). The essential point is that a combination of a 2D shear flow in the vertical xz plane with an irrotational Stokes drift of the wave field in the same direction is unstable to spanwise (i.e., in y) disturbances. Write now the vorticity vector as $\boldsymbol{\omega} = (\omega_x, \omega_y, \omega_z)^T$. Two different forms of CL-instability are recognised:

1. **CL1-type** in which the vorticity-component ω_x can be generated by a Stokes drift which varies in the lateral direction
2. **CL2-type** in which the vorticity component ω_x may be generated by a lateral uniform Stokes drift acting on a pre-existing vertical vorticity ω_z .

The CL2-type instability is described by Leibovich (1977) and amounts to the following. It is supposed that the wind stress has produced a parallel shear flow $\bar{u}(z)$ and a Stokes drift $\bar{u}^S(z)$. A perturbation of the shear flow is now considered such that the total flow is described by $(\bar{u}(z) + \hat{u}, \hat{v}, \hat{w})^T$. A perturbation of the pressure is not needed here. Then, the following behaviour of the perturbations is considered:

$$\begin{aligned} \hat{w} &= \phi(z) \exp[\sigma t + i(my + kz)] \quad , \quad \hat{u} = \frac{1}{(m^2 + k^2)} \left(ik\hat{w}_z - m^2\hat{w} \frac{\hat{u}}{f} \right) \\ \hat{v} &= \frac{m}{(m^2 + k^2)} \left(i\hat{w}_z + k\hat{w} \frac{\hat{u}}{f} \right) \quad , \quad f = \sigma + ik(\bar{u} + \bar{u}^S) \quad , \end{aligned}$$

with \tilde{u} being the wave part of the current. For $\phi(z)$ then is obtained in the non-viscous approximation the Rayleigh equation

$$\frac{\partial^2 \phi}{\partial z^2} - (m^2 + k^2) \phi + \left\{ \frac{k}{if} \frac{\partial^2 \bar{u}}{\partial z^2} + \frac{m^2}{f^2} \frac{\partial \bar{u}}{\partial z} \frac{\partial \bar{u}^S}{\partial z} \right\} \phi = 0. \quad (9)$$

With the further simplification of rolls aligned with the mean flow (i.e., $k = 0$) we get

$$\sigma^2 \left(\frac{\partial^2 \phi}{\partial z^2} - m^2 \phi \right) + m^2 \mathcal{M}(z) \phi = 0 \quad \text{with} \quad \mathcal{M}(z) = \frac{\partial \bar{u}^S}{\partial z} \frac{\partial \bar{u}}{\partial z}. \quad (10)$$

The condition for instability now reads $\mathcal{M}(z) > 0$ anywhere in the interval for z . The corresponding maximum growth is $\mathcal{M}^{1/2}(0)$. For the growth of Langmuir circulations it is thus necessary that $\mathcal{M}(z)$ is positive anywhere in the fluid, in other words, a positive shear of the current is required because the Stokes drift diminishes for increasing depth. However, Nepf and Monismith (1991) found experimentally, in a flume, that vortices developed for both $\mathcal{M}(z) > 0$ and $\mathcal{M}(z) < 0$, see also the discussion in Nepf et al. (1995).

Manipulation of the vertical momentum equation

The numerical evaluation will be performed within an existing free-surface flow model in which the treatment of the vertical momentum equation will be worked out in a number of ways.

Hydrostatic approach

For the handling of the vertical momentum equation several possibilities exist. A very simple one consists of ignoring the vertical momentum equation altogether and determining the vertical velocity afterwards by an integration of the continuity equation in which the solutions u and v from the horizontal momentum equations are used. These horizontal momentum equations in most simple form are

$$\frac{du}{dt} + \frac{\partial \bar{\pi}}{\partial x} = \frac{1}{\rho} \frac{\partial \bar{\sigma}'_{k1}}{\partial x_k} \quad \text{and} \quad \frac{dv}{dt} + \frac{\partial \bar{\pi}}{\partial y} = \frac{1}{\rho} \frac{\partial \bar{\sigma}'_{k2}}{\partial x_k} + \bar{u}^S \frac{\partial u}{\partial y}. \quad (11)$$

One of the ways of explaining the measured mean current profiles is the following qualitative one. We consider waves and current in a laboratory flume. In the lateral (y) direction, changes in the velocity field should occur. This has to be generated by the wall effects. The basic idea is as follows. Suppose that a circulation cell has developed. Suppose that the cell is such that in the middle of the flume the flow is in downward direction. The situation is as sketched in Figure 2. In the upper part of the fluid, water with a small amount of momentum is transported towards the middle of the flume and consequently decelerates, while in the lower part of the fluid the reverse situation occurs. In the upper half of

Figure 2: Flow in a lateral vertical section

the fluid the downward velocity increases and in the lower half it decreases. In the middle of the flume $\partial v / \partial y = 0$ because of symmetry. From the continuity equation $u_x + w_z = 0$ in the middle of the flume then follows that $\partial u / \partial x < 0$ in the upper half and $\partial u / \partial x > 0$ in the lower half of the fluid. Consequently, the profile $u(z)$ turns back in the upper part of the fluid and increases in the lower part. The result is a more uniform horizontal velocity profile in the vertical.

A semi-Poisson approach

A more precise formulation consists of splitting the pressure in a hydrostatic and a non-hydrostatic part. The solution procedure then consists of two steps. In the first step only the hydrostatic part of the pressure is used and in the second step a Poisson equation for the non-hydrostatic part has to be solved. Such a method has also been used by Casulli (1995). We write the pressure as the sum of a hydrostatic part p_h and a non-hydrostatic part q : $p = p_h + q$. The computation is split in two parts.

Step 1

Consider the continuity equation and for the momentum equations we only use the hydrostatic part of the pressure. These momentum equations, which are to be solved in the first step then are, in vectorial form

$$\frac{d\bar{\mathbf{u}}}{dt} + \frac{1}{\rho} \text{grad } p_h = -\mathbf{g} + \frac{1}{\rho} \text{div } \bar{\boldsymbol{\sigma}}' \quad \text{with } \mathbf{g} = (0, 0, -g)^T. \quad (12)$$

Step 2

In the second step we consider the momentum equations without the convective terms and we only account for the non-hydrostatic part of the pressure. Furthermore the vortex force is accounted for here. We then have the system:

$$\frac{\partial \bar{\mathbf{u}}}{\partial t} + \frac{1}{\rho} \text{grad } q = \bar{\mathbf{T}}_0 \quad (13)$$

with the vortex force $\bar{\mathbf{T}}_0$ given by (3).

We now apply the operation div on (13). For the velocities it is mandatory that $\text{div } \bar{\mathbf{u}} = 0$ (i.e., the continuity equation is applied as a side condition because it was already used in the first step). The result is a Poisson equation for the

non-hydrostatic part of the pressure:

$$\operatorname{div} \left(\frac{1}{\rho} \operatorname{grad} q \right) = \operatorname{div} \left[\left(0, \bar{u}^S \frac{\partial u}{\partial y}, \bar{u}^S \frac{\partial u}{\partial z} \right)^T \right] \quad (14)$$

After solving the pressure part q of this Poisson equation, the solution q is substituted in Eq. (13) yielding new estimates for the velocities. This completes step 2.

Notice that the splitting is such that in step 1 a usual free-surface flow computation is performed. The second step gives the correction to the hydrostatic pressure, which correction is due to the vortex force. The vortex force, figuring at the right-hand side of the Poisson equation, is computed with the velocities estimated in the first step.

Numerical experiments

We now perform some computations to compare with the results of measurements of Klopman's physical experiments in the so-called Scheldt flume, which has a width of 1 m while the mean water depth in the experiments is 0.5 m. The walls of the flume are made of glass and are therefore hydraulically smooth. The bed was roughened with sand with a grain size of approximately 2 mm. The roughness of the bed was determined experimentally and the Nikuradse roughness was found to be 1 mm. The experimental set-up consists of two wave boards near each end of the flume; both wave boards generated waves and, at the same time, absorbed reflected waves. A discharge was generated with a constant outflow of 80 litres/s. For further details about the lay-out of these experiments we refer to Klopman (1994).

We only consider the regular-wave experiments. The main parameters are

wave period	$T = 1.44 \text{ s}$
wave amplitude	$a = 0.06 \text{ m}$
current velocity	$\bar{u} = 0.16 \text{ m/s}$
mean depth	$h = 0.50 \text{ m}$
bottom roughness height	$z_0 = 0.04 \text{ mm}$

Following waves

In order to obtain enough shear for the CL-vortex force to be effective, the computations are started first without the CL force included and as initial value a uniform velocity of 0.16 m/s is used, whereas the turbulent kinetic energy k and the dissipation ϵ are initially taken to be zero. After 200 s the turbulent logarithmic shear flow has developed sufficiently for the CL-vortex force to be effective. From that moment on the CL-vortex force is included in the computations. At $t = 300 \text{ s}$ a new steady state is obtained with two eddies in the cross-section of

the flume. For the situation of waves following the current, the velocity profile in a cross section of the flume has been shown in Fig. 3. The development of the

Figure 3: Velocity field in cross section at time $t = 300$ s.

vertical profile of the horizontal velocity in time is shown at the left-hand side of Fig. 4; the time that logarithmic profile is developed is now taken as the origin of the time-axis for the further discussion.

Figure 4: Development in time of the vertical profile of the horizontal velocity for the situation of waves following the current (*left*); Comparison of the vertical profile for following waves with the measured profile (*right*).

Because in the measurements a reference velocity, averaged over the depth, was based on the total flow, with the assumption of uniform flow over the width of the flume, a correction procedure is necessary now to account for the side-wall effects. For the situation of current alone (no waves) the computed vertically averaged horizontal velocity, evaluated in the centre of the flume, was taken as reference for the vertically averaged velocity as resulting from the measurements, likewise taken in the centre of the flume. This requires an enlargement of the measured velocity in the centre of the flume by a factor 1.135. This factor has been applied to all measurements, also those with following and opposing waves. The comparison of the vertical profile of the computation and the measurement with this correction is shown at the right-hand side of Fig. 4. The inclusion

of the CL-vortex force thus has, for following waves, the effect of increasing the near-bottom horizontal velocity and decreasing the horizontal velocity near the free surface, as was also measured. The profile of the current over the width of the flume is shown for a height of 5 cm above the bottom at the left-hand side of Fig. 5. At the right-hand side is shown the development of the vertical current in the centre of the flume.

Figure 5: The horizontal current across the width of the flume for following waves, without waves (the logarithmic profile) and 300 s later (with waves); development in time of the vertical profile of the vertical velocity for the situation of waves following the current (*right*); Comparison of the vertical profile for following waves with the measured profile (*right*).

A test on the possibility of Langmuir circulations was devised by taking a very wide flume with otherwise the same parameters. In this situation also only two circulation cells developed and therefore the possibility of obtaining true Langmuir circulations is ruled out for this situation. In the present situation the flow is boundary-driven. The rigid side walls act as an agent for the development of the circulation cells.

Waves propagating against the current

Also in this case two eddies are generated, rotating in opposite directions as those generated for waves propagating in the same direction as the current. This is as was expected. The development of the vertical profile for the horizontal current is shown in Fig. 6. This shows that the flow near the bed is reduced, and that the flow near the free surface is not increased as was to be expected. Notice that Nepf and Monismith (1991) found from measurements in a flume for both waves following and against the current that circulation cells developed. This is also the case in the present computations. Why almost no effect on the current profile is found for opposing waves is not yet clear. This deserves further investigation.

Conclusion

The numerical experiments lead to the following conclusions.

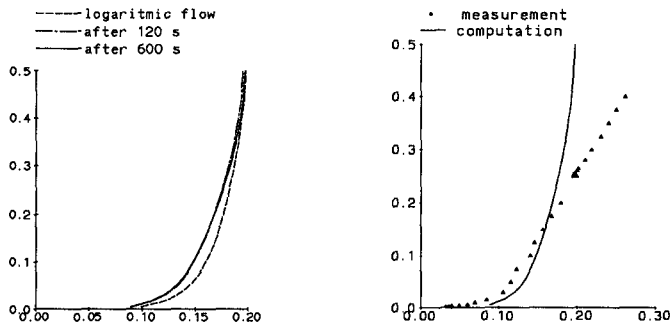

Figure 6: Development in time of the vertical profile of the horizontal velocity for the situation of waves propagating against the current (*left*); Comparison of the vertical profile of the horizontal velocity for waves propagating against the current with the measured profile (*right*).

1. Because also for a very wide flume only two circulation cells will develop, we conclude that the possibility of Langmuir circulation is ruled out for this situation. The flow is boundary-driven.
2. The principal mechanism of change of the near-surface velocities is the lateral transport of low-momentum fluid from the rigid side walls to the centre of the flume. Therefore, we conclude that the CL-vortex force is, at least partly, responsible for the observed change in velocities due to waves upon currents.
3. For both following and opposing waves circulation cells are found in the computations, which is in accord with the experiments of Nepf et al. (1995). Why the case for opposing waves has so little effect on the change of the current profile compared to the case without waves is not yet clear and deserves further investigation.
