New York, New York 10017-2398

Abstract:

This proceedings contains over 370 papers presented at the 25th International Conference on Coastal Engineering which was held in Orlando, Florida, 2-6 September, 1996. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation, erosion and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering.

FOREWORD

The *Silver Conference* represents the 25th International Conference on Coastal Engineering. The first conference was held in Long Beach, California, in 1950, approximately a half a century ago. This conference series has maintained and still represents the major forum for presentation and discussion of the ongoing research in the field of coastal engineering, applications to design projects and case histories of completed projects. Moreover, the conference is not limited to just coastal engineers but it is open to other related disciplines including geologists, meteorologists, oceanographers and construction for example. Traditionally, each conference was hosted by a different country to allow the problems and solutions of that country to be shared with others attending from around the world. This also provided a unique opportunity for the young engineers to benefit by having a coastal engineering conference hosted in their country which they could more easily attend. As the conference series evolved, many formats have been introduced to help promote the discussion and learning opportunities, but the conference series has remained dedicated to the highest standard of presentation and dissemination of information that can aid the practitioners as well as the researchers. The competition to present work at the conference has continued to increase as the research has increased and the works become ever larger and more exciting.

In recognition of the *Silver Conference* (also know as ICCE96) and celebration of our "Coastal Engineering History and Heritage," the organizers of the conference commissioned a coastal engineer in each of the countries which had hosted a conference in the series to prepare a history of coastal engineering in that country. Papers were prepared by authors representing 15 countries, presented at the conference and published in a separate volume¹ edited by the Conference co-chair Dr. Nicholas C. Kraus. The volume is available from the American Society of Civil Engineers.

The *Silver Conference* was the largest in the long series with largest number of papers being submitted for consideration. The 850 papers were each reviewed by four members of the technical review panel. Unfortunately, only 435 papers could be accepted for presentation during the week long conference. This necessitated changing the normal 30 minute presentations to 20 minute presentations in order to accommodate the large number of presentations --nearly 100 more papers than previous conferences have accommodated. The technical aspects of ICCE96 were very successful and to support the discussions, informative field trips to the East and West shorelines of Florida were arranged and well attended. This allowed participants to view the coastal engineering solutions to problems in inlet management, beach fill technology, shoreline and environmental protection and restoration and coastal water quality.

Lastly, the 25th International Conference on Coastal Engineering was a family oriented meeting with special emphasis on an "American Experience." Being located in Orlando, Florida, near such facilities as Disneyworld, Epcot Center, MGM Studios and Sea World, provided many opportunities for family and social interaction.

¹ Kraus, Nicholas C. 1996. *History and Heritage of Coastal Engineering*. American Society of Civil Engineers. New York, NY.

The first 25 conferences have been held at venues noted in the table below; the table also includes the upcoming ICCE conferences which have been selected.

Conference	Year	Venue
1	1950	Long Beach, California
2	1951	Houston, Texas
3	1952	Cambridge, Massachusetts
4	1953	Chicago, Illinois
5	1954	Grenoble, France
6	1957	Gainesville, Florida
7	1960	The Hague, The Netherlands
8	1962	Mexico City, Mexico
9	1964	Lisbon, Portugal
10	1966	Tokyo, Japan
11	1968	London, United Kingdom
12	1970	Washington, D.C.
13	1972	Vancouver, Canada
14	1974	Copenhagen, Denmark
15	1976	Honolulu, Hawaii
16	1978	Hamburg, Germany
17	1980	Sydney, Australia
18	1982	Cape Town, South Africa
19	1984	Houston, Texas
20	1986	Taipei, Taiwan
21	1988	Torremolinos, Spain
22	1990	Delft, The Netherlands
23	1992	Venice, Italy
24	1994	Kobe, Japan
25	1996	Orlando, Florida
26	1998	Copenhagen, Denmark
27	2000	Sydney, Australia

The Editor would like to acknowledge the work of the Local Organizing Committee in developing a very successful conference. Being a member of the LOC brings into sharp focus the amount of work required to develop and conduct a successful conference. The members of the LOC worked tirelessly to ensure the success of the ICCE96. In addition to the Local Organizing

Committee, the work of the eight members of the technical review panel were critical to selecting the highest quality papers to be presented. Each reviewer was responsible for a critical review of 425 abstracts in a very brief period of time. One special person deserving of recognition who continues to support the conference and the preparation of the *Proceedings* and communicates with authors of papers is Becky Edge. She has unselfishly given her time and energy to producing the databases from which the conference and *Proceedings* are maintained and over the years has developed a network among those who contribute papers to the Conference. To the above and to the many others who have helped to produce these *Proceedings*, I say "Thanks."

FINANCIAL SUPPORT

The Conference Organizing Committee expresses sincere gratitude to the exhibitors for their financial support of the conference.

SUPPORTING ORGANIZATIONS

American Geophysical Union
Canadian Society for Civil Engineering
Florida Shore and Beach Preservation Association
Institution of Civil Engineers, United Kingdom
international Association for Hydraulic Research, Maritime Hydraulics Section
Japan Society of Civil Engineers, Committee on Coastal Engineering
Permanent International Association of Navigation Congresses (PIANC)
Royal Institution of Engineers in The Netherlands
Society of Danish Engineers
U. S. Geological Survey
U. S. Army Corps of Engineers, Waterways Experiment Station

CONTENTS

Part I Characteristics of Coastal Waves and Currents

CHAPTER 1	
Experimental Study of Breaking Waves over a Shoal	2
<i>Arun Chawla, H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 2	
A Method for Estimating Standardized Bimodal Directional Spectra	16
<i>Ryuichi Fujiwara, Masahiko Isobe</i>	
CHAPTER 3	
The Effects of Currents on Estimations of Directional Wave Spectra	30
<i>Yasuyuki Nakagawa, Hiroichi Tsuruya, Noriaki Hashimoto</i>	
CHAPTER 4	
A Method for Estimating Directional Spectra in a Field of Incident and Reflected Waves	43
<i>Hiromune Yokoki, Masahiko Isobe</i>	
CHAPTER 5	
Active Absorption of Multidirectional Waves	55
<i>Hemming A. Schaffer, Jesper Skourup</i>	
CHAPTER 6	
Time-Averaged Wave Field Evolution in Coastal Zone	67
<i>Jianlu Xu, Rodney J. Sobey</i>	
CHAPTER 7	
Quality Control of GEOSAT Wave Data for Engineering Applications	81
<i>M. Siddabathula, Vijay G. Panchang</i>	
CHAPTER 8	
Boussinesq Type Equations with High Accuracy in Dispersion and Nonlinearity	95
<i>P.A. Madsen, B. Banijamali, H.A. Schaffer, O.R. Sorensen</i>	
CHAPTER 9	
Wave Kinematics Computations Using Boussinesq Models	109
<i>J. Bosboom, G. Klopman, J.A. Roelvink, J.A. Battjes</i>	
CHAPTER 10	
Effects of Mode Truncation and Dissipation on Predictions of Higher Order Statistics ...	123
<i>James M. Kaihatu, James T. Kirby</i>	
CHAPTER 11	
Field Observation of Movement of Sand Body Due to Waves and Verification of Its Mechanism by Numerical Model	137

CHAPTER 129	
Field Investigations on Wave-Dissipating Concrete Blocks Covering Vertical Wall Breakwater	1652
<i>Michio Gomyoh, Kazuhiko Sakai, Tomotuka Takayama, Kojiro Suzuki, Shigeo Takahashi</i>	
CHAPTER 130	
New Stability Formula for Wave-Dissipating Concrete Blocks Covering Horizontally Composite Breakwaters	1665
<i>Minoru Hanzawa, Hirokazu Sato, Shigeo Takahashi, Kenichiro Shimosako, Tomotsuka Takayama, Katsutoshi Tanimoto</i>	
CHAPTER 131	
Breakwater Stability under Regular and Irregular Wave Attack	1679
<i>Thomas Jensen, Henning Andersen, John Gronbech, Etienne P.D. Mansard, Michael H. Davies</i>	
CHAPTER 132	
Roundhead Stability of Berm Breakwaters	1693

CHAPTER 133	
Improvement of Composite Breakwater on Solid Bottom Against Severe Tsunamis	1707
<i>Yoshiaki Kimura, Hideo Kondo, Shinji Kuwabara, Akira Kawamori</i>	
CHAPTER 134	
Hydraulic Stability Analysis of Leese Slopes of Overtopped Breakwaters	1721
<i>M.D. Kudale, N. Kobayashi</i>	
CHAPTER 135	
Influence of the Core Configuration on the Stability of Berm Breakwaters	1735
<i>Nikolay Lissev, Alf Torum</i>	
CHAPTER 136	
Model Study of Reservoir Riprap Stability	1748
<i>Etienne P. D. Mansard, Michael H. Davies, Octave Caron</i>	
CHAPTER 137	
Prototype Measurements of Wave Pressures on a Wave Screen: Comparison to Physical and Analytical Models	1762
<i>F.L. Martin, M. A. Losada, C. Vidal, J.L. Diaz Rato</i>	
CHAPTER 138	
Velocity Field Measurements over Breakwater Heads under 3D Waves	1776
<i>Yoshiharu Matsumi, Akira Kimura, Kenichi Ohno</i>	
CHAPTER 139	
Wave Climate Simulation and Breakwater Stability	1789
<i>Josep R. Medina</i>	
CHAPTER 140	
Incipient Motion of Breakwater Armor Units	1803
<i>J. A. Melby, N. Kobayashi</i>	
CHAPTER 141	
Overtopping Reduction in Crownwall Design	1816
<i>Jose Luis Monso, Alfonso Vidoar, Cristina Cadevall, Cristina Garcia</i>	
CHAPTER 142	
Stable Profiles of Reshaping Breakwaters with a Berm Below the Water Level	1826
<i>C.I. Moutzouris</i>	
CHAPTER 143	
Experiments on a Non-Wave Overtopping Type Seawall	1840
<i>Keisuke Murakami, I. Irie, Y. Kamikubo</i>	
CHAPTER 144	
A Condition and Performance Rating System for Breakwaters and Jetties	1852
<i>John Oliver, Don Plotkin, John Lesnik, Douglas Pirie</i>	

CHAPTER 145	
Wave Overtopping and Stability of Armor Units under Multidirectional Waves	1862
<i>T. Sakakiyama, R. Kajima</i>	
CHAPTER 146	
Numerical Modeling of Breach Growth in a Sanddike	1876
<i>Guus S. Stelling, Willem T. Bakker, Christine van Kuik, Christel Somers</i>	
CHAPTER 147	
Aging and Stability of Placed Block Revetments	1888
<i>Theo Stoutjesdijk, Hans Johanson, Mark Klein Breteler</i>	
CHAPTER 148	
Experimental Analysis of the Settlement Failure Mechanism Shown by Caisson-Type Seawalls	1902
<i>Shigeo Takahashi, Kojiro Suzuki, Katsumasa Tokubuchi, Ken-ichiro Shimosako</i>	
CHAPTER 149	
Full Scale Measurements of Wave Attenuation Inside a Rubble Mound Breakwater . . .	1916
<i>Peter Troch, Marc De Somer, Julien De Rouck, Luc van Damme, Dierik Vermeir, Jean-Pierre Martens, Conan van Hove</i>	
CHAPTER 150	
Numerical Modelling of Wave Interaction with Dynamically Stable Structures	1930
<i>Marcel R.A. van Gent</i>	
CHAPTER 151	
Monitoring of Zeebrugge Breakwaters	1944
<i>Luc van Damme, Julien de Rouck</i>	
CHAPTER 152	
Influence of Rock Shape and Grading on Stability of Low-Crested Structures	1957
<i>Jentsje W. van der Meer, W.H. Tutuarima, G. Burger</i>	
CHAPTER 153	
Toe Stability of Rubble Mound Breakwaters	1971
<i>Ton van der Meulen, Gerrit J. Schiereck, Kees d'Angremond</i>	
CHAPTER 154	
Seawall Effects on Historically Receding Shorelines	1985
<i>Bryan N. Jones, David R. Basco</i>	
CHAPTER 155	
Control of Wave Propagation Angle by Tapered-Submerged Breakwater	1998
<i>Satoshi Takewaka, Isao Irie</i>	
CHAPTER 156	
Multidirectional Wave Loads on Vertical Breakwaters	2008
<i>Claudio Franco, Jentsje W. Van der Meer, Leopoldo Franco</i>	

CHAPTER 157	
Modelling the Impact of Detached Breakwaters on the Coast	2022
<i>K.J. Bos, J.A. Roelvink, M.W. Dingemans</i>	
CHAPTER 158	
Evaluation of Beach Modelling Techniques Behind Detached Breakwaters	2036
<i>Philip Axe, Suzana Ilic, Andrew Chadwick</i>	
CHAPTER 159	
Numerical Modelling of Bed Evolution Behind a Detached Breakwater	2050
<i>Philippe Pechon, Charles Teisson</i>	
CHAPTER 160	
Combined Diffraction and Transmission of Water Waves around a Porous Breakwater	
Gap	2063
<i>Xiping Yu, Hiroyoshi Togashi</i>	
CHAPTER 161	
Prediction of Wave Reflection from Rock Structures: An Integration of	
Field & Laboratory Data	2077
<i>Mark A. Davidson, Paul A.D. Bird, David A. Huntley, Geoff N. Bullock</i>	
CHAPTER 162	
Performance Evaluation of Buoy-Membrane Wave Barriers	2087
<i>M.H. Kim, B. L. Edge, S.T. Kee, L. Zhang</i>	
CHAPTER 163	
An Improved Design Method for the Riprap of Earthfill Dams of Large Reservoirs ...	2101
<i>Jean-Pierre Tournier, Pierre Dupuis, Raymond Ares</i>	
CHAPTER 164	
Geotextile Systems in Coastal Engineering - An Overview -	2114
<i>Krystian W. Pilarczyk</i>	
CHAPTER 165	
Groynes on the East Frisian Islands: History and Experiences	2128
<i>Hans Kunz</i>	
CHAPTER 166	
Permeable Pile Groins	2142
<i>Thomas Trampenau, Frank Goricke, Arved J. Raudkivi</i>	
CHAPTER 167	
The Effect of Groundwater on Scour Near Structures	2152
<i>John H. Loveless, Geoffrey T. Grant, Robert I. Karlsson</i>	
CHAPTER 168	
Abrasion of Steel Pipe Piles by Sediment Motion in Coastal Zones	2166
<i>Gaku Matsuoka, Shinichi Ito, Toshihiko Yamashita, Hiroshi Saeki, Yoshihisa Kariyazono, Koichi Sato</i>	

CHAPTER 169	
A Viscous Rotational Model for Wave Overtopping over Marine Structure	2178
<i>Fei Zhuang, Jiin-Jen Lee</i>	
CHAPTER 170	
Overtopping of Waves at a Wall: A Theoretical Approach	2192
<i>M. Jervis, D.H. Peregrine</i>	
CHAPTER 171	
Wind Effects on Runup and Overtopping of Coastal Structures	2206
<i>Donald L. Ward, Jun Zhang, Christopher G. Wibner, Charles M. Cinotto</i>	
CHAPTER 172	
Wave Overtopping of Vertical Structures Including Wind Effect	2216
<i>Johannes P. de Waal, Patrick Tonjes, Jentsje W. van der Meer</i>	
CHAPTER 173	
Bridge Pier Scour Assessment for the Northumberland Strait Crossing	2230
<i>C.D. Anglin, R.B. Nairn, A.M. Cornett, L. Dunaszegi, J. Turnham, G.W. Annandale</i>	
CHAPTER 174	
Wave Setup at River Entrances	2244
<i>David J. Hanslow, Peter Nielsen, Kevin Hibbert</i>	
CHAPTER 175	
Scour at Coastal Inlet Structures	2258
<i>Steven A. Hughes, J. William Kamphuis</i>	
CHAPTER 176	
Probability Distribution of the Maximum Wave Height along a Sea Wall with Finite Width	2272
<i>Akira Kimura, Takao Ohta</i>	
CHAPTER 177	
Beach Response in Front of Wave-Reflecting Structures	2284
<i>Roy C. Seaman, Tom O'Donoghue</i>	
CHAPTER 178	
Fundamental Characteristics of Wave Transformation around Artificial Reefs	2298
<i>Toshio Aono, Eric C. Cruz</i>	
CHAPTER 179	
Performance of a Submerged Breakwater for Shore Protection	2312
<i>Albert E. Browder, Robert G. Dean, Renjie Chen</i>	
CHAPTER 180	
Nonlinear Wave Transformation over a Submerged Triangular Breakwater	2324
<i>Lifen Dong, Akira Watanabe, Masahiko Isobe</i>	
CHAPTER 181	
Breaking Limit, Breaking and Post-Breaking Wave Deformation Due to Submerged	

Structures2338
<i>Koichiro Iwata, Koji Kawasaki, Do-Sam Kim</i>	
CHAPTER 182	
Italian Experience on Submerged Barriers as Beach Defence Structures2352
<i>Alberto Lamberti, Alessandro Mancinelli</i>	
CHAPTER 183	
Resonant Reflection and Refraction-Diffraction of Surface Waves Due to Porous Submerged Breakwaters2366
<i>Hajime Mase, Akira Kimura, Hiroshi Sakakibara</i>	
CHAPTER 184	
BEM-FEM Combined Analysis of Nonlinear Interaction between Wave and Submerged Breakwater2377
<i>N. Mizutani, W.G. McDougal, A.M. Mostafa</i>	
CHAPTER 185	
Regulation of Nearshore Circulation by Submerged Breakwater for Shore Protection .	.2391
<i>Hisamichi Nobuoka, Isao Irie, Hajime Kato, Nobuo Mimura</i>	
CHAPTER 186	
Submerged Breakwaters for the Defence of the Shoreline at Ostia - Field Experiences, Comparison2404
<i>Ugo Tomasicchio</i>	
CHAPTER 187	
Wave Transmission of Low-Crested Structures2418
<i>Kees d'Angremond, Jentsje W. van der Meer, Rutger J. De Jong</i>	
CHAPTER 188	
Effect of Submerged Breakwater on Profile Development2428
<i>Martin D. Groenewoud, Jan van de Graaff, Edward W.M. Claessen, Stephan C. van der Biezen</i>	
CHAPTER 189	
Cause and Characteristics of Impact Pressure Exerted by Spilling and Plunging Breakers on a Vertical Wall2442
<i>Seyed Ali Azarmsa, Takashi Yasuda, Hidemi Mutsuda</i>	
CHAPTER 190	
Dynamic Response of Vertical Elastic Walls to Breaking Wave Impact2456
<i>Masatato Hattori, Nobuaki Tsujioka</i>	
CHAPTER 191	
Wave Transmission Past Vertical Wave Barriers2470
<i>David L. Kriebel, Chad A. Bollmann</i>	
CHAPTER 192	
Physical Study of the Nature of High Peak Wave Pressures2484
<i>Jordan Marinski</i>	

CHAPTER 193	
A Design Short-Crested Wave Force Model for Vertical Deep-Water Breakwaters2494
	<i>S.-Y. Tzang, S.-R. Liaw</i>
CHAPTER 194	
New Design Methods for Wave Impact Loadings on Vertical Breakwaters and Seawalls . .	.2508
	<i>N.W.H. Allsop, J.E. McKenna, D. Vicinanza, T.T.J. Whittaker</i>
CHAPTER 195	
Scale Effects of Wave Impact Pressures on Cob Armour Units2522
	<i>M.W. Howarth, N.W.H. Allsop, A.M. Vann, R.J. Jones, J.P. Davis</i>
CHAPTER 196	
Wave Impact Loading of Vertical Face Structures for Dynamic Stability	
Analysis - Prediction Formulae -2534
	<i>P. Klammer, A. Kortenhaus, H. Oumeraci</i>
CHAPTER 197	
Analysis on the Interaction of Waves with Flexible Floating Structure	
by BE-FE Combined Method2548
	<i>Xiaodong Liu, Shigeki Sakai</i>
CHAPTER 198	
Design Wave Height Related to Structure Lifetime2560
	<i>Zhou Liu, Hans F. Burcharth</i>
CHAPTER 199	
Wave Impact Beneath a Horizontal Surface2573
	<i>D.J. Wood, D.H. Peregrine</i>
CHAPTER 200	
Wave Impulse Prediction for Caisson Design2584
	<i>Michael J.A. Walkden, Peter J. Hewson, Geoffrey N. Bullock</i>
CHAPTER 201	
Wave Overtopping Rate and Reflection Coefficient for Obliquely Incident Waves2598
	<i>Yoichi Moriya, Masaru Mizuguchi</i>
CHAPTER 202	
Sediment Transport and Wave Reflection near a Seawall2612
	<i>Jonathon R. Miles, Paul E. Russell, David A. Huntley</i>

Part IV Coastal Processes and Sediment Transport

CHAPTER 203	
Wave Energy Dissipation in Kelp Vegetation2626
	<i>Alfonse Dubi, Alf Torum</i>
CHAPTER 204	
Experimental Study on the Effect of Gravity Drainage System on Beach Stabilization . .	.2640
	<i>Hiroshi Kanazawa, Fumihiko Matsukawa, Kazumasa Katoh, Iwao Hasegawa</i>

CHAPTER 205	
Field Experiment on the Effect of Gravity Drainage System on Beach Stabilization . . .	2654
<i>Kazumasa Katoh, Shin-ichi Yanagishima</i>	
CHAPTER 206	
On the Change of Velocity Field in Nearshore Zone Due to Coastal Drain and the Consequent Beach Transformation	2666
<i>Michio Sato, Tadaihiro Fukushima, Ryuichiro Nishi, Masahiko Fukunaga</i>	
CHAPTER 207	
Evaluation of a Beach Dewatering System: Nantucket, USA	2677
<i>William R. Curtis, Jack E. Davis, Ian L. Turner</i>	
CHAPTER 208	
Sediment Transport Processes at Ocean Beach, San Francisco, California	2691
<i>Robert T. Battalio, Dilip Trivedi</i>	
CHAPTER 209	
Two Treatments of Shore Erosion in Extreme Floods on U.S. Great Lakes	2705
<i>Robert J. Hallermeier</i>	
CHAPTER 210	
Long-Term Beach Response to Shore Stabilization Structures on the Oregon Coast . . .	2718
<i>G.E. Hearon, W.G. McDougal, P.D. Komar</i>	
CHAPTER 211	
Profile Volumes as a Measure of Erosion Vulnerability	2732
<i>Timothy W. Kana, Ram Krishna Mohan</i>	
CHAPTER 212	
Breach Growth: Experiments and Modelling	2746
<i>Harry de Looff, Henk J. Steetzel, Arie W. Kraak</i>	
CHAPTER 213	
The Impact of an Extreme Event on the Sediment Budget: Hurricane Andrew in the Louisiana Barrier Islands	2756
<i>Jeffrey H. List, Mark E. Hansen, Asbury H. Sallenger, Jr., Bruce E. Jaffe</i>	
CHAPTER 214	
Beach Maintenance Strategies, a Comparison for a Recreational Beach	2770
<i>M. Pluijm, G. Kant, R. Nolten, A.P. de Looff</i>	
CHAPTER 215	
Littoral Impact of Ocean City Inlet, Maryland, USA	2779
<i>Julie Dean Rosati, Bruce A. Ebersole</i>	
CHAPTER 216	
Extreme Water Levels, Wave Runup and Coastal Erosion	2793
<i>P. Ruggiero, P.D. Komar, W.G. McDougal, R.A. Beach</i>	

CHAPTER 217	
A Morphological “Mixed-Type” Model for the Ebro Delta Coast	2806
<i>Agustin Sanchez-Arcilla, Jose A. Jimenez</i>	
CHAPTER 218	
Sea Dike Erosion and Coastal Retreat at Nam Ha Province, Vietnam	2820
<i>Ton That Vinh, G. Kant, Nguyen Ngoc Huan, Z. Pruszk</i>	
CHAPTER 219	
Beach Profile Analysis around Indian River Inlet, Delaware, U.S.A	2829
<i>Kirk F. Bosma, Robert A. Dalrymple</i>	
CHAPTER 220	
Improved 3-D Beach Evolution Model Coupled with the Shoreline Model (3D-SHORE)	2843
<i>Takuzo Shimizu, Takahiro Kumagai, Akira Watanabe</i>	
CHAPTER 221	
Evaluation of Shoreface Nourishments by Line Modelling	2857
<i>Martin D. Groenewoud, Willem T. Bakker, Jan van de Graaff, Ruud Spanhoff, Christian Laustrup</i>	
CHAPTER 222	
Beach Monitoring Program of Valencia (Spain)	2871
<i>Jose Serra, Josep R. Medina</i>	
CHAPTER 223	
Bar Migration and Duneface Oscillation on Decadal Scales	2884
<i>Marcel J.F. Stive, Jorge Guillen, Michele Capobianco</i>	
CHAPTER 224	
Morphological Development of the Terschelling Shoreface Nourishment in Response to Hydrodynamic and Sediment Transport Processes	2897
<i>P. Hoekstra, K.T. Houwman, A. Kroon, B.G. Ruessink, J.A. Roelvink, R. Spanhoff</i>	
CHAPTER 225	
Justification for Beach Nourishment	2911
<i>John G. Housley</i>	
CHAPTER 226	
Beach Nourishment Versus Shore Protection Structures	2918
<i>Alexander Khabidov, Yuri Bazhenov, Marina Glodenis, Nadya Ivanova, Liya Kaskevitch, Oleg Rybak, Valery Savkin, Anatoly Trizno, Grigory Zelensky, Veniamin Yedapin</i>	
CHAPTER 227	
Comparison of Beach and Shoreface Nourishment Torsminde Tange, Denmark	2927
<i>Christian Laustrup, Holger Toxvig Madsen, Per Sorensen, Ida Broker</i>	
CHAPTER 228	
Mathematical and Physical Modeling of Beach Nourishment Projects	2941
<i>W. Eric Rogers, Paul A. Work</i>	

CHAPTER 229	
Coastal Zone Dynamics during Artificial Nourishment	2955
<i>Elzbieta Zawadzka</i>	
CHAPTER 230	
Dune Damage Curves and Their Use to Estimate Dune Maintenance Costs	2969
<i>David R. Basco, Cheol S. Shin</i>	
CHAPTER 231	
Hurricane Opal Induced Changes on Natural and Nourished Beaches, West-Central Florida	2982
<i>Richard A. Davis, Jr., Ping Wang</i>	
CHAPTER 232	
Modelling Sand Transport and Profile Evolution on Macrotidal Beaches	2994
<i>Paul R. Fisher, Tim J. O'Hare</i>	
CHAPTER 233	
Beach Evolution Under Random Waves	3006
<i>Patrick Holmes, Thomas E. Baldock, Ray T.C. Chan, M. Ahmad L. Neshaei</i>	
CHAPTER 234	
Beach Profile Surveys Along the U.S. Pacific Coast 1945-1947	3020
<i>Nicholas C. Kraus, Robert L. Wiegel, Willard N. Bascom</i>	
CHAPTER 235	
Mechanism and Calculation of Sand Dune Erosion by Storms	3034
<i>Ryuichiro Nishi, Nicholas C. Kraus</i>	
CHAPTER 236	
Simulation of Coastal Profile Development Using a Boussinesq Wave Model	3048
<i>K.A. Rakha, R. Deigaard, P.A. Madsen, I. Broker, J.K. Ronberg</i>	
CHAPTER 237	
Cross-shore Sediment Transport and Beach Deformation Model	3062
<i>RattanapitikonWinyu , Tomoya Shibayama</i>	
CHAPTER 238	
Experimental Study on Sediment Transport in Surf and Swash Zones Using Large Wave Flume	3076
<i>Takao Shimizu, Masaaki Ikeno</i>	
CHAPTER 239	
The Influence of Long Waves on Macrotidal Beach Morphology	3090
<i>David J. Simmonds, Tim J. O'Hare, David A. Huntley</i>	
CHAPTER 240	
Mathematical Models for Waves and Beach Profiles in Surf and Swash Zones	3104
<i>Akira Watanabe, Mohammad Dibajnia</i>	

CHAPTER 241
Comparisons of Erosion Models for Storms at Ocean City, Maryland3115
Jie Zheng, Robert G. Dean

CHAPTER 242
Measurements of Wave Generated Bedforms3129
Christopher D. Jette, Daniel M. Hanes

CHAPTER 243
Field Measurement of Bed Roughness for Waves on an Offshore Reef3143
Raymond C. Nelson

CHAPTER 244
Effect of Wave-Induced-Pressure on Seabed Configuration3155
Tetsuo Sakai, Hitoshi Gotoh

CHAPTER 245
The Measurement of Bed Form Shapes in Hydraulic Models3169
Ian E. Shepherd

CHAPTER 246
Asymmetric Boundary Layer Flow above Sand Ripples under Progressive Waves3183
Takao Toue, Kazuo Nadaoka, Hidehiro Katsui

CHAPTER 247
Undertow Profiles in the Bottom Boundary Layer under Breaking Waves3194
Daniel T. Cox, Nobuhisa Kobayashi

CHAPTER 248
**A Comparison of Field Observations and Quasi-Steady Linear Shear Instabilities
of the Wave Bottom Boundary Layer**3207
D.L. Foster, A.J. Bowen, R.A. Beach, R.A. Holman

CHAPTER 249
Wave Boundary Layer Flows and Pore Pressures in Permeable Beds3219
H.H. Hwung, K.S. Hwang, B.H. Lee

CHAPTER 250
Backfilling of Trenches Exposed to Waves3231
Jacob Hjelmager Jensen, Jorgen Fredsoe

CHAPTER 251
A Closed-Form Solution for Turbulent Wave Boundary Layers3244
Magnus Larson

CHAPTER 252
Observed Suspended Sediments in Storm Conditions3257
*J.J. Williams, C.P. Rose, P.D. Thorne, L.E. Coates, J.R. West, P.J. Harcastle, J.D. Humphery,
S.P. Moores, D.J. Wilson*

CHAPTER 253	
Ebb Tidal Delta Evolution of Coastal Inlets	3270
<i>Michael R. Dombrowski, Ashish J. Mehta</i>	
CHAPTER 254	
Adjustments toward Equilibrium of a Large Flood -Tidal Delta after a Major Dredging Program, Tauranga Harbour, New Zealand	3284
<i>Terry Healy, Joseph Mathew, Willem de Lange, Kerry Black</i>	
CHAPTER 255	
Laboratory Mobile Bed Model Studies on Ebb Tidal Shoal Evolution	3295
<i>Xu Wang, Lihwa Lin, Hsiang Wang</i>	
CHAPTER 256	
Interaction of the Colorado River Project, Texas, with Longshore Sediment Transport ..	3309
<i>Daniel J. Heilman, Billy L. Edge</i>	
CHAPTER 257	
A Comprehensive Field Study of Tidal Inlet Processes at Ponce de Leon Inlet, Florida ..	3323
<i>Gary L. Howell</i>	
CHAPTER 258	
Transport of Fluid Mud Generated by Waves on Inclined Beds	3337
<i>Thijs van Kessel, C. Kranenburg, J.A. Battjes</i>	
CHAPTER 259	
Wave on Pebble Beach and Deformation of Pebble Beach	3349
<i>Ichiro Deguchi, Masanobu Ono, Toru Sawaragi</i>	
CHAPTER 260	
Wind-Induced Waves and Currents in a Nearshore Zone	3363
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroshi Kawakami</i>	
CHAPTER 261	
Predicting Large-Scale, Cross-Shore Sediment Movement from Orbital Speeds	3378
<i>Edward B. Hands, John P. Ahrens, Donald T. Resio</i>	
CHAPTER 262	
Small-scale Morphology Related to Wave and Current Parameters Over a Barred Beach	3391
<i>A.F. Garcez Faria, E.B. Thornton, T.P. Stanton</i>	
CHAPTER 263	
Prediction of Shoreline Change Considering Cross-Shore Sediment Transport	3405
<i>Yoshimichi Yamamoto, Kiyoshi Horikawa, Katsutoshi Tanimoto</i>	
CHAPTER 264	
The Influence of Rollers on Longshore Currents	3419
<i>Daniel A. Osiecki, William R. Dally</i>	

CHAPTER 265	
Velocity Field Measurements in a “Coastal Buffer Zone”	3431
<i>Hiroshi Yagi, Hirofumi Hinata, Kazuo Nadaoka</i>	
CHAPTER 266	
Development of Underwater Beach Profile by Monochromatic and Random Waves ...	3442
<i>Karsten Peters, Jurgen Newe, Hans-H. Dette</i>	
CHAPTER 267	
Turbulent Stresses in the Surf-Zone: Which Way Is Up?	3453
<i>John W. Haines, Guy Gelfenbaum</i>	
CHAPTER 268	
Asymmetric and Irregular Wave Effects on Bedload: Theory Versus Laboratory and Field Experiments	3467
<i>Leszek M. Kaczmarek, Rafal Ostrowski</i>	
CHAPTER 269	
Kinematics and Shear Stresses from Combined Waves and Longshore Currents in the UK Coastal Research Facility	3481
<i>Richard R. Simons, Ruairi D. MacIver, Wameidh M. Saleh</i>	
CHAPTER 270	
Movable Bed Roughness in the Flow of Irregular Waves and Currents Over Movable Beds	3495
<i>Zai-Jin You, Peter Nielsen</i>	
CHAPTER 271	
Seabed and Foundation Response to Wave Loading	3507
<i>Michael H. Davies</i>	
CHAPTER 272	
Interannual Shoreline Variations at Duck, NC, USA	3521
<i>Nathaniel Plant, Rob Holman</i>	
CHAPTER 273	
Long Term Behaviour of the Sediment Volume inside a Tidal Basin after Poldering ...	3534
<i>Ernst Schroeder, Roland Goldenbogen, Hans Kunz</i>	
CHAPTER 274	
Wave Groups in a Barred Nearshore	3546
<i>B. Boczar-Karakiewicz, W. Romanczyk, J.L. Bona, B. Greenwood</i>	
CHAPTER 275	
Coastal Morphodynamic Instabilities	3560
<i>Albert Falques, Amadeu Montoto, Vicente Irazo</i>	
CHAPTER 276	
On Validation of a Sand Waves and Sand Banks Model	3574
<i>Suzanne J.M.H. Hulscher</i>	

CHAPTER 277	
Transverse Bars in Duck, North Carolina	3588
<i>Kathryn M. Konicki, Rob A. Holman</i>	
CHAPTER 278	
On the Systematic Offshore Decay of Breaker Bars	3600
<i>Kathelijne M. Wijnberg</i>	
CHAPTER 279	
Longshore Bed-Load Transport	3614
<i>Jesper S. Damgaard, Richard L. Soulsby</i>	
CHAPTER 280	
Design Capacity of a Longshore Current Recirculation System for a Longshore Sediment Transport Laboratory Facility	3628
<i>David G. Hamilton, Julie D. Rosati, Jimmy E. Fowler, Jane M. Smith</i>	
CHAPTER 281	
Influence of Nearshore Hardbottom on Regional Sediment Transport	3642
<i>Paul C.-P. Lin, R. Harvey Sasso</i>	
CHAPTER 282	
Improvement of the Most Accurate Longshore Transport Formula	3652
<i>J.S. Schoonees, A.K. Theron</i>	
CHAPTER 283	
Cross-shore Structure of Longshore Currents during Duck94	3666
<i>Falk Feddersen, R.T. Guza, Steve Elgar, T.H.C. Herbers</i>	
CHAPTER 284	
Three-Dimensional Hydrodynamics on a Barred Beach	3680
<i>Tae-Myoung Oh, Robert G. Dean</i>	
CHAPTER 285	
Rip Current Generation on a Plane Beach	3694
<i>D.A. Suriamihardja, Yoshito Tsuchiya</i>	
CHAPTER 286	
Nearshore Placement of Sand	3708
<i>Scott L. Douglass</i>	
CHAPTER 287	
Influence of Nearshore Berm on Beach Nourishment	3722
<i>Paul A. Work, Emre N. Otay</i>	
CHAPTER 288	
Accuracy of Sand Volumes as a Function of Survey Density	3736
<i>Jennifer L. Irish, W. Jeff Lillycrop, Larry E. Parson</i>	
CHAPTER 289	
Shoreline Analysis Using Digital Photogrammetry	3750

CHAPTER 290	
Application of Satellite Images to the Detection of Coastal Topography	3762
<i>Ji Wu, Jea Tzyy Juang</i>	
CHAPTER 291	
Sediment Transport in Swash Zone under Obliquely Incident Waves	3770
<i>Toshiyuki Asano</i>	
CHAPTER 292	
Sheet Flow Modelled As Pure Convection	3784
<i>Stephen Clark, Peter Nielsen</i>	
CHAPTER 293	
A Transport Rate Formula for Mixed-Size Sands	3791
<i>Mohammad Dibajnia, Akira Watanabe</i>	
CHAPTER 294	
Modelling of 3D Sediment Transport in the Surf Zone	3805
<i>Berry Elfrink, Ida Broker, Rolf Deigaard, Erik Asp Hansen, Peter Justesen</i>	
CHAPTER 295	
A Numerical Model of Sheet Flow Sediment Transport	3818
<i>Sadakazu Katori, Masaru Mizuguchi, Akira Watanabe</i>	
CHAPTER 296	
Numerical Modeling of Nearshore Morphological Changes under a Current-Wave Field	3830
<i>Taerim Kim, Hsiang Wang</i>	
CHAPTER 297	
An Analysis of Particle Saltation Dynamics	3846
<i>Michael R. Krecic, Daniel M. Hanes</i>	
CHAPTER 298	
Sediment Movement and Stress Condition in Sea Bed	3860
<i>Yoshihiko Maeno, Motoyasu Ishikawa, Kozo Bando, Yoshinobu Akiyama, Kouichi Yabe</i>	
CHAPTER 299	
Application of the Depth of Closure Concept	3874
<i>Robert J. Nicholls, William A. Birkemeier, Robert J. Hallermeier</i>	
CHAPTER 300	
Numerical Modeling of Sediment Transport for Various Mode	3888
<i>Masanobu Ono, Ichiro Deguchi, Toru Sawaragi</i>	
CHAPTER 301	
Nearbed Sediment Concentration from Tracer Studies	3901
<i>Zbigniew Pruszk, Ryszard Wierzchnicki, Andrzej Owczarczyk, Ryszard B. Zeidler</i>	

CHAPTER 302	
A Sloping Duct for the Study of Sediment Transport	3913
<i>Jesper S. Damgaard, Richard J.S. Whitehouse, Richard L. Soulsby</i>	
CHAPTER 303	
Sediment Dynamics and Profile Interactions: DUCK94	3921
<i>Donald K. Stauble, Mary A. Cialone</i>	
CHAPTER 304	
A Study on Flow Structure and Suspended Sediment Concentration over Seaweed Bed ..	3935
<i>Gozo Tsujimoto</i>	
CHAPTER 305	
An Energetics Approach for Suspended Sand Transport on Macrotidal Ridge and Runnel Beaches	3948
<i>George Voulgaris, Travis Mason, Michael B. Collins</i>	
CHAPTER 306

CHAPTER 1

EXPERIMENTAL STUDY OF BREAKING WAVES OVER A SHOAL

Arun Chawla, H. Tuba Özkan-Haller and James T. Kirby¹

ABSTRACT: The aim of this paper is to study the transformation of irregular directional waves over a circular shoal. An experimental study has been carried out. The resulting data has been used to test the accuracy of an existing refraction-diffraction model. Model to data comparisons have been carried out for the entire basin region including about 3 shoal diameters downwave of the shoal, with satisfactory results. Several physical processes have been identified which lead to possible disparities in the comparisons.

INTRODUCTION

Wave modeling of random waves over a varying bathymetry is a subject of considerable importance to coastal engineers. The development of the classical mild slope equation by Berkhoff (1972) allowed coastal engineers to study the combined effects of refraction and diffraction. A wide family of equations have been derived from the mild slope equation to increase the accuracy and the speed of the models. One such set of equations are the parabolic equations, first derived for ocean waves by Radder (1979), which have gained popularity because of their speed of computation, even though they have a fixed direction of propagation and a limited range of angles from the assumed propagation direction over which they are valid. Nonlinear formulations of parabolic equations (Kirby and Dalrymple 1983) have been found to give more accurate results than the linear mild slope equation (Kirby and Dalrymple 1984). The limitation in the range of angles has been relaxed using Padé approximants (Booij, 1981).

Although relatively accurate parabolic models have been developed to study the evolution of waves over an irregular bottom, all these models have been derived for monochromatic waves only. Coastal engineers have traditionally approximated the offshore irregular sea states by representative monochromatic waves in order to use these models to make predictions. However, investigators such as Goda (1985) (using an analytical approach), Vincent and Briggs (1989) (by conducting an experimental study) and Panchang *et al.* (1990) (using a numerical approach) have shown that such an approximation may result in large errors due to vast dissimilarities in the refraction-diffraction patterns of the two

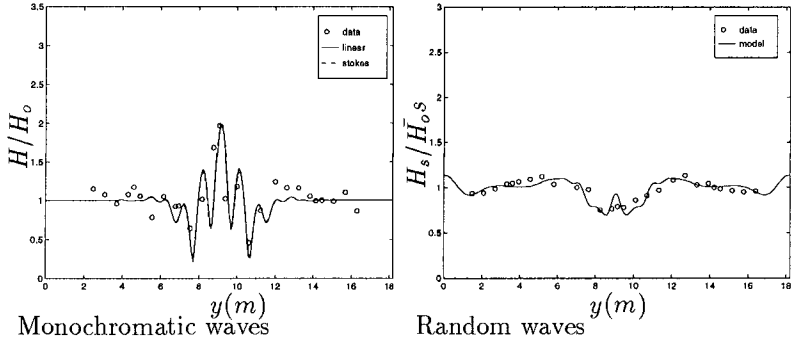

Figure 1: Wave height distribution behind a shoal for a monochromatic wave and a directional sea state

wave fields. Our own experiments confirm this and Figure 1 shows the vast differences in the wave height distribution along a transect (transect D-D in Figure 2) behind a submerged shoal.

Recently, methods for computing the evolution characteristics of a directional spectral sea state using parabolic models for monochromatic waves have been developed. Panchang *et al.* (1990), Grassa (1990) and Izumiya and Horikawa (1987) have developed models using a spectral calculation method which consists of discretizing the offshore spectrum into individual monochromatic directional components, determining the wave transformations of each component with the help of monochromatic wave models, and then assembling the wave components by linear superposition at the respective grid points in the domain to obtain the statistical characteristics of the spectrum at those points.

In this paper a numerical model which has been developed using the parabolic formulation of Kirby (1986a), is tested against data for a range of breaking wave conditions. Experimental study of random directional waves breaking over a submerged circular shoal has been carried out for two different directional spreadings and energy variances to study their effects on wave height distribution. Extensive surface elevation measurements have been made on top of and around the shoal, and some aspects of the frequency spectra have been looked into.

NUMERICAL MODEL

The parabolic model for spectral wave conditions used here simulates the evolution of directional random waves in the nearshore zone. The model predicts the effects of refraction, diffraction, shoaling and breaking. Therefore, the model is particularly applicable to regions where an incoming random sea propagates over complicated bathymetry towards shore. The bathymetry may include a shoal formation at the mouth of an inlet or estuary, where refraction, diffraction, shoaling and depth-limited breaking will be simultaneously important.

The model requires the specification of the incoming directional random sea at the offshore boundary. The random sea is represented by a two-dimensional spectrum which is discretized into wave components, resulting in wave components of amplitude A with associated frequency f and angle of incidence θ to

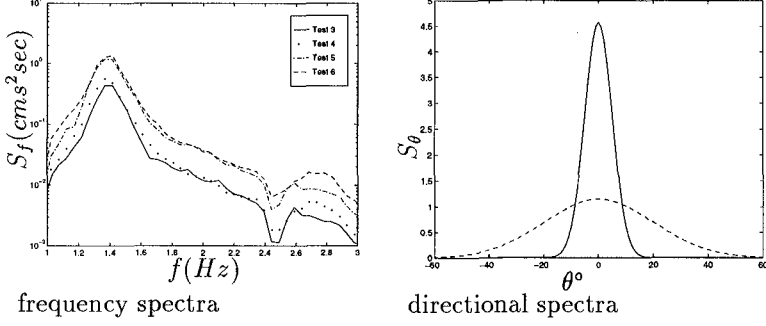

Figure 3: Design frequency and directional spectra for the 4 directional sea states

 \end{aligned}$$

where U and V are the currents in the x and y directions, α is a dissipation coefficient for wave breaking, \bar{k}_n is a representative wave number corresponding

Figure 4: Refraction diagram at peak frequency, $f_p = 1.37 \text{ Hz}$ for the given bathymetry.

to the peak frequency, and

$$\begin{aligned}
 \sigma_n &= \omega_n - k_n U, \\
 \beta_n &= \frac{(k_n)_x}{k_n^2} + \frac{(k_n ((CC_g)_n - U^2))_x}{2k_n^2 ((CC_g)_n - U^2)}, \\
 \Delta_1 &= a_1 - b_1, \\
 \Delta_2 &= 1 + 2a_1 - 2b_1, \\
 \Delta'_n &= a_1 - b_1 \frac{\bar{k}_n}{k_n}.
 \end{aligned} \tag{4}$$

The model coefficients

$$a_0 = 1; \quad a_1 = -0.75; \quad b_1 = -0.25 \tag{5}$$

recover the Padé approximant of Booij(1981).

The statistical information obtained after each step in the parabolic scheme is used to construct a model for the dissipation of energy due to breaking. To determine the energy dissipation, a simple model by Thornton and Guza (1983) is used. The energy dissipation model is built into the model equation using an additional breaking term αA_n in (3), so that it is unnecessary to have any criterion for turning breaking on or off. The coefficient α is given by

$$\alpha = \frac{3\sqrt{\pi} \bar{f} B^3}{4 \gamma^4 h^5} H_{rms}^5. \tag{6}$$

Figure 5: Significant wave height distribution along transect A-A

where h is the local water depth and \bar{f} is a representative frequency for the frequency spectrum and is chosen to be the peak frequency. B and γ are constants and are chosen to be equal to 1 and 0.6, respectively (Mase and Kirby, 1992). H_{rms} is the root-mean-square wave height, and is obtained as a statistical quantity from the wave model,

$$H_{rms}(x, y) = 2 \sqrt{\sum_{n=1}^N |A(x, y)_n|^2} \quad (7)$$

The dissipation model of Thornton and Guza (1983) was originally derived assuming that the waves continue breaking once they have started, and has been validated for waves breaking on a monotonic beach. Though we can see from (6) that the dissipation term α is artificially reduced with increase in local water depth h we are not certain if this correctly simulates the reforming of waves with increased water depth. Also, no modifications have been made in the dissipation model to account for directional effects. Only change in energy flux in the x direction is considered, and energy flux in the y direction does not take part in the dissipation model.

EXPERIMENTAL SETUP

The experiments were conducted at the Center for Applied Coastal Research, University of Delaware. The wave basin is approximately 18.2m long and 18.2m

Figure 6: Significant wave height distribution along transect F-F

wide. It has a three-dimensional wavemaker at one end, consisting of 34 flap type paddles which creates the desired wave field. The bottom is flat except for a circular shoal in the center, and a stone beach at the far end minimizes the reflections. A schematic view of the experimental layout, together with the gage locations is given in Figure 2.

A total of ten capacitance wave gages were used in the experiment, of which nine were placed on an array. This array was then placed at fourteen different positions (denoted by thick lines in Figure 2) to obtain a total of 126 measuring points around the shoal. Depending upon their orientation, one or more array positions form a transect along which comparisons are made with the numerical model. There is one longitudinal transect (A-A) going over the top of the shoal and six transverse transects (B-B, C-C, D-D, E-E, F-F and G-G) behind and on top of the shoal (see Figure 2).

The circular shoal has a diameter of $5.2m$ and a maximum height of $37cm$. Geometrically it is the top portion of a circular sphere of radius $9.1m$. The center of the shoal is placed at $x = 5m$ and $y = 8.98m$. The equation for the perimeter of the shoal is given by

$$(x - 5)^2 + (y - 8.98)^2 = (2.57)^2 \quad (8)$$

and for the bathymetry is given by

$$z = -h + \sqrt{82.81 - (x - 5)^2 - (y - 8.98)^2} - 8.73 \quad (9)$$

Figure 7: Significant wave height distribution along transect E-E

where h is the water depth away from the shoal.

Four different directional sea test conditions (Test 3, Test 4, Test 5 and Test 6) were run with a TMA spreading function (Bouws *et al.*, 1985) in frequency, and a wrapped normal directional spreading function (Borgman, 1984) in direction. The water depth away from the shoal (h in (9)) was 40cm, and the water depth on top of the shoal was 3cm. All four tests had similar frequency spreadings except that the energy variance in Tests 3 and 4 were lower, and the frequency spectra for the four test cases is given in Figure 3. In all the four cases the waves were breaking on top of the shoal, with more waves breaking for Tests 5 and 6. Two different directional spreadings were used (Figure 3), with the mean angle normal to the wavemaker ($\theta_m = 0^\circ$). Tests 3 and 5 have a narrow directional spread ($\pm 11^\circ$), while Tests 4 and 6 have a broad directional spread ($\pm 45^\circ$).

The initial significant wave height (H_{0s}), peak period (T_p), mean angle (θ_m) and the range of directional spreading for the four different test cases are given in Table 1. Data was collected at a sampling rate of 50Hz for 655 seconds (32768 sample points) at all the gages.

DATA TO MODEL COMPARISONS

Significant wave height information was obtained from the data using a zero-upcrossing method, while from the model it was obtained from the statistics assuming a Rayleigh wave height distribution. Reflections from the beach at the

Figure 8: Significant wave height distribution along transect D-D

far end of the basin (see Figure 2) are a matter of concern but have been ignored here since the reflected wave field could not be separated from the incident wave field. In each case the input frequency spectrum to the model was directly measured from the wave data. The input directional spectrum was taken to be the same directional spreading function used to generate incident waves for the respective test cases (Figure 3).

A wave refraction pattern for the peak frequency (Figure 4) shows that the focusing is quite severe on top of the shoal, and that some of the wave rays are moving at angles greater than 90° . Since the model can predict wave conditions accurately only within a range of wave angles of $\pm 45^\circ$, some discrepancies between model and data results are expected in this region.

For each test case, all significant wave height comparisons have been normalized by the respective initial significant wave height (H_{0s}) given in Table 1. Figure 5 gives the wave height comparisons along transect A-A. The model tends to overpredict the wave height distribution near the region of focus. This is probably due to the severe focusing in this region (Figure 4), which the model cannot properly simulate. Since the focusing is taking place inside the surf zone, another probable cause for the discrepancy could be the limitations of the breaking model, and a different breaking model might give more accurate results.

Comparisons along the six transverse transects are shown in Figures 6 – 10. In all the cases the model predicts large wave heights at the side walls. This is because the no flux boundary condition at the side wall causes the waves to

Figure 9: Significant wave height distribution along transect C-C

Figure 10: Significant wave height distribution along transect B-B

form an antinode there for each wave component, which when superimposed lead to large significant wave heights. On top of the shoal (Figure 6) and along transect E-E (Figure 7) where the waves are breaking and focusing, the same energy discrepancy that was seen in Figure 5 is observed, but the spread of the wave heights is simulated reasonably well by the model. The comparisons further behind the shoal (Figures 8 – 10) on the other hand are extremely good. In general we see that the wave height distribution behind the shoal is more smoothed out for the broad directional test cases (Tests 4 and 6) as compared to the narrow directional test cases (Tests 3 and 5). An interesting observation is that behind the shoal the wave height distributions are more a function of the type of directional distribution of the input spectrum, instead of being a function of the energy content of the spectrum. Before the focusing takes place (Figure 6), the wave height distributions for Tests 3 and 4, and Tests 5 and 6 are quite similar, while after focusing (Figures 6 – 10) Tests 3 and 5, and Tests 4 and 6 have similar wave height spreadings. This effect can also be seen clearly in Figure 5, where the wave height distribution till $x = 5m$ is a function of the energy content of the spectrum, and beyond that depends on the directional spreading of the spectrum.

Though the model gives reasonable significant wave height comparisons, it is unable to predict wave-wave interactions since it is based on a linear superposition of monochromatic wave components. These interactions lead to the formation of higher harmonics in nature, and become more pronounced with increased nonlinearity. A comparison of model spectra to data spectra on top of

Figure 11: Frequency spectra comparisons (Test 3) showing nonlinear wave-wave interactions on top of the shoal

the shoal (Figure 11) shows this disparity quite clearly. The higher harmonics (second peak) in the data have considerable amount of energy compared to the primary wave field (first peak), all of which are not predicted by the model. These higher harmonics are seen in the data on top of the shoal and in the region of focus where the wave field is highly nonlinear.

CONCLUSIONS

A parabolic model for simulating the evolution of wave spectra over a gently sloping bottom has been tested with experimental data. Wave height comparisons have shown that the model works reasonably well in simulating wave height distributions for breaking random waves. Some discrepancies exist in the region of focus which could be due to the parabolic limitations of the model. Discrepancies could also be due to limitations of the breaking model, and in predicting non-linear effects. To get a better idea as to whether the discrepancy between the data and the model on top of the shoal is due to the limitations of the numerical model, or errors in the experimental data, comparisons need to be made to a model which will be able to simulate waves with no limitations on the range of angles and also predict the generation of higher harmonics on top of the shoal.

Nonetheless, we find that the spectral model works well in simulating transformations of a random wave field over an irregular bathymetry, even for broad directional spectra. Although certain aspects of the frequency spectrum cannot be obtained accurately from the model, it can be used to obtain useful estimates of significant wave heights.

CHAPTER 2

A Method for Estimating Standardized Bimodal Directional Spectra

Ryuichi Fujiwara¹ and Masahiko Isobe²

Abstract

Random sea waves are described by directional spectra which sometimes have bimodal distributions. Frequency spectra are often expressed in standardized forms which contain several parameters. This makes it easy to accumulate and analyze a large number of data obtained in various fields and to specify incident wave conditions in designing practice. In the present study, a method is proposed for estimating directional spectra in the form of a standardized bimodal distribution. The validity of the method is verified by numerical simulation for a three-component array (water surface elevation and horizontal two components of the water particle velocity). Furthermore, several applications to field data are shown.

Introduction

Many of methods have been proposed for estimating directional spectra : e.g. DFTM (Barber, 1963), parametric method (Longuet-Higgins *et al.*, 1963, Panicker and Borgman, 1974; Mitsuyasu *et al.*, 1975), MLM (Capon, 1969), EMLM (Isobe *et al.*, 1984), MEP (Kobune and Hashimoto, 1986) and BDM (Hashimoto and Kobune, 1988). In the last few years, it has become possible to estimate directional spectra accurately and stably. Degrees of freedom of estimated directional spectra, however, are too large to derive a standard form except for parametric method.

In recent years field observations have been carried out in deep area for

¹ Senior Research Engineer, Hydraulic Engineering Laboratory, Technical Research Institute, Toyo Construction Co. Ltd., 3-17-6 Naruohama, Nishinomiya, Hyogo 663, Japan

² Dr. Eng., Professor, Department of Civil Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan

investigating directional spectra property. To utilize the data in designing practice, it is important to express directional spectra in a standardized form which has a limited number of parameters. This makes it easy to accumulate and analyze a large number of data, and then to specify incident wave conditions in designing coastal and ocean structures as is done for frequency spectra.

In the present study, a method for estimating directional spectra with a standardized bimodal distribution is proposed by taking into consideration, the statistical variability of the Fourier coefficients which have Gaussian distributions.

Theory

(1) Bimodal directional spectrum

A bimodal directional spectrum is expressed in a standard form which is a superposition of two unimodal distribution functions. The unimodal distribution function employed is proposed by Mitsuyasu *et al.* (1975). Then the directional spectrum, $S(f, \theta)$, is expressed by Eq.(1) :

$$S(f, \theta) = \sum_{i=1}^2 P_i(f) \frac{2^{2S_i(f)-1} \Gamma^2 \{S_i(f) + 1\}}{\pi \Gamma \{2S_i(f) + 1\}} \cos^{2S_i(f)} \left\{ \frac{\theta - \theta_i(f)}{2} \right\} \quad (1)$$

where, $P_i(f)$, $\theta_i(f)$ and $S_i(f)$ are, respectively, the power spectrum, the peak wave direction and the directional concentration parameter of each unimodal directional spectrum, Γ the gamma function, f the frequency, and θ the wave direction. To estimate the directional spectrum for a certain frequency f , the unknown parameters are $P_1(f)$, $P_2(f)$, $\theta_1(f)$, $\theta_2(f)$, $S_1(f)$ and $S_2(f)$. For simplicity, we omit “(f)” hereinafter. Next, by the following relationship, we transform the spectrum parameters to P , α , θ_1 , θ_2 , S_1 and S_2 which are denoted by λ_1 , λ_2 , λ_3 , λ_4 , λ_5 and λ_6 , respectively:

$$P = \alpha P + (1 - \alpha) P = P_1 + P_2 \quad (2)$$

A component directional distribution function should have the following two properties: first, it has only one peak and varies smoothly; second, it can express both narrow and broad banded distributions.

(2) Definition of cross-power spectrum

The general relationship between the cross-power spectrum, ϕ_{mn} , of m -th and n -th quantities in the irregular wave field, and the directional spectrum, $S(f, \theta)$, is derived by Isobe *et al* (1984) as:

$$\phi_{mn} = \int_0^{2\pi} H_m(f, \theta) \overline{H_n(f, \theta)} \exp\{-ik(\mathbf{x}_n - \mathbf{x}_m)\} S(f, \theta) d\theta \quad (3)$$

where \mathbf{k} is the wave number vector, \mathbf{x}_m and \mathbf{x}_n the measuring locations, H_m the transfer function from the water surface elevation to the m -th quantity and $\overline{\quad}$ denotes the complex conjugate.

(3) Definition of likelihood

When the directional spectrum, $S(f, \theta)$, are expressed in a standard form, the expected cross-power spectrum, ϕ_{mn} , becomes a function of prescribed parameters, $\lambda_i (i=1, 6)$. The maximum likelihood method is employed to determine the most probable values of these parameters. The likelihood, L , is defined by Isobe(1990) as:

$$L(A^{[j]}; \phi) = \left\{ p(A^{[1]}) \times p(A^{[2]}) \times \cdots \times p(A^{[j]}) \times \cdots \times p(A^{[J]}) \right\}^{1/J} \quad (4)$$

$$= \frac{1}{(2\pi\Delta f)^M |\phi|} \exp\left(-\sum_{m=1}^M \sum_{n=1}^M \phi_{mn}^{-1} \hat{\phi}_{nm}\right)$$

$$\hat{\phi}_{nm} = \frac{1}{2J\Delta f} \sum_{j=1}^J \overline{A_n^{[j]}} A_m^{[j]} \quad (5)$$

where $p(A^{[j]})$ is a joint probability density function of the Fourier coefficients, $A^{[j]}$ the Fourier coefficients of the time series, Δf the frequency interval, and $|\phi|$ the determinant of the matrix, ϕ_{mn} and $\hat{\quad}$ denotes the quantity obtained from measured data.

The likelihood takes the maximum value, L_{\max} when the expected cross-power spectrum corresponding to the assumed directional cross-power spectra agrees with the measured one:

$$L_{\max} = \frac{e^M}{(2\pi\Delta f)^M |\phi|} \quad (6)$$

Therefore, we can define a degree of fitting by computing the ratio, L/L_{\max} .

(4) Most probable values of parameters

The most probable values of the parameters λ_i in Eq.(4) are obtained by maximizing the likelihood, L , through the relationship between ϕ_{mn} and λ_i . The most probable values of the parameters are determined so that all the partial derivatives of L with respect to directional spectrum parameters vanish:

$$\frac{\partial L}{\partial \lambda_i} = \sum_{k=1}^M \sum_{l=1}^M \frac{\partial L}{\partial \phi_{kl}} \frac{\partial \phi_{kl}}{\partial \lambda_i} = 0 \quad (7)$$

Substitution of Eq.(4) with Eq.(7) yields

$$\sum_{k=1}^M \sum_{l=1}^M \left\{ -\phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \phi_{ln}^{-1} \hat{\phi}_{mn} \phi_{mk}^{-1} \right\} \frac{\partial \phi_{kl}}{\partial \lambda_i} = 0 \quad (8)$$

The solution of Eq.(8) are obtained numerically by using the Newton-Raphson method. First, the left-hand side is defined as a function of the parameters λ_i :

$$f_i(\lambda_i) = \sum_{k=1}^M \sum_{l=1}^M \left\{ -\phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \phi_{ln}^{-1} \hat{\phi}_{nm} \phi_{mk}^{-1} \right\} \frac{\partial \phi_{kl}}{\partial \lambda_i} \quad (9)$$

The values of $\lambda_i^{(j+1)}$ at the $(j+1)$ -th iteration of the calculation is expressed in terms of the previous values, λ_i^j , as follows:

$$\lambda_i^{(j+1)} = \lambda_i^{(j)} - \left[\sum_{i'=1}^M \left[\frac{\partial f_i}{\partial \lambda_{i'}} \right]^{-1} f_{i'} \right]_{\lambda_i = \lambda_i^{(j)}} \quad (10)$$

where $\partial f_i / \partial \lambda_{i'}$ is expressed by Eq.(11) :

$$\begin{aligned}
\frac{\partial f_i}{\partial \lambda_{i'}} &= \sum_{k=1}^M \sum_{l=1}^M \left\{ -\phi_{lk}^{-1} + \sum_{n=1}^M \sum_{m=1}^M \phi_{ln}^{-1} \hat{\phi}_{nm} \phi_{mk}^{-1} \right\} \frac{\partial^2 \phi_{kl}}{\partial \lambda_{i'} \partial \lambda_i} \\
&\quad - \sum_{k'=1}^M \sum_{l'=1}^M \sum_{k=1}^M \sum_{l=1}^M \frac{\partial \phi_{k'l'}}{\partial \lambda_{i'}} \frac{\partial \phi_{kl}}{\partial \lambda_i} \\
&\quad \times \left[-\phi_{l'k}^{-1} \phi_{lk'}^{-1} + \left\{ \begin{aligned} &\phi_{lk'}^{-1} \sum_{m=1}^M \sum_{n=1}^M \phi_{ln}^{-1} \hat{\phi}_{nm} \phi_{mk}^{-1} \\ &+ \phi_{l'k}^{-1} \sum_{m=1}^M \sum_{n=1}^M \phi_{ln}^{-1} \hat{\phi}_{nm} \phi_{mk'}^{-1} \end{aligned} \right\} \right]
\end{aligned} \tag{11}$$

Application to three-component array

A three-component array is composed of the water surface elevation and horizontal two components of the water particle velocity. The main reason for choosing this array is that it is able to detect bimodal directional spectra (Isobe, 1990). Other reasons are: since it is a point sensor, it is easy to implement in the field; and since cross-power spectra of this array are represented theoretically as real values, the theoretical development becomes simple.

By applying Eq.(3) to a three-component array, the cross-power spectra, ϕ_{mn} , have real values as:

$$\phi_{\eta\eta} = P \tag{12}$$

$$\phi_{\eta u} = PH_u \{ \alpha m_{11} \cos \theta_1 + (1 - \alpha) m_{12} \cos \theta_2 \} \tag{13}$$

$$\phi_{\eta v} = PH_u \{ \alpha m_{11} \sin \theta_1 + (1 - \alpha) m_{12} \sin \theta_2 \} \tag{14}$$

$$\phi_{uu} = PH_u^2 \{ \alpha (\frac{1}{2} + m_{21} \cos 2\theta_1) + (1 - \alpha) (\frac{1}{2} + m_{21} \cos 2\theta_1) \} \tag{15}$$

$$\phi_{vv} = PH_u^2 \{ \alpha (\frac{1}{2} - m_{21} \cos 2\theta_1) + (1 - \alpha) (\frac{1}{2} - m_{22} \cos 2\theta_2) \} \tag{16}$$

$$\phi_{uv} = PH_u^2 \{ \alpha m_{21} \sin 2\theta_1 + (1 - \alpha) m_{22} \sin 2\theta_2 \} \tag{17}$$

where

$$m_{11} = S_1 / (S_1 + 1) \tag{18}$$

$$m_{12} = S_2 / (S_2 + 1) \tag{19}$$

$$m_{21} = S_1(S_1 - 1) / \{2(S_1 + 1)(S_1 + 2)\} \quad (20)$$

$$m_{22} = S_2(S_2 - 1) / \{2(S_2 + 1)(S_2 + 2)\} \quad (21)$$

and H_u is the transfer function from a water surface elevation to horizontal component of a water particle velocity. Subscripts, η , u and v represent the water surface elevation and horizontal two components of the water particle velocity, respectively.

Numerical calculation

(1) Procedure

Numerical simulation is performed to verify the validity of the present method. The method to estimate the directional spectrum is independent of the wave frequency, the simulation is performed under a fixed frequency. The procedure is summarized as follows:

- ① Define a true directional spectrum, $S(f, \theta)$ as Eq.(1).
- ② For a given data set, compute the cross-power spectra, ϕ_{mn} , using Eq.(12) to Eq.(17)
- ③ Calculate the estimated directional spectrum parameters using Eq.(10).
- ④ The estimated directional spectrum is compared with the true one.

(2) Simulated cross-power spectrum

The simulated cross-power spectra for the three-component array are given by in Eq.(12) to Eq.(17). In the present study, we created sets of cross-power spectra by using the Mitsuyasu-type directional distribution function with the directional spectrum parameters given in **Table 1**.

(3) Initial values for numerical calculation

For the three-component array, estimated directional spectrum by EMLM (Extended Maximum Likelihood Method) is able to represent the bimodal distribution (Horikawa ed.,1985). The following three parameters are available to estimate in the iteration procedure.

First, directional splitting parameter, γ'/γ , are defined as follows:

Table 1: Values of the directional spectrum parameters

P ($m^2 \cdot s$)	S_1	S_2	θ_1 (deg.)	θ_2 (deg.)	$P_2/P_1 =$ ($1 - \alpha$)/ α
1.0	100	100	0	10	1.0
		50			
		10			
	50	100			20
		50			30
		10			60
		10			90
	10	100			120
		10			150
		5			160
		1			170
		1			180
	5	50			0.5
		10			
		1			
1	10	0.2			
	10				
1	10	0.1			
	10				

$$\left(\frac{\gamma'}{\gamma}\right)^2 = \frac{4}{\gamma^2} \left[m_{00}(m_{20}m_{02} - m_{11}^2) + 2m_{10}m_{01}m_{11} - (m_{10}^2m_{02} + m_{01}^2m_{20}) \right] / \left[3m_{00}(m_{20} + m_{02})^2 - 4(m_{10}^2 + m_{01}^2)(m_{20} + m_{02}) + m_{00} \left\{ (m_{20} - m_{02})^2 + 4m_{11}^2 \right\} \right] \quad (22)$$

where γ is the long crestedness parameter, and m_{pq} are the normalized cross power spectra defined as follows:

$$m_{00} = \phi_{\eta\eta} \quad (23)$$

$$m_{20} = \phi_{uu} / H_u^2 \quad (24)$$

$$m_{02} = \phi_{vv} / H_u^2 \quad (25)$$

$$m_{10} = \phi_{\eta u} / H_u = \phi_{u\eta} / H_u \quad (26)$$

$$m_{01} = \phi_{\eta v} / H_u = \phi_{v\eta} / H_u \quad (27)$$

$$m_{11} = \phi_{uv} / H_u^2 = \phi_{vu} / H_u^2 \quad (28)$$

if small amplitude wave theory is used to evaluate H_u , errors due to nonlinear

effect or inaccurate will be included. Therefore, the following definition of the transfer function is used:

$$H_u = \sqrt{(\phi_{uu} + \phi_{vv})/\phi_{\eta\eta}} \quad (29)$$

Secondly, intersecting angle, Δ , of the two peak directions is defined as follows:

$$\Delta = 2 \cos^{-1} \frac{\sqrt{(m_{01}m_{11} - m_{10}m_{02})^2 + (m_{10}m_{11} - m_{01}m_{20})^2}}{\sqrt{\left\{ (m_{10}^2 - m_{01}^2) - m_{00}(m_{20} - m_{02}) \right\}^2 + 4(m_{10}m_{01} - m_{00}m_{11})^2}} \quad (30)$$

Thirdly, the bias of wave energies in the two directions is defined as follows:

$$r_p = \frac{\tan(\theta_m - \theta'_c)}{\tan(\Delta/2)} \quad (31)$$

where θ_m is the mean wave direction, θ'_c , the median wave direction defined as follows:

$$\theta'_c = \tan^{-1} \left\{ \frac{2(m_{10}m_{01} - m_{00}m_{11})}{(m_{10}^2 - m_{01}^2) - (m_{00}m_{20} - m_{00}m_{02})} \right\} \quad (32)$$

Now, the initial values of θ_1 , θ_2 and α are given as follows:

$$(\theta_1)_0 = (\theta'_c \pm \delta_1) - (\Delta + \delta_2)/2 \quad (33)$$

$$(\theta_2)_0 = (\theta'_c \pm \delta_1) - (\Delta + \delta_2)/2 \quad (34)$$

$$(\alpha)_0 = (1 - r_p)/2 \quad (35)$$

where $\delta_1 = 10^\circ$, 20° and 30° and $\delta_2 = 0^\circ$, 10° , 20° and 30° are tried to obtain

the largest value of L . For S_1 and S_2 , initial values are derived under the assumption that degrees of directional concentration are the same. First, S is derived by Eq.(37) from γ_1 which is calculated by Eq.(22) and Eq.(36), and $(S_1)_0$ and $(S_2)_0$ are given as $0.5S$. Also, $(P)_0$ is given as $\phi_{\eta\eta}$.

$$(\gamma'/\gamma)^2 = (1/\gamma)^2 \gamma_1^2 \quad (36)$$

$$\gamma_1 = (2S + 1) / (S^2 + S + 1) \quad (37)$$

(4) Directional spectra

Before examining the present method, a few remarks should be made concerning the solution by the three-component array. The directional spectrum parameters cannot be determined uniquely by the three-component array, since the number of independent cross-power spectrum is less than that of directional spectrum parameters. Thus, even when the likelihood is equal to L_{\max} , the estimated values of the directional spectrum parameters are not always equal to the true values. The directional spectrum for these parameters, however, agrees well with the true directional spectra. Moreover, it is observed that, when both S_1 and S_2 are greater than 5, and α is between 0.3 and 0.7, the estimated values of the directional spectrum parameters almost agree with the true values.

The following figures show the result of closer examination of the present method. **Figure 1** shows examples of estimated directional spectrum parameters : $\theta_1 = 0^\circ$, $\theta_2 = 90^\circ$, and $(1 - \alpha) / \alpha (=P_2/P_1) = 1.0, 0.1$. The abscissa represents the wave direction, and the ordinate represents the normalized directional spectrum. Also, the results of EMLM are included in the figure for comparison. The results of estimation agree well with the true directional functions.

The accuracy of the method, however, becomes poor as the difference between S_1 and S_2 becomes large. Nevertheless, the accuracy of this method is higher than that of EMLM. **Figure 2** shows examples in which $S_1/S_2 = 0.1, 10$ and $\theta_1 = 0^\circ$ and $\theta_2 = 90^\circ$.

Figure 3 shows examples for small intersection angles or small $(1 - \alpha) / \alpha$. The results estimated as unimodal directional spectra are also included in the figure for comparison. These estimated distribution agree well with true values. In these cases, assumption of bimodal spectrum is almost the

same as that of unimodal spectrum.

(a) $S_1=10, S_2=10, P_2/P_1=1.0$

(b) $S_1=10, S_2=10, P_2/P_1=0.1$

(c) $S_1=50, S_2=50, P_2/P_1=1.0$

(d) $S_1=50, S_2=50, P_2/P_1=0.1$

(e) $S_1=10, S_2=5, P_2/P_1=1.0$

(f) $S_1=50, S_2=25, P_2/P_1=1.0$

Figure 1 Directional spectra computed by the estimated directional spectrum parameters(1) : $\theta_1 = 0^\circ$ and $\theta_2 = 90^\circ$

(5) Directional spectrum parameters

Figure 4 shows the accuracy of the estimated directional spectrum parameters. The estimated values of P , α , θ_1 and θ_2 agree well with true values. The accuracy of estimated S_1 and S_2 , however, becomes poor in comparison with the other parameters.

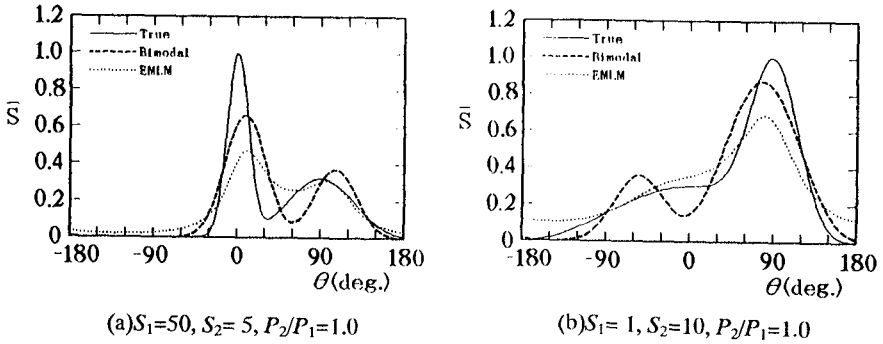

Figure 2 Directional spectra computed by the estimated directional spectrum parameters(2) : $\theta_1 = 0^\circ$ and $\theta_2 = 90^\circ$

Figure 3 Directional spectra computed by the estimated directional spectrum parameters(3) : $(1 - \alpha) / \alpha = 1.0$

Application to field data

Figure 5 shows the arrangement of three-component arrays in the observation field in east coast of Japan facing to the Pacific Ocean. The water depth at the measurement points are about 20m. A three-component array consists of an ultrasonic wave gage and a two-component electromagnetic current meter, and all the devices are packed together in one container. A pressure-type wave gage is also packed in the same container to increase the reliability of measurement.

Point A is affected by reflected waves from upright caissons; however, phase lags are considered to be random between incident waves and reflected waves because of a fairly large distance from the caisson. Point B, on the other hand, is not affected by reflected waves. **Figure 6** shows examples of the estimated directional spectra at Points A and B. It is clear that the directional

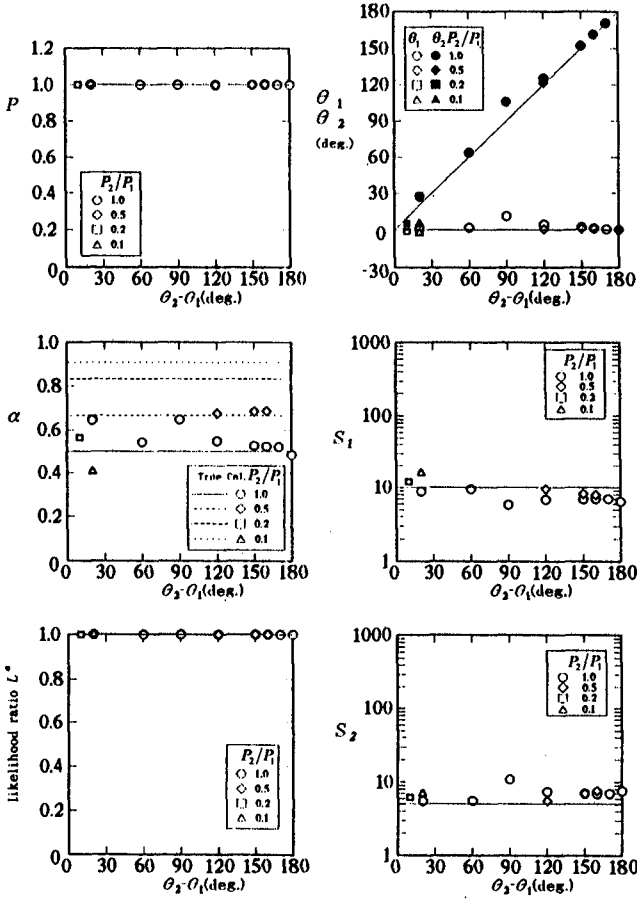

Figure 4 Estimated directional spectrum parameters

Figure 5 The arrangement of the three-component array in the observation field

spectrum have a bimodal distribution at Point A because of the reflected waves. Therefore, significant wave height, $H'_{1/3}$, of the incident waves was estimated from the wave energy contained in the range of incident wave direction:

$$H'_{1/3} = H_{1/3} / \sqrt{1 + K_R^2}, \quad K_R = \sqrt{E_R / E_I}$$

($H_{1/3}$: total significant wave height, E_I and E_R : incident and reflected wave energy).

The range of the incident wave direction is defined as **Figure 6**. **Figure 7** shows the relationship between $H'_{1/3}$ at Point A and $H_{1/3}$ at Point B. Good agreement suggests that the directional spectra are reasonably estimated.

Figure 6 Estimated directional spectra

Figure 7 The relationship between the estimated significant wave height at Point A and the significant wave height at Point B

Conclusion

The following conclusions are obtained in this study.

- A method is proposed to estimate a bimodal directional spectrum expressed in a standard form.
- The validity of the method is verified by numerical simulation for a three-component array which is easy to be implemented in the field.
- Application to field data yields reasonable results.

CHAPTER 3

THE EFFECTS OF CURRENTS ON ESTIMATIONS OF DIRECTIONAL WAVE SPECTRA

Yasuyuki Nakagawa¹, Hiroichi Tsuruya¹, Noriaki Hashimoto¹

Abstract

To investigate the effects of currents on estimations of directional wave spectra, the problems with the existing methods for obtaining directional wave spectra are discussed when they are applied to wave fields in the existence of currents. The characteristics of distortion of the estimated spectra by current effects are examined through numerical simulations and analyses of experimental data. Both the numerical and experimental tests with wave gages, show that the directional spread of estimated spectra becomes narrower than that of the actual wave field and the value of the spectral peak is overestimated for the case of adverse currents. The extent of these distortions depends on the relative speed and direction of the current and waves. The relation of the error and these factors is summarized in the present study.

Introduction

Several methods have been developed for estimating directional wave spectra. These techniques, however, are generally restricted for the analysis of directional random sea waves in the absence of currents. When conventional methods are applied to wave fields with currents, misinterpretations of the actual phenomena may result. Methods are, therefore, needed to evaluate how currents will modify conventional directional spectral analyses so that corrective measures can be taken. This paper discusses the limitations associated with the existing methods for computing directional spectra of waves on currents. The effects of uniform currents on spectra are then estimated using numerical simulation techniques and these results are compared with the estimated directional spectra of wind waves propagating on uniform currents in an experimental channel.

¹ Port and Harbour Research Institute, 3-1-1 Nagase, Yokosuka 239, JAPAN.

Estimation of Directional Wave Spectra on Currents

(1) Existing methods

The basic equation for estimating directional wave spectra is described as the simultaneous integral equation,

$$\Phi_{mn}(f) = \int_0^{2\pi} H_m(f, \theta) \cdot H_n^*(f, \theta) \times \left[\cos\{k(x_{mn} \cos\theta + y_{mn} \sin\theta)\} - i \sin\{k(x_{mn} \cos\theta + y_{mn} \sin\theta)\} \right] \times S(f, \theta) d\theta, \quad (1)$$

where $\Phi_{mn}(f)$ is the cross power spectrum between the m -th and n -th wave motion parameters, $H(f, \theta)$ is the transfer function from surface elevation to other wave motion parameters and * denotes their complex conjugates. $S(f, \theta)$ is the directional spectrum, $x_{mn} = x_m - x_n$, and $y_{mn} = y_m - y_n$.

Based on some assumptions and approximations to directional distribution functions in Equation (1), the existing methods try to determine the unique solution of a directional spectrum with a limited number of wave motion parameters (See e.g. Hashimoto *et al.* 1994). In the process of getting a solution with these methods, the wave numbers and the transfer functions of wave components with arbitrary wave frequency are evaluated by using linear wave theory, and do not consider the presence of currents. Therefore, simply applying the existing methods to the analysis of the combined wave-current field may not produce accurate results. The following points have to be noted when analyzing such cases.

(2) Dispersion Relation in Currents

When the analysis is carried out with wave records measured at separate locations, e.g. a measurement with an array of wave gages, the wave number has to be put into Equation (1) corresponding to arbitrary frequency. In order to do this, the existing methods use the following equation as a dispersion relation,

$$\omega^2 = (2\pi f)^2 = gk_0 \tanh k_0 h, \quad (2)$$

where k_0 is the wave number, and h is the water depth. The subscript 0 denotes in the absence of currents. This relation is, however, not appropriate in the wave field on currents. For the simple case, assuming the propagation of waves in a uniform current in space and time, the relation becomes,

$$(\omega - U_c k_c \cos\theta_r)^2 = (2\pi f - U_c k_c \cos\theta_r)^2 = gk_c \tanh k_c h, \quad (3)$$

where U_c is the speed of the uniform current, and θ_r is the relative angle between the directions of current and wave propagation. The subscript c denotes in the presence of currents. This equation shows that, the wave number for a wave of given frequency

depends on the direction and the speed of the current. **Figure 1(a)** shows this dependence of the change in wave number with the relative direction of the current. Here the wave period is assumed to be 10 s, the water depth 100 m and the speed of the current 1.0 m/s. In the region where adverse currents are dominant, around $\theta_r = 180^\circ$, the wave numbers become larger than that of the wave of the same period and depth condition in the absence of a current. The computation of wave numbers with Equation (2), therefore, can not describe the distribution of the wave number correctly in the current field. This is one source of inaccuracies in present methods. These deviations of wave numbers are also governed by the speed of currents in relation to the wave celerity as shown in **Figure 1(b)**. In the figure, where a negative current speed means adverse current, the deviation of the wave number increases with the magnitude of the current speed. The effect of the currents is significant for waves of higher frequency.

(a) Variation of wave numbers in relation to the relative angle

(b) Variation of wave numbers in relation to current speed

Figure 1. Deviations of wave numbers by the effect of currents

(3) The Transfer Functions

As a set of data for the analysis, several wave motion parameters measured at the same location are also used for the computation of directional wave spectra. In this case, the appropriate transfer functions from free surface elevation to other wave properties must be evaluated for the estimation procedure with the existing methods. For example, the transfer function to the horizontal particle velocities induced by the

wave motion is expressed as,

$$H_0(f, \theta) = \frac{gk_0}{\omega} \frac{\cosh k_0(h+z)}{\cosh k_0h}, \quad (4)$$

where z is the vertical coordinate with positive value taken upwards from the mean water level and k_0 is determined by the relation of Equation(2). Assuming again that the current is uniform, the expression becomes,

$$H_c(f, \theta) = \frac{gk_c}{(\omega - U_c k_c \cos \theta_r)} \frac{\cosh k_c(h+z)}{\cosh k_c h}, \quad (5)$$

where the relation between frequencies and wave numbers, k_c , is based on Equation (3). Since the wave numbers are modified by the currents, as mentioned in the previous

(a) Horizontal water particle velocities

(b) Hydrodynamic pressure

Figure 2. Deviations of transfer functions by the effect of currents

section, the transfer function also changes depending on the relative speed and direction of the current to the direction of wave propagation. The deviation of the transfer function of horizontal water particle velocities with frequency in the adverse and following current cases are shown in **Figure 2(a)** as a ratio of the function in currents, $H_c(z)$, to that in no current, $H_0(z)$. In the figure, it is seen that the deviation of the functions are maximum at the bottom, and the trend decreases towards the surface, and reverses just below the free surface. This means that estimations based on data of horizontal water particle velocities may be different depending on the depth of the measuring instruments such as a current meter.

In the case of the transfer function of the hydrodynamic pressure it is expressed, in the absence of currents, as,

$$H_0(f, \theta) = \rho g \frac{\cosh k_0(h+z)}{\cosh k_0 h} \quad (6)$$

It can be shown that the hydrodynamic pressure transfer function in a uniform current is identical to Equation (6), with wave number and frequency governed by Equation (3). Their ratio is compared in **Figure 2(b)** for the same condition as **Figure 2(a)**. The maximum deviations by currents are at the bottom in the same manner as the horizontal water particle velocities. The transfer function ratio in a following current is greater than one and less than one in an adverse current, at all depths. Therefore the estimation, by existing methods which do not consider these differences, may also lead to inaccurate results of the directional wave spectrum.

Numerical Simulations

(1) Procedure of Simulation

To investigate the effects of currents on the directional spectrum estimation, a series of numerical simulations was performed by using an existing estimation method, known as Extended Maximum Entropy Principle method, EMEP by Hashimoto *et al.* (1994). The numerical tests were conducted in the same manner as the examination of another estimation method, Extended Maximum Likelihood Method, EMLM by Isobe *et al.* (1984). Prior to the estimation of the directional spectrum in the simulation, the cross power spectra of wave motions with target frequency are computed by numerical integration of the basic equations expressed by Equation (1). The directional spreading function is given arbitrarily as a model function. In the present study, since the objective wave field is supposed to be in uniform currents, the dispersion relation expressed by Equation (2) is used to obtain the cross power spectra. Based on the computed cross power spectra for the assumed wave field with currents, the analyses with the existing method are used to estimate directional spectra. Since the presence of currents is ignored at this stage of the estimating procedure, the estimation results may be distorted from the model function due to the incompatibilities of the existing methods, as mentioned in the previous section. In the following sections, some estimation results and their comparisons with the model function are demonstrated.

(2) Results of Simulation

A 10 s wave propagating in a uniform current of 1.0 m/s, in a water depth of 100 m was used as the target wave field for the simulation. The model function is expressed here as a conventional cosine-powered function,

$$G(\theta) = \cos^{2S} \left(\frac{\theta - \theta_w}{2} \right), \tag{7}$$

where S is the spreading parameter and θ_w the principal wave direction. The estimated directional spreading functions by the EMEP for the above condition are shown in **Figure 3**. A star array consisting of four wave gages is assumed as the simulated observation condition. In the case of adverse currents to the principal wave propagation, the estimated directional spectrum shows a narrower distribution and

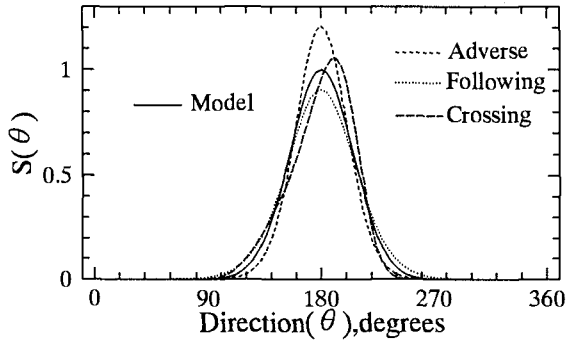

Figure 3. Estimated directional wave spectra by EMEP for various current directions using star array

Figure 4. Relative errors of estimated peak value in relation to current speed

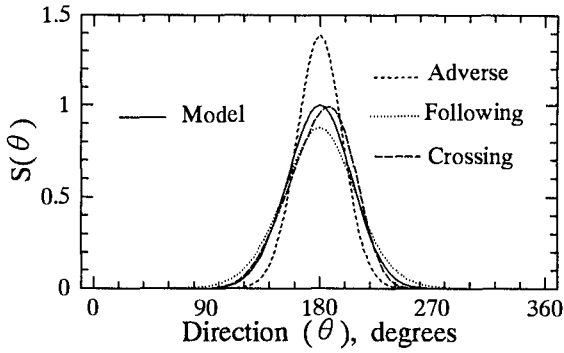

higher peak value than the model function which is represented by the solid line. The opposite trend appears in the following current case. When the direction of wave propagation and the current direction are at right angles, the peak of the estimated function is shifted downstream of the current but the effect of this current is considerably less than the adverse and following current cases. The over- and under-estimation of the peak of the directional distribution in the adverse and following current cases, respectively, are shown in **Figure 4**. In relation to the change in the wave numbers by the effect of currents shown in **Figure 1(b)**, the error in estimation results increases with the speed of currents and is greater for higher frequency waves.

Similar results have been obtained for the case of the three measured quantities; sea surface elevation and two components of horizontal water particle velocity at the same location. These results are shown in **Figure 5(a)**, with the water particle velocities assumed to be measured at the free surface. **Figure 5(b)** shows the estimated result for the same condition as in **Figure 5(a)** except now the depth at which the particle velocities were measured is 20 m. It should be noted that the trend of the error in the estimated results (**Figure 5(b)**) are opposite to the results obtained in **Figure 5(a)**. For example when the spectrum is estimated for the following current case using water particle velocities measured at the surface, the estimated peak is lower and the shape is wider than the model. For the same current scenario using water particle velocities measured 20 m below the surface, the estimated directional spectrum has a higher peak and is narrower than the model. This is ascribed to the deviation of the transfer functions and their vertical distribution in the presence of currents as shown in **Figure 2(a)**. The ratios of the transfer functions for adverse and following currents cross unity at a depth beneath the surface. This introduces a distortion of the estimated directional wave spectra depending on the depth at which the wave motion parameters were measured.

In shallow water regions near coasts, it is possible to use a measurement system at the sea bottom with sensors that measure hydrodynamic pressure and horizontal water particle velocities for directional spectra analysis. Assuming such observation conditions, directional wave spectra were estimated in cases for a wave period of 10 s, water depth 30 m and a current speed of 1.0 m/s. The results are shown in **Figure 6**. For reference, another estimated result is shown in **Figure 7** where the free surface elevation and horizontal water particle velocities at the surface were used as a measurement system for the same conditions as for the previous case in **Figure 6**. By the comparison of these figures, it is clear that the errors in **Figure 6** are extremely large. The reason of the large errors is that the deviation of the transfer functions for the wave properties are maximum at the bottom as explained in the previous section.

(3) Simulations with Consideration of Currents

As shown in the previous section, when the existing methods are applied to the wave field with currents, the estimated directional spectra are distorted by the effects of the current. Under the assumption of a uniform current, if the current speed is known, the wave numbers and the transfer functions can be modified appropriately by using Equations (3) and (5). The results of simulations using these modifications for the same following current conditions as **Figure 3** are shown in **Figure 8** by the dots.

(a) Using horizontal water particle velocities at $z = 0$ m

(b) Using horizontal water particle velocities at $z = -20$ m

Figure 5. Estimated directional wave spectra by EMEP for various current directions

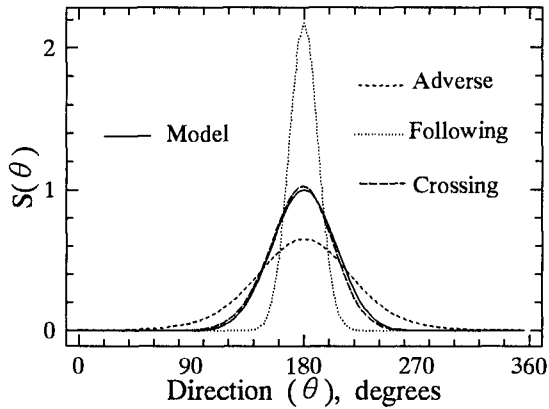

Figure 6. Estimated directional wave spectra by EMEP for various current directions using u , v , and p at the bottom

Figure 7. Estimated directional wave spectra by EMEP for various current directions using u , v , at the mean water level and η

Figure 8. Estimated directional wave spectrum by EMEP with the modification of wave numbers by Equation (3)

It can be seen that the simulated results show almost complete agreement with the model. Simulations for adverse and crossing current scenarios were also conducted using Equation (3) with equally good agreements to the model.

In order to reduce the calibration error of field data measured at the same location, it was proposed by Isobe *et al.* (1984) to use the ratio between the power spectra of different wave properties instead of using theoretical expressions like Equation (7). The following expression was used for wave data to include surface elevation and the two components of horizontal water particle velocities,

$$H(\omega) = \sqrt{\frac{S_{uu}(\omega) + S_{vv}(\omega)}{S_{\eta\eta}(\omega)}} \quad (8)$$

Here $S_{uu}(\omega)$, $S_{vv}(\omega)$ and $S_{\eta\eta}(\omega)$ represent the power spectra of horizontal water particle velocities, u and v and the surface elevation, η , respectively. The estimation result of the directional spectra for the same conditions as in **Figure 3** are shown in **Figure 9**, where Equation (8) is used for the determination of the transfer function. In each case, the degree of distortion is substantially diminished. The reason for this good agreement with the model function may be explained with **Figure 10**. In this figure, the transfer functions approximated with Equation (8) in the following and adverse current cases are indicated by the horizontal lines. Although they may not approximate the model transfer function in all directions, they come very close to the true transfer functions for the direction where the wave energy is highly concentrated. That is, for the estimation of directional spectra, the complete agreement with the theoretical function is not required for the directions where the wave energy does not exist. Equation (8) makes it possible to get reasonable transfer functions near the peak of the directional wave spectrum. Therefore, the analysis with Equation (8) is very effective in estimating directional spectra for wave fields with currents when the wave directionality is narrow.

Figure 9. Estimated directional wave spectra by EMEP for various current directions with the transfer function approximated by Equation (8)

Figure 10. Approximation of transfer functions by Equation (8) for various currents

Analysis of Experimental Data

Estimations of directional spectra have also been carried out using the experimental data of directional waves in a wind-wave channel at the Port and Harbour Research Institute (PHRI). The channel is 30 m in length, 1.5 m in width, and has a water depth of 0.5 m as shown in **Figure 11**. The waves were generated by wind blowing into the channel at a speed of 10.4 m/s at 40 cm above the still water level. Uniform currents were superimposed on the waves in following and adverse directions to the waves. For this analysis, surface elevations were measured with four wave gages installed at the location as shown in **Figure 11**. The sampling frequency was 50 Hz and the sampling duration was 2.5 minutes. The frequency power spectra of the wind waves on the currents are shown in **Figure 12**. The difference in peak frequencies of the spectra are

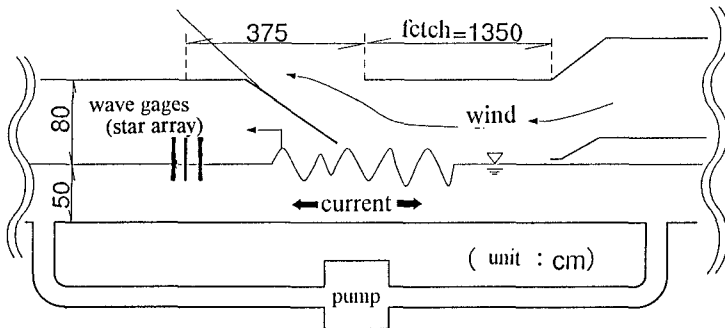

Figure 11. Sketch of wind-wave and current channel

Figure 12. Power spectra of wind waves for various current directions

caused by the change in the effective fetch length (Kato and Tsuruya, 1978). By using these data, the analysis of directional spectra was estimated by EMEP. **Figures 13** and **14** show the results of estimated directional spectra near the peak frequency, for following and adverse currents, respectively. The dashed lines represent the estimated spreading function and the solid lines represent the results with the modification of wave numbers per Equation (3). In the following current case, **Figure 13**, the function estimated by EMEP predicts a wider distribution than the modified estimation. Under adverse current conditions, **Figure 14**, the estimated distribution has a narrower shape and a higher peak than the modified case. The trend of the results are the same as those obtained by the numerical simulations.

Figure 13. Estimated directional wave spectrum (following current)

Figure 14. Estimated directional wave spectrum (adverse current)

Conclusion

Numerical simulations of directional wave spectra estimations for wave fields with currents have shown that the degree and trend of the distortion of wave spectra by the currents depends not only on the relative speed and direction of the waves and current but also on the measuring system of the wave properties. To reduce the errors of these estimation results, modifications of wave numbers and transfer functions by the theoretical relations for currents have been confirmed to be effective in uniform current cases. The transfer function defined as the ratio of each power spectra is particularly useful in reducing the error of estimated directional spectra in the presence of currents when the directionality of the waves is narrow. From analyses of experimental data with a wind wave channel, similar distortion trends to those estimated by the numerical simulations have been observed.

Acknowledgment

We wish to express our sincere gratitude to Mr. Sidney W. Thurston III, National Sea Grant Fellow of NOAA, who kindly gave us many valuable comments and advice on the present study.

CHAPTER 4

A METHOD FOR ESTIMATING DIRECTIONAL SPECTRA IN A FIELD OF INCIDENT AND REFLECTED WAVES

Hiromune Yokoki¹ and Masahiko Isobe²

Abstract

A method for estimating the directional spectrum as well as the reflection coefficient in a incident and reflected random wave field is developed for practical use. In the method, the directional spectrum is assumed to be expressed by a circular normal distribution which includes three parameters. Then the parameters are estimated by the maximum likelihood method. The present method is applied to laboratory data, and the parameters are estimated for two kinds of wave gauge arrays. A measure of accuracy of the estimated parameters is also proposed.

Introduction

Recently it has become usual in the design of coastal, harbor and ocean structures to take into account the randomness of sea waves with respect to wave direction as well as to wave frequency. Directional wave spectra can describe the randomness of sea waves as the distribution of wave energy among the wave frequency and direction. However, there are a lot to be studied in the estimation of directional spectra, especially in a field composed of incident and reflected waves. No existing method can estimate the reflection coefficient accurately enough for practical use.

In this paper, we propose a method for estimating the directional spectrum in a short-crested random wave field by introducing a standard directional function which is expressed by the circular normal distribution function (Yokoki *et al.*,

Figure 1: Definitions of variables

1992, 1994). The parameters in the function are determined by the Maximum Likelihood Method (Isobe, 1990).

Then we apply the method to laboratory data. The estimated results confirm its applicability to the existing data.

A method is also proposed for measuring the accuracy of the estimated parameters by means of the root-mean-square values of the errors. We propose the appropriate configurations of wave gauge arrays for estimating the directional spectrum parameters accurately.

Theory

Cross-power spectrum

In a wave field which consists of incident and reflected waves, the cross-power spectrum, $\Phi_{pq}(\sigma)$, between the water surface fluctuations at points p and q is represented as Eq. (1) (e.g., Horikawa, 1988; Isobe and Kondo, 1984):

$$\Phi_{pq}(\sigma) = \int_{\mathbf{k}} S(\mathbf{k}, \sigma) \{ \exp(i\mathbf{k}\mathbf{x}_p) + r \exp(i\mathbf{k}\mathbf{x}_{pr}) \} \times \{ \exp(-i\mathbf{k}\mathbf{x}_q) + r \exp(-i\mathbf{k}\mathbf{x}_{qr}) \} d\mathbf{k} \quad (1)$$

where $S(\mathbf{k}, \sigma)$ is the directional spectrum, \mathbf{k} the wave number vector, \mathbf{x}_p the measuring position vector, \mathbf{x}_{pr} the point symmetrical to \mathbf{x}_p with respect to the reflective wall (y -axis), and r the reflection coefficient (Fig. 1).

We rewrite Eq. (1) by using the transformation of variables as follows.

$$\left. \begin{aligned} \mathbf{k} &= (k \cos \theta, & k \sin \theta &) \\ \mathbf{x}_p - \mathbf{x}_q &= (R_{pq} \cos \Theta_{pq}, & R_{pq} \sin \Theta_{pq} &) \\ \mathbf{x}_{pr} - \mathbf{x}_{qr} &= (R_{pq} \cos(\pi - \Theta_{pq}), & R_{pq} \sin(\pi - \Theta_{pq}) &) \\ \mathbf{x}_{pr} - \mathbf{x}_q &= (R_{pqr} \cos \Theta_{pqr}, & R_{pqr} \sin \Theta_{pqr} &) \\ \mathbf{x}_p - \mathbf{x}_{qr} &= (R_{pqr} \cos(\pi - \Theta_{pqr}), & R_{pqr} \sin(\pi - \Theta_{pqr}) &) \end{aligned} \right\} \quad (2)$$

The definitions of variables are also indicated in Fig. 1. Substituting Eq. (2) into Eq. (1), we obtain the expression of the cross power spectrum, $\Phi_{pq}(f)$:

$$\begin{aligned} \Phi_{pq}(f) &= \int_0^{2\pi} S(f, \theta) \\ &\times [\exp\{ikR_{pq} \cos(\theta - \Theta_{pq})\} + r^2 \exp\{ikR_{pq} \cos(\theta - \pi + \Theta_{pq})\}] \\ &+ r \exp\{ikR_{pqr} \cos(\theta - \Theta_{pqr})\} + r \exp\{ikR_{pqr} \cos(\theta - \pi + \Theta_{pqr})\}] d\theta \end{aligned} \quad (3)$$

where f represents the frequency connected with the wave number, $|\mathbf{k}|$, by the dispersion relation, and r the reflection coefficient of the reflective wall.

In the present study, we assume the directional spectrum, $S(f, \theta)$, is expressed by using the circular normal distribution function, so that we can obtain the cross power spectrum analytically and the numerical calculation becomes faster. Thus, the directional spectrum, $S(f, \theta)$, is expressed by Eq. (4):

$$S(f, \theta) = P(f) \frac{1}{2\pi I_0(a)} \exp\{a \cos(\theta - \theta_0)\} \quad (4)$$

where I_0 is the modified Bessel function of zero order.

Then the relationship between the cross-power spectrum and the parameters is written as follows:

$$\Phi_{pq}(f) = \left\{ \begin{array}{l} \varphi(a, \theta_0, R_{pq}, \Theta_{pq} | f) \\ + r^2 \varphi(a, \theta_0, R_{pq}, \pi - \Theta_{pq} | f) \\ + r \varphi(a, \theta_0, R_{pqr}, \Theta_{pqr} | f) \\ + r \varphi(a, \theta_0, R_{pqr}, \pi - \Theta_{pqr} | f) \end{array} \right\} \times (1 + \delta_{pq} \varepsilon_p) P(f) \quad (5)$$

$$\begin{aligned} \varphi(a, \theta_0, R, \Theta | f) &= \frac{1}{2\pi I_0(a)} \int_0^{2\pi} \exp\{-ikR \cos(\theta - \Theta)\} \exp\{a \cos(\theta - \theta_0)\} d\theta \end{aligned} \quad (6)$$

where R and Θ , respectively, indicate the length and the angle of the vector $\mathbf{x}_p - \mathbf{x}_q$, and R_r and Θ_r those of the vector $\mathbf{x}_{pr} - \mathbf{x}_q$.

Finally, the cross-power spectrum, $\Phi_{pq}(f)$, becomes a function of five parameters: the degree of directional concentration, a ; the peak wave direction, θ_0 ; the reflection coefficient, r ; the frequency spectrum, $P(f)$, of the incident wave; and the ratio, ε_p , of the noise component to the power at the point p .

Most probable values of parameters

The five directional spectrum parameters including the reflection coefficient should be determined so that the cross-power spectrum, $\Phi_{pq}(f)$, in Eq. (5) would approximate the observed cross-power spectrum, $\hat{\Phi}_{pq}(f)$. In the present study, the parameters are determined by the Maximum Likelihood Method (MLM). The likelihood L is defined by Isobe (1990):

$$L = \frac{1}{(2\pi\Delta f)^M |\Phi|} \exp \left(- \sum_{p=1}^M \sum_{q=1}^M \Phi_{pq}^{-1} \hat{\Phi}_{qp} \right) \quad (7)$$

where Δf is the interval of the frequency, M the number of measuring points, and $|\Phi|$ the determinant of the cross-power spectrum matrix, Φ_{pq} .

The maximum likelihood method implies that the most probable values of the parameters, λ_i , are the solutions of the equation:

$$\frac{\partial L}{\partial \lambda_i} = \sum_{j=1}^M \sum_{l=1}^M \frac{\partial L}{\partial \Phi_{jl}} \frac{\partial \Phi_{jl}}{\partial \lambda_i} = 0 \quad (8)$$

Equation (8) is expressed as a nonlinear simultaneous equation through some algebraic calculation (Yokoki *et al.*, 1994) as follows:

$$\sum_{j=1}^M \sum_{l=1}^M \left\{ -\Phi_{lj}^{-1} + \sum_{p=1}^M \sum_{q=1}^M \Phi_{lp}^{-1} \hat{\Phi}_{qp} \Phi_{pj}^{-1} \right\} \frac{\partial \Phi_{jl}}{\partial \lambda_i} = 0 \quad (9)$$

The directional spectrum parameters, λ_i , which satisfy Eq. (9) for all i ($i = 1 \sim 7$) are the most probable values.

The modified Marquardt method (*ex.* Fletcher, 1971) is adopted instead of the Newton-Raphson method to solve Eq. (9) iteratively, and thus the solutions are obtained more robustly and quickly.

In the modified Marquardt method, the values of $\lambda_i^{(k+1)}$ at the $(k+1)$ -th iteration is expressed in terms of the previous values, $\lambda_i^{(k)}$, as follows:

$$\boldsymbol{\lambda}^{(k+1)} = \boldsymbol{\lambda}^{(k)} - \left[\mathbf{A} + \mu^{(k)} \{ \mathbf{E} + \text{diag}(\mathbf{A}) \} \right]^{-1} \mathbf{f}^{(k)} \quad (10)$$

where $\boldsymbol{\lambda}$ is the vector expression of λ_i , $\mathbf{A} = [A_{ij}] = [\partial f_i / \partial \lambda_j]$, $\mathbf{f} = [f_i]$, f_i is the left hand side of Eq. (9), $\text{diag}(\mathbf{A})$ the diagonal matrix of \mathbf{A} , and \mathbf{E} the unit matrix.

If Eq. (9) is strongly nonlinear, the parameter μ increases during in the iterations, and finally Eq. (10) reduces as follows:

$$\lambda_i^{(k+1)} \approx \lambda_i^{(k)} - \left(1 + \frac{\partial f_i}{\partial \lambda_i} \right)^{-1} f_i^{(k)} \quad (11)$$

If μ is small, Eq. (9) reduces to the same form as the Newton-Raphson method.

Application to Laboratory Data

Laboratory data

To verify the validity of the present method, we applied it to experimental data. Figure 2 shows the layout of wave gauges in the multi-directional wave basin, where the water depth is uniformly 50cm, the reflective wall (y -axis) is vertical and no wave absorber is installed. The water surface elevations were measured by two kinds of wave gauge arrays: The array I is linear and normal to the reflective wall, and the array II parallel to the reflective wall.

Multi-directional incident waves were generated by using the Bretschneider-Mitsuyasu spectrum proposed by Mitsuyasu *et al.* (1975). The incident wave conditions and the corresponding wave gauge arrays are listed in Table 1.

Figure 3: Estimated values of parameters (No. 4151)

Estimated parameters

Figure 3 shows the estimated values of the parameters by the array I composed of the wave gauges A, B and C, for which the incident wave condition is No. 4151 in Table 1. Figure 4 shows the estimated values for the incident wave condition No. 4191. The dashed lines in the graphs for the power, $P(f)$, indicate the frequency spectrum of the incident waves. From these figures, we can see that the array I estimates the reflection coefficient and the peak wave direction accurately around the peak wave frequency, but not the directional concentration.

Figures 5 and 6 show the estimated values of the parameters by the array II composed of the wave gauges F, G and I, for which the incident wave conditions are No. 4152 and 4192 respectively. These figures show that the peak wave direction and the directional concentration are accurately estimated by the array II, though the reflection coefficient cannot be estimated accurately.

Accuracy of Estimated Parameters

Definition of accuracy of parameters

In this section, we show how to evaluate the performance of wave gauge arrays for estimating the directional spectrum parameters. We proposed Eq. (12) as a measure of the accuracy of the estimated parameters:

$$\text{Err}(\lambda_i) = \frac{1}{\bar{\lambda}_i} \sqrt{\frac{1}{N_{\text{total}}} \sum_{j=1}^{N_{\text{total}}} (\lambda_{i,j} - \bar{\lambda}_i)^2} \quad (12)$$

where $\lambda_{i,j}$ is the estimated values of the parameter, λ_i in the j -th sample, $\bar{\lambda}_i$ is the (given) true value, N_{total} is the total number of samples, and $\bar{\lambda}_i$ is the value by which the error is normalized.

Equation (12) is regarded as the normalized root-mean-square value of the error. We used Eq. (12) to evaluate the performance of the array for the twenty-seven incident wave conditions shown in Table 2. In all cases, the incident directional wave spectra are calculated by using the Bretschneider-Mitsuyasu frequency spectrum, and the directional function proposed by Mitsuyasu *et al.* (1975). The significant wave height, $H_{1/3}$, is 0.1m and the significant wave period, $T_{1/3}$, is 1.0s.

Errors were calculated for the parameters estimated by the various arrays shown in Fig. 7: two kinds of linear arrays, and the three kinds of triangular arrays. The errors are calculated for each array by changing the distance, D_p , from the reflective wall and the interval, D , of the wave gauges.

Calculated accuracy

Figure 8 shows calculated errors in the peak wave direction, θ_0 , the directional concentration, a , and the reflection coefficient, r .

We can see from Fig. 8 that the linear array (1) and the triangular array (3) cannot estimate the peak wave direction accurately, and the linear array (2) cannot estimate the reflection coefficient accurately, either. In other words, the linear array parallel to the reflective wall and the triangular array can estimate

Figure 7: Arrays of wave gauges

the peak wave direction accurately, and the linear array normal to the reflective wall and the triangular array can estimate the reflection coefficient accurately. No particular trends relationship was found for the the directinal concentration.

Concluding Remarks

Major concluding remarks of the present study are as follows:

1. A method is derived for estimating the directional spectrum in a field of incident and reflected waves using the cicular normal distribution function.
2. The method is proved to be valid for data in laboratory experiments.
3. The performance of wave gauge arrays is estimated through the root-mean-square error of the estimated paramters.

CHAPTER 5

ACTIVE ABSORPTION OF MULTIDIRECTIONAL WAVES

Hemming A. Schäffer¹⁾ and Jesper Skourup²⁾

Abstract

The development of a control system for active absorption of multidirectional waves is described. The present work is an extension of a two-dimensional flume system to include the wave propagation direction. The hydrodynamic feedback necessary for the active absorption is taken to be the surface elevation measured at each segment of the multidirectional wavemaker. A frequency-direction domain transfer function relating the paddle position to the measured and desired elevations is derived. For practical applications a two-dimensional digital filter is used for a time-space realization of the generation/absorption procedure. Experimental verification is made in a numerical wave tank using a Boundary Element Model. The numerical setup includes a moving boundary representing a segmented wavemaker. This ensures a realistic reproduction of evanescent wave modes, which can be important for the system performance. The numerical tests show that a quasi three-dimensional system consisting of an array of absorbing wavemakers developed for wave flumes is far better than having no active absorption. The present fully three-dimensional absorption system is shown to further reduce spurious reflections to around one third in the examples treated. Although the system is capable of simultaneous wave generation and active absorption, only the absorption ability was used in these preliminary tests.

1. Introduction

Spurious wave reflection remains an important problem in physical as well as numerical model testing of coastal and offshore structures. Open boundaries are often modelled by passive absorbers using e.g. physical perforated plates and numerical sponge layers. In numerical models the absorption performance is often poor for very oblique waves and unwanted diffraction into the sponge layer is a problem for waves travelling along such boundaries. In physical models spurious re-reflection from the wavemaker can lead to considerable distortion of the incident wave field or even to spurious resonance in the model.

Figure 1 Absorption coefficients for active absorption tests in a numerical wave flume using 2D-AWACS. The full curve gives the theoretical performance. Water depth 1m.

This work primarily regards the problem of active absorption from a physical model point of view, but the system developed is also relevant for numerical modelling. The performance of the system is actually analysed using a numerical wave tank.

Recently, the original electric system used for active absorption in flumes at the Danish Hydraulic Institute was revised, leading to a digital Active Wave Absorption Control System called AWACS. The theoretical background and preliminary performance results are given in Schäffer et al. (1994). Since then, enhancements of the recursive filters involved have further improved the results. Applying the technique used in the AWACS, Skourup and Schäffer (1995) demonstrated that the absorption performance could be investigated using a numerical wave flume based on a Boundary Element Model (BEM). Figure 1 compares numerically determined absorption coefficients (found by analysing surface elevation time series from the numerical simulation) with theoretical values (given by the theory behind the active wave absorption system). Similar results were obtained from physical model tests and it appears that the BEM is well suited for a numerical test of an active absorption system for multidirectional waves, as pursued in this work.

The most simple way of introducing active absorption for a segmented multidirectional wavemaker is to apply a system developed for a wave flume to the control of each segment. This was done by e.g. Hirakuchi et al. (1992) using the flume system of Hirakuchi et al. (1990). However, this method only works well for weakly oblique waves. The trouble is that the system overreacts for oblique waves resulting in spurious wave generation.

When generating waves by the snake principle it is well known that for a fixed wave height, oblique waves require a smaller stroke than normally emitted waves. Specifically, the transfer function relating the wavemaker paddle stroke to the amplitude of the progressive wave is proportional to $\cos \theta$ where θ is the angle of emission (zero for normally emitted waves). Since active absorption is the reverse process of wave generation (i.e. reversing time), this $\cos \theta$ should also

be accounted for in the absorption of oblique waves. When the hydrodynamic feedback to the control system is taken as the elevation measured on the paddle front the presence of evanescent modes can be important. In this case the simple $\cos \theta$ -variation of the involved transfer function is changed to a more complicated one which not only includes a θ -dependent amplitude but also a θ -dependent phase shift.

The flume AWACS has two inputs and one output. At each time step the inputs are the elevation of the desired incident waves and the elevation measured at the paddle of the wavemaker. The output is the position of the wavemaker paddle. The two inputs are combined in a simple manner reducing the system to a single-input-single-output system. For the multidirectional wave case a general multiple-input-multiple-output system is in principle required. The input represents desired incident waves and the hydrodynamic feedback, e.g. surface elevation measured on each paddle, and the output is the position of each paddle. Using a number of flume systems in parallel (which is the equivalent of making the approximation $\cos \theta = 1$) the multiple-input-multiple-output system is simplified to a number of parallel single-input-single-output systems. However, if $\theta \neq 0$ is to be accounted for, each paddle should at least be influenced by the hydrodynamic feedback at neighbouring flaps. Such a system is developed allowing for any number of directions to be represented at each frequency. Analysis of the system performance is made using the BEM to simulate the physical wave tank including the moving boundary representing the segmented wavemaker.

Since the 2D-AWACS is the basis for the present 3D system the next chapter gives a short review. In Chapter 3 the theory for multidirectional active wave absorption is derived and Chapter 4 gives some basic ideas for the practical inclusion of directional information. The general approach taken for the 3D-AWACS is shown in Chapter 5 and verification by experiments in a numerical wave tank is given in Chapter 6. Finally, summary and conclusions are presented in Chapter 7.

2. Review of the 2D-AWACS

The active wave absorption control system for wave flumes (2D-AWACS) presented by Schäffer et al. (1994) is based on a frequency domain expression for the wavemaker paddle position which may be formulated as

$$X_a = (2A_I - A_0) F_0; \quad F_0 \equiv \frac{1}{\sum_{j=0}^{\infty} c_j^*} \quad (1)$$

in which “*” denotes complex conjugation and i is the imaginary unit. Here A_I and A_0 are the complex amplitudes of the desired incident wave elevation and the elevation measured on the wave board. F_0 is a complex transfer function based on a real transfer function c_0 and some imaginary transfer functions c_j . Here c_0 , which is sometimes called the Biésel transfer function, relates the amplitude of the generated wave to the amplitude of the paddle motion in the case of pure wave generation. The rest of the series in (1) is imaginary, and it relates the amplitude of the evanescent modes at the wave board to the amplitude of the paddle motion. For a piston type wavemaker we have

$$c_j = \frac{4 \sinh^2 k_j h}{2k_j h + \sinh 2k_j h} \quad (2)$$

see e.g. Schäffer (1996) for results for different types of wave paddles. Here k_j is the j 'th solution to

$$\omega^2 = gk_j \tanh k_j h \quad (3)$$

which is the linear dispersion relation generalized to complex wave numbers. It has one real solution, say k_0 , and an infinity of purely imaginary solutions k_j , $j \geq 1$, where $ik_j > 0$.

Practical application in the time domain is made by use of the recursive digital filter

$$v_n = \sum_{k=0}^M a_k u_{n-k} + \sum_{k=1}^N b_k v_{n-k} \quad (4)$$

where the input u_n is $2\eta_I - \eta_0$ evaluated at time $t = n\Delta t$ and the output v_n is the wavemaker position, $X(n\Delta t)$. The transfer function of this recursive filter was fitted to match the transfer function F_0 over a wide frequency range by optimization of the filter coefficients (a_k, b_k) under stability constraints (see e.g. Antoniou, 1979). With these coefficients (4) provides the instantaneous paddle position for irregular as well as regular waves. The system only needs the instantaneous elevations of the desired incident-wave elevation, η_I and the elevation measured at the wave board, η_0 . No a priori knowledge on the waves to be generated or absorbed is required.

3. Absorption theory – frequency-direction representation

Let $\eta_I(x, y, t)$ denote the elevation of the desired incident wave (i.e. the wave emitted from the wavemaker), let $\eta_0(y, t)$ be the elevation measured on the paddles of the wavemaker and let the position of these paddles be $X(y, t)$. Here (x, y) is a Cartesian coordinate system with $x = 0$ on the wavemaker.

In a linear representation the wave field to be absorbed or generated can be described as a superposition of a number of unidirectional monochromatic wave components. Thus, in this section active absorption is examined in the frequency domain concentrating on just one frequency and one wave propagation direction. Let A_I, A_0 , and X_a be complex amplitudes and let c.c. denote the complex conjugate of the preceding term, then we have

$$X = \frac{1}{2} \{ X_a e^{i(\omega t - k_y y)} + \text{c.c.} \} \quad (5)$$

$$\eta_I = \frac{1}{2} \{ A_I e^{i(\omega t - k_x x - k_y y)} + \text{c.c.} \} \quad (6)$$

$$\eta_0 = \frac{1}{2} \{ A_0 e^{i(\omega t - k_y y)} + \text{c.c.} \} \quad (7)$$

where (k_x, k_y) are the components of the wave number vector. Since waves impinging on the wavemaker will typically be reflections from some beach or structure their complex amplitude will be denoted A_R and their re-reflections from the wavemaker are termed A_{RR} . Thus, the waves emitted from the wavemaker are due to both the paddle motion and re-reflections:

$$A_I = iX_a e_0 + A_{RR} \quad (8)$$

Here e_0 is a frequency and direction dependent transfer function defined below and i is the imaginary unit representing a 90° phase shift. When no reflections

are present there will be no re-reflections and (8) reduces to an expression for pure wave generation. On the other hand, when pure active absorption is wanted then $A_I \equiv 0$ and thus the paddle generates progressive waves cancelling the re-reflections. The elevation measured on the paddle front includes both reflections and re-reflections as well as the waves generated by the movement of the paddle including the evanescent modes due to the mismatch between the shape of the paddle and the vertical structure of a progressive wave:

$$A_0 = iX_a \sum_{j=0}^{\infty} e_j + A_R + A_{RR} \quad (9)$$

Assuming full reflection at the wave paddle, we further have

$$A_R = A_{RR} \quad (10)$$

Eliminating (A_R, A_{RR}) from (8)–(10) and solving for X_a yields

$$X_a = (2A_I - A_0) F; \quad F \equiv \frac{1}{i \sum_{j=0}^{\infty} e_j^*} \quad (11)$$

in which “*” denotes complex conjugation. This simple relation is the frequency-direction basis for the control of simultaneous generation and active absorption. For practical application this needs to be transformed to a time-space domain representation as shown in Chapter 5. The transfer functions constituting F are

$$e_j = \begin{cases} \frac{1}{\sqrt{1 - k_y^2/k^2}} c_0 = \frac{1}{\cos \theta} c_0 & \text{for } j = 0 \\ \frac{1}{\sqrt{1 + k_y^2/|k_j^2|}} c_j & \text{for } j = 1, 2, \dots \end{cases} \quad (12)$$

where (k_j, c_j, e_j) are real for $j = 0$ and imaginary for $j = 1, 2, \dots$. This is for the normal case, where $(k_y < k)$, so that e_0 corresponds to progressive waves. If $(k_y > k)$, then e_j is imaginary even for $j = 0$ and all modes are evanescent. For the two-dimensional case (11) reduces to (1). The transfer functions given by (12) do not account for spurious wave generation due to finite segment width of the directional wavemaker.

In addition to the frequency variation (11) also depends on the wave direction. Thus, the task is now to formulate this in the time domain somehow including the directional information. Our first ideas on how this could be done are still useful for illustrating the more general approach finally adopted. These ideas are given in the next chapter.

4. Basic ideas for inclusion of directional information

In this chapter the discussion is simplified by disregarding evanescent wave modes and considering monochromatic, unidirectional, oblique waves. Under these assumptions (11) reduces to

$$X_a = (2A_I - A_0) \frac{\cos \theta}{i c_0} \quad (13)$$

where the factor $\cos \theta$ makes the only difference from the flume case. Thus, for a known wave direction the correct time domain response can be obtained by replacing $2\eta_I - \eta_0$ by $(2\eta_I - \eta_0) \cos \theta$ in the instantaneous evaluation of the position of each paddle. Skourup (1996) used a numerical wave tank to show examples where this worked very well. However, generally θ is not known and an online determination of $\cos \theta$ is needed. Including the variation along the wavemaker in the amplitudes, (13) becomes

$$\hat{X}_a = \left(2\hat{A}_I - \hat{A}_0\right) \frac{\cos \theta}{ic_0} \quad (14)$$

where

$$\left(\hat{X}_a(y), \hat{A}_0(y), \hat{A}_I(y)\right) \equiv (X_a, A_0, A_I)e^{-ik_y y}; \quad k_y = k \sin \theta \quad (15)$$

The idea is now to differentiate this expression in order to obtain some kind of directional variation. The n 'th derivative

$$\frac{\partial^n}{\partial y^n} \left(2\hat{A}_I - \hat{A}_0\right) = (ik \sin \theta)^n \left(2\hat{A}_I - \hat{A}_0\right) \quad (16)$$

provides a directional variation in terms of $\sin^n \theta$, but since a cosine was the goal, we use the expansion

$$\cos \theta = \sum_{n=0}^N a_{2n} \sin^{2n} \theta \quad (17)$$

where a_{2n} are expansion coefficients and N is the order of the expansion. Using (16) and (17), we get

$$\left(2\hat{A}_I - \hat{A}_0\right) \cos \theta = \sum_{n=0}^N \frac{b_{2n}}{k^{2n}} \frac{\partial^{2n}}{\partial y^{2n}} \left(2\hat{A}_I - \hat{A}_0\right) \quad (18)$$

where

$$b_{2n} = (-1)^n a_{2n} \quad (19)$$

In principle (18) provides the input for the absorption system. In a time domain representation instantaneous elevations would replace the amplitudes. These elevations would then be given by their discrete values in time and in space along the wavemaker, typically with a spacing equal to the segment width of the wavemaker. A second derivative would then e.g. be evaluated by a central difference including three points: the elevation at the actual segment and at the two neighbouring segments. Generally, the evaluation of the $2n$ 'th derivative would involve (at least) $2n + 1$ points i.e. n neighbouring points to each side.

Since we have avoided nonlinear relations (e.g. for expressing the cosine in terms of sines) the formulation is not restricted to one direction at one particular frequency. Application to irregular waves requires that the frequency dependent factors $1/k^{2n}$ are replaced by time domain recursive digital filters, approximating $1/k^{2n}$ for their frequency domain transfer function. Since $k \sim \omega$ in shallow water (and even $\sim \omega^2$ in deep water) $1/k^{2n}$ represents a low pass filter

of increasing order for increasing n . This filter just balances the amplification at high frequency caused by the differentiations in (18). For the general case of irregular waves the procedure outlined above involves a separate fitting of the coefficients b_{2n} and coefficients for the recursive filters representing $1/k^{2n}$. Furthermore, it relies on the neglect of evanescent modes and altogether it is more suited for explaining the principles than for practical application.

In conclusion to this chapter, differentiations of the elevations along the wavemaker are in principle able to provide the directional information required for active absorption of oblique waves. Since differentiation is equivalent to convolution with a set of filter weights it appears natural to formalize this in terms of a digital filter in space regarding the segmentation of the wavemaker as the spatial discretization. Since, for irregular waves, recursive filtering was already used with respect to the time variable, the general approach calls for a two-dimensional digital filter in time and space.

5. General approach to the time-space realization

We now return to the general case including the evanescent modes i.e. without a restriction to rather shallow water. Equation (11) in Chapter 3 gives a frequency-direction recipe for simultaneous generation and active absorption. Inspired by the above ideas we now take a general two-dimensional filter approach to the practical time-space realization of this recipe. The input to the system is a combination of desired and measured elevations and the output is the paddle position. Both input and output are regarded as functions of the coordinate along the wavemaker, y , and of time, t , sampled at $(n\Delta t, m\Delta y)$. The two-dimensional Fourier transform relates (t, y) -space to (ω, k_y) -space. Thus, we need to regard the target transfer function F from (11) as a function of (ω, k_y) instead of (ω, θ) . From this point of view we can use a two-dimensional digital filter for practical time-space application:

$$v_{n,m} = \sum_{l=-M_2}^{M_2} \sum_{k=0}^{M_1} a_{kl} u_{n-k, m-l} + \sum_{l=-N_2}^{N_2} \sum_{k=1}^{N_1} b_{kl} v_{n-k, m-l} \quad (20)$$

Here the input $u_{n,m}$ is $2\eta_I - \eta_0$ evaluated at $(t, y) = (n\Delta t, m\Delta y)$ and the output $v_{n,m}$ is $X(n\Delta t, m\Delta y)$. Like the filter given in (4) for the flume case, this filter must be causal in time as the future is unknown. Thus, the counter k only takes non-negative values. However, this restriction does not apply in space, and thus the counter l runs through negative as well as positive values. The transfer function of this recursive filter was fitted to match the transfer function $F(\omega, k_y)$ over a wide range of frequencies and directions by optimization of the filter coefficients (a_{kl}, b_{kl}) . Generally, the stability constraints for two-dimensional recursive filters are very complicated. At present, we omit the recursive element with respect to the spatial part of the filter, i.e. restricting ourselves to $N_2 = 0$ in (20). Furthermore, $M_2 = 1$ is used which means that at each time step the evaluation of the paddle position is only influenced by the signals at neighbouring segments. With our choice of $(\Delta t, \Delta y) = (0.025s, 0.5m)$ this allows information to travel with a speed of $\Delta y/\Delta t = 20m/s$ along the wavemaker. Since F is an even function of k_y , we get $a_{k,l} = a_{k,-l}$. It can be shown that by these restrictions the formulation basically contains the spatial

Figure 2 Top view of the numerical wave tank with a distorted rectangular grid. Wave generation at the west boundary, fully reflecting walls on the two sides and an absorbing segmented wavemaker on the oblique boundary.

derivatives from the preliminary analysis leading to (18). Only now the coefficients are found directly by fitting to the general transfer function F from (11) including evanescent-mode effects.

6. Experimental verification in a numerical wave tank

Skourup et al. (1992) developed a three-dimensional Boundary Element Model solving an integral equation for the potential flow problem in combination with an explicit time stepping procedure for updating the boundaries of the computational domain, including the free surface. Applications to a numerical wave tank equipped with a moving boundary to simulate a segmented wavemaker was described by Skourup (1996), who considered active absorption of oblique waves where the propagation direction was known a priori. In the present work this facility is used for a performance test of the 3D-AWACS as if it was a physical wave tank. However, the flexibility available in a numerical wave tank is used in the experimental setup as shown in Fig. 2. Longcrested regular waves are generated at the west boundary and propagate unaffected by the perpendicular side walls until they reach the oblique eastern boundary simulating the absorbing segmented wavemaker. The computations were made on a distorted rectangular grid fitting the boundaries. Different orientations of the oblique boundary was used to obtain a variety of different angles of wave attack relative to the absorbing wavemaker. Regular waves at two different frequencies and at angles of attack ranging from zero to 60 degrees were investigated. We first look at a frequency $f = 0.4Hz$ at which the 2D-AWACS has an almost ideal performance, cf. Fig. 1. For a wave attack of 45 degrees Fig 3 shows the instantaneous picture of the free surface after 12 periods of simulation time. Three different conditions were used on the oblique boundary to show the difference between having no absorption at all (Fig. 3a), using independent 2D-AWACS's for each

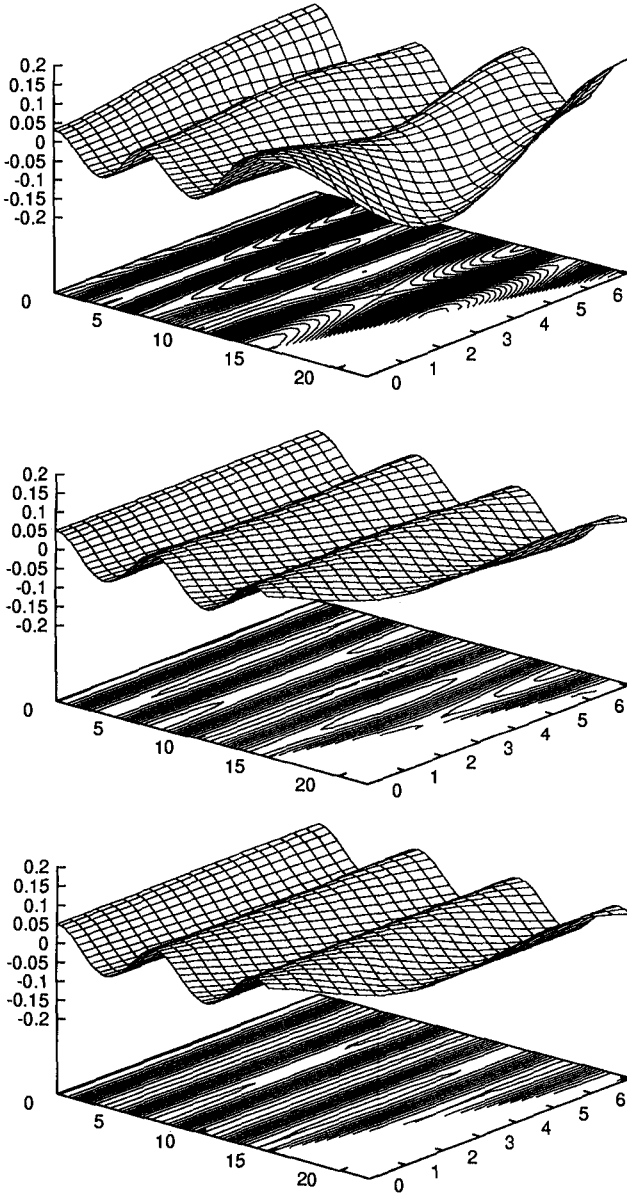

Figure 3 Waves of frequency $0.4Hz$ generated at the west boundary reflected or absorbed at the oblique boundary using a) no boundary movement b) partial absorption using 2D-AWACS c) better absorption using 3D-AWACS. Water depth 1m.

Figure 4 Reflection coefficients (%) for regular waves of frequency $0.4Hz$ versus angle of attack for a) 2D-AWACS and b) 3D-AWACS. The full curves give the theoretical performance. Water depth 1m.

segment (Fig. 3b), and using the 3D-AWACS (Fig. 3c). The pronounced cross-wave pattern for the fully reflective case (Fig. 3a) is significantly improved by use of the 2D-AWACS (Fig. 3b). Further improvement is obtained by using the 3D-AWACS.

In order to quantify the performance, time series of surface elevation and components of vertical velocity at a point in the vicinity of the absorbing wavemaker were analysed assuming the presence of three wave components: 1) One of direction θ impinging on the absorbing wavemaker 2) its (small) reflection and 3) its re-reflection from the side wall. In the postprocessing of the numerical data the angles of these three components were known and their amplitudes were calculated and used for estimation of the (small) reflection coefficients from the absorbing wavemaker. The markers on Fig. 4 show this reflection coefficient for angles θ ranging from vanishing obliqueness, $\theta = 0$ to $\theta = 60$ degrees. The performance of the 2D-AWACS is shown in Fig. 4a, while Fig. 4b gives the results for 3D-AWACS. The full curve gives the theoretical variation of the coefficient. For both systems this can be determined from the theory behind the 3D-AWACS. Again it appears that the 2D-AWACS is far better than having no absorption at all, i.e. the coefficients are small compared to 100%. The use of the 3D-AWACS further reduces the reflection to approximately one third.

The second frequency to be studied is $f = 0.7Hz$ at which the absorption coefficient of the 2D-AWACS has a local minimum, i.e. the poorest performance within a wide frequency range. Figure 5 shows the resulting reflection from the absorbing wavemaker. For the 2D-AWACS (Fig. 5a) the trend is the same as for $f = 0.4Hz$ that increasing obliqueness gives increasing reflection. However, for the 3D-AWACS, the performance is actually best around $\theta = 30$ degrees.

For these preliminary tests the aspect ratio of the boundary elements was rather high near the absorbing wavemaker in case of large θ . This gave unreliable results at $f = 0.7Hz$ and $\theta > 40$ degrees, explaining why these data do not appear in Fig. 5.

Figure 5 As Fig. 4, but for a frequency of $0.7Hz$.

7. Summary and conclusions

The development of an Active Absorption Control System for multidirectional waves called 3D-AWACS has been outlined. The theoretical basis has been derived in the frequency-direction domain and practical realization has been shown to be possible by use of a two-dimensional digital filter operating in the time-space domain, where the spatial coordinate runs along the absorbing wavemaker.

The preliminary performance of the system has been tested in a numerical wave tank including a moving boundary to simulate the segmented absorbing wavemaker. Comparative tests with a quasi three-dimensional system consisting of an array of two-dimensional absorption systems (2D-AWACS) in parallel shows that the 2D system is very much better than no active absorption and that the 3D-AWACS can further reduce spurious reflection significantly. Although the system is capable of simultaneous wave generation and active absorption, only the absorption ability was shown in these preliminary tests.

CHAPTER 6

TIME-AVERAGED WAVE FIELD EVOLUTION IN COASTAL ZONE

Jianlu Xu¹ and Rodney J. Sobey²

1. Introduction

Flow circulation and the field variation of wave height and setup are important data in coastal engineering practice. This paper presents a wave-averaged model for simulating wave transformation and associated mean flow circulation in coastal regions. It is intended for applications where interest centers on the evolution of wave-averaged parameters such as wave height, setup and wave-induced current, and where the resolution of wave phase is unnecessary.

2. Governing Equations

An analysis technique used in turbulent shear flow is adapted to develop the governing equations for wave height, wave setup and mean flow. Variables are decomposed into a slowly varying mean flow and a fluctuating residual which includes both wave and turbulent components. For example, a general velocity vector is decomposed into a wave-averaged velocity vector ($\bar{u}, \bar{v}, \bar{w}$) and a fluctuating velocity vector ($\tilde{u}, \tilde{v}, \tilde{w}$).

Subsequently the conservation equations of mass, momentum and energy are averaged over a wave period and integrated over water depth. The time-averaging introduces apparent stress- or Reynolds stress-style terms corresponding to the time scale of the wave period. The wave-averaged and depth-integrated continuity equation reads (Sobey & Thieke 1988).

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \bar{u} dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \bar{v} dz = 0 \quad (1)$$

where x, y and z denote the Cartesian coordinates with z directed upward, t denotes the time, $\bar{\eta}$ is the local wave setup, η_c is the local wave crest elevation, and h is the local water depth from a datum plane in the global SWL. Equation (1) is identical to the long wave continuity equation.

The depth-integrated and wave-averaged x - and y -momentum equations are

$$\begin{aligned} \frac{\partial}{\partial t} \int_{-h}^{\eta_c} \bar{u} dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \bar{u}^2 dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \bar{u} v dz = \\ -g(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} + \frac{1}{\rho} \left[\frac{\partial}{\partial x} \int_{-h}^{\eta_c} s_{xx} dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} s_{xy} dz - \tau_{bx} \right] \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial}{\partial t} \int_{-h}^{\eta_c} \bar{v} dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \bar{u} v dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \bar{v}^2 dz = \\ -g(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial y} + \frac{1}{\rho} \left[\frac{\partial}{\partial x} \int_{-h}^{\eta_c} s_{xy} dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} s_{yy} dz - \tau_{by} \right] \end{aligned} \quad (3)$$

where s_{xx} , s_{xy} , s_{yy} are wave apparent stresses, and τ_{bx} and τ_{by} are the bottom shear stress components in the x and y direction, respectively. The wave energy equation is written as

$$\begin{aligned} \frac{1}{2} \frac{\partial}{\partial t} \int_{-h}^{\eta_c} (\bar{u}^2 + \bar{v}^2 + \bar{w}^2) dz + g \bar{\eta}^2 + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \left[\frac{\bar{p}_d \bar{u}}{\rho} + \frac{1}{2} (\bar{u}^3 + \bar{u} \bar{v}^2 + \bar{u} \bar{w}^2) \right] dz \\ - \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \left[\frac{\bar{p}_d \bar{v}}{\rho} + \frac{(\bar{v} \bar{u}^2 + \bar{v}^3 + \bar{v} \bar{w}^2)}{2} \right] dz = - \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \bar{u} (\bar{u}^2 + \bar{v}^2 + \bar{w}^2) dz - \frac{\partial \bar{u}}{\partial x} \int_{-h}^{\eta_c} \bar{u}^2 dz \\ - \left(\frac{\partial \bar{v}}{\partial x} + \frac{\partial \bar{u}}{\partial y} \right) \int_{-h}^{\eta_c} \bar{u} \bar{v} dz - \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \bar{v} (\bar{u}^2 + \bar{v}^2 + \bar{w}^2) dz - \frac{\partial \bar{v}}{\partial y} \int_{-h}^{\eta_c} \bar{v}^2 dz - D_{bf} - D_{wb} \end{aligned} \quad (4)$$

where D_{bf} and D_{wb} are energy dissipation due to bottom friction and wave breaking, respectively.

3. Closure Solution Surfaces

Equations (1)-(4) contain wave setup, mean flow velocity and wave apparent stresses, among other unknowns. The number of the unknowns far exceeds the number of governing equations. This is the apparent stress closure problem familiar in turbulence. As our closure hypothesis, the Reynolds stress-style terms are established as a function of wave height, wave period and water depth from Fourier approximation wave theory. For simplicity, the closure variables are defined in the propagation direction of plane waves. In addition, a two-layer flow structure is assumed with the kinematics above wave trough (surface layer) being dominated by wave motion and the mean flow current being confined below the wave trough (bottom layer). The closure parameters for the local layer-averaged wave apparent stresses are, e.g., defined as

$$S_s = \frac{1}{H} \int_{\eta_{tr}}^{\eta_c} [-\Delta p + \rho(\bar{w}^2 - \bar{u}^2)] dz \quad \text{for the surface layer} \quad (5)$$

$$S_b = \frac{1}{h - \eta_{tr}} \int_{-h}^{\eta_{tr}} \rho(\bar{w}^2 - \bar{u}^2) dz \quad \text{for the bottom layer} \quad (6)$$

where η_{tr} is the local wave trough elevation, and Δp is the local pressure residual due to the partial submergence of a point above the wave trough during a wave period. Sixteen closure variables (η_{tr} , \hat{U}_s , U_{rms} , \hat{U}_b^2 , \bar{U}_b^2 , S_s , S_b , N_s , N_b , W_s , W_b , $\bar{\eta}^2$, F_s , F_b , K_s and E_p) are similarly established and these closure variables are normalized by angular

wave frequency ω and the acceleration due to gravity, g . For example, S_s and S_b are normalized by $\rho\omega^2/g^2$. Following the above procedure, closure solution surfaces are established with water depth ranging from deep to shallow and wave height upto the breaking limit.

Upon substituting the closure parameters into Equations (1) to (4), a closed system for the wave height, H , wave setup, $\bar{\eta}$, and mean flow velocity, U_b and V_b , is developed. The integral, dimensionless continuity equation reads

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x} [(H U_s \cos \phi) + (h + \bar{\eta} + \eta_{tr}) U_b] + \frac{\partial}{\partial y} [(H U_s \sin \phi) + (h + \bar{\eta} + \eta_{tr}) V_b] = 0 \quad (7)$$

The integral x- and y-momentum equations are

$$\begin{aligned} \frac{\partial}{\partial t} [H U_s \cos \phi + (h + \bar{\eta} + \eta_{tr}) U_b] + \frac{\partial}{\partial x} [H U_s^2 \cos^2 \phi + (h + \bar{\eta} + \eta_{tr}) U_b^2 + (h + \frac{\bar{\eta}}{2}) \bar{\eta}] \\ + \frac{\partial}{\partial y} [H U_s^2 \frac{\sin 2\phi}{2} + (h + \bar{\eta} + \eta_{tr}) U_b V_b] = -\bar{\eta} \frac{\partial h}{\partial x} - \frac{\partial}{\partial x} [H(S_s + \sin^2 \phi N_s) \\ + (h + \bar{\eta} + \eta_{tr})(S_b + \sin^2 \phi N_b)] - \frac{\partial}{\partial y} [\frac{\sin 2\phi}{2} (H N_s + (h + \bar{\eta} + \eta_{tr}) N_b)] - \frac{\tau_{bx}}{\rho} \end{aligned} \quad (8)$$

$$\begin{aligned} \frac{\partial}{\partial t} [H U_s \sin \phi + (h + \bar{\eta} + \eta_{tr}) V_b] + \frac{\partial}{\partial x} [H U_s^2 \cos^2 \phi + (h + \bar{\eta} + \eta_{tr}) U_b V_b] \\ + \frac{\partial}{\partial y} [H U_s^2 \sin^2 \phi + (h + \bar{\eta} + \eta_{tr}) V_b^2 + (h + \frac{\bar{\eta}}{2}) \bar{\eta}] = -\bar{\eta} \frac{\partial h}{\partial y} - \frac{\partial}{\partial x} \{ [\frac{\sin 2\phi}{2} (H N_s \\ + (h + \bar{\eta} + \eta_{tr}) N_b)] \} + \frac{\partial}{\partial y} [H(S_s + \cos^2 \phi N_s) + (h + \bar{\eta} + \eta_{tr})(S_b + \cos^2 \phi N_b)] - \frac{\tau_{by}}{\rho} \end{aligned} \quad (9)$$

And the integral wave energy equation is

$$\begin{aligned} \frac{1}{2} \frac{\partial}{\partial t} [\bar{\eta}^2 + H W_s + (h + \bar{\eta} + \eta_{tr}) W_b] + \frac{\partial}{\partial x} \{ \cos \phi [H(F_s + K_s) + F_b (h + \bar{\eta} + \eta_{tr})] \} + \\ \cos^2 \phi H N_s \frac{\partial U_s}{\partial x} + (N_b \cos^2 \phi + \frac{W_b}{2}) (h + \bar{\eta} + \eta_{tr}) \frac{\partial U_b}{\partial x} + \frac{U_b}{2} \frac{\partial}{\partial x} [W_b (h + \bar{\eta} + \eta_{tr})] + \\ H N_s \frac{\sin 2\phi}{2} (\frac{\partial U_s}{\partial y} + \frac{\partial V_s}{\partial x}) + (h + \bar{\eta} + \eta_{tr}) N_b \frac{\sin 2\phi}{2} (\frac{\partial V_b}{\partial x} + \frac{\partial U_b}{\partial y}) + \\ \frac{\partial}{\partial y} \{ \sin \phi [H(F_s + K_s) + (h + \bar{\eta} + \eta_{tr}) F_b] \} + (h + \bar{\eta} + \eta_{tr}) (N_b \frac{\sin 2\phi}{2} + \frac{W_b}{2}) \frac{\partial V_b}{\partial y} + \\ \frac{V_b}{2} \frac{\partial}{\partial y} [(h + \bar{\eta} + \eta_{tr}) W_b] + H N_s \sin^2 \phi \frac{\partial U_s}{\partial y} = -\frac{2}{3\pi} f_w \bar{U}_b^3 - f_{wb} \omega H^2 \end{aligned} \quad (10)$$

where H is the wave height, ϕ is the direction of wave propagation from the x-axis, f_w is the bottom friction factor and f_{wb} is a dimensionless factor for predicting energy dissipation rate due to wave breaking.

4. Simulation of Mean Wave Parameters in One Spatial Dimension

In a one-dimensional space with x denoting the direction of wave propagation, the integral continuity equation reads

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x} [H U_s + (h + \bar{\eta} + \eta_{tr}) U_b] = 0 \quad (11)$$

The dimensionless integral momentum equation becomes

$$\begin{aligned} \frac{\partial}{\partial t} [H U_s + (h + \bar{\eta} + \eta_{tr}) U_b] + \frac{\partial}{\partial x} [H U_s^2 + (h + \bar{\eta} + \eta_{tr}) U_b^2] = \\ -(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} + \frac{\partial}{\partial x} [H S_s + (h + \bar{\eta} + \eta_{tr}) S_b] - \frac{\tau_{bx}}{\rho} \end{aligned} \quad (12)$$

and the dimensionless integral wave energy equation becomes

$$\begin{aligned} \frac{1}{2} \frac{\partial}{\partial t} [E_p + H W_s + (h + \bar{\eta} + \eta_{tr}) W_b] + \frac{\partial}{\partial x} [H F_s + (h + \bar{\eta} + \eta_{tr}) F_b] \\ = -\frac{\partial}{\partial x} (K_s H) - H N_s \frac{\partial U_s}{\partial x} - [(N_b + \frac{W_b}{2})(h + \bar{\eta} + \eta_{tr})] \frac{\partial U_b}{\partial x} \\ - \frac{U_b}{2} \frac{\partial}{\partial x} [W_b (h + \bar{\eta} + \eta_{tr})] - \frac{2}{3\pi} f_w \bar{U}_b^3 - f_{wb} \omega H^2 \end{aligned} \quad (13)$$

4.1 Characteristic Equations and Numerical Solution

The integral equations (11)-(13) can be written into a quasilinear system

$$\frac{\partial \bar{q}}{\partial t} + A \cdot \frac{\partial \bar{q}}{\partial x} = S(x, t, \bar{q}) \quad (14)$$

where \bar{q} is a dependent variable vector,

$$\bar{q} = [H, \bar{\eta}, U_b]^T \quad (15)$$

S is a source or sink vector, and A is a 3×3 Jacobian coefficient matrix. The propagation of the information described by Equation (14) can be characterized using the eigenvalues of the coefficient matrix, A . The eigenvalue of a matrix is defined as

$$\det[\lambda I - A] = 0 \quad (16)$$

where \det denotes the determinant, λ is the eigenvalue, and I is a 3×3 unit matrix. Equation (16) is generally a third order polynomial in λ . If all three roots of the polynomial, λ_1 , λ_2 and λ_3 , are real and distinct, the system is hyperbolic. For a hyperbolic system, each eigenvalue denotes the propagation speed of some particular information. It is advantageous to obtain the numerical solutions of Equation (14) by the method of characteristics since the corresponding characteristic equations are ordinary differential equations.

The characteristic equations are established by combining the original system equations with an eigenvector of the coefficient matrix as follows

$$\bar{l}_i \cdot \left[\frac{\partial}{\partial t} + A \frac{\partial}{\partial x} \right] \bar{q} = \bar{l}_i \cdot S \quad i = 1, 2, 3 \quad (17)$$

where \bar{l}_i is the left eigenvector such that

$$\bar{l}_i \cdot [\lambda I - A] = 0 \quad (18)$$

Equation (17) can be written as ordinary differential equations

$$\bar{l}_i \cdot \frac{d\bar{q}}{dt} = \sum \bar{l}_i \cdot S \quad i = 1, 2, 3 \quad (19)$$

along the characteristic curve

$$\frac{d}{dt} = \frac{\partial}{\partial t} + \lambda_i \cdot \frac{\partial}{\partial x} \quad (20)$$

The numerical solutions, say at a point "o" and at time level n , can be obtained by

solving three characteristic equations integrated over the characteristic curves

$$\bar{\ell}_i \cdot (\bar{q}_o^n - \bar{q}_{x_j}^{n-1}) = \Delta t \cdot \sum \bar{\ell}_i \cdot S \quad i, j=1,2,3 \quad (21)$$

where Δt is the time step, x_1, x_2 and x_3 denote three points traced back from the point “o” through three characteristic curves over one time step. Numerical stability requires that the Courant condition is satisfied

$$\frac{\Delta t \cdot |\lambda|_{\max}}{\Delta x} \leq 1 \quad (22)$$

where Δx is the spacing step and $|\lambda|_{\max}$ is the maximum eigenvalue throughout the entire simulation period and over the entire computational domain.

To provide some insight into the characteristics of this system, eigenvalues and the corresponding eigenvectors are computed for three typical coastal conditions as shown in Table 1. T is the wave period, and L is the local wave length.

Table 1 Characteristics for Three Typical Coastal Conditions

Case	H (m)	T (sec)	h (m)	h/L	C _L (m/s)	C _g (m/s)	Eigenvalue (m/s)	Eigenvector		
								ℓ ₁	ℓ ₂	ℓ ₃
A	1.0	10	100	0.64	31.32	7.80	31.32	0.01	0.50	1.00
							8.32	1.00	-0.01	-0.01
							-31.32	0.01	-0.50	1.00
B	1.0	10	10	0.11	9.90	8.02	10.00	0.28	1.00	0.61
							7.85	1.00	-0.19	-0.10
							-9.90	0.01	1.00	-0.61
C	1.0	10	2	0.04	4.43	4.45	5.24	0.63	1.00	0.23
							3.84	-0.61	1.00	0.29
							-4.48	0.01	1.00	-0.26

Cases A, B and C represent deep, intermediate and shallow water condition, respectively. The linear long wave speed $C_L=(gh)^{1/2}$ and wave group speed C_g estimated from Fourier approximation wave theory are included Table 1 for comparison with the eigenvalues. Based on the above investigation, the following observations are appropriate:

- In each of the three cases, the three eigenvalues are real and distinct. Thus the system is generally hyperbolic.
- In both Case A and Case B, the first and third eigenvalues are almost equal to the linear long-wave speed in magnitude. This is expected since the mean flow part of the system is similar to the shallow water wave equations, as stated in Section 2. The characteristics corresponding to these eigenvalues are termed wave characteristics(Katopodes and Strelkoff 1979).
- The second eigenvalue in each case is almost equal to the wave group speed. Thus the characteristics corresponding to this eigenvalue describes wave energy transfer, and they are accordingly termed energy characteristics(Xu 1996).
- As implied in Equation (17), the eigenvector measures the interaction among the characteristic equations. In Case A, the first component of the eigenvectors for the wave characteristics is always much smaller than the second and third components, while the first component of the eigenvector for the energy

characteristics is much greater than the other two components. This suggests that the wave energy transfer in deep waters is little affected by the mean flow circulation, and vice versa. From Case A to Case C, the first component ℓ_1 of the first eigenvector increases, suggesting that interaction between the mean flow and the wave energy transfer becomes stronger as the water shallows.

- In all three cases, the first component of the eigenvector of the third eigenvalue (negative) is always much smaller than other two components. This indicates that the backward propagation of the information described by the wave characteristics is little affected by the forward wave energy transfer.

4.2 Open Boundary Conditions

Numerical simulation in coastal engineering normally focuses on only a small portion of a larger system. Open boundaries are present at the locations of truncation from the larger system. In the numerical model, open boundary conditions must be specified to allow information to cross the open boundaries unhampered, as would be in the real situation.

For this case, three constraints are necessary and sufficient at the boundary. To permit interior information to propagate out of the domain, the characteristic equations corresponding to the eigenvalue denoting outgoing propagation should be used as part of the boundary conditions. In general, additional constraints would be required to supplement the characteristic equations for outgoing information. Ideally field data should meet such a need, but field data is only rarely available. Instead, additional (and artificial) conditions are generally called for. These extra boundary conditions coupled with the characteristic equations for outgoing information should be non-reflective or at most weakly reflective.

In this study, the Hedstrom(1979) approximate open boundary conditions are used whenever necessary. Hedstrom's approximate boundary conditions for a three-equation hyperbolic system are briefly described here. Suppose that of the three eigenvalues, $m(<3)$ eigenvalues denote outgoing characteristics. The boundary conditions

$$\bar{\ell}_i \bullet \frac{\partial \bar{q}}{\partial t} = 0 \quad (m < i \leq 3) \quad (23)$$

prevents back reflection of waves into the solution domain from the boundary if there are only simple waves going out. In a linear case, the eigenvalues and eigenvectors are constant. The condition described by Equations (23) is equivalent to

$$\bar{\ell}_i \bullet \bar{q} = \text{constant} \quad (m < i \leq 3) \quad (24)$$

This is the Riemann invariant along the incoming characteristics, i.e., the projection of the dependent variable vector on the incoming characteristic curve is constant.

Wave height is normally given at the offshore boundary as external forcing. Then only one of the Equation (23) conditions is needed, because the given wave height and the characteristic equation corresponding to outgoing waves would provide two boundary conditions. The extra condition corresponding to the wave characteristics should be used because the specification of wave height makes the condition corresponding to the energy characteristic redundant.

4.3 Application to Wave Propagation at Egmond Beach

The cross shore bottom profile at Egmond beach (Derks and Stive 1984) is shown in Figure 1. The incident wave period and height are 8.7 seconds and 2.46m, respectively. The wave forcing is suddenly imposed at the offshore boundary and persists throughout the simulation. The system is assumed to be initially quiescent, with wave height, wave setup and current all zero at the beginning of the simulation.

The computational domain is about 3000 m long, with a water depth at the offshore boundary of about 16 m. A uniform space step of 10 m is used with a corresponding time step of 0.7 second.

Figure 1 Bathymetric Profile At Egmond Beach

The wave height, wave setup and undertow velocity at eight time levels are shown in Figures 2 through 4. After seven minutes, a steady state wave height profile is established. It takes about fourteen minutes for the wave setup and undertow current to reach an equilibrium state. As waves approach to the shoreline, the mass transport is predominantly shoreward, causing a significant water surface pulse (Figure 3) and shoreward mass transport. After waves reach the shoreline, seaward undertow current develops (Figure 4). The transient wave setup and undertow current are much greater than steady state wave setup and undertow current, suggesting that the transient dynamics in coastal process could be very important. The observed (Derks and Stive 1984) wave height and setup are also plotted in Figures 2 and 3 as the small circles. Good agreement is found for both wave height and wave setup.

The above case study leads to the following conclusions: (1) the numerical scheme is appropriate for simulating the evolution of mean wave parameters in one spatial dimension; (2) the open boundary conditions work satisfactorily.

5. Simulation of Mean Wave Parameters in Two Spatial Dimensions

The integral governing equations in two spatial dimensions, Equations (7) through (10), can be written in the quasilinear form

$$\frac{\partial \bar{q}}{\partial t} + A_x \frac{\partial \bar{q}}{\partial x} + A_y \frac{\partial \bar{q}}{\partial y} = S \quad (25)$$

where \bar{q} is the dependent variable vector, $\bar{q} = [H, \bar{\eta}, U_b, V_b]$, A_x and A_y are the

Figure 2 Evolution of Wave Height Profile

Figure 3 Evolution of Mean Water Surfaces

Figure 4 Evolution of Undertow Velocity

coefficient matrices, and S denotes the sink or source vector. Due to the limit of space for this paper, the complexity of the integral equations and, the introduction of closure variables, the exact expressions for the coefficient matrices and the sink terms are not presented here; see Xu (1996) for details.

5.1 Characteristic Equations and System Properties

Again the information propagation described by equation (25) can be characterized using the eigenvalues of the coefficient matrices, A_x and A_y . In two spatial dimensions, however, the eigenvalues are azimuth-dependent. If the azimuth on the x - y plane is denoted by a normal vector $\vec{n} [\cos(\theta), \sin(\theta)]$, then the eigenvalues for Equation (25) are defined as

$$\det[\lambda \cdot I - A_x \cos(\theta) - A_y \sin(\theta)] = 0 \quad (26)$$

which in general is a fourth order polynomial in λ . If the four roots of λ are all real and distinct, the system is hyperbolic. The eigenvalues for the entire range of the azimuth form a family of characteristic surfaces with its normal vector defined as $[-\lambda, \cos(\theta), \sin(\theta)]$. These characteristic surfaces are generally inscribed by a cone. The generation lines of the cone are termed bi-characteristics. The characteristic equations can be derived by linearly combining the system equations through the eigenvector of the coefficient matrices

$$\bar{\ell}_j \left(\frac{\partial \bar{q}}{\partial t} + A_x \frac{\partial \bar{q}}{\partial x} + A_y \frac{\partial \bar{q}}{\partial y} \right) = \bar{\ell}_j S \quad j = 1, 4 \quad (27)$$

where $\bar{\ell}_j$ is the left eigenvector

$$\bar{\ell}_i \left[\lambda \cdot I - A_x \cos(\theta) - A_y \sin(\theta) \right] = 0 \quad (28)$$

On the characteristic surfaces, the characteristic equations can be written with differentiations in two directions only, conventionally along the bi-characteristics and a cross-direction which is almost perpendicular to the bi-characteristics. Such characteristic equations are still partial differential equations. There are infinite sets of eigenvalues and characteristic equations at a point since they are azimuth-dependent.

To appreciate the characteristics of this system, the eigenvalues are computed numerically for the following condition: wave direction $\phi = \pi/2$, wave height = 1.0 m, water depth $h = 10$ m, mean water elevation $\bar{\eta} = 0$, and mean flow velocities under wave trough $U_b = 0.5$ m/s and $V_b = 0.5$ m/s. The eigenvalues as a function of the azimuth in the range from 0 to 2π are shown in Figure 5. Also shown in the figure are the three eigenvalues of the shallow water wave equations under the same condition along with their analytical expressions. Of the four eigenvalues at each azimuth, two are identified by λ_w , denoting wave characteristics, one labeled by λ_e , referring to the energy characteristic, and the fourth by λ_f denoting the flow characteristic (Katopodes 1979). The flow characteristics is an extra characteristic family in the two spatial dimensions. The magnitude of the eigenvalue of the flow characteristics is the same order of the magnitude as the flow velocity. The following observations are appropriate:

- This system is generally hyperbolic because the four eigenvalues at any azimuth under the given condition are real and distinct.
- Under the assumed condition, the eigenvalues of wave and flow characteristics are almost identical to those for the shallow water wave equations. The eigenvalue of the energy characteristics may be approximated by $C_g \cos(\phi - \theta)$, in which C_g is the plane wave group speed.

Figure 5 Variation Of Eigenvalue λ With Azimuth θ

- The eigenvalues λ_w^+ and λ_w^- of the wave characteristics are identical when considering the entire range of azimuth (0, 2π) since $\lambda_w^+(\theta) = -\lambda_w^-(\theta + \pi)$. Only one of them, conventionally λ_w^+ , is used in describing wave characteristics. The eigenvalues of the wave characteristics vary slightly with azimuth. Information spreads out at an almost uniform speed.
- The maximum eigenvalue is of particular importance to numerical simulation because it defines the domain of influence or dependence. The direction corresponding to the maximum eigenvalue is termed a principal direction (Xu 1996). In the principal direction, the eigenvalues and characteristic equations of the shallow water wave equations in two spatial dimensions are the same as those in one spatial dimension

5.2 Numerical Scheme

The method of characteristics is used to obtain numerical solutions. The major issues in numerically simulating the evolution of mean wave parameters in two spatial dimensions are (1) evaluation of wave propagation direction, which is used in the closure of wave apparent stresses, (2) development of a numerical scheme recognizing that there are infinite characteristic equations, (3) open boundary conditions, and (4) evaluation of derivatives in the cross direction (cross-derivatives). Due to the limit of space here, the evaluation of wave direction is not discussed.

The bi-characteristic method proposed by Bulter (1962) is adapted to develop a numerical scheme for the present system. This method is based on the combination of the characteristic equations along several bi-characteristics to minimize the coefficients of the cross derivatives. A total of six directions are involved in this case.

Figure 6 Illustration of Bi-characteristics Scheme

The six points traced back from point “p” by the respective characteristic velocity are labeled as 1 to 6 at time level n. Of the six points, 1,2,3 and 4 are on the wave bi-characteristics corresponding to azimuth $\theta=0, \pi/2, \pi$ and $3\pi/2$, respectively. Point 5 is on the flow path, and point 6 is along the wave propagation direction. The coordinates of the points 1 through 6 can be estimated by using the following expressions with sufficient accuracy (Xu 1996)

$$\begin{aligned}
 x_{2,4,5} &= x_p - U_b \Delta t; & x_{1,3} &= x_p - (U_b \mp C) \Delta t; & x_6 &= x_p - \lambda_e \Delta t \cos \phi \\
 y_{2,4,5} &= y_p - V_b \Delta t; & y_{1,3} &= y_p - (V_b \mp C) \Delta t; & y_6 &= y_p - \lambda_e \Delta t \sin \phi
 \end{aligned}
 \tag{29}$$

where C is the long wave speed and ϕ is the wave propagation direction. The values at these points are interpolated from the values at surrounding grid points.

The integration of the energy characteristic equation along 6-p gives

$$\begin{aligned} \ell_1^6 H_p + \ell_2^6 \bar{\eta}_p + \ell_3^6 U_{b,p} + \ell_4^6 V_{b,p} = & \ell_1^6 H_6 + \ell_2^6 \bar{\eta}_6 + \ell_3^6 U_{b,6} + \ell_4^6 V_{b,6} + [a_6 \frac{\partial H}{\partial x} \\ & + b_6 \frac{\partial H}{\partial y} + c_6 \frac{\partial \bar{\eta}}{\partial x} + d_6 \frac{\partial \bar{\eta}}{\partial y} + e_6 \frac{\partial U_b}{\partial x} + f_6 \frac{\partial U_b}{\partial y} + g_6 \frac{\partial V_b}{\partial x} + h_6 \frac{\partial V_b}{\partial y} + S_6] \cdot \Delta t \end{aligned} \quad (30)$$

Summing up the four wave characteristic equations along 1-p, 2-p, 3-p and 4-p and subtracting twice the continuity equation along 5-p gives

$$\begin{aligned} (\sum_{i=1,4} \ell_1^i) H_p + (\sum_{i=1,4} \ell_2^i - 2) \bar{\eta}_p + (\sum_{i=1,4} \ell_3^i) U_{b,p} + (\sum_{i=1,4} \ell_4^i) V_{b,p} = \\ [\sum_{i=1,4} \ell_1^i H_i + (\sum_{i=1,4} \ell_2^i \bar{\eta}_i - 2\bar{\eta}_5) + \sum_{i=1,4} \ell_3^i U_{b,i} + \sum_{i=1,4} \ell_4^i V_{b,i} + \\ (\sum_{i=1,4} a_i) \frac{\partial H}{\partial x} + (\sum_{i=1,4} b_i) \frac{\partial H}{\partial y} + (\sum_{i=1,4} c_i) \frac{\partial \bar{\eta}}{\partial x} + (\sum_{i=1,4} d_i) \frac{\partial \bar{\eta}}{\partial y} + \\ (\sum_{i=1,4} e_i) \frac{\partial U_b}{\partial x} + (\sum_{i=1,4} f_i) \frac{\partial U_b}{\partial y} + (\sum_{i=1,4} g_i) \frac{\partial V_b}{\partial x} + (\sum_{i=1,4} h_i) \frac{\partial V_b}{\partial y} + (\sum_{i=1,4} S_i)] \cdot \Delta t \end{aligned} \quad (31)$$

Subtracting the wave characteristic equation along 1-p from that along 3-p gives

$$\begin{aligned} (\ell_1^1 - \ell_1^3) H_p + (\ell_2^1 - \ell_2^3) \bar{\eta}_p + (\ell_3^1 - \ell_3^3) U_{b,p} + (\ell_4^1 - \ell_4^3) V_{b,p} = \\ \ell_1^1 H_1 - \ell_1^3 H_3 + \ell_2^1 \bar{\eta}_1 - \ell_2^3 \bar{\eta}_3 + \ell_3^1 U_{b,1} - \ell_3^3 U_{b,3} + \ell_4^1 V_{b,1} - \ell_4^3 V_{b,3} + \\ [(a_1 - a_3) \frac{\partial H}{\partial x} + (b_1 - b_3) \frac{\partial H}{\partial y} + (c_1 - c_3) \frac{\partial \bar{\eta}}{\partial x} + (d_1 - d_3) \frac{\partial \bar{\eta}}{\partial y} + (e_1 - e_3) \frac{\partial U_b}{\partial x} \\ + (f_1 - f_3) \frac{\partial U_b}{\partial y} + (g_1 - g_3) \frac{\partial V_b}{\partial x} + (h_1 - h_3) \frac{\partial V_b}{\partial y} + S_1 - S_3] \cdot \Delta t \end{aligned} \quad (32)$$

Similarly, subtracting the characteristic equation along 2-p from that along 4-p gives

$$\begin{aligned} (\ell_1^2 - \ell_1^4) H_p + (\ell_2^2 - \ell_2^4) \bar{\eta}_p + (\ell_3^2 - \ell_3^4) U_{b,p} + (\ell_4^2 - \ell_4^4) V_{b,p} = \\ \ell_1^2 H_2 - \ell_1^4 H_4 + \ell_2^2 \bar{\eta}_2 - \ell_2^4 \bar{\eta}_4 + \ell_3^2 U_{b,2} - \ell_3^4 U_{b,4} + \ell_4^2 V_{b,2} - \ell_4^4 V_{b,4} + \\ [(a_2 - a_4) \frac{\partial H}{\partial x} + (b_2 - b_4) \frac{\partial H}{\partial y} + (c_2 - c_4) \frac{\partial \bar{\eta}}{\partial x} + (d_2 - d_4) \frac{\partial \bar{\eta}}{\partial y} + (e_2 - e_4) \frac{\partial U_b}{\partial x} \\ + (f_2 - f_4) \frac{\partial U_b}{\partial y} + (g_2 - g_4) \frac{\partial V_b}{\partial x} + (h_2 - h_4) \frac{\partial V_b}{\partial y} + S_2 - S_4] \Delta t \end{aligned} \quad (33)$$

It can be verified that the coefficients of the cross derivatives through these combinations are much smaller than those without using such combinations. Equations (30) through (33) are used to obtain the solutions for H , $\bar{\eta}$, U_b and V_b .

5.3 Open Boundary Conditions

At an open boundary, some bi-characteristics lie outside the computational domain. So only some of Equations (30) through (33) can be derived. As a result, extra boundary conditions need to be specified.

In the study of the characteristics of the shallow water wave equations, it is found that the characteristics along a flow path in a two dimensional space behave exactly the same as in a one-dimensional space (Xu 1996). Heuristically, the Hedstrom open boundary conditions introduced in Section 4.2 may be extended approximately to two spatial dimensional problems as long as the open boundary conditions are applied in the flow direction.

If there are m outgoing characteristics, then the 4- m Hedstrom approximate

boundary conditions in the flow direction are formed as

$$\vec{\lambda}_j \cdot \frac{\partial \vec{q}}{\partial t} = 0 \quad j = m. 4 \tag{34}$$

5.4 Simulation of Oblique Wave Propagation

To test the performance of the numerical scheme and open boundary conditions, the numerical model is applied to simulate oblique wave propagation. Waves are assumed to propagate into an initially quiescent square domain from the left lower corner at an angle of 45° with the x-axis. The water depth of the domain is 10 m, and the incident wave height is 0.5 m with a wave period of 10 seconds. A uniform grid with Δx=Δy=10m is used, coupled with a time step of 0.5 second. Wave height is gradually imposed at the inflow boundaries over three time steps.

The computed wave height surfaces at six time levels are shown in Figure (7). At time 50 seconds, waves pass through the computational domain, and a steady state wave field is established. The solutions at the inflow and outflow boundaries are smooth at all six time levels, demonstrating that the imposed boundary conditions do not cause any appreciable numerical reflection at the boundaries.

The propagation speed is estimated by dividing the distance by the time interval. The estimated speed of energy transfer is 8.25 m/s, which is close to the wave group speed estimated from Fourier approximation wave theory of 8.34 m/s.

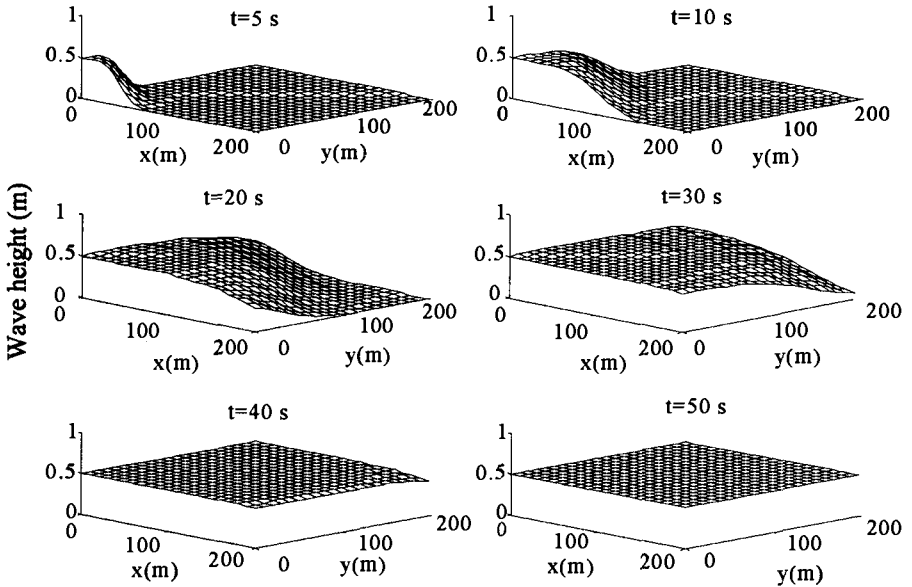

Figure 7 Evolution of Wave Height Envelops

6. Summary

In this study, a wave-averaged depth-integrated model for the evolution of mean wave parameters was developed. This model is valid for both shoaling waves and surf zones provided that periodic motion is dominant over turbulence. The physical processes that this model can simulate include wave shoaling, refraction, diffraction, wave-current interaction and mean flow circulation, etc. The proposed numerical scheme can be used to obtain the numerical solutions effectively and with negligible reflection at open boundaries. The transient behavior in the evolution of mean wave field can be adequately modeled.

It was clearly shown in this study that transient dynamics may be important for coastal evolution. The wave-driven current and mean water surface variation are significantly greater than the respective steady state values. Since the wave conditions in deep water are rarely invariant, the simulation of transient behavior is a significant feature of this model.

CHAPTER 7

Quality Control of GEOSAT Wave Data for Engineering Applications

M. Siddabathula¹ and Vijay G. Panchang²

Introduction

Engineers are often confronted by a paucity of useful wave data needed for a variety of applications. Available information is presently derived from three sources: wave buoy measurements, wave model calculations, and ship observations. Of these, buoy measurements constitute the only reliable data source. However, they provide exceedingly sparse spatial resolution. (For instance, there are only about 45 wave buoys in operation in US waters (Franklin 1992)). Wave modeling (with models such as WAM and the Army Corps' Wave Information Studies) provide a data base of uniform spatial and temporal resolution, but despite many advances, wave modeling must still be considered an evolving field and model results are not fully reliable. Visual ship observations have been used to construct global wave climatologies (e.g. the US Navy Marine Climatic Atlas of the world). However, ship-reported wave observations are irregular and usually regarded as highly imprecise.

This difficulty with traditional data sets may be overcome to some extent by using the large amounts of data collected in recent years by satellites (GEOS-3, SEASAT, Geosat etc.). The US Navy satellite GEOSAT has recorded ocean wave data for almost 5 years. Circling the globe about 15 times a day, GEOSAT gave the densest coverage compared with all existing data. After the initial 18 months of its mission (31 March 1985 to 30 September 1986), it was maneuvered into an exact repeat mission (ERM; November 1986 to January 1990), when the satellite executed 17-day repeat cycles. Global oceanographic information for some 30 oceanographic parameters were recorded every second. These data have been processed by the National Ocean Service (Cheney et al. 1991a, b) and are disseminated to the user community on CD-ROM's. The data are in the form of "Geophysical Data Records" (or GDR's) for the ERM period and "Crossover Difference Records" (or XDR's) for the initial 18 month period. Significant wave heights (SWH) measured by an on-board altimeter were calculated as an average of 10 values recorded every second. About 50,000 measurements, made every 6.4 km along track, were reported daily.

The quality of GEOSAT SWH measurements has been examined by Dobson et al. (1987) and others by comparing them with buoy data. The agreement has been found to be generally good. Of course satellite measurements do not always coincide

¹Programming Analyst, Valanki Information Systems, Somerset, NJ 07783.

²Associate Professor, Civil Engg Dept., University of Maine, Orono, ME 04469.

with buoy measurements in space and time, and allowing various windows of separation, they report the following differences (not "errors" but differences):

Max Separation	Average Separation	Separation		Difference in SWH	
Distance	Time	Separation	Time	rms	mean
50 km	30 min.	35 km	15 min.	0.49 m	0.36 m
50 km	15 min.	35 km	8 min.	0.1 m	
20 km.	30 min.	14 km	15 min.	0.2 m	

Table 1: Comparison of satellite and buoy wave heights (after Dobson et al. 1987)

It is clear that when the two measurements coincide in space and time, the difference between satellite and buoy measurements of significant wave heights are insignificant, at least for most practical uses. Dobson and Porter (1989) and Young (1994) have used these data for their global climatological studies.

In spite of the above observations, there remains some uncertainty regarding the accuracy of GEOSAT SWH data as disseminated to the user community on the CD-ROM's, especially in regions close to land. No comparison has been made with wave data close to land. A closer inspection of the GEOSAT SWH dataset performed here indicates that it contains several erroneous values. Some of the reported measurements are extremely large and have the potential to adversely influence wave statistics calculated on the basis of this dataset (Panchang et al. 1997). In addition, the unintentional use of faulty data on the CD-ROM's is likely to hinder other applications of these data e.g. wave model/data comparisons.

A rigorous assessment of the quality of the GEOSAT SWH data was therefore performed. As noted by Young (1994), quality control of satellite data is difficult; this work involved manual inspection of the satellite and buoy data on a track-by-track basis. This is necessary to eliminate erroneous records from the dataset and to prevent inclusion of similar erroneous records from future satellite missions. A computer program was developed in this study to (a) conveniently extract SWH data in any desired region from the CD-ROM's (since they use a format which is somewhat cumbersome for routine use), and (b) apply rigorous quality control criteria to the SWH data.

Existing Quality Control Criteria

Several quality control criteria were used during the processing of the satellite altimeter data prior to installation on the CD-ROM's (Cheney et al. 1991a, b). Laxon & Rapley (1987), Brooks & Lockwood (1990) and Hayne & Hancock (1990) also describe techniques to flag data of poor quality as measured by SEASAT & GEOSAT satellites. However, these techniques apply to the sensory data records, i.e. the raw satellite data which are not generally available; even if they were, it would be extremely tedious for the user to reprocess the raw data. This study deals only with the data as presented to the end-user on the CD-ROM's. For assessing the quality of these SWH's, the parameters given in Table 2 (out of the 34 oceanographic parameters presented in the GDR's) are of relevance to this study.

During previous studies that have utilized Geosat wave data, some effort had been devoted towards quality control. For instance, Dobson and Porter (1989) discarded those GDR's which had the following criteria: (1) $\sigma_h > 10$ cm; (2) the height bias and satellite attitude were out of range, as determined from bit 2 in the

"Flags" parameter; (3) no value of attitude was available on the GDR (attitude = 0); (4) any one of the 10 per second heights was flagged as bad (as determined by bit 3 in the "Flags" parameter). See Table 2 for a definition of the symbols.

Similarly, in a comparison of wave model and satellite data, Romeiser (1993) used the following criteria to discard measurements: (1) attitude is outside the interval between 0.25° and 1.2°; (2) AGC < 18 dB; (3) $\sigma_0 < 6$ dB; (4) $\sigma_{swh} > 12$ cm. In the remainder of this paper, the above criteria will be referred to as the D&P criteria and the R criteria, respectively. Young (1994) also has used certain quality control criteria in his global climatological studies using the ERM data. His criteria, however, are based on the examination of 50 consecutive records, which tend to eliminate large quantities of coastal wave data.

Date, Time	Provided in the Universal Time Constant format.
Latitude	Latitude in degrees (positive for north, negative for south).
Longitude	Longitude in degrees (positive for east, negative for west).
H	1-second average sea surface height derived from 10 per second heights recorded.
σ_h	Standard deviation from a linear fit to the 10 per second sea surface height values used in computing H.
SWH	Significant wave height as an average of 10 values recorded in one second.
σ_{swh}	Standard deviation of the 10 per second wave height values used in computing SWH.
AGC	Automatic gain control determined onboard the spacecraft at a rate of 10 per second. Indicates signal strength at the altimeter receiver.
σ_{agc}	Standard deviation of the 10 per second values used to compute AGC
σ_0	Backscatter coefficient computed from AGC. Also referred to as normalized radar cross section
Flags	A 16 bit integer, where each bit conveys information about the GDR; of these the following are relevant here: bit 0 = 1 if over water (based on a 1/12 degree mask) or 0 if over land; bit1 = 1 if over water depth over 1000 m . bit2 = 1 if there is height bias reported bit3 = 1 if any of 10 per second values of surface height are bad, (marked 32767)
Attitude	Spacecraft off-nadir orientation angle estimated by ground processing of the return waveform trailing edge.

Table 2: Partial list of GDR parameters (after Cheney et al. 1991b)

In a study of the GEOSAT wave data in the Gulf of Maine, it was found that the above criteria were inadequate. A rigorous examination was therefore performed of the satellite measurements in this region in conjunction with data from several buoys. The Gulf of Maine is particularly well-suited to this study because of the availability of 5 buoys which were operational during the satellite mission and their relative proximity to the satellite tracks (Fig. 1). The adequacy of the D&P and the R quality control criteria was examined and new criteria were developed as necessary. A computer program was then developed to automatically eliminate questionable data. The new criteria and the program were then tested against satellite data in the Gulf of Mexico (Fig. 2).

Wave Data in the Gulf of Maine

There are 14 tracks pertaining to the ERM period of the Geosat mission in the Gulf of Maine. Ascending tracks are denoted here by 0a, 1a, 2a, ... 7a and descending tracks are denoted by 0d, 1d, 2d, ... 5d (Fig. 1). However, the GDR's associated with tracks 0a, 7a, and 0d were found to contain negligible quantities of data in the Gulf of Maine and were hence not used for assessing the quality of the SWH's. It must be noted that even during the ERM phase, the tracks were not exactly self-repeating. As determined from the GDR's, successive passes have a small lateral displacement. Therefore, the lines denoting the tracks in Fig. 1 actually represent a group of closely-clustered tracks. For assessing the quality of the satellite wave measurements, data for the following wave buoys were obtained from NDBC on CD-ROMs (Franklin, 1992): Buoy 44005 (42.7° lat, 68.3° long), buoy 44007 (43.5° lat, 70.1° long), buoy 44008 (40.5° lat, 69.5° long), buoy 44011 (41.1° lat, 66.6° long), and buoy 44013 (42.4° lat, 70.8° long).

As seen in Fig. 1, the satellite tracks never coincide with the exact location of the buoys. Moreover, buoys provide SWH's every hour, while the satellite provides them every second. Therefore, there is never an exact overlap of the measurements for comparison. Automatic comparison of the measurements is thus not sufficient for quality control of the satellite data; differences in the measurements may be entirely attributable to the space/time offset. It was therefore necessary to perform a manual comparison, using as much data as possible as well as a significant level of individual judgment for accepting or discarding satellite data. A complete listing of the satellite data on a track-by-track basis along with the buoy data at the nearest half-hour in the vicinity of the satellite tracks is given in Siddabathula and Panchang (1996).

Quality Control of Satellite Data in the Gulf of Maine

We first performed a detailed examination of the data from the track 2d. The 33 ERM tracks belonging to this class emanate from the west of the Bay of Fundy and proceed southwest past the Cape Cod (Fig. 1). A typical satellite pass in Gulf of Maine region reported 40 to 80 measurements. This variation was due to the fact that sometimes the satellite started tracking several seconds after emerging over water relative to the rest of the tracks in this class. Immediately after emerging over water from west of the Bay of Fundy, the satellite flew over a group of islands; similarly, proximity to land was also encountered near the Cape Cod area. Data from these tracks were examined in detail in conjunction with data from buoys 44005, 44007, 440013 and 44008. Buoy 44011 was considered to be too remote for validation of the data from track 2d.

Fig. 1 Geosat Satellite ground tracks and buoys in the Gulf of Maine

The D&P criteria would have detected a total of 99 erroneous measurements; this amounts to 5% of the GDR's (See summary Table 12). Detailed visual examination of these data revealed, however, a number of additional erroneous data records. The R criteria, on the other hand, eliminated almost 50% of the GDR's in this class of tracks (Table 12). There were instances (e.g. the track on 2 March 1987, Siddabathula and Panchang, 1996) where a complete track was flagged as erroneous by the R criteria while visual examination showed that the altimeter data did agree very well with buoy measurements (Siddabathula, 1996). It can therefore be inferred that the R criteria are too stringent for the 2d tracks. The D&P criteria (all but the third) were therefore used as a baseline. Errors which escape detection by the D&P criteria appear to fall in 3 categories for the 2d tracks. These are denoted as E1, E3 and E4. These errors and ways to detect them are described below.

Error type 1 (E1): Consider the following record pertaining to the 2d track (a complete listing can be found in Siddabathula and Panchang, 1996):

Date	Time	Latit.	Longit.	σ_h	SWH	σ_{swh}	bit0	bit1	bit2	bit3
				(cm)	(m)	(cm)				
870109	222251	41.677	290.117	365	0.29	27	1	0	0	0
870109	222253	41.570	290.045	8	10.17	73	1	0	0	0

Table 3: Subset of 2d track data for 9 Jan 1987

At the closest half-hour, the buoys measurements were about 1.5 m (Table 4):

Buoy	Closest Distance from track (km)	SWH(m)
44005	58	1.5
44007	99	0.3
44008	97	1.5
44011	248	2.5
44013	94	0.2

Table 4: Buoy-SWH data for 9 Jan 1987 in the Gulf of Maine.

Clearly the satellite measurement of 10.17 m appears to be in error. This error would not have been detected by the D&P criteria. (Although detected by the R-criteria since $\sigma_{swh} \geq 12$ cm, this criterion, on its own eliminates too many acceptable GDR's, as seen in Table 7). This error appears to stem from a jump in the recording sequence, i.e. no measurement is reported for some time (1 sec in this case, more in some other cases). This may be due to the altimeter shutting off for an interval of time or due to criteria that prevented any faulty data during this time from being installed on the CD-ROM's in the first place. Such errors were found more than 10 (tracks) times out of 33 inspected. Wave heights seemed erroneous each time such a gap in sequence is detected. To automatically detect such faulty data, we have routinely eliminated the first reported record after a gap in the time sequence.

Error type 2 (E2): To be disregarded (Siddabathula, 1996).

Error type 3 (E3): Consider the subset of 2d track data for 16 July 1987 shown in Table 5 (reproduced from Siddabathula and Panchang, 1996). The SWH measurements reported by nearby buoys are shown in Table 6:

Date	Time	Latit.	Longit.	σ_h	SWH	σ_{swh}	bit0	bit1	bit2	bit3
870716	114257	41.176	289.769	23	12.51	51	1	0	0	0
870716	114258	41.122	289.733	141	2.53	25	1	0	0	0
870716	114259	41.069	289.697	324	19.92	0	1	0	0	0
870716	114300	41.016	289.661	39	17.80	79	1	0	0	0
870716	114301	40.962	289.626	13	13.56	51	1	0	0	0
870716	114302	40.909	289.590	10	12.33	42	1	0	0	0
870716	114303	40.855	289.554	5	11.63	39	1	0	0	0
870716	114304	40.802	289.519	6	7.55	22	1	0	0	0
870716	114305	40.748	289.483	5	5.47	13	1	0	0	0
870716	114306	40.695	289.448	4	3.33	7	1	0	0	0

Table 5: Subset of 2d track data for 16 July 1987.

Buoy	Closest Dist. from track (km)	SWH(m)
44005	59	0.8
44007	99	0.2
44008	85	0.8
44011	248	-
44013	94	0.4

Table 6: Buoy-SWH data for 16 July 1987 in the Gulf of Maine.

After careful inspection, it appears that SWH data in all GDR's except the last one are suspect. The first five SWH measurements in Table 5 are discarded by D&P criterion #1. It was also noted that the average SWH is about 1.5m - 2m in the remainder of the track (Siddabathula, 1996). With buoy data showing waves smaller than 1 m, it appears that the last 5 records in Table 5, with SWH of the order of 5.4 m to 12.33 m, are probably erroneous. Also, these records have an $\sigma_{swh} > 12\text{cm}$. The SWH measurement returns to normal once the σ_{swh} value falls below 12cm, which in this example, occurs for the last record. This phenomenon of consecutive erroneous SWH measurements occurred especially in descending tracks. It mostly occurred at the beginning of the 2d tracks and in the proximity of Cape Cod area.

This example is indicative of a typical descending satellite track near coastal regions. This error has occurred about 24 times (72%) out of total 33 tracks. The threshold value of 12cm for σ_{swh} was chosen on the basis of visual inspection. For quality control, all GDRs with $\sigma_{swh} \geq 12\text{cm}$ occurring immediately after a series (one or more) of GDRs with a land flag or a GDR with $\sigma_h > 10\text{cm}$ were regarded as faulty.

Error type 4 (E4): It was found that a GDR has an erroneous SWH measurement if σ_h is equal 10 cm. Consider the following subset of GDR's (Table 7):

Date	Time	Latit.	Longit.	σ_h	swh	σ_{swh}	bit0	bit1	bit2	bit3
881226	011611	42.737	290.844	4	2.35	0	1	0	0	0
881226	011612	42.684	290.807	3	2.25	13	1	0	0	0
-	-	-	-	-	-	-	-	-	-	-
-	-	-	-	-	-	-	-	-	-	-
881226	011618	42.365	290.583	2	2.29	0	1	0	0	0
881226	011619	42.312	290.546	2	2.52	15	1	0	0	0
881226	011620	42.259	290.509	7	2.17	12	1	0	0	0
-	-	-	-	-	-	-	-	-	-	-

Table 7: Subset of 2d track data for 26 Dec 1988.

The nearest buoy 44005, about 58 km from the satellite track, has reported an SWH = 2.6 m (not shown). It appears that while the last record in Table 7 represents a viable SWH value, the one above it (4.09 m) may be considered suspect. A closer visual inspection of complete listing of the data for this track indicate waves of about 2m and the fact that $\sigma_{swh} = 0$ further justifies its elimination. This criterion can be considered as a refinement of the D&P criterion #1. It appears that in coastal regions, this threshold value for σ_h is necessary to eliminate errors which would escape all the above criteria as well as D&P criteria. This kind of error was observed 5-6 times in 2d tracks.

In order to fine-tune the editing criteria, a detailed examination of data pertaining to 3d and 1d tracks (Fig. 1) was performed. This led to 2 new criteria. Tracks belonging to the 3d class encounter close proximity (the shortest distance being 15 km) with buoy 44005 in the middle and buoy 44008 at the outskirts of the Gulf of Maine. Similar proximity to buoy 44007 (near Portland) and buoy 44013 (near Boston) occurs for track 1d. Therefore data from these tracks were examined in detail in conjunction with data from buoys 44005, 44007, 44013 and 44008. There are 34 tracks in the 3d class and 17 in 1d class. The reason for the small number of 1d tracks is perhaps its proximity to the coastline and the inherent lateral displacement among passes (as noted earlier), resulting in some passes falling largely on land.

Error type 5 (E5): Consider the partial listing of 3d track data for 21 October 1988 in the Gulf of Maine shown in Table 8. Some GDR's in Table 8 depict SWH's as small as 2 cm. These values do not appear to be consistent with the somewhat rougher sea state in the Gulf of Maine region as deduced from the wave buoy measurements in given in Table 9. These small wave heights are probably erroneous and escape detection by all the earlier criteria. This kind of error is found often, about 10 times out of 34 tracks in the 3d tracks and 7 times out of 17 tracks in the 1d class. Detailed examination revealed that satellite SWH's below 0.2 m are almost always suspect, when compared with the buoy measurements near the track and also with successive measurements in the rest of the track. A GDR is thus marked for elimination if the $SWH \leq 0.2$ m.

Table 10: Subset of 3d track data for 4 July 1989.

In all likelihood, the 5th record in the above table is erroneous, even though the flags field and rest of the parameters (associated with the D&P criteria) do not indicate so. Although reasonable close to buoy measurements (Table 11), this altimeter record may be suspect because the GDR is sandwiched between the other faulty GDRs (having, for example, on board instrumentation error denoted by 32767). Also, the parameter $\sigma_{swh} = 0$ for this GDR, which is doubtful. Such values are therefore considered erroneous and a criterion (E6) is used to flag them. Automatic detection of such errors is done by checking whether there are one or more "32767" type GDR's or other faulty GDR's preceding and following (thus sandwiching) the GDR in question.

Buoy #	Closest Dist. from track (Km)	SWH(m)

44007	198	0.5
44008	15	0.7
44011	149	1.1
44013	194	0.3

Table 11: Buoy-SWH data for 4 July 1989 in the Gulf of Maine.

In tracks belonging to other classes in the Gulf of Maine, the behavior of erroneous SWH measurements is similar to that of those associated with 2d, 3d and 1d classes of tracks. A detailed analysis of data belonging to the other classes is therefore not presented. It can also be inferred that the cases discussed so far are representative of the editing criteria needed for data pertaining to satellite wave data covering any region in general. Table 12 gives a summary of the relative performance of each of the editing criteria applied to all the tracks in Gulf of Maine region. It is interesting to note that for tracks 1d & 2a, the new criteria actually eliminate more GDR's than the R criteria which are generally too stringent.

Data Extraction and Quality Control Program

The Gulf of Maine study described above led to the following criteria which were found to successfully and optimally eliminate GDR's (as presented on the CD-ROM's) with erroneous SWH measurements:

1. $\sigma_h \geq 10$ cm. [D&P, R and E4]
2. The height bias and satellite attitude were out of range determined from Flags field bit 2. [D&P]
3. Any one of the 10 per second heights was flagged as bad (Flags field bit 3). [D&P]
4. First record reported after a gap in the time sequence. [E1]
5. All GDRs with σ_{swh} greater than or equal to 12cm until σ_{swh} falls below 12cm, occurring immediately after a series (one or more) of GDRs with a land flag or a GDR with σ_h greater 10cm. [E3, R]
6. $SWH \leq 0.2$ m. [E5]
7. Record sandwiched between one or more GDRs above and below with instrumentation errors (32767 in SWH or σ_{swh} field) or other faulty GDRs.[E6]

GEOSAT data (during the ERM phase) presented to users on CD-ROM's (Cheney et al. 1991b) are sequential in time. Data for some of 34 oceanographic parameters are presented at intervals of 1 second during the satellite's spirograph-like track. This format is cumbersome if only SWH data for a particular area are needed. (The complexity is greater for the XDR's). To facilitate efficient usage, a computer program was developed to read the satellite data from the CD-ROMs, to filter the data according to the above criteria, and to output a filtered dataset for any rectangular region specified by 4 latitude/longitude coordinates.

Table 12: Relative performance of editing criteria applied to data in the Gulf of Maine.

Validation of Data Extraction & Quality Control Program

The quality control program described above was based on data in the Gulf of Maine region (Fig. 2). In order to test the reliability and usefulness of the new criteria and the program, the program was applied to satellite wave data in the Gulf of Mexico region, bounded by coordinates [24° N, 268.5° E], [31° N, 268.5° E], [31° N, 274.25° E], [24.2° N, 274.25° E]. There are a total of 24 ERM tracks in the Gulf of Mexico region. Fig. 2 also shows the location of several buoys in this region. This

Fig. 2 Geosat satellite ground track and buoys in Gulf of Mexico

region is larger than the primary test site (i.e. Gulf of Maine). For the purpose of validation, data pertaining to 4 ERM tracks (each of which is a cluster of self-repeating tracks in the ERM phase of the satellite mission) falling in the study area were examined in detail. The satellite wave data are compared with measurements from the following 4 wave buoys in this region: 42001, 42003, MPCL1 and 42007. There are a total of 171 tracks, which fall into 4 track classes: 1, 2, 3, and 4 as shown in Fig. 2.

It was found that the program was extremely effective in automatic elimination of questionable data. The D&P criteria would have eliminated only 270 erroneous measurements, allowing several errors to escape detection. The R criteria, on the other hand, would eliminate 2067 records, many of which contain acceptable wave measurements. (In some instances data for the entire pass was discarded by the R criteria, even though most measurements agreed very well with buoy measurements). Application of the program developed here eliminates 1422 data records. The relative performance is given in Table 13. (For additional details, see Siddabathula, 1996).

Table 13: Relative performance of editing criteria

Concluding Remarks

The Geosat wave data provide the most exhaustive ocean wave data ever obtained and the potential for using them for a variety of engineering applications (e.g. Panchang et al. 1997) is great. However the dataset available to the user community contain several erroneous wave measurements. Previous efforts at quality control have been largely driven by the synoptic use of these data and have led to criteria that either eliminate large quantities of acceptable data or allow erroneous data to escape detection. Unintentional use of these data can have an adverse influence on various applications. For example, Table 3 shows an SWH measurement of 10.17 m, which, as shown, is probably incorrect and can adversely influence wave statistics calculated with these data (e.g. Young, 1994; Panchang et al. 1997) or data assimilation for wave modeling (e.g. Lionello et al. 1992).

A visual examination of all of the ERM SWH data in the Gulf of Maine on a track-by-track basis in conjunction with wave buoy data led to a set of new criteria which eliminated nearly all the erroneous measurements with minimal loss of acceptable data. A computer program was developed to facilitate SWH data extraction from the CD-ROM's and to perform automatic quality control for any region bounded by 4 latitude/ longitude coordinates. This program may be obtained from the authors.

The criteria and the program were validated by application to satellite wave data in the Gulf of Mexico region. The overall results in Table 13 indicate that the

criteria were effective for quality control in the GDR's in both study areas. Application of the program developed here can prevent cumbersome visual inspection of SWH data by users (as done by Young, 1994; Romeiser, 1993). It may be also used for the Geosat Follow-On mission for post-processing the results of existing data-processing algorithms prior to installation on CD-ROMs for the users.

CHAPTER 8

BOUSSINESQ TYPE EQUATIONS WITH HIGH ACCURACY IN DISPERSION AND NONLINEARITY

P.A. Madsen*, B. Banijamali*, H.A. Schäffer* and O.R. Sørensen*

Abstract

Two sets of Boussinesq type equations with high accuracy in dispersion as well as in nonlinearity are presented. The first set, which is expressed in terms of the depth-averaged velocity, includes up to fifth-derivative terms in the momentum equation, while the second set, which is expressed in terms of the velocity at an arbitrary z-level, includes up to third-derivative terms in the continuity equation as well as in the momentum equation. Both sets of equations provide linear dispersion characteristics, which are accurate for wave numbers (kh) up to 6, and nonlinear characteristics which are superior to previous Boussinesq formulations. The high quality of dispersion is also achieved for the Doppler shift in connection with wave-current interaction. A numerical model based on the new equations in two horizontal dimensions is presented and verified with respect to nonlinear transformation of waves in shallow water and refraction-diffraction in deep and shallow water.

1. Introduction

The classical Boussinesq equations as formulated by e.g. Peregrine (1967) are known to incorporate only weak dispersion and weak nonlinearity. For many applications the weak dispersion is the most critical limitation and it has achieved considerable attention in the last 5 years, where a number of alternative lower order Boussinesq type equations have been presented with the purpose of improving the linear dispersion characteristics (see e.g. Madsen et al., 1991; Nwogu, 1993; Schäffer and Madsen, 1995). It has been demonstrated that the accuracy of the dispersion for larger wave numbers is sensitive to the choice of velocity equa-

* International Research Centre for Computational Hydrodynamics (ICCH). Located at the Danish Hydraulic Institute, Ager Alle 5, DK-2970 Hørsholm, Denmark

tions, and with minor modifications the lower order Boussinesq type equations can incorporate significantly improved dispersion characteristics. A similar improvement of the nonlinear properties is more difficult to obtain and will be addressed in this work.

This paper presents two sets of Boussinesq type equations with high accuracy in dispersion (μ) as well as in nonlinearity (ϵ). The first set, which is expressed in terms of the depth-averaged velocity, includes dispersive terms of order μ^4 and nonlinear terms up to order $\epsilon^5\mu^4$ (Chapter 3). The second set, which is expressed in terms of the velocity at an arbitrary z -level, includes dispersive terms of order μ^2 and nonlinear terms up to order $\epsilon^3\mu^2$ (Chapter 4). Using the technique suggested by Madsen et al. (1991) and Schäffer and Madsen (1995) we enhance the new equations and obtain excellent linear dispersion characteristics corresponding to a Pade [4,4] expansion of linear Stokes theory. A Fourier analysis also demonstrates that the accuracy of the nonlinear energy transfer is improved considerably compared to previous Boussinesq formulations. This allows for a much more accurate description of wave-wave interactions in irregular wave trains. Finally, it turns out that the high quality of dispersion is also achieved for the Doppler shift in connection with wave-current interaction and it allows for a study of wave-blocking due to opposing currents. These aspects will be studied in a companion paper at this conference by Chen et al. (1996).

A numerical model based on the new equations from Chapter 4 is presented in Chapter 5 and it is verified with respect to nonlinear transformation of waves in shallow water and refraction-diffraction in deep and shallow water.

2. Derivation of Boussinesq type equations

In the following presentation the adopted coordinate system is Cartesian with the x' -axis and y' -axis located at the still water level (SWL) and with the z' -axis pointing vertically upwards. The fluid domain is bounded by the sea bed at $z' = -h'(x', y')$ and the free surface at $z' = \eta'(x', y', t')$. Non-dimensional variables (denoted without primes) are introduced in the conventional way (see e.g. Nwogu, 1993) by the use of a characteristic water depth (h_0), wave length (l_0) and wave amplitude (a_0) and we introduce the classical measures of nonlinearity and frequency dispersion by $\epsilon = a_0/h_0$ and $\mu = h_0/l_0$.

With the usual assumptions of irrotational flow in an incompressible fluid, the nondimensional form of the governing equations and boundary conditions read:

$$\Phi_{zz} + \mu^2 \nabla^2 \Phi = 0, \quad -h < z < \epsilon \eta \quad (1a)$$

$$\Phi_z + \mu^2 \nabla h \cdot \nabla \Phi = 0, \quad z = -h \quad (1b)$$

$$\Phi_t + \eta + \frac{\epsilon}{2} \left((\nabla\Phi)^2 + \frac{1}{\mu^2} (\Phi_z)^2 \right) = 0, \quad z = \epsilon\eta \quad (1c)$$

$$\Phi_z - \mu^2(\eta_t + \epsilon\nabla\eta \cdot \nabla\Phi) = 0, \quad z = \epsilon\eta \quad (1d)$$

where Φ is the velocity potential and ∇ the horizontal gradient operator.

The basic idea in Boussinesq-type derivations is to reduce the three dimensional description to a two-dimensional one and this is achieved by expanding the velocity potential as a power series in the vertical coordinate:

$$\Phi(x, y, z, t) = \sum_{n=0}^{\infty} z^n \Phi^{(n)}(x, y, t) \quad (2)$$

by which $\Phi^{(0)}(x, y, t) = \Phi(x, y, 0, t)$. While traditional Boussinesq theory assumes $\mu < 1$ and $\epsilon = O(\mu^2)$, the present expansion allows for arbitrary ϵ .

The individual steps in the derivation of Boussinesq-type equations are as follows: Firstly, the velocity potential is determined in terms of spatial derivatives of $\Phi^{(0)}$ by combining (2) with (1a) and (1b). By the use of the gradient operator this also defines the horizontal velocity vector in terms of the velocity, \hat{u} at the still water level. Secondly, the velocity potential is inserted in the dynamic free surface condition (1c), and by using the horizontal gradient operator a momentum equation is derived in terms of \hat{u} . Thirdly, the horizontal velocity vector expressed in terms of \hat{u} is substituted into the depth-integrated continuity equation. The resulting equations in terms of \hat{u} can be found in Madsen & Schäffer (1996) and will not be given here.

3. Equations in terms of the Depth-Averaged Velocity

Traditionally, Boussinesq models are not based on equations formulated in terms of the velocity at the still water level. This is partly because of the rather complicated form of the continuity equation expressed in this variable and partly because of the relatively poor dispersion characteristics of these equations. A more common choice is the depth-averaged velocity U which is defined by

$$U \equiv \frac{1}{h + \epsilon\eta} \int_{-h}^{\epsilon\eta} u dz \quad (3)$$

One of the obvious advantages of using this variable is that the continuity equation becomes exact and relatively simple,

$$\eta_t + \nabla \cdot (\bar{h} + \epsilon \eta) \mathbf{U} = 0 \quad (4)$$

3.1. Formulation of momentum equations

In order to formulate the momentum equation in terms of \mathbf{U} we use the procedure as follows: Firstly, a relation in which \mathbf{U} is expressed in terms of \hat{u} is established by the use of (2) and (3). Secondly, this relation is inverted into a relation in which \hat{u} is expressed in terms of \mathbf{U} , by the use of successive substitutions starting at lowest order in μ^2 . Now \hat{u} can be eliminated from the momentum equation and replaced by functions of \mathbf{U} . The resulting higher order momentum equations truncated at the order μ^6 take the form of

$$\mathbf{U}_t + \nabla \eta + \frac{\epsilon}{2} \nabla (U^2) + \mu^2 \mathbf{\Gamma}_2^I + \mu^4 \mathbf{\Gamma}_4^I = 0 (\mu^6) \quad (5)$$

where

$$\mathbf{\Gamma}_2^I \equiv [\mathbf{\Lambda}_{20}^I + \epsilon \mathbf{\Lambda}_{21}^I + \epsilon^2 \mathbf{\Lambda}_{22}^I + \epsilon^3 \mathbf{\Lambda}_{23}^I] \quad (6a)$$

$$\mathbf{\Gamma}_4^I \equiv [\mathbf{\Lambda}_{40}^I + \epsilon \mathbf{\Lambda}_{41}^I + \epsilon^2 \mathbf{\Lambda}_{42}^I + \epsilon^3 \mathbf{\Lambda}_{43}^I + \epsilon^4 \mathbf{\Lambda}_{44}^I + \epsilon^5 \mathbf{\Lambda}_{45}^I] \quad (6b)$$

Notice that $\mathbf{\Lambda}_{mn}^I$ is used to express the Boussinesq terms, where subscript m accounts for the power of μ (dispersion) and subscript n for the power of ϵ (non-linearity). The equations include full nonlinearity up to the truncated order of dispersion, i.e. retaining $\epsilon^3 \mu^2$ and $\epsilon^5 \mu^4$ -terms, and involve higher order spatial derivatives incl. third and fifth-derivative terms. The actual expressions for the $\mathbf{\Lambda}_{mn}^I$ -terms can be found in Madsen & Schäffer (1996) and will not be given here. We note that if only terms up to the order $O(\epsilon, \mu^2)$ are retained we obtain the classical Boussinesq equations by Peregrine (1967) and if terms of order $O(\epsilon \mu^2, \mu^4)$ are retained as well we obtain the higher order Boussinesq equations by Dingemans (1973).

The final step in the derivation procedure is to apply the technique introduced by Madsen et al. (1991) and Schäffer & Madsen (1995) for improving the dispersion characteristics of (4) and (5). This procedure is illustrated on a horizontal bottom in the following: Firstly, (5) is truncated omitting $O(\mu^4)$, the gradient operator is applied twice and the result is multiplied by $\alpha \mu^2 h^2$, where α is a free parameter of the order $O(1)$:

$$\alpha \mu^2 h^2 \nabla^2 \left(\mathbf{U}_t + \nabla \eta + \frac{\epsilon}{2} \nabla (U^2) + \mu^2 \mathbf{\Gamma}_2^I \right) = 0 (\mu^6) \quad (7a)$$

Secondly, (5) is truncated omitting $O(\mu^2)$, the gradient operator is applied four times and the result is multiplied by $\beta\mu^4h^4$, where β is a free parameter of the order $O(1)$:

$$\beta\mu^4h^4\nabla^4\left(\mathbf{U}_t + \nabla\eta + \frac{\epsilon}{2}\nabla(U^2)\right) = O(\mu^6) \quad (7b)$$

We can now consistently modify (5) by subtracting (7a) and adding (7b), which yields an enhanced set of higher order Boussinesq equations truncated at $O(\mu^6)$. The coefficients α and β are yet to be determined.

3.2. Fourier Analysis for weakly nonlinear waves

Although the equations have been derived under the assumption of $\mu \ll 1$ and $\epsilon = O(1)$, we shall analyse the imbedded linear and nonlinear characteristics by assuming that $\epsilon < 1$ while μ is arbitrary. We look for analytical solutions of the form

$$\eta = a_1\cos(\omega t - kx) + \epsilon a_2\cos(2\omega t - 2kx) \quad (8a)$$

$$U = U_1\cos(\omega t - kx) + \epsilon U_2\cos(2\omega t - 2kx) \quad (8b)$$

At first order (ϵ^0) non-trivial solutions require the dispersion relation

$$\frac{\omega^2}{k^2h} = \frac{1 + \alpha k^2h^2 + \beta k^4h^4}{1 + \left(\alpha + \frac{1}{3}\right)k^2h^2 + \left(\beta + \frac{\alpha}{3} - \frac{1}{45}\right)k^4h^4} \quad (9)$$

which should be compared with Stokes relation for linear waves on arbitrary depth, i.e. $\tanh(kh)/kh$. The ratio between the two expressions is shown as a function of kh in Fig 1. If we omit the enhancement of the higher order equations using $(\alpha, \beta) = (0, 0)$ the resulting dispersion relation (9) corresponds to a Padé [0,4] expansion in kh of the Stokes relation. For these equations the deviation is significant and in fact a singularity occurs for $kh = 4.2$. This singularity shows up in numerical calculations as an instability even in the case of initially calm water, and actually makes (5) quite useless without the enhancement. On the other hand, by using the enhanced equations incl. (7a-b) with $\alpha = 1/9$ and $\beta = 1/945$ the resulting dispersion relation (9) corresponds to a Padé [4,4] expansion. This is an extremely good approximation to the exact linear relation even for kh as large as 6. The dispersion relation of lower order Boussinesq equations is obtained by ignoring the k^4h^4 terms in (9). With $\alpha = 0$ (Padé [0,2]) this corresponds to the classical equations of Peregrine (1967) and with $\alpha = 1/15$ it corresponds to the Padé

[2,2] formulation introduced by Madsen et al. (1991). Both cases are shown as a reference in Fig 1.

Fig 1 Relative phase celerity, c/c^{Stokes} , for various forms of the Boussinesq equations. 1: Padé [0,2]; 2: Padé [2,2]; 3: Padé [0,4]; 4: Padé [4,4].

Extending the Fourier analysis to second order we determine a_2 in terms of a_1^2/h times a transfer function. In this respect the target solution is

$$a_2^{\text{Stokes}} = \frac{1}{4} \frac{a_1^2}{h} kh \coth(kh) (3 \coth^2(kh) - 1) \quad (10)$$

according to Stokes second order theory. Fig 2 shows the variation of a_2/a_2^{Stokes} as a function of kh . The curve corresponding to the new higher order equations is seen to be superior to the results obtained from the equations of Dingemans (1973) and Peregrine (1967).

It is straight-forward to extend the Fourier analysis to second order sub-harmonics and super-harmonics and the results can be found in Madsen and Schäffer (1996).

Fig 2 Ratio of second harmonic, a_2/a_2^{Stokes} . 1: Peregrine (1967); 2: Dingemans (1973) 3: Present e.g. eqs. (4) & (5) with (7a-b), $\alpha=1/9$, $\beta=1/945$.

3.3 Ambient currents and Doppler shift

Yoon and Liu (1989) introduced separate scaling of waves and currents and showed that additional terms were to be added to the classical formulation of Peregrine (1967) if a correct Doppler shift was to be obtained in connection with ambient currents. In the present work we analyse the new equations for the case of a strong but constant ambient current U_c and obtain the following dispersion relation,

$$\frac{(\omega - kU_c)^2}{k^2h} = \frac{1 + \alpha k^2h^2 + \beta k^4h^4}{1 + \left(\alpha + \frac{1}{3}\right)k^2h^2 + \left(\beta + \frac{\alpha}{3} - \frac{1}{45}\right)k^4h^4} \quad (11)$$

This provides a correct Doppler shift including Padé [4,4] dispersion characteristics. Fig. 3 shows lines of 2 per cent wave number errors as a function of $(F, h/L_0)$, F being the Froude number (U_c/\sqrt{gh}) of the current and L_0 being the deep water wave length for the case of no currents. The application range of the Padé [4,4] curve is seen to be superior to the Padé [0,2] corresponding to Yoon & Liu's formulation as shown for comparison.

4. Equations in terms of the velocity at an arbitrary z-location

In the previous section we have demonstrated that highly accurate linear dispersion and nonlinear characteristics can be obtained by formulating higher order equations including up to fifth-derivative terms in the momentum equation. In this section we shall, however, show that almost the same accuracy can be obtained with only third-derivative terms, if the lower order equations are formulated in terms of the velocity vector at an arbitrary z-location i.e.

$$\tilde{\mathbf{u}} \equiv \mathbf{u}(x, y, \tilde{z}, t) \quad (12)$$

This variable was introduced by Nwogu (1993).

From the expression derived for the velocity potential we can establish an expression for $\tilde{\mathbf{u}}$ in terms of $\hat{\mathbf{u}}$. This relation is then inverted into a relation in which $\hat{\mathbf{u}}$ is expressed in terms of $\tilde{\mathbf{u}}$, by the use of successive substitutions starting at lowest order in μ^2 . Now $\hat{\mathbf{u}}$ can be eliminated from the original mass and momentum equations and replaced by functions of $\tilde{\mathbf{u}}$ and the resulting equations truncated at the order μ^4 take the form of

$$\eta_t + \nabla \cdot (\tilde{\mathbf{u}}(h + \epsilon \eta) + \mu^2 \Gamma_2'') = 0(\mu^4) \quad (13a)$$

$$\tilde{u}_t + \nabla\eta + \frac{\epsilon}{2}\nabla(\tilde{u}^2) + \mu^2\Gamma_2^{III} = O(\mu^4) \quad (13b)$$

where

$$\Gamma_2^{II} \equiv \left[\Lambda_{20}^{II} + \epsilon\Lambda_{21}^{II} + \epsilon^2\Lambda_{22}^{II} + \epsilon^3\Lambda_{23}^{II} \right] \quad (14a)$$

$$\Gamma_2^{III} \equiv \left[\Lambda_{20}^{III} + \epsilon\Lambda_{21}^{III} + \epsilon^2\Lambda_{22}^{III} + \epsilon^3\Lambda_{23}^{III} \right] \quad (14b)$$

These equations, which were first derived by Wei et al. (1995), include full nonlinearity up to the truncated order of dispersion i.e. retaining $\epsilon^3\mu^2$. If only terms up to the order $O(\epsilon, \mu^2)$ are retained we obtain the equations of Nwogu (1993). With a specific choice of the z-location defining the velocity variable, Nwogu and Wei et al. achieved Padé [2,2] dispersion characteristics.

Here we shall further enhance the equations (13a-b) to improve dispersion as well as nonlinearity. Again we apply the technique as described in section 3 and illustrate the procedure on a horizontal bottom: Firstly, (13a & b) are truncated omitting $O(\mu^2)$, the gradient operator is applied twice and the results are multiplied by μ^2h^2 and two free parameters (α, β) which are of the order $O(1)$:

$$\alpha\mu^2h^2\nabla^2\left(\tilde{u}_t + \nabla\eta + \frac{\epsilon}{2}\nabla(\tilde{u}^2)\right) = O(\mu^4) \quad (15a)$$

$$\beta\mu^2h^2\nabla^2(\eta_t + \nabla\cdot(\tilde{u}(h+\epsilon\eta))) = O(\mu^4) \quad (15b)$$

We can now consistently modify (13a-b) by subtracting (15a-b), which yields an enhanced set of lower order Boussinesq equations. The detailed formulation is given in Madsen & Schäffer (1996).

The linear dispersion relation of the enhanced equations reads

$$\frac{\omega^2}{k^2h} = \frac{1 + \left(\alpha + \beta - \gamma - \frac{1}{3}\right)k^2h^2 + \alpha\left(\beta - \gamma - \frac{1}{3}\right)k^4h^4}{1 + (\alpha + \beta - \gamma)k^2h^2 + \beta(\alpha - \gamma)k^4h^4} \quad (16)$$

where

$$\gamma \equiv \frac{\tilde{z}}{h} + \frac{1}{2}\left(\frac{\tilde{z}}{h}\right)^2 \quad (17)$$

As shown by Schäffer & Madsen (1995) Padé [4,4] characteristics can be obtained by choosing one of four different sets of parameters. It turns out that one of these

sets is superior with respect to nonlinear properties, hence we recommend the parameter set

$$(\gamma, \beta, \alpha) = \left(\frac{-3 - \sqrt{23/35} - 2\sqrt{19/7}}{18}, \frac{28 - 2\sqrt{133}}{126}, \frac{105 - 3\sqrt{805}}{1890} \right) \quad (18)$$

Extending the Fourier analysis to second order we determine a_2 in terms of a_1^2/h times a transfer function. Fig 4 shows the variation of a_2/a_2^{Stokes} as a function of kh . We notice that the curve corresponding to the new enhanced equations is superior to the results obtained from Nwogu's and Wei et al's equations as shown for comparison. A full analysis of second order sub-harmonics and super-harmonics can be found in Madsen and Schäffer (1996).

Fig 4 Ratio of second harmonic, a_2/a_2^{Stokes} . 1: Nwogu (1993); 2: Wei et al. (1995); 3: Present e.g. eqs. (13a-b) with (15a-b) & (18).

5. Numerical model and its verification

A numerical model has been developed to solve the two-dimensional equations formulated in Chapter 4. The equations are discretized in space by applying higher order central-differencing with the variables defined on a space-staggered rectangular grid while the temporal integration is performed by using a fourth order Adams-Bashforth-Moulton predictor-corrector method. More details about the numerical method can be found in Banijamali et al. (1997).

5.1 Wave transformation over a submerged bar

One of the most demanding tests for Boussinesq-type models is the study of wave transformation over a submerged bar. In this case nonlinearity increases considerably during the propagation at the upward slope and results in energy transfer to the higher harmonics. As long as the depth is decreasing the higher harmonics will be bound or phase-locked to the primary wave train, but on the downward slope the harmonics will be released and propagate as free waves. This introduces the peculiarity that a linear regular shallow water wave will be converted into a linear irregular deep water wave after the passage over the bar. This situation calls for highly accurate dispersion characteristics and for this reason most Boussinesq models fail to predict the process.

Beji and Battjes (1993) and Luth et al. (1994) presented a series of accurate measurements of wave transformation over a trapezoidal bar with an upward slope of $1/20$, a downward slope of $1/10$, a depth of 40 cm on both sides of the bar and 10 cm on top of the bar (Fig 6a). The data have previously been used in an inter-comparison study in MAST-G8M, see Dingemans (1994). As one example from this test series we have selected the case of a wave period of 2.02s and a wave height of 2.0 cm.

Fig 5 shows the measured time series of surface elevations at three locations: We notice the transformation from a sinusoidal, linear-wave profile at $x=5.2\text{m}$, to a profile of a strongly nonlinear wave at $x=13.5\text{m}$ and back to a profile of a fairly linear wave at $x=19.0\text{m}$, where the significant frequency obviously has been doubled.

Fig 5 Harmonic generation over a submerged bar.
Measured timeseries of surface elevations at three locations
Input: wave period=2.02s, wave height=0.02m, 1: $x=5.2\text{m}$;
2: $x=13.5\text{m}$ and 3: $x=19.0\text{m}$.

The energy transformation to higher harmonics is in fact seen more clearly in Fig 6b-c, which is based on FFT analysis of time series from a numerical solution of the Boussinesq equations. Here we clearly notice the rapid growth of the second

(and third) harmonics at the upward slope and the release of these harmonics after the bar.

Fig 6 Harmonic generation over a submerged bar
 a) Spatial evolution of harmonics (third & fourth); b) Spatial evolution of harmonics (first & second); c) Bathymetry
 Markers are measurements.

In Fig 7 we compare the measured time series at $x=21.0$ m with the numerical results corresponding to two different versions of the Boussinesq model: One using $(\gamma, \alpha, \beta) = (-2/5, 0, 0)$ leading to Padé [2,2] dispersion characteristics (corresponding to the model of Wei et al., 1995) and one using the parameter set of (18) leading to Padé [4,4] characteristics.

The latter is seen to be superior and it provides a highly accurate result.

Fig 7 Computed and measured surface elevations at $x=21\text{m}$
 1: Eqs. (13a-b) with (15a-b) & (18), Padé [4,4] 2: Wei et al. (1995), Padé [2,2] 3: Measurements

5.2 Nonlinear refraction-diffraction

As a second demanding test for the Boussinesq model we study nonlinear refraction-diffraction over a semicircular shoal with depth contours varying between 0.4572m and 0.1524m as investigated experimentally by Whalin (1971).

Fig 8 Whalin's nonlinear refraction-diffraction. Spatial evolution of first and second harmonics along the centreline. Input: wave period = 1.0s, wave height = 0.039m. Markers are measurements.

In the present work we focus on the case of incoming regular waves with period 1.0s and wave height 0.039m. At the boundary the waves are linear but after the focusing on the shoal higher harmonics become significant due to nonlinear effects. An FFT analysis of time series in each grid point along the centreline has been computed and the resulting spatial evolution of first and second harmonics is compared with Whalin's experimental data in Fig 8. The agreement is found to be most acceptable.

CHAPTER 9

WAVE KINEMATICS COMPUTATIONS USING BOUSSINESQ MODELS

J. Bosboom^{1,2}, G. Klopman^{1,2}, J.A. Roelvink^{1,2}, J.A. Battjes¹

ABSTRACT

Existing Boussinesq models are extended to include the computation of the vertical structure of the horizontal velocity. A time-domain model is tested against laboratory measurements of the vertical profile of the horizontal velocity in regular waves; good results are obtained, especially in the near-bed zone. A spectral model, which includes a dissipation formulation to account for wave breaking, is tested against laboratory measurements of bottom velocities in (partially) breaking irregular waves. For moderately long waves, the comparison on velocity variance and skewness, which are relevant to sediment transport, yields good results.

1. INTRODUCTION

The development of numerical models capable of reproducing the hydrodynamics field in the shoaling region and the surf zone is of particular interest to coastal morphological problems. From an evaluation of sediment transport formulations (Bailard, 1981; Roelvink and Stive, 1989), it appears that the third and fourth order oscillatory velocity moments ($\langle u^3 \rangle$ and $\langle |u|^3 u \rangle$ respectively), are the most important parameters in determining the magnitude of the wave-induced sediment transport. These moments are non-zero only for asymmetric (non-linear) motions such as occur in shallow water. Boussinesq equations, describing (weakly) non-linear, relatively long waves propagating in water of varying depth, are suitable for the description of these asymmetries.

Many different forms of Boussinesq equations exist, which differ in frequency-dispersion and shoaling characteristics. Efforts have recently been spent on

improving the linear frequency dispersion with respect to the conventional Boussinesq equations. Reference is made to Witting (1984), Madsen et al. (1991), Madsen and Sørensen (1992), Nwogu (1993), Dingemans (1994b) and Schröter (1995).

On the basis of these time-domain formulations, frequency-domain formulations have been developed leading to coupled evolution equations for slowly-varying complex Fourier amplitudes. Applications and verifications of spectral evolution equations valid for a mildly sloping bottom and non-breaking waves (Freilich and Guza, 1984) were reported in numerous papers (Elgar and Guza, 1985, 1986; Elgar et al., 1990; Freilich et al., 1990). Spectral evolution equations with improved frequency dispersion were presented by Madsen and Sørensen (1993). They concluded that the agreement between the evolution equations and the time-domain counterpart is most satisfactory, except for the peak values of the highest waves which are underestimated by the spectral evolution equations.

Attempts have also been made to include a formulation for wave breaking in Boussinesq equations to extend their applicability to the surf zone. The concept of surface rollers (Deigaard, 1989) was incorporated in conventional time-domain Boussinesq equations by Schäffer et al. (1993). Eldeberky and Battjes (1996) supplemented the spectral evolution equations of Madsen and Sørensen (1993) with a spectral breaking term which accounts for the energy dissipation due to wave breaking (see, also, Battjes et al., 1993).

Only few efforts have been spent on testing Boussinesq models against velocity data. Verification of conventional Boussinesq models (Brocchini et al., 1992 and Quinn et al., 1994) with a description of the breaking process according to Schäffer et al. (1993) against velocity data for waves breaking partially on a gently sloping beach showed fairly good agreement with measured vertical profiles, especially in the near-bed zone. Elgar et al. (1990) obtained accurate estimates of the velocity variance and skewness in the shoaling region using the model of Freilich and Guza (1984).

The purpose of this paper is to verify the Boussinesq modelling of horizontal velocities under (breaking) waves, especially in the near-bed zone. We use a time-domain model (Dingemans, 1994a) for non-breaking waves and a spectral Boussinesq model (Elderberky and Battjes, 1996) assuming a parabolic expression for the calculation of the vertical structure of the horizontal particle velocities, as is consistent with the Boussinesq approximation.

2. TIME-DOMAIN MODEL

The time-domain equations with improved frequency-dispersion and good shoaling behaviour (Dingemans, 1994a) read in one horizontal dimension:

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} [(h + \zeta)\bar{u}] = 0 \quad (1a)$$

$$\frac{\partial \bar{u}}{\partial t} + \bar{u} \frac{\partial \bar{u}}{\partial x} + g \frac{\partial \zeta}{\partial x} = h \frac{\partial}{\partial t} \left[\left(\frac{1}{2} + b \right) \frac{\partial^2 (h\bar{u})}{\partial x^2} - \frac{1}{6} h \frac{\partial^2 \bar{u}}{\partial x^2} \right] + b g h \frac{\partial^2}{\partial x^2} \left[h \frac{\partial \zeta}{\partial x} \right] \quad (1b)$$

where b is a fitting parameter for obtaining the best agreement with the frequency dispersion according to Stokes' first order theory. For $b = 1/15$ the phase celerity errors are minimized over the whole range of kh (see Madsen and Sørensen, 1992 and Dingemans, 1994b).

Solution of Eqs. (1) yields values for the surface elevation and the computational (depth-averaged) horizontal velocity. The vertical structure of the horizontal velocity is related to the computational velocity through a parabolic expression depending on the vertical coordinate (Dingemans, 1994b):

$$u(x, z, t) = \bar{u} - \left[\frac{1}{2} h + z \right] (h\bar{u})_{xx} + \left[\frac{1}{6} h^2 - \frac{1}{2} z^2 \right] \bar{u}_{xx} \quad (2)$$

where $z = 0$ corresponds to the undisturbed position of the free surface.

The numerical integration is based on the scheme as applied by Beji and Battjes (1994), which is essentially based on the formulation by Peregrine (1967). The finite difference equations, in which central difference formulations are used both for time and space derivatives, are solved by using a predictor-corrector method.

The extension to reconstruct the horizontal velocity profile is implemented by discretizing the second-order derivatives in the parabolic expression (2) using central differences in space. A low-pass filter is applied to the values of \bar{u} to obtain stable estimates of the second-order derivative \bar{u}_{xx} and $(h\bar{u})_{xx}$.

3. VERIFICATION OF THE TIME-DOMAIN MODEL

Experimental data

The model described above was verified against laboratory measurements of non-breaking monochromatic waves performed by Luth et al. (1994) in a wave flume with a submerged trapezoidal bar (see Fig. 1) as part of the EU-sponsored Large Installations Plan. The flume was 45 m long, 1 m wide and had a still water depth of 80 cm on each side of the bar. The incident wave conditions are $T =$

1.50 s and $H = 0.06$ m. Velocity measurements were carried out at different points in the vertical at 15.50 m and 21.72 m from the wave maker using two 3-beam, 2-component Laser Doppler Velocimeters.

Fig 1 Experimental set-up, all dimensions in m, from Luth et al (1994)

Computational parameters

The time and spatial steps used in the computation were approximately equal to 1/150 of the incident wave period and wave length, respectively. At the seaward boundary, the Courant number $c(\Delta t/\Delta x)$ was approximately one.

Discussion of results

Fig. 2 shows for both stations time-domain comparisons of the measured and computed bottom velocity as well as the velocity evaluated at a level close to where the depth-averaged velocity may be found ($z \approx -0.4 h$). For the measured bottom velocity in Fig. 2, the value at approximately 2 cm from the bed, just outside the boundary layer, was taken. The time-window in Fig. 2 was chosen in such a way that permanent wave profiles are obtained in the computations. Fig. 3 gives the vertical profiles of the horizontal velocity profile for two different wave phases, corresponding to a crest and a trough in the computations.

Fig. 2 shows that the asymmetry about the horizontal axis occurring on the seaward slope is well represented. The depth-averaged velocity at the crest is slightly overestimated by the Boussinesq model, while the agreement is very good for the trough values. It was found that the surface elevation exhibits a similar overestimation of the crest values. The bottom velocities are predicted quite well, with a small overestimation of the trough values by the model.

Fig. 3 shows a fair agreement between the measured and computed velocity profiles, especially for the lower half of the profile. A small but systematic overestimation of the velocity is found, which is particularly evident for the crest values near the surface.

Fig. 2 Measured (solid line) and computed (dotted line) horizontal velocity u_m , evaluated at a level close to where the depth-averaged velocity may be found (top), and near-bed velocity u_b , evaluated at approximately 2 cm from the bed (bottom), for $x = 15.50$ and 21.72 m respectively.

4. FREQUENCY DOMAIN MODEL

Assuming slowly-varying complex Fourier amplitudes and uni-directional wave propagation, evolution equations for the complex amplitudes were derived by Madsen and Sørensen (1993) and extended by Eldeberky and Battjes (1996) with a formulation for dissipation of energy due to breaking which reduces the spectral amplitudes in the same proportion without affecting the spectral shape. Starting point of the derivation of the spectral evolution equations were time-domain Boussinesq equations (Madsen and Sørensen, 1992) valid for a slowly-varying bottom ($|dh/dx| \ll kh$).

Madsen and Sørensen (1993) formulated solutions for the free-surface elevation in terms of Fourier series with spatially varying coefficients:

$$\zeta(x,t) = \sum_{p=-\infty}^{\infty} A_p(x) \exp[i(\omega_p t - \psi_p(x))] , \quad (3)$$

where p indicates the rank of the harmonic, A_p is the complex Fourier amplitude, ω_p is the angular frequency and $d\psi_p/dx = k_p(x)$ is the wave number in the linear

Fig. 3 Comparison of measured (triangles) and computed (dotted line) horizontal velocity vertical profile at $x = 15.50$ m and 21.72 m respectively, for two different wave phases corresponding to a trough (left) and a crest (right)

approximation. Note that $\omega_p = -\omega_p$, $\psi_p = -\psi_p$, $A_p = A_p^*$ with "*" denoting the complex conjugate. The frequencies are determined by $\omega_p = p\Delta\omega$ where $\Delta\omega$ is the lowest frequency of interest. The wave number k_p can be determined from the linear dispersion relation of the equations.

The evolution equations read, with p covering the interval from $p = 1$ to ∞ ,

$$\frac{dA_p}{dx} = -\beta_5 \frac{h_x}{h} A_p - i2g (F_p^+ + F_p^-) - \frac{1}{2} \frac{D}{F} A_p, \quad (4)$$

where the first term in the right-hand side of Eqs. (4) represents linear shoaling, the second and the third term represent the triad sum and difference interactions respectively and the last term is the dissipation term representing the contribution due to wave breaking. Here F is the total local rate of energy flux per unit width and D is the total local rate of random-wave energy dissipation per unit area due to breaking. Expressions for the terms F_p^+ and F_p^- and the shoaling coefficient β_5 can be found in Madsen and Sørensen (1993). The energy dissipation rate D can be computed using the energy dissipation model of Battjes and Janssen (1978) or comparable methods (e.g. Thornton and Guza, 1983); here we use the model of Battjes and Janssen (1978).

In the linear approximation, the depth-averaged velocity is expressed in terms of surface elevation using the lowest-order approximation for the volume flux q in a progressive wave:

$$\bar{u}(x,t) \approx \frac{q}{h} \approx \sum_{p=-\infty}^{\infty} \frac{\omega_p}{k_p h} A_p(x) \exp[i(\omega_p t - \psi_p(x))] . \quad (5)$$

Note that in this way only the purely oscillating part of the horizontal velocity is predicted by the model; the time-averaged component of the velocity is eliminated upon linearization.

In order to compute the horizontal velocity profile as a function of the depth, we use the parabolic profile for the constant depth situation (Eq. 2 with h -derivatives omitted). Substituting Eq. (5) while neglecting all x -derivatives of A_p , k_p and h , yields the following expression for the horizontal velocity profile in terms of Fourier series:

$$u(x,z,t) = \sum_{p=-\infty}^{\infty} \frac{\omega_p}{k_p h} A_p(x,z) \left[1 + k_p^2 \left[\frac{1}{3} h^2 + zh + \frac{1}{2} z^2 \right] \right] \exp[i(\omega_p t - \psi_p(x))] . \quad (6)$$

The evolution equations which are first-order ordinary differential equations are numerically integrated using a fourth-order Runge-Kutta method. The upwave boundary condition for the integration is a set of complex amplitudes A_p ($p = 1, 2, 3 \dots P$).

5. VERIFICATION OF THE FREQUENCY DOMAIN MODEL

Experimental data

The prediction of horizontal velocities and velocity moments was verified against wave channel measurements of irregular (partially) breaking waves propagating over a concave sandy beach. The experiments were carried out within the framework of the EU-sponsored Large Installations plan (Arcilla et al., 1993; Roelvink and Reniers, 1995). Two different experimental data sets (i.e. test 1a and 1c) were used. The incident peak period T_p and significant wave height H_{m0} are $T_p = 4.9$ s and $H_{m0} = 0.9$ m and $T_p = 8.0$ s and $H_{m0} = 0.6$ m for tests 1a and 1c respectively. In the experiments the low frequency energy is kept at a reasonable level by an active wave absorption system at the wave-maker. Surface elevations and velocities were measured at several locations along the wave channel. The velocity measurements were carried out at several distances from the bed. Since the spectral model only predicts the purely oscillating part of the velocity the time-averaged velocity component was filtered from the measured signals.

In experiment 1a the wave breaking is strong. The monotonic sandy beach profile (Fig. 4) allows for wave breaking to take place over a large distance; the experiments showed a gradual decrease of the significant wave height at distances from 100 m up to about 140 m from the wave board, beyond which the wave breaking gets strong. In experiment 1c on the contrary, a barred beach profile is present (Fig. 5). The wave breaking is mild and is concentrated behind the bar, the crest of which is located around 138 m.

The upwave boundary conditions used in the numerical computations are obtained from the measured surface elevations at 20 m by the use of a standard FFT algorithm.

Computational parameters

Besides the bottom geometry and the upwave boundary, the model input comprises the breaking coefficient $\gamma = H_m/h$ in which H_m is the maximum wave height, the bandwidth Δf , the number of frequency components P and the spatial step Δx . The spatial step was chosen $\Delta x = 0.5$ m and the breaking coefficient $\gamma = 0.85$ in accordance with the γ -value used by Eldeberky and Battjes (1996). A cut-off frequency of 1 Hz was used in the simulations. The length of the simulated time record was $T = 2048$ s for both experiments, resulting in a number of frequency components $P = 2048$ and a bandwidth $\Delta f = 4.883 \cdot 10^{-4}$ Hz.

Analysis of time-series

The comparison between measurements and computations was carried out on amongst others velocity variance and third order velocity moments, the latter being the most important variable in determining the magnitude of the net bed-load transport rate. In computing the variance and third order moment of the

bottom velocity it was assumed that the total oscillatory velocity signal u consists of a short wave averaged low-frequency component u_{lo} and a short wave component u_{hi} . The lowest short wave frequency was set to half the peak frequency.

Assuming u_{lo} and u_{hi} to be uncorrelated, the velocity variance is given by:

$$\langle u^2 \rangle = \langle u_{hi}^2 \rangle + \langle u_{lo}^2 \rangle , \quad (7a)$$

where the $\langle \rangle$ indicate time-averaging over the short wave and wave group scale.

Assuming in addition that $u_{lo} \ll u_{hi}$, Roelvink and Stive (1989) demonstrated that the most important contributions of the oscillatory part of the velocity to the third order velocity moment are given by:

$$\langle u^3 \rangle = \langle u_{hi}^2 u_{hi} \rangle + 3 \langle u_{hi}^2 u_{lo} \rangle + \dots . \quad (7b)$$

The first term in the right-hand side of Eq. (7b) is related to the short wave asymmetry, whereas the second term is associated with the interaction between the long wave velocity and the slowly-varying short wave velocity variance.

For both the measured and the computed bottom velocity time series, the three terms in Eqs. (7a-b) were separately calculated and plotted.

Discussion of results

Fig. 4 shows that, except for the last station behind the bar, the short wave velocity variance is very well predicted, indicating that the spectral energy density for the higher frequencies is well reproduced by the model. The model slightly underestimates the total velocity variance for the stations closest to the bar. This can be seen to originate from the inaccurate reproduction of the long wave velocity variance for these stations. This may be the result of a standing low-frequency wave pattern present in the channel with a node in the low-frequency surface elevation and hence large velocity amplitudes around station 5, which are not reproduced by the model because of the assumption of uni-directional wave propagation. Another possible cause could be a too strong reduction of the low frequency energy by the wave breaking formulation.

The third order velocity moment, which can be seen to be dominated by the short wave asymmetry, is largely underestimated by the model. This appeared to be a result of an underestimation of the peak values of the highest waves, which was already reported by Madsen and Sørensen (1993). The agreement is reasonable for the last two stations where strong wave breaking occurs. The long wave contribution is predicted rather well. Increasing the maximum frequency and the frequency resolution did not improve the numerical results.

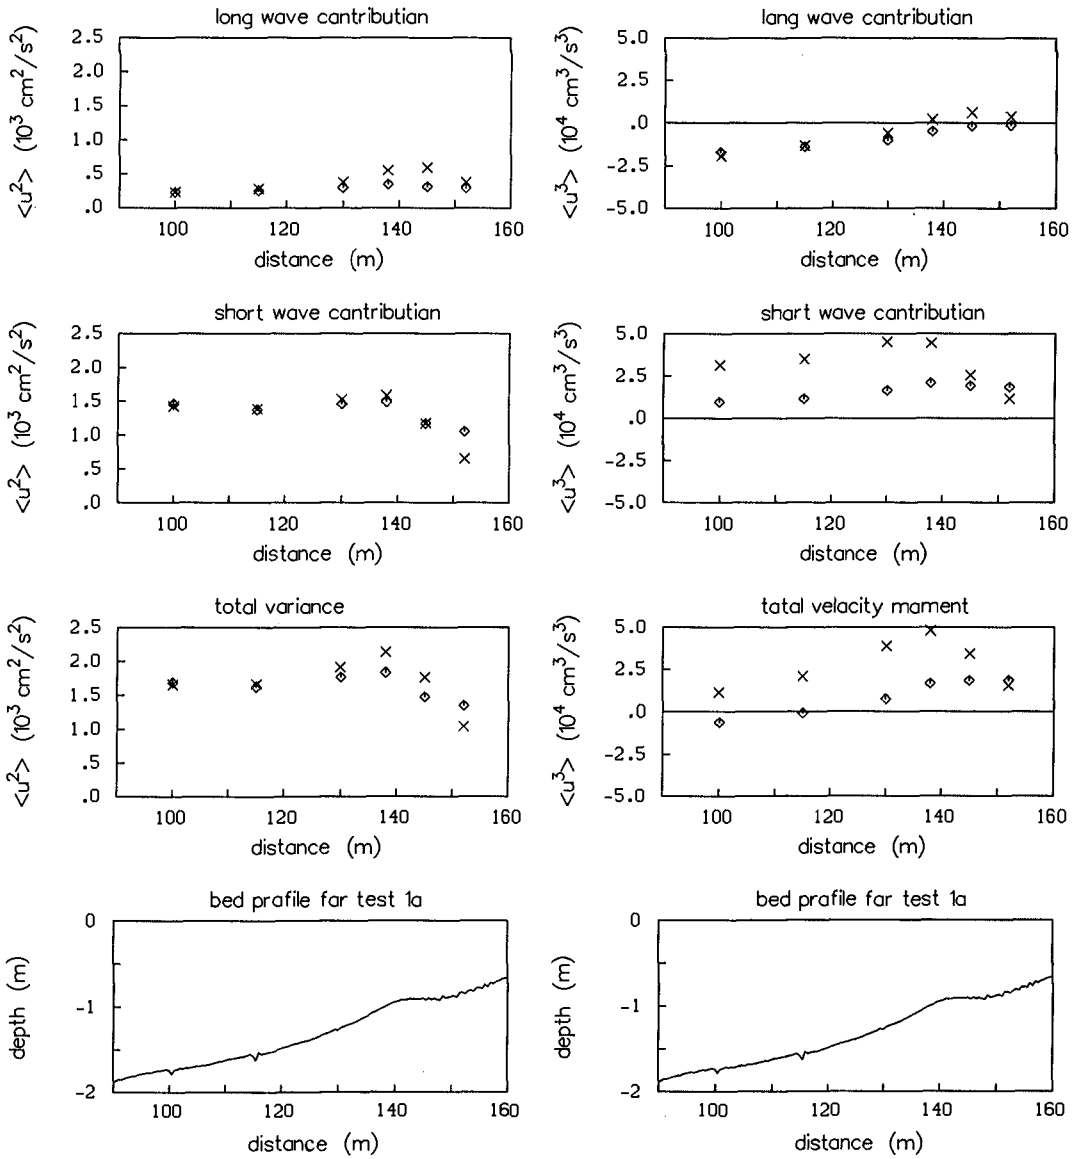

Fig. 4

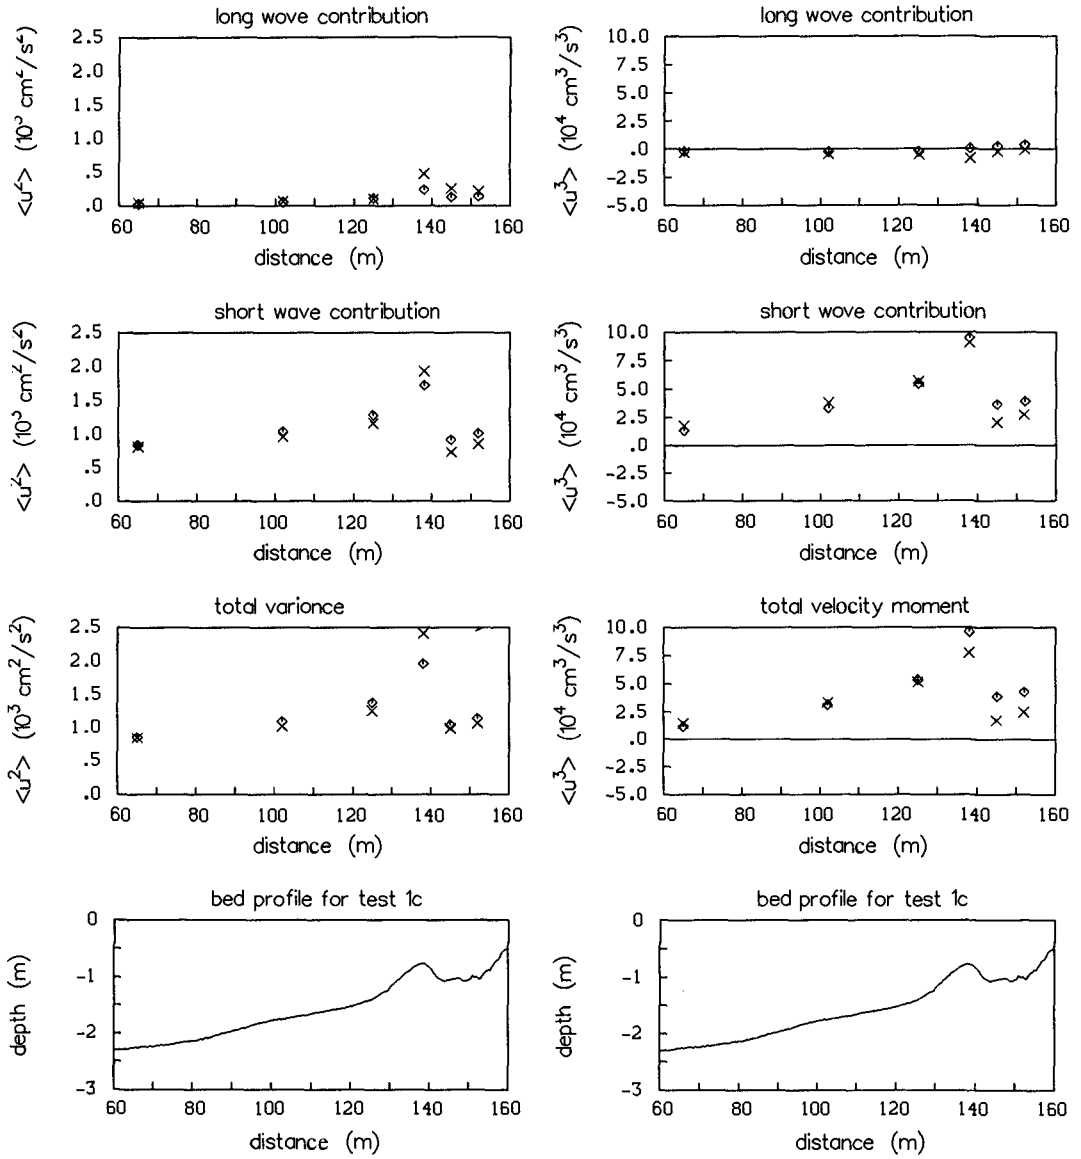

Fig. 5 Comparison of measured (crosses) and computed (diamonds) bottom velocity variance (left) and third order moments (right): long wave contribution, short wave contribution and total moment respectively; experiment 1c. Reprinted from J. Coastal Eng., Bosboom et al., 1996, with kind permission from Elsevier Science-NL, Amsterdam, The Netherlands.

Test 1c shows an encouraging agreement between measured and predicted variance and third order moments (Fig. 5), especially up to the bar crest. The underestimation of the peak values was found to be less significant than for test 1a. The less good agreement beyond the bar crest, also found by Eldeberky and Battjes (1996) for surface elevation spectra, can possibly be ascribed to the relatively steep bottom beyond the bar crest ($|h_x|/kh = 0.52$ for the primary wave) which is in contrast with the assumption of slowly-varying bottom ($|h_x|/kh \ll 1$).

The velocity variance in test 1c (Fig. 5) is predicted well. The difference between the total velocity variance determined from the computed and measured time series at the bar crest is for the larger part the result of the incorrect representation of the long wave energy. As for test 1a, this is can possibly be ascribed to a standing wave pattern in the wave channel or to a too strong reduction of low-frequency energy by the breaking formulation.

It can be concluded that for test 1c the third order velocity moments compare very well with the measurements. For test 1a as well as 1c, the short wave energy is predicted well by the model. The underprediction of the short wave asymmetry by the model in test 1a is therefore the result of an incorrect representation of the phases of the harmonic components. This might be partly due to the larger degree of non-linearity as compared to test 1c, such that the wave breaking already occurs at 100 m from the wave board and continues for a large propagation distance. Besides, the peak period is smaller in test 1a which decreases the accuracy of the frequency dispersion as well as the validity of the assumption of slowly-varying complex amplitudes underlying the evolution equations.

6. CONCLUSIONS

The modelling of horizontal velocities in non-breaking and breaking waves on a beach using Boussinesq-type models has been studied. Time-domain simulations of regular waves indicate that the use of a parabolic vertical distribution of the horizontal particle velocity yields realistic predictions, especially in the near-bed zone.

Horizontal velocities in the near-bed zone in (partially) breaking random waves have been simulated using a frequency-domain Boussinesq model. A fair prediction of the velocity variance was found. For the test with the longer wave period, the third order velocity moments are predicted well by the model. The shorter wave test however, shows an underestimation of the velocity moments due to an underestimation of the crest values of the highest waves. This was seen to be the result of an inaccurate representation of the phases of the higher harmonics.

Further research is necessary to determine whether the discrepancies result from the water-depth restrictions of the Boussinesq equations or from additional assumptions made in the derivation of the evolution equations. Further, attention

should be paid to the inclusion of higher-order derivatives in the spectral evolution equations and the mean velocity in the velocity computation.

CHAPTER 10

EFFECTS OF MODE TRUNCATION AND DISSIPATION ON PREDICTIONS OF HIGHER ORDER STATISTICS

James M. Kaihatu¹ and James T. Kirby, Member, ASCE²

Abstract

We investigate the effects mode truncation and dissipation characteristics have on predictions of wave shape statistics such as skewness and asymmetry. We demonstrate the effect of mode truncation by calculating wave shape statistics for data from a laboratory experiment using an increasing number of frequency components each calculation. We find that the values of skewness and asymmetry converge to a maximum as more components are retained, with the maximum values attained when components out to the Nyquist frequency are kept. We run a lowest order Boussinesq shoaling model and a nonlinear dispersive shoaling model with the data, retaining more components with each simulation. Both models show the same convergence characteristics as the data as the number of retained frequency components increases. The lowest order Boussinesq model, despite its shallow water formalism, yields skewness and asymmetry values closer to those of the data than those of the dispersive model. This is likely due to the phase mismatches in the dispersive model, which become large in deep water and thus violate the slowly-varying amplitude assumption. We also investigate the effect of spectral dissipation on these predictions. We run the lowest order Boussinesq shoaling model with different proportions of frequency-dependent dissipation and calculate wave shape statistics. We find that the distribution must take into account some aspect of $(f)^2$ variation in the dissipation for reliable wave shape statistics.

Introduction

The Boussinesq equations (Peregrine 1967) are robust predictors of weakly nonlinear wave propagation in shallow water. The “consistent” frequency domain Boussinesq model of Freilich and Guza (1984) has been used in a number of studies (e.g., Elgar and Guza 1985; Elgar et al. 1990) concerning nearshore wave propagation; they have shown that this model does predict shallow water wave spectra reliably provided that $kh \ll O(1)$, where k is the wave number and h the water depth.

¹ Oceanographer, Oceanography Division (Code 7322), Naval Research Laboratory, Stennis Space Center, MS 39529-5004

² Professor, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716

In recent years, however, frequency domain models with fewer restrictions on the value of kh have been developed (e.g., Madsen and Sorensen 1993; Agnon et al. 1993; Kaihatu and Kirby 1995). These models, because of their dispersive nature, can be applied in greater water depths (and take into account a greater frequency range) than the lower-order Boussinesq-type models. Application of these models to laboratory data have shown their utility.

A different test of these frequency domain models would be to evaluate their ability to replicate surface shape characteristics. This involves evaluating quantities such as skewness and asymmetry. These higher order statistical quantities track the free surface characteristics of waves, and thus lend insight into the effect nonlinear energy exchange has on the evolution of the wave shape.

Elgar et al. (1990) have investigated skewness and asymmetry predictions from the consistent model of Freilich and Guza (1984) and compared these quantities to field data taken at both Torrey Pines, CA and Santa Barbara, CA in 1980. Because of the lowest order dispersion characteristics of the model, the simulations required an upper frequency cutoff that was based on the relative magnitude of the dispersion parameter kh . This upper frequency was established prior to simulation and analysis so that no nonlinear interaction with frequencies beyond the cutoff could occur. They found good data-model agreement for relatively narrow banded spectra, but somewhat poorer agreement for broad banded spectra. This is primarily due to the spectral energy content beyond the cutoff frequency for the broad spectra data.

No corresponding studies have been undertaken for the more dispersive frequency domain models, particularly as applied to field measurements. The ability of these models to simulate processes at frequencies beyond the small kh limit is particularly germane to this problem. Bowen (1994) showed that the calculation of skewness and asymmetry varied significantly with the number of harmonics of the spectral peak retained. He used his laboratory data of shoaling irregular waves on a slope to calculate these quantities with varying numbers of harmonics of the spectral peak, and found that the values of skewness and asymmetry converged to a maximum as the number of components retained increased. The maximum values of skewness and asymmetry were reached when the upper limit cutoff frequency reached the Nyquist limit. Bowen (1994) also noted that the differences between the values of skewness and asymmetry as the number of components increased were most marked in the breaking zone. This would likely be due to the increased nonlinear shifting of energy to the higher frequency components. The dependence of skewness and asymmetry on the number of retained components was not evident in the work of Elgar et al. (1990) due to the dispersion-based upper frequency cutoff for both model and data. This upper frequency cutoff is not a function of kh in the more dispersive frequency domain models, so a different criteria needs to be applied to determine this cutoff. Kaihatu and Kirby (1995), for example, use percentage of total variance. Other concerns, such as upper frequency limitations on pressure to surface conversions

(required when deducing free surface fluctuations from pressure records), can also affect the choice of cutoff frequency.

In this study we wish to investigate the effect the upper frequency cutoff has on simulating these higher order statistics. We will first investigate skewness and asymmetry values gleaned from experimental data. This will also lend insight into the sensitivity of these statistics to cutoff frequency. We will then run two shoaling models and determine the effect that retaining various numbers of components has on the reliability of predictions of skewness and asymmetry. We will find that the nature of the model has a strong effect on the predictions.

Skewness and Asymmetry in the Wavefield

As waves in the nearshore shoal, nonlinear effects become more important. The wave crests become sharper and the crests flatter. This is represented as an increase in skewness (asymmetry about a horizontal plane). As the waves begin to approach breaking, the front face of the wave becomes steeper. This is quantified as an increase in negative asymmetry (in this context, referring to asymmetry about a vertical plane).

Skewness is defined as:

$$skewness = \frac{\langle \eta^3 \rangle}{\langle \eta^2 \rangle^{\frac{3}{2}}} \quad (1)$$

and asymmetry as:

$$asymmetry = \frac{\langle H(\eta^3) \rangle}{\langle \eta^2 \rangle^{\frac{3}{2}}} \quad (2)$$

where the brackets denote a time average, η is the free surface elevation and H is the Hilbert transform.

We will be working with the Case 2 data of Mase and Kirby (1992); full details of the experimental setup can be found therein. The tank consisted of a constant depth section ($h=47cm$) of $10m$ length, and a 1:20 slope. A Pierson-Moskowitz spectrum was input at the wave paddle. For Case 2, the value of kh at the spectral peak in the deep portion of the tank was 1.9, a severe test of the dispersive wave models. In this experiment, the sampling rate $\Delta t = 0.05s$ with the data divided into seven realizations at 2048 points each. The Nyquist frequency was $10Hz$. The evolution characteristics of this data are shown in Figure 1. This figure shows the spectra at several gages taken out to the Nyquist frequency. It is apparent that the high frequency tail increases in energy, particularly in shallow water.

We use (1) and (2) to calculate the higher order statistics from the data. For each calculation we retain in turn 300, 500, 700, 900, and 1024 frequency

components (1024 components takes the calculation to the Nyquist limit). Plots of H_{rms} (root-mean-square wave height), skewness and asymmetry appear in Figure 2. There is not much difference between the measured H_{rms} values for different numbers of retained components; this implies that $N=300$ retains a significant percentage of the energy content in the spectrum. However, the skewness and asymmetry values clearly indicate that the number of retained frequency components has a profound effect on the calculation of high order statistics, with an increase in the number of components evidencing a convergence to a maximum value. The differences are most apparent in the nearshore, as nonlinearity becomes more prevalent in the wavefield. Additionally, the skewness measure for the $N=300$ case is clearly less than those for more retained components even in the offshore area, an indication that this number of components is insufficient to describe the evolution of the shape of the wavefield. This is in spite of the fact that $N=300$ retains sufficient energy for H_{rms} quantification.

Shoaling Models

Now that we have demonstrated the effect the number of retained components has on the evaluation of skewness and asymmetry, we now wish to determine how this affects our ability to accurately model these effects. This is more germane for the dispersive models, since the linear characteristics of the higher frequencies could be more accurately modeled

The consistent model of Freilich and Guza (1984) is:

$$A_{nx} + \frac{h_x}{4h} A_n - \frac{in^3 k^3 h^2}{6} A_n + \frac{3ink}{8h} \left(\sum_{l=1}^{n-1} A_l A_{n-l} + 2 \sum_{l=1}^{N-n} A_l^* A_{n+l} \right) = -\alpha_n A_n \quad (3)$$

where A is the complex amplitude, and N is the index of the highest frequency component considered. The right hand side is a dissipation term that removes energy from the spectrum in accordance with the probabilistic dissipation expression of Thornton and Guza (1983). The distribution of that dissipation over the frequency range is discussed in a later section. The second term in (3) is the Green's Law shoaling term.

The nonlinear finite-depth shoaling model of Kaihatu and Kirby is:

$$A_{nx} + \frac{C_{gnx}}{2C_g} A_n + \frac{i}{8\omega_n C_{gn}} \left(\sum_{l=1}^{n-1} R A_l A_{n-l} e^{i\Theta} + 2 \sum_{l=1}^{N-n} S A_l^* A_{n+l} e^{i\Psi} \right) = -\alpha_n A_n \quad (4)$$

where R and S are interaction coefficients, and:

$$\Theta = \int k_l + k_{n-l} - k_n dx \quad (5)$$

$$\Psi = \int k_{n+l} - k_l - k_n dx \quad (6)$$

are referred to as “phase mismatches” since they determine the relative amount of detuning away from resonance in x . They have the capacity to become quite large in deep water, thus causing the nonlinear term to oscillate. The expansion technique used to derive (4) assumes that the amplitudes are slowly varying in space, an assumption which may be violated in deep water.

We use the shoaling models to determine the effect of the cutoff frequency on the simulation of these higher order statistics. Both models utilized error-checked variable stepsize ODE integration schemes; the consistent model used the Bulirsch-Stoer method with Richardson extrapolation, while the dispersive model used a fourth order Runge-Kutta scheme. We note that the consistent model of Freilich and Guza (1984) is formally invalid in this water depth. The lack of phase mismatch in the model is due to the nondispersive nature of the

Figure 1. Evolution of spectra in experiment of Mase and Kirby (1992). Top figure: $h=47\text{cm}$ (solid), $h=25\text{cm}$ (dashed), $h=15\text{cm}$ (dotted), $h=7.5\text{cm}$ (dash-dot), $h=2.5\text{cm}$ (dash-x)

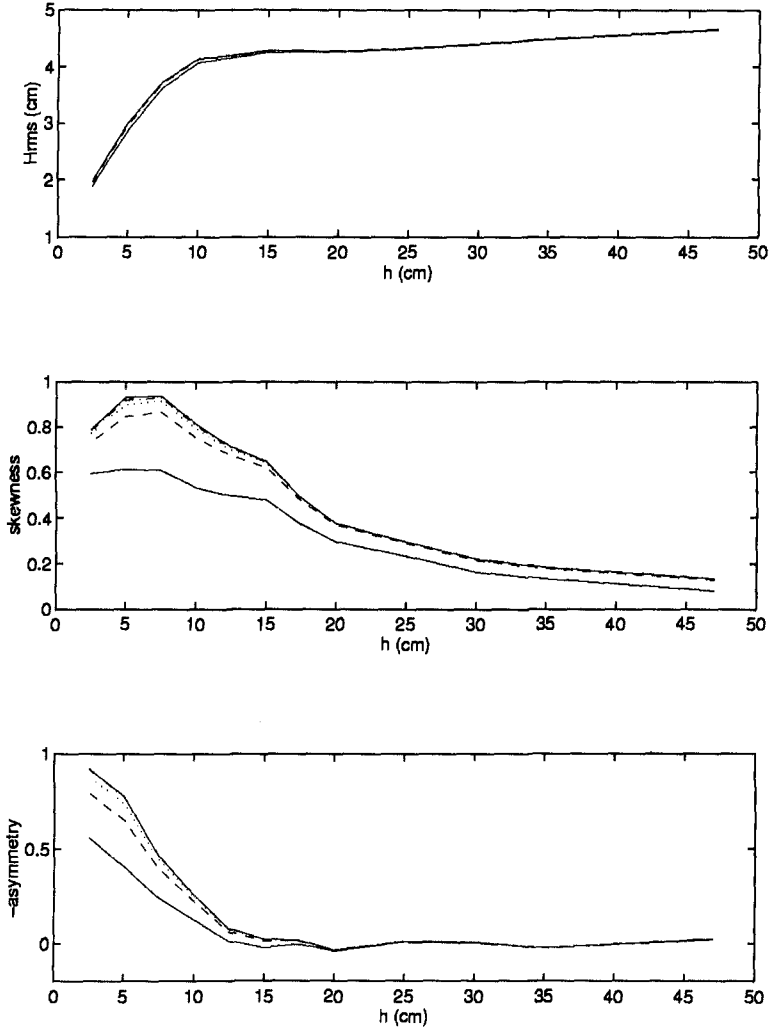

Figure 2. Statistics calculated from Case 2 data of Mase and Kirby (1992). In each figure: $N=300$ (bottom solid), $N=500$ (dashed), $N=700$ (dotted), $N=900$ (dash-dot), $N=1024$ (top solid). Top figure: H_{rms} . Middle figure: skewness. Bottom figure: - asymmetry.

nonlinear terms; in shallow water $k_n = nk_l$, where k_l is the wavenumber associated with the lowest frequency ω_l in the spectrum. This causes the phase mismatches to become zero. The dispersive models, with the finite phase mismatches, have linear characteristics that work well in deep water, but have nonlinear terms that may oscillate fast enough in deep water to cause difficulty in replicating the wave shape. The phase mismatches are a consequence of the somewhat misordered derivation of the dispersive models.

We ran the two models with increasing numbers of components ($N=300, 500, 700, 900$ and 1024) to simulate the experiment of Mase and Kirby (1992). Then we filter the data similarly, and calculate H_{rms} and third moments. The comparisons between the consistent model and the data are shown in Figure 3. We were able to simulate the spectrum out to the Nyquist frequency with this model; it is relatively expedient compared to the more computationally intensive dispersive model (4). Even so, the consistent model with $N=900$ and $N=1024$ requires substantial computational resources. Most runs were performed on the US Army Waterways Experiment Station Cray YM-P. The $N=900$ and $N=1024$ runs, however, required a Cray batch queue with a very low assigned priority; thus these were done, one realization at a time, on a Silicon Graphics Indy.

Figure 3 shows that the consistent model greatly overpredicts the H_{rms} values of the data. This is not surprising, since the model is clearly outside its area of validity; Green's Law, the linear shoaling mechanism in the consistent model, overpredicts the shallow water spectral amplitudes when initialized in deep water. In addition, the model results for all simulations agree, which indicates that $N=300$ is sufficient for describing the energy level in the spectrum. The skewness and asymmetry values, on the other hand, agree reasonably well with the data. This seems inconsistent with the fact that the consistent model is far outside its range of validity. Additionally, the model results show the same tendency to converge to a maximum value as N increases as shown by the data.

The dispersive model (4) required significantly more computational resources than the consistent model. This is primarily due to the phase mismatches of the dispersive model; their size in deep water causes difficulty in solving the sets of equations. Available computational resources only allowed the $N=300$ and $N=500$ cases to be run with this model.

Figure 4 shows the comparisons between the statistics from the experiment of Mase and Kirby (1992) and the dispersive model (4). The H_{rms} comparison is not unexpected, since the dispersive model does have the ability to reliably model spectral shoaling from deep to shallow water. The third moment comparisons, however, look worse than those of the consistent model. This is somewhat surprising, since the dispersive model has linear characteristics that can be applied to deeper water. However, the likely cause of these deleterious comparisons are the phase mismatches. We define a normalized phase mismatch:

$$M = \frac{|k_1 - k_{N-1} - k_N|}{k_N} \quad (7)$$

The magnitude of M when $N=1024$ is 25 in the deep portion of the tank. This magnitude of mismatch can induce oscillations which have deleterious effects on the replication of the free surface. Thus, these phase mismatches serve to keep the wave from attaining a realistic form. This is not evident in spectra comparisons shown in studies of dispersive frequency domain models (e.g., Agnon et al. 1993; Kaihatu and Kirby 1995) since these effects are averaged.

One feature that is apparent with both the consistent and dispersive model simulations is that the model results underpredict the skewness and asymmetry values seen in the data for each particular cutoff frequency; this is true even at the Nyquist frequency. One reason for this underprediction for $N < 1024$ is that all frequencies of the data have undergone nonlinear energy exchange with all others, while the model simulations are limited to those below the cutoff.

Effect of Dissipation Mechanism on Statistics

Both models have a dissipation mechanism that removes energy in the spectrum based on a probabilistic decay function developed by Thornton and Guza (1983). This dissipation mechanism is:

$$\alpha_n = \alpha_{n0} + \left(\frac{f_n}{f_{peak}} \right)^2 \alpha_{n1} \quad (8)$$

where:

$$\alpha_{n0} = F\beta(x) \quad (9)$$

$$\alpha_{n1} = \left(\beta(x) - \alpha_{n0} \right) \left(\frac{f_{peak}^2 \sum_{n=1}^N |A_n|^2}{\sum_{n=1}^N f_n^2 |A_n|^2} \right) \quad (10)$$

where f_{peak} is the peak frequency of the spectrum, f_n is the n^{th} frequency, F is a weighting factor, and $\beta(x)$ is the simple dissipation model of Thornton and Guza:

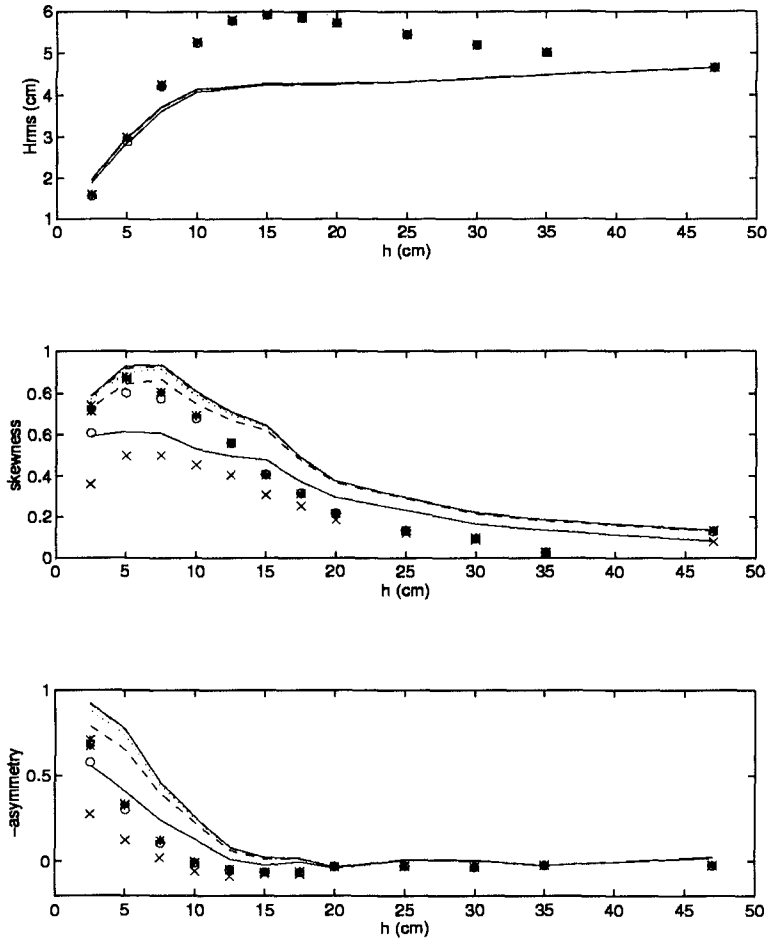

Figure 3. Comparison of modeled statistics to data of Mase and Kirby (1992) using the consistent model of Freilich and Guza (1984). In each figure: $N=300$ (bottom solid line is data, bottom “x” is model), $N=500$ (dashed line is data, “o” is model), $N=700$ (dotted line is data, “*” is model), $N=900$ (dash-dot line is data, “+” is model), $N=1024$ (top solid line is data, top “x” is model). Top figure: H_{rms} . Middle figure: skewness. Bottom figure: -asymmetry.

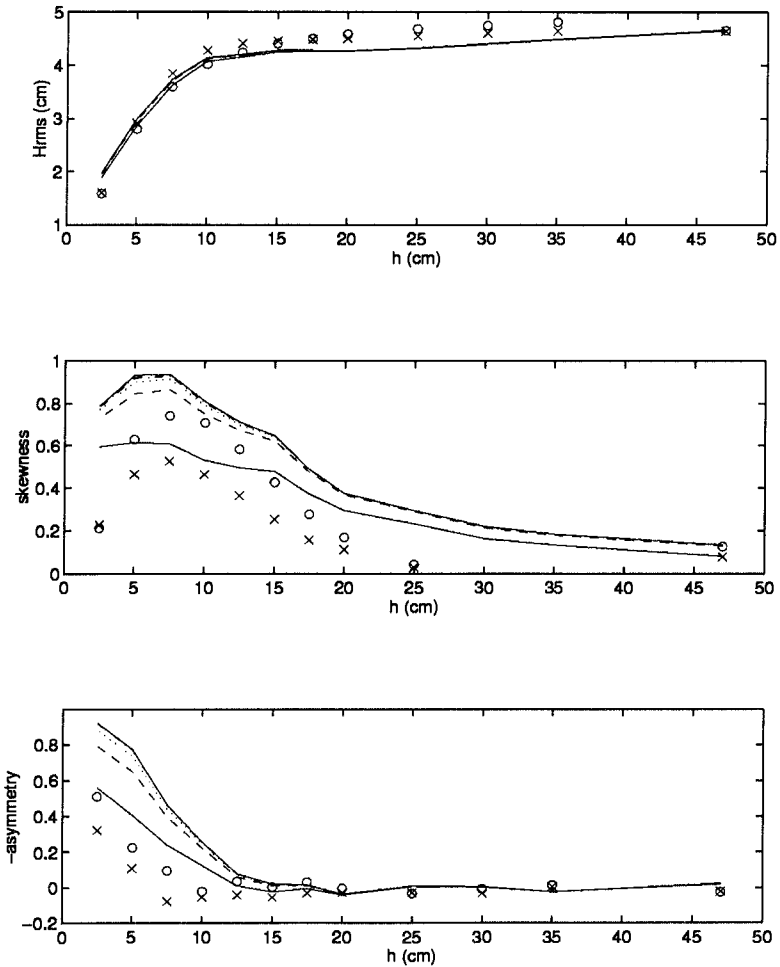

Figure 4. Comparison of modeled statistics to data of Mase and Kirby (1992) using the dispersive model of Kaihatu and Kirby (1995). In each figure: $N=300$ (bottom solid line is data, bottom "x" is model), $N=500$ (dashed line is data, "o" is model), $N=700$ (dotted line is data), $N=900$ (dash-dot line is data), $N=1024$ (top solid line is data). Top figure: H_{rms} . Middle figure: skewness. Bottom figure: -asymmetry.

$$\beta(x) = \frac{3\sqrt{\pi}B^3\bar{f}H_{rms}^5}{4\sqrt{gh}\gamma^4h^5} \quad (11)$$

where B and γ are free parameters set to 1.0 and 0.6, respectively. The mean frequency \bar{f} is taken to be the peak frequency. These values are close to those found by Thornton and Guza (1983). The proper value of F is a matter of some discussion; this weighing factor determines the dependence of the dissipation on frequency. Setting $F=1.0$ causes the dissipation to be equal across all frequencies, while setting $F=0$ weights the dissipation proportionally to $(f)^2$. Physical arguments for the proper value of F are presented elsewhere (Eldeberky and Battjes 1996; Kirby and Kaihatu 1996) and thus will not be presented here. The primary intent in this section is to discern the effect the particular value of F has on higher order statistics.

Realizing that we will not obtain accurate predictions of these quantities (for the reasons described earlier), we instead look for the effect various values of F have on the *trends* of the skewness and asymmetry values as waves propagate into shallow water. We ran both the consistent model of Freilich and Guza (1984) for various values of F , using $N=300$. Figure 5 shows skewness and asymmetry results for the consistent model with $F=0., 0.25, 0.5, 0.75,$ and 1.0 . The skewness results indicate that $F=0.75$ follows the trend of the data best, while the asymmetry results show that $F=0.5$ is most representative. However, what is more instructive are the comparisons between the simulations. The skewness values for $F=0, F=0.25$ and $F=0.5$ show a decrease at the last three gages. These values of F weight the dissipation higher towards higher frequencies, thus suppressing the nonlinear energy transfer to higher frequencies. The converse trend is evident in the asymmetry predictions. The $F=0$ has the most negative asymmetry for water depths up to $7.5cm$, at which point the negative asymmetry unexpectedly decreases in the inner surfzone. The fact that the $F=0$ curve exhibits the most negative asymmetry until its sudden downturn is indicative of the sawtooth shape of the breaking waves, which are in line with an $(f)^2$ distribution of dissipation. Kirby and Kaihatu (1996) discuss the physical basis behind this supposition. As mentioned before, the $F=0.5$ best matches the trend of the data for the entire range of water depths. The fact that the $F=1.0$ curves are not the best representations of the skewness and asymmetry trends indicates that some weighting of the dissipation toward higher frequencies is required to simulate this reliably, contrary to Eldeberky and Battjes (1996), who indicate that no such weighting need take place. In fact, it may be that if all components of the spectrum out to the Nyquist frequency were retained we can rely solely on the $(f)^2$ representation of the dissipation distribution, and that retention of α_{n_0} in (8) is an artifact of the truncation of the spectrum below the Nyquist frequency. Additionally, the sudden downturn of both skewness and asymmetry from the model results in the inner surf zone may also be an artifact of the mode truncation; Kirby and Kaihatu

(1996) show a comparison of third moments between the Case 2 data of Mase and Kirby (1992) and the time-domain extended Boussinesq code of Wei et al. (1995). This comparison, which utilized the entire unfiltered data set in the model simulation, showed that the time-domain model can reliably replicate third moment statistics.

Conclusions

We used the data of Mase and Kirby (1992) and two nonlinear shoaling models to investigate the effect mode truncation and dissipation mechanisms have on the prediction of third order statistics. We found that the number of components used in the calculation has a strong effect on the skewness and asymmetry values; this was true for both the data and the model simulations. The consistent model of Freilich and Guza (1984), though formally invalid for the peak kh values of the experiment, actually modeled the third order moments better than the dispersive model of Kaihatu and Kirby (1995). This is due to the phase mismatches in the dispersive model; their size in deep water causes the nonlinear term to oscillate considerably, keeping the wave from attaining a realistic form. We also looked at the effect different weightings of frequency dependent dissipation mechanisms have on the predictions of these statistics, and found that these mechanisms must contain some frequency dependence to model skewness and asymmetry realistically. This is contrary to Eldeberky and Battjes (1996), who maintained that a constant distribution of dissipation over frequency is optimum. Further work in this area will focus on continued development of the dissipation models.

CHAPTER 11

FIELD OBSERVATION OF MOVEMENT OF SAND BODY DUE TO WAVES AND VERIFICATION OF ITS MECHANISM BY NUMERICAL MODEL

Uda, Takaaki ¹, Yoshimichi Yamamoto ², Naoki Itabashi ² and Kosuke Yamaji ²

ABSTRACT

Bottom sounding data collected from 1983 to 1993 on the Shizuoka coast were analyzed. The results reveal the existence of a sand body moving downcoast at a velocity of about 233m/yr. It is the first time that this kind of phenomenon was observed in the quantitative sense including the spatial and temporal changes in longitudinal profile of the beaches, and this propagation mode is a very interesting phenomenon. In this study, sand movement shoreward and offshoreward of the detached breakwaters is modeled, and a model to predict successive contour line changes is developed, taking into account of time lag caused by the obstruction effect of longshore sand transport due to the detached breakwater. The new phenomenon observed on the Shizuoka coast is well explained by the present model. The propagation velocity of the sand body reproduced by this model is 230m/yr and it is well in agreement with the field observation value.

I . INTRODUCTION

Recently, beach erosion has proceeded at many coasts in Japan. According to the analysis of beach erosion, many of the beach deformations are caused by the imbalance of the longshore sand transport by the obstruction of continuous longshore sand transport due to breakwater, etc., decrease in sediment supply from rivers/sea cliffs, or change in wave field due to the construction of a large-scale harbor breakwater. In all these cases, the basic principle itself of beach deformation is already known, but there still remain many unknown points regarding the quantitative evaluation of the longshore sand transport and an external force of the topographic change, especially the research is insufficient on the change in mechanism of the longshore sand transport associated with the installation of shore protection facilities against erosion such as detached breakwater and headland. This leads to the decreased accuracy in predicting the beach deformation when countermeasures against erosion are taken, and in order to enhance the accuracy of the prediction, this kind of problem must be clarified.

Of the beach deformations due to the above three factors, this study

focuses on the beach deformation due to a sharp decrease in sediment discharge from a river and the Shizuoka coast facing Suruga Bay is selected as the case study area. Through the analysis recent recovery process of the sandy beach due to the increase of the sediment discharge is discussed. As for beach deformation of the Shizuoka coast, Uda et al.(1994) found out that the sediment supplied from the Abe River was moved downdriftward by the longshore sand transport while forming a large mass of sediment (hereinafter called sand body) along the coastline. Tsuchiya(1995) also discussed erosional waves on the Shizuoka coast on the basis of the field data of Toyoshima et al.(1981). As for the shoreline change, this phenomenon is classified into the longshore sand waves recently discussed by Thevenot-Kraus(1995) or can be classified as a type of phenomenon in which the wave-like shoreline propagates alongshore while keeping its form. In addition, there are various names for the longshore sand waves. Sonu(1968) calls them cusp-type sand waves, Bruun(1954) and Grove et al.(1987) migrating sand humps, Inman(1987) accretion and erosion waves, and Verhagen(1989) simply sand waves. Of these studies, especially the accretion and erosion waves by Inman(1987) are produced when a coastal structure such as a groin is installed or the sediment supply from a river or the source of littoral drift, is sharply increased due to flood, and they propagate along the coastline while being accompanied by weak diffusion.

On the Shizuoka coast, the erosion waves were produced from the beginning of the 1970s to around 1983 before the movement of the sand body, and propagated alongshore, and this is completely the same phenomenon as the erosion waves mentioned by Inman(1987). On the Shizuoka coast, seawalls, many wave dissipating armour units and detached breakwaters were installed on the eroded beach after the erosion waves were gone, and the foreshore was almost completely lost. Subsequently, the movement of the sand body started. Such a characteristic change has shown that the sediment was accumulated only when the leading portion of the sand body arrived. In all the past studies, the sand waves propagated alongshore on the coast with a continuous sandy beach. And in this respect, the longshore sand waves subject to this study are remarkably different from others. In this study, a soliton, instead of many waves, propagated alongshore while being accompanied by weak diffusion, and so this may be called by the movement of a sand body different from other types and its occurrence mechanism will be discussed.

As to the theoretical study on the longshore sand waves, Thevenot-Kraus(1995) numerically solved a diffusion equation including the advection term on the shoreline change, and they well explain the propagation of the longshore sand waves on Southampton Beach, New York, U.S.A. But their study is on the predictive model of shoreline change and has not reached the level of predicting the three-dimensional beach deformation. On the Shizuoka coast a number of detached breakwaters have been installed, and they are considered to be closely related to the movement of the sand body, which suggests the necessity of modeling of the obstruction effect of littoral transport by the detached breakwaters. For this reason, in this study, contour line change model which can predict three-dimensional topographic changes by assuming the depth distribution of the longshore sand transport rate, is applied to the Shizuoka coast to clarify the movement of the sand body.

II. OBSERVATION OF MOVEMENT OF SAND BODY ON SHIZUOKA COAST

(1) General

The Shizuoka coast is located on the west shore of Suruga Bay and is a sandy beach extending 7.8km northeastward from the Abe river mouth, as shown in Fig.1, Fig.2 shows the sea bottom contours off the Shizuoka and Shimizu coasts. On the Shizuoka coast as well as the Shimizu coast, it is very steep as 1/10 near the shoreline. In the offshore zone ranging from 10m to 30m depth, a continental shelf of mild slope of 1/150 spreads, but the bottom slope at the tip of the Mihono-matsubara sand spit is steep at about 1/5.

During the Jomon Transgression of the sea level, it is considered that hill side of Mt. Kuno was eroded to supply sediment toward the Mihono-matsubara sand spit, but at the present sea level, the only supply source of sediment to the sand spit is the Abe River. In the Abe River, the river bed excavation was carried out extensively before 1967, causing sharp decrease of the sediment discharge of this river and then serious beach erosion was triggered from near the river mouth and spread out northeastward. Presently, the most severely eroded portion of the beach is approaching the tip of the Mihono-matsubara sand spit. Much sediment supplied from the Shimizu coast is transported from the northeast end of the Mihono-matsubara sand spit into submarine canyons.

The study area ranges from No. 0, 7.8km away northeastward from the Abe River mouth, to No. 78 of the Abe river mouth, as shown in Fig. 2. The interval of the measuring line is 100m. On the Shizuoka coast, bottom soundings have been done along these measuring lines once a year. According to the sampling test of bottom materials conducted at 9 points in 1km intervals alongshore from the Abe River mouth on February 20, 1989, the median diameter of the beach materials near the shoreline of the Shizuoka coast is around 7.5mm

Fig.1 Location of Shizuoka coast in Suruga Bay.

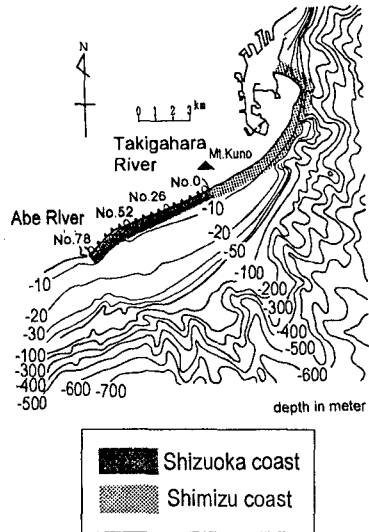

Fig.2 Sea bottom contours of Shizuoka and Shimizu coasts and alignment of measuring lines.

(2) Change in Shoreline Position and Longitudinal Profile on Shizuoka coast

On the basis of the bottom sounding data, the change in shoreline position by selecting 1989 as the reference year, is shown in Fig. 3. In the figure, No. 78 is located next to the left bank of the Abe River mouth, and the origin of the longshore distance is set at 7.8km east-northeast from the river mouth. On the top of the figure, approximate locations of various shore protection facilities (detached breakwater, seawall, groin, wave dissipating armour units and jetty) are shown.

The main change in shoreline position started near the Abe River mouth, the source of the littoral drift on the Shizuoka coast. In the beginning, the erosion concentrated on the south side of the jetty of the Hama River as the boundary, but after 1990, the erosion spread fast northward of the jetty of the Hama River. Simultaneously with the northward spread of the accretion area, the shoreline retreated fast in the areas (e.g. section between No. 66 and No. 70 in 1987) where the shoreline had been remarkably advancing in the beginning, and as a whole, the aggregate of sediment (sand body) moved northward with mild deformation. In 1993, north of No. 38 where the leading edge of the sand body seems to have arrived, the shoreline hardly moved in comparison with the southern side, indicating that the beach was completely eroded and there is no sediment to move because the area is totally covered with seawalls and wave-dissipating armour units and no foreshore exists. From Fig. 3, the propagation velocity of the leading edge of the sand body between 1984 and 1993 is calculated to be 233m/yr.

The profile change of the beach associated with this sand body movement is investigated in two sections : No. 67 between breakwaters in the area where the shoreline greatly advanced until 1988 but retreated subsequently, No. 62 without breakwaters.

Fig. 4 shows the profile change of No. 67. Until 1988, the accretion took place in the area shallower than -4m, but subsequently the accretion occurred in a wide area shallower than 7m depth. Taking into account of the fact that the breakwaters were installed at a depth of 3m in this area, it is found that the accretion occurred shoreward of the breakwaters until 1988, but after that the area was filled with sand, littoral drift started to pass through the offshore side of the breakwaters, causing the accretion in that area. In the period between 1983 and 1993, remarkable profile changes were seen mostly in the area shallower than -7m.

As to the profile change of No. 62 shown in Fig. 5, much sediment

Fig.3 Change in shoreline position on Shizuoka coast (reference year:1983)

accumulated in the area shallower than -4m until 1989, but subsequently an erosion occurred. In this profile, too, the topographic changes were seen mostly in the area shallower than -7m, but the bottom fluctuation between -5m and -7m was small in contrast to the remarkable bottom changes between -5m and -7m at No. 67 located between breakwaters.

Fig.4 Change in longitudinal profile along measuring line No. 67 on Shizuoka coast.

Fig.5 Change in longitudinal profile along measuring line No. 62 on Shizuoka coast.

(3) Littoral Drift and Propagation Velocity of Center of Gravity of Sand Body

As to beach deformation of the Shizuoka coast, it was found that the sea bottom slope greatly changed with the accretion of sediment. As an index of the change in cross-sectional area, the change in cross-sectional area of the beach between +5m and -3m equivalent to the water depth at the shore end of the detached breakwaters, and between +5m and -7m equivalent to the critical depth for sand movement were determined and their spatial and temporal changes were investigated.

The sand volume shallower than -7m was increasing with the elapse of years, but the longshore stretch where the remarkable volume change was observed was limited in each year. Therefore, the region shown in Table 1 was selected in each year, and the volume change was calculated and the time change in sand volume together with the change in the foreshore area is shown in Fig. 6. From this, it is realized that on the average from 1983 to 1993, the total sand volume increased at the rate of $10 \times 10^4 \text{ m}^3/\text{yr}$, though some fluctuation existed. In this area, as a whole,

northeastward littoral drift is dominant, and the only sediment supply source is the Abe River. On the northeast side of the tip of the sand body, seawalls and wave-dissipating armour units

Table 1 Integration region of sand volume and location of center of gravity of sand body.

Measured year	Integretion region	Longshore distance of accretion zone(m)	Longshore distance(m) of center of gravity from No.78
1984	No. 60~No. 78	1,800	471
1985	No. 60~No. 78	1,800	508
1986	No. 55~No. 76	2,100	997
1987	No. 55~No. 76	2,100	1,247
1988	No. 55~No. 75	2,000	1,376
1989	No. 46~No. 72	2,600	1,586
1990	No. 46~No. 72	2,600	1,773
1991	No. 38~No. 72	3,400	2,078
1992	No. 39~No. 72	3,300	2,263
1993	No. 38~No. 78	4,000	2,373

have been installed, and no beach deformation has been observed, and in fact, the littoral drift rate is considered as 0. Therefore, the increase rate of the total sand volume shown in Fig. 6 should be equal to the littoral transport rate supplied to this area from the Abe River mouth. Uda·Yamamoto(1994) estimated, on the basis of the time change in beach topography, that the littoral transport rate on the Shimizu coast was about $13 \times 10^4 \text{ m}^3/\text{yr}$. Before the Shizuoka and Shimizu coasts were eroded, almost the same littoral transport rate was considered to exist over the entire area, and therefore the littoral transport rate in this area is also assumed to be about $13 \times 10^4 \text{ m}^3/\text{yr}$. The littoral transport rate after 1983 is about 77% in comparison with this.

The foreshore area and total sand volume in the zone higher than 0m and shallower than -3m shown in Fig. 6 increased until 1989, but thereafter they remained almost at certain values, implying that although the accretion seems to have stopped in view of the change in sand volume shoreward of the detached breakwaters, actually the accretion continues in the offshore zone.

Fig. 7 shows the time change of the longshore distance from No.78 of the center of gravity of the accretion area. In all cases except the period of 1983-1984, the center of gravity of the sand body moved monotonously northward and the average propagation velocity of the center of gravity is 235m/yr. The fact that the propagation velocity of the center of gravity is identical in all three types of integration regions means that almost the

Fig.6 Time change in sand volume and foreshore area of the beach (reference year:1983)

Fig.7 Movement of center of gravity of sand body.

same propagation velocity of the center of gravity existed at any place. While the sand volume of the beach shoreward of the detached breakwaters saturated in 1989, the center of gravity moved with keeping almost the same velocity. This means that although the sand volume shoreward of the detached breakwaters does not change, it, as a whole, is also moving at the same velocity. Uda·Yamamoto(1994) estimated from the shoreline changes that the phase velocity of the erosion wave before the construction of the detached breakwaters was 0.5 to 0.8km/yr. In comparison with this value, it is realized that the propagation velocity was reduced to 0.47-0.29 times due to the installation of the detached breakwaters.

III. REPRODUCTION OF PROPAGATION PHENOMENON OF SAND BODY BY CONTOUR LINE CHANGE MODEL

(1) Contour Line Change(CLC) Model

Uda-Kawano(1996) developed a model which can predict the spatial and temporal changes of the contour line by assuming depth change in littoral transport rate. This model is designed for a coast with a steep slope near the shoreline and without the existence of bar/trough topography and it can model the effects of coastal structures such as groin, seawall and breakwaters. But in the former study it was difficult to model the permeable detached breakwaters installed in the breaker zone. For this reason, here modeling of the permeable breakwaters is carried out.

The Shizuoka coast has a steep slope near the shoreline and has no bar/trough, suggesting that the beach deformation is caused only by the action of the littoral transport even around the breakwaters. From this, the CLC model to predict the topographic changes due to the littoral transport may be applicable for reproducing the propagation phenomenon of the sand body. With the CLC model, it is possible to predict the three-dimensional topographic changes including the profile changes of the beach by assuming the depth change in littoral transport rate.

The fundamental equations of the model is shown below. If the breaker angle of waves is assumed to be sufficiently small using the Savage formula, Eq.(1) stands.

$$Q = F_0 \left(\tan \alpha_0 - \frac{\partial y_s}{\partial x} \right) \quad (1)$$

Where Q : littoral transport rate, F_0 : a coefficient of littoral transport rate dependent on wave energy flux, α_0 : breaker angle, x : longshore distance, and y_s : shoreline position measured normal to x axis. Eq.(1) is established under the assumption that the beach profile makes parallel movement in time and space.

Now a region is divided by n contour lines, and the littoral transport rate at each water depth corresponding to $k=1 \dots n$ is set to be q_k and if a similar relationship is assumed to be satisfied between the contour line position y_k and q_k in analogy with Eq. (1), the following equation is obtained.

$$q_k = F_{0k} \left(\tan \alpha_0 - \frac{\partial y_k}{\partial x} \right) \quad (2)$$

Where $F_{0k} = F_0 \cdot \mu_k$, $\sum \mu_k = 1$. Eq. (2) assumes that the littoral transport

rate in each layer is governed by the relationship between each contour line and incident wave direction at breaking point. In the CLC model, therefore, the contour lines do not need to make parallel movement like the shoreline change model, and this makes it possible for the littoral transport to pass the offshore zone of the detached breakwaters. This is because even if the shoreline is perpendicular to the direction of the breaking waves, they are obliquely incident to the offshore contour lines, which makes it possible for the littoral transport to move. From the above, the littoral transport rate in the shoreline change model and the littoral transport obtained by integrating littoral transport rate in each layer in the CLC model are not equal except in the case of parallel contour lines.

μ_k is a coefficient to give the littoral transport rate for each water depth and is calculated using Eq. (3) by giving the depth change of the littoral transport rate.

$$\mu_k = \int_{z_k}^{z_k+1} \xi(z) dz / \int_{-h_c}^{h_r} \xi(z) dz \quad (3)$$

where z is the vertical distance with reference to the still water level as the reference, h_r wave run-up height and h_c critical depth for sand movement. The continuity equation of the littoral transport is given as follows :

$$\frac{\partial q_k}{\partial x} + h_k \frac{\partial y_k}{\partial t} = 0 \quad ; \quad k = 1 \dots n \quad (4)$$

where h_k ($k = 1 \dots n$) is the characteristic height of beach changes as given by Eq.(5)

$$h_k = Z_k - Z_{k-1} \quad (5)$$

If the functional form of $\xi(z)$ is given, μ_k is calculated by Eq. (3), and so the contour line change for each depth is calculated by simultaneously solving Eqs.(2) and (4). The depth change in littoral transport rate may be assumed to have such a distribution that it varies between the wave run-up height(h_r) and critical depth for sand movement(h_c), so as to satisfy empirically the field and experimental data.

$$Z^* = Z / H_b \quad , \quad h_c^* = h_c / H_b \quad (6)$$

When $-h_c \leq z \leq h_r$,

$$\xi(Z^*) = 2 / h_c^{*3} (h_c^* / 2 - Z^*) (Z^* + h_c^*)^2 \quad (7)$$

When $z < -h_c$ and $z > h_r$,

$$\xi(Z^*) = 0 \quad (8)$$

In this model stabilization mechanism of beach profile is taken into account as described in detail in Uda-Kawano(1996). If the bottom slope between contours exceeds a critical slope on the foreshore the sea bottom, the local slope is reset by the critical slope and the position of the contour lines is adjusted so as to satisfy the eroded and accreted areas in the profile are equivalent.

In the calculation it is necessary to determine the wave height and breaker angle. There are various methods for predicting wave field. Here the numerical calculation method of the energy balance equation by Karlsson(1969) is used, including the refraction, shoaling and diffraction effects for irregular waves. Wave dissipation effect is calculated using the method of Takayama et al.(1991) and wave breaking was evaluated by Goda's breaker index. Since this study deals with the permeable detached breakwater, wave energy transport is set to be proportional to the square of the wave transmission coefficient of the detached breakwater.

(2) Modeling of Detached Breakwater

Without detached breakwaters, the depth change in littoral transport rate is given by Eqs.(7) and (8). Even when there are detached breakwaters, these equations are applicable if the breaking point is located shoreward of the detached breakwaters, but the dominant sand movement zone is narrowed because the breaker height is decreased. If, on the other hand, the breaking point is off the detached breakwaters, further modeling is required. This is because under such a condition that the breaking point moves off the detached breakwaters, and the cusped spit has been already developed behind the detached breakwaters. Since the detached breakwaters are permeable, the cusped spit does not become the tombolo to completely reach the detached breakwaters, leaving seawater surface between the cusped spit and the detached breakwaters. In this case, the cusped spit, like the groin, obstructs the longshore sand movement, but sand can still pass in the gap between the cusped spit and detached breakwaters.

Now, the depth change in littoral transport off the detached breakwaters is calculated by Eqs.(7) and (8) using the breaker height in the offshore zone, and the distribution of littoral transport rate shoreward of the detached breakwaters is calculated by multiplying the littoral transport rate given by these equations by the obstruction rate (ϵ) of the littoral transport. Since it may be considered that the obstruction rate of the littoral transport is proportional to the cross-sectional shape of the cusped spit, the following expression is assumed.

$$\epsilon = 1.0 - \left(\frac{y_1}{y_{d0}} \right)^n \quad (9)$$

Where the offshore distance from the seawall to the detached breakwaters is y_{d0} and the distance from the seawall to each contour line (including the contour lines of the land portion) is y_1 (see Fig. 8).

If the obstruction rate (ϵ) of the littoral transport is equal to 1.0, the littoral transport rate passing behind the detached breakwaters is 0, equivalent to that of the impermeable groin. At $\epsilon = 0.0$, the littoral transport rate passing behind the detached breakwaters is completely the same as that of the natural sandy beach.

Fig.8 Definition of obstruction rate of littoral transport due to detached breakwater.

(3) Application of Model

In Fig. 3, the extension of the area where the remarkable movement of the sand body was observed is about 4km from the Abe River mouth. As shown in Fig. 2, the Abe River mouth forms a river-mouth delta with a considerably protruded shoreline, and in this area the movement of

the sand body is not clear, whereas in the area with almost parallel contour lines on the northeast side of the mouth, remarkable movement is observed. From this reason, the parallel contour lines are simply assumed in this study. But the existence of the detached breakwaters is important for investigating the movement of the sand body, and so due attention must be paid to the modeling of the detached breakwaters. Fig. 9 shows the contour of initial topography. The slope near the shoreline is steep and the offshore is a flat bottom. Along this coastline, seawall and wave-dissipating armour units have been installed and the contour line cannot retreat from the initial position, and therefore the contour line shape given by the initial topography is regarded as the retreat limit. The validity of this assumption will be realized from the fact that in the profile change along the measuring line No. 62 as shown in Fig. 5, the shoreline advanced, but was again eroded and returned to the original concave profile vertically upward. In Fig. 9, 28 detached breakwaters of 80m long are installed at intervals of 40m. Actually the detached breakwaters on the Shizuoka coast have been installed over years, but here the detached breakwaters are installed at the same time to simplify the calculation.

For the numerical calculation, the finite difference method is used, and the area shown in Fig. 9 is meshed at intervals of 10m. The wave transmission coefficient of the detached breakwaters is set at 0.4.

As to the wave conditions, from the observation results of 1976 to 1991 at the Irozaki Observatory of the Meteorological Agency, 3.0m significant wave with the occurrence rate of 2% is selected as the high wave to give a dominant effect on the topographic change, and the period is set at 9s from the correlation of the wave height/period based on the same observation results. In the calculation, the continuous period of the above mentioned high wave is set at 27 days per year so that the incident energy of the waves per year is approximately equal to the measured value. As to the wave direction, SSE is set based on the predominant wave direction observed at the Mochimune Fishery Harbor located 2.5km southwest of the Abe River mouth. The time step for the topographic change calculation is 10min. As the topography changes, the wave field also changes. The repetitive time interval must be set in consideration of the situation of the topographic change. Here the calculation aims at the prediction of the long-term and relatively mild topographic changes, and so the repetitive time was set at 3 days, sufficiently shorter than the annual order (27 days).

Fig.9 Model beach for movement of sand body.

In the calculation, h_c and h_r were set to be 4.0m and 7.0m, and the contour line deformation is predicted at intervals of 1m.

The boundary condition of sediment supply greatly depends on the flood. Due to the flood records since 1980 at a location 4.7km upstream from the river mouth, floods of $1000\text{m}^3/\text{s}$ or larger in daily average of flood discharge occurred seven times between 1980 and 1993 as shown in Table 2, and especially

Table 2 Flood discharge of Abe River.

DATE	Daily average of flood discharge [m^3/s]	Maximum flood discharge [m^3/s]
Aug. 2, 1982	1,129	} 3,857
Aug. 3, 1982	1,466	
Sep. 12, 1982	1,723	
Aug. 2, 1983	1,731	2,981
July. 2, 1985	1,523	————
Aug. 10, 1990	1,005	————
Sep. 2, 1991	1,396	2,511

on September 12, 1982, the flood of the largest discharge $3857\text{m}^3/\text{s}$ occurred, but thereafter large-scale floods hardly occurred. From this, as a boundary condition, the constant sand supply of $10 \times 10^4\text{m}^3/\text{yr}$ was given as the total littoral transport from $x=4.0\text{km}$ and distributed to the littoral transport rate for each contour line by Eq.(7). On the other hand, the $x=0.0\text{km}$ was set as the passing boundary.

In Case 1, the power n ($n=1.0$) of Eq.(9) is assumed as the obstruction rate of the littoral transport behind the detached breakwaters. In this case, the propagation velocity of the sand body becomes excessive in comparison with the measured value, and in Case 2, the power $n=1.6$ was used.

In the calculation of the topographic changes around the detached breakwaters using the present model under the above mentioned conditions, the contour lines around the detached breakwaters tend to locally protrude with the elapse of time, and there are some cases in which the condition that the breaker angle of waves is sufficiently small is not satisfied even after the wave refraction. In such a case, in order to enhance the stability of the calculation, even if the reproduction of the local shape of the leading edge of the sand body is somewhat sacrificed, the upper limit is set to be 30° for the angle (θ) between the contour line and the wave crest line at the breaking point.

(4) Results of the Calculation

First the topographic change in Case 1 is shown in Fig. 10. Sand is supplied from $x=4.0\text{km}$ and from there sand passes through a group of the detached breakwaters located on the downcoast. Sand clearly moves as the sand body downdriftward, and sand supplied from the river mouth does not show rapid diffusion pattern. Although the mechanism of the sand transport is due to the littoral transport associated with wave breaking, the diffusion of sand is suppressed because of the existence of the detached breakwaters and instead of this, the sand body movement is observed. In this case, the propagation velocity of the leading edge of the sand body is $360\text{m}/\text{yr}$, 56% higher than observed $233\text{m}/\text{yr}$.

It is considered as the cause that the obstruction rate of the littoral transport behind the detached breakwaters is too small(that is, the passing rate of littoral transport is excessive), and in Case 2, therefore, the obstruction rate of the littoral transport behind the detached breakwaters was increased by setting the power n in Eq.(9) as $n = 1.6$. The results are shown in Fig. 11. The beach changes are similar to those of

Fig.10 Predicted beach changes (case ①).

Case 1, but the propagation velocity of the leading edge of the sand body is 230m/yr, in agreement with the 233m/yr of the observed result. Since the obstruction rate of the littoral transport shoreward of the detached breakwaters increased, +2m contour line further advanced.

In the topographic changes shown in Figs. 10 and 11, the profile changes on the updrift side of the littoral transport monotonously with time, and therefore it is sufficient to show the profile change at one section. Fig. 12 shows the profile changes of the section passing at the center of the detached breakwaters shown by A-A' in Fig. 11.

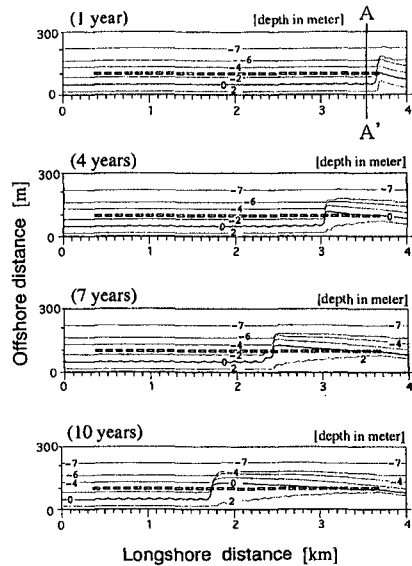

Fig.11 Predicted beach changes (case ②)

Fig.12 Predicted beach profile changes

It is clearly understood that in the beginning accretion concentrated shoreward of the detached breakwaters, and when the accretion in the zone between the detached breakwater and the seawall becomes full, the accretion advances off the detached breakwaters. As shown in the beach profile after 770 days, the cusped spit is sufficiently developed, but even in this stage, the littoral drift pass over the foreshore behind the detached breakwaters. The accretion off the detached breakwaters well corresponds to the observed results on the Shizuoka coast shown in Figs. 4 and 5.

IV. DISCUSSION

In this study, the propagation phenomenon of the sand body was discovered through the analysis of the field data of the Shizuoka coast and investigated its occurrence mechanism by means of the CLC model. Occurrence of the sand body can be summarized as follows. First, the littoral transport sand is supplied from the updrift side of the coast provided with detached breakwaters, and when it passes through a group of the detached breakwaters, sand accumulates behind each detached breakwater. When the sand volume accumulated behind the detached breakwater becomes sufficiently large, the sand passes off the detached breakwaters and moves downdriftward, and in the meantime, time lag occurs. As a result, when many detached breakwaters are installed, the propagation phenomenon such as the sand body occurs and looks as if the solitary wave propagates. In comparison with the already clarified propagation velocity of the erosion wave in the eroded area on the Shizuoka coast, the propagation velocity of the sand body is smaller (0.47 to 0.29 times), and this means that the detached breakwaters obstruct it. Presently, the Shimizu coast located northeast of the Shizuoka coast is exposed to severe erosion, but since the velocity of the movement of the sand supplied from the Abe River mouth to the Shimizu coast is greatly reduced, it will take about 30 years for the sand body to move 8.2km from the leading edge of the sand body of the Shizuoka coast to the remarkably eroded point of Shimizu coast (where detached breakwaters are installed as in the case of the Shizuoka coast). This indicates that the countermeasures against erosion on the Shimizu coast must be considered without expecting the sand supply from the upcoast over about 30 years in the future. During this period the sand supply it is required will be minimal, and so to carry out beach nourishment until the sediment reaches the Shimizu coast in order to maintain the sandy beach.

IV. CONCLUSIONS

The main conclusions of this study is summarized as follows.

(1) Observing the beach deformation in the period of 1983 to 1993 on the Shizuoka coast, it was found that the sediment aggregate (sand body) moved downdriftward while deforming. The propagation velocity of the center of gravity of the sand body was 235m/yr, 0.47 to 0.29 times the phase velocity of the erosion wave before the detached breakwaters were installed in the same area.

(2) In this sand body area, the sediment of $10 \times 10^4 \text{ m}^3/\text{yr}$ was accumulated from 1983 to 1993. The sediment supply source of the Shizuoka coast is the Abe River only, and since it is considered that the outflow of sediment beyond the leading edge of the sand body is very small, this accumulated volume is equal to the sand volume supplied from the Abe River into this area. This drift sand volume is about 77% of the estimated sand volume of $13 \times 10^4 \text{ m}^3/\text{yr}$ before the remarkable erosion occurred.

(3) The contour line change model so far limited to the utilization for predicting the topographic changes at the natural sandy beach and around the groin, seawall, and breakwater was extended so that it can be also utilized for predicting the topographic changes around the permeable detached breakwaters installed within the breaker zone. This makes it possible for the contour line change model, so far limited to the application to steep-sloped coasts, to be utilized for predicting

topographic changes around all the structures normally installed on coasts.

(4) By applying this model for reproducing the propagation phenomenon of the sand body observed at the Shizuoka coast, it is found to be attributable to the existence of the detached breakwaters installed along the coastline and the occurrence of floods of the Abe River, the sediment supply source to this coast. That is, when the drift sand flows from the upstream side, accretion develops first shoreward of the detached breakwaters, and when the shore-side area becomes full, accretion develops off detached breakwaters, making it difficult for the drift sand to pass through around the detached breakwaters, and this is the main factor for the propagation phenomenon of the sand body.

CHAPTER 12

Wave Groups in the Surf-Zone: Model & Experiments

J. Veeramony and I. A. Svendsen¹

Abstract: Experiments were conducted with regular wave groups incident on a plane beach to analyze the behaviour of the groups in the breaking region and in the surf-zone. The groups were composed of individual cnoidal waves. Emphasis was laid on obtaining measurements in the breaking region and in the surf-zone. It was found that the location of the start of breaking of the individual waves was affected by the groupiness of the waves. The structure of the groups were also seen to be different inside the surf-zone, which changes the forcing for the long wave. The long wave motion is forced at the group frequency and can be resolved into two components, an incident forced wave, which varies along the tank and a free standing wave. The standing wave is generated because the free outgoing long wave is reflected at the wavemaker, where there was no absorption of waves. A conservation model was developed using the kinematic conservation equation and the energy conservation equation. The dispersion relation was used to close the system of equations. Cnoidal theory was used in the shoaling region and bore theory was used in the surf-zone. It was found that the model accurately predicts the group structure and the individual wave location in the shoaling region, but does not do well in the surf-zone.

1. Introduction.

Wave groups have been long recognized as one of the primary driving mechanisms for long wave generation (Kostense, 1984; Watson et al. 1994; Longuet-Higgins & Stewart, 1962; Symonds et al, 1982; Schäffer & Svendsen, 1988; Schäffer, 1993; List 1991). However, the lack of comprehensive data in the breaking region and in the surf-zone has precluded the understanding of how the groups develop in that region.

The first part of this study reports experimental results for the development of wave groups in the shoaling region and in the inner surf-zone. The experiments also provide information about the variation of the break point of the individual

¹Center for Applied Coastal Research, Ocean Engineering Lab, University of Delaware, Newark, DE 19716, USA. Correspondence e-mail: jay@coastal.udel.edu

waves in the group. The long wave motion will also be analyzed from the measurements (for further details on the experimental results, see also Svendsen and Veeramony, 1995).

In the second part, we will focus on efforts to model the development of the wave groups on the basis of two conservation equations, namely kinematic conservation and energy conservation. The results of the model will be compared to the measurements described in the experimental part of the study.

2. Experimental set-up.

The experiments were conducted in a wave flume (figure 1) which is 30 m long, 0.75 m wide and 1.0 m deep. The water depth for the experiments was maintained at 0.4 m. The wave flume has a 1:35 beach, the toe of which starts at 11.85 m from the mean position of the piston type wavemaker.

Figure 1: Definition sketch of the experimental setup.

The wave groups were composed of a series of five cnoidal waves, each of which was generated according to the method given by Goring (1978). The individual cnoidal waves were joined at the mean water line to form a group (figure 2). The height of the waves in the group was specified as

$$H_i = H_m \left(1 + \frac{G}{2} \sin \frac{2\pi i}{n} \right); \quad i = 1, \dots, 5 \quad (1)$$

where H_i represents the height of the i^{th} wave in the group, H_m the mean wave height, and $G = \Delta H / H_m$ is the variation of the wave height in the group.

In all, seven experiments were conducted. In this paper, discussion will be limited to three of those experiments, the parameters of which are shown in table 1.

Each experiment was repeated many times with different positions of the wave gages. It is therefore important to verify the repeatability of the experiments.

Figure 3 shows the measured wave groups at three different locations for experiment W06. At the reference gage [Figure 3(a)], the variation from wave group to group is seen to be negligible. Inside the breaking region [Figure 3(b)] and inside the surf-zone [Figure 3(c)], there is seen to be some variability which is expected. To an extent, this is caused by the variations in the horizontal position of the waves in the group.

Figure 2: Schematic of the wave group generated at the wavemaker.

Experiment number	H_m/h_0	$T_m\sqrt{g/h_0}$	Groupiness factor G
W01	0.167	7.43	$\pm 10\%$
W03	0.237	12.38	$\pm 20\%$
W06	0.25	7.92	$\pm 50\%$

Table 1: Wave parameters at the wavemaker. H_m is the mean height of the short waves, T_m is the period of the short waves and h_0 is the water depth at the wavemaker.

To eliminate the effect of initial disturbances and surges in the tank, the data collection for each run was not started until 30 minutes after the start of wave generation.

3. Wave breaking.

One of the important questions is how the wave groupiness affects the individual wave breaking. There is no one method for the prediction of wave height or water depth at breaking, even for monochromatic waves. All current methods for predicting wave breaking are based on empirical formulations extracted from existing data. However, it is known that both the wave height and the wave height to water depth ratio have a maximum at or near the breaking point. In this analysis, we use the maximum of the wave height to water depth ratio as the definition of the break point, which can be expressed mathematically as

$$\left(\frac{H}{h}\right)_b \equiv \left(\frac{H}{h}\right)_{max}. \quad (2)$$

Figure 3: The variability of the wave profiles at three different positions in the tank: (a), at the reference gage, $x = 4.0$ m; (b), inside breaking region, $x = 20.9$ m; and (c), inside surf-zone, at $x = 23.1$ m, for experiment W06. Breaking occurs between $x = 19.2$ m and $x = 21.4$ m.

The wave heights, wave periods and phase speed obtained from the data, using the zero-upcrossing analysis was used to find other parameters such as the wave length and the slope parameter $S \equiv h_x L/h$, defined as the change in water depth over one wavelength L and h_x is the bottom slope.

The experimental data is compared with similar results obtained for regular waves by Svendsen & Hansen (1976). They found that the H/h ratio at breaking was very well predicted by the local value of S . Svendsen (1987) suggested the following empirical formula as a fit to the experimental data:

$$\left(\frac{H}{h}\right)_b = 1.9 \left(\frac{S_b}{1 - 2S_b}\right)^{\frac{1}{2}} \quad (3)$$

where the subscript b denotes the value at breaking. Hansen (1990) gives a simpler approximation to the data for the range $0.25 < S < 1$ as

$$\left(\frac{H}{h}\right)_b = 1.05 S^{0.20} \quad (4)$$

Figure 4(a) shows the result for W01, which has a groupiness of $\pm 10\%$. It is seen that, for this case, the two empirical formulae predict the wave breaking height very accurately. Note that wave 3, which is the highest wave at the wavemaker, has the lowest ratio of $(H/h)_b$, and wave 1, the smallest wave at the wavemaker has the highest ratio of $(H/h)_b$.

Figure 4(b) shows the results for W03 (groupiness of $\pm 20\%$) and figure 4(c) shows the results for W06 (groupiness of $\pm 50\%$). The empirical formulae again

Figure 4: Variation of break point for W01, W03 and W06. The curves shown are from Svendsen, 1987 (—) and Hansen, 1990 (---). The points shown are for the individual waves in the group, wave 1 (*), wave 2 (o), wave 3 (●), wave 4 (x) and wave 5 (+).

predict the breaking height accurately although the spread in the breaking region is larger. The two smaller waves at the wavemaker have the largest $(H/h)_b$ ratio.

The variation in breaker height combined with variations in the position of the breaking determines the height of each individual wave in the surf-zone. The resulting surf-zone wave motion generally shows a shift in groupiness as demonstrated below.

4. Structure of the wave groups.

This variation in the start of breaking implies that the structure of the groups change as the waves propagate shoreward. To illustrate this, we look at the phase averaged wave groups at different locations in the tank, from the shoaling region through to the inner surf-zone.

First, we look at the shoaling region (figure 5). The vertical axis shows the x -location and the horizontal axis shows the time. The solid line is the phase-averaged η , the filled circles are the zero-upcrossing locations of the individual waves and the broken line show the location of the waves if they were traveling at speed \sqrt{gh} .

Wave 3 is the highest wave at the toe of the beach and the form of the group is essentially unchanged in the shoaling region. The individual waves are seen to travel slightly slower than the shallow water wave speed (\sqrt{gh}).

Figure 6 shows the groups around the breaking region. Up until breaking, wave 3 is the highest wave in the group. As the individual waves start to break, they lose energy and the wave height decreases rapidly. The highest wave, which

Figure 5: Development of the form of the wave groups for W06 in the shoaling region. $x = 11.85 \text{ m}$ is at the toe of the beach.

breaks at the largest depth (although, as seen before, the ratio H/h is not the largest), loses energy rapidly enough that, at the end of the breaking region, it is no longer the largest wave in the group. Wave 2 is seen to be the largest wave in the group at that location. Also, the wave speed after breaking is seen to be larger than \sqrt{gh} , which is expected.

Figure 7 shows the development of the structure in the inner surf-zone. The waves groups have evolved such that the smallest wave at the wavemaker is the largest wave here and the wave height is the smallest for wave 4. Note also that as the waves approach the shoreline, wave 4 is captured by wave 5 around $x = 25 \text{ m}$. For further details, see Svendsen & Veeramony (1995).

5. Analysis of the long wave motion.

The wavemaker only generates the amplitude modulated short waves. Therefore, the set-down wave associated with the wave groups is generated as the groups propagate shoreward, taking energy out of the short wave motion. No

Figure 6: Development of the form of the wave groups for W06 in the breaking region. Breaking starts between $x = 19.20$ m and $x = 21.60$ m.

attempt was made to verify whether the set-down wave has reached an equilibrium value before the group reaches the toe of the beach. On the slope, the transformation of the groups represents a change in the forcing, which implies that the long wave motion changes continuously towards the shoreline.

It was clear, from watching the long period motion of the shoreline, that, apart from viscous effects, the long wave motion was fully reflected from the shore and essentially, sent back out as a free wave. This wave is re-reflected from the wavemaker, and over time, this process creates a standing long wave component. Hence, the total long wave motion in the tank can be analyzed as a forced wave propagating shoreward and a standing free long wave, both at the group frequency. At each gage, therefore, the long wave motion can be represented by an expression of two such components

$$\eta_l(x_j, t) = a(x_j)e^{i(kx_j - \omega t)} + bJ_0\left(\frac{2\omega}{\sqrt{gh}}(l - x_j)\right)e^{-i\omega t} \quad (5)$$

Figure 7: Wave profile development for experiment W06 in the region near the shore-line where wave 4 in the group ceases to exist. (Vertical scale changed from Fig. 5 & Fig. 6).

where $a(x)$ is the amplitude of the forced wave which includes both the shoaling and the variation caused by the short wave forcing and b is the amplitude of the standing wave component.

The coefficients a and b are determined from the data. The results of this analysis is shown in figure 8. Figure 8(a) shows the total long wave water surface elevation (\bullet), η , at a time when η due to the standing wave is zero (which is essentially the forced wave motion) and also the total long wave water surface elevation when η due to the standing wave is maximum (\circ). Figure 8(b) shows the amplitude variation of the forced wave, obtained from the data shown in (a). It is seen that, after an initial increase, the energy in the forced wave decreases steadily up to the breaking region ($x = 19.2 \text{ m}$ to $x = 21.6 \text{ m}$). After breaking, energy is fed back into the forced wave which reaches a constant value inside the surf-zone. Figure 8(c) shows the standing wave water surface elevation, calculated from the data (\bullet) and from the linear representation given in equation (5) (—). It can be seen that the standing wave is quite well represented by the zeroth-order

bessel function.

Figure 8: Long wave motion in the tank for W06: (a) water surface elevation of the propagating long wave at time $t = t_0$, (b) amplitude of the propagating long wave as a function of the distance from the wave maker, (c) the standing long wave in the tank at $t = t_0 + T_g/4$ ('•' is data and 'o' is the least-squares fit).

6. Modelling of short wave properties.

In this section, the short wave motion, described in the previous section, is modelled using the kinematic conservation equation and the energy conservation equation. The dispersion relation is used to close the system. Since cnoidal waves are generated by the wavemaker, the same theory is used in the modelling to evaluate the necessary coefficients.

We limit our consideration to a 1-D wave motion and the basic assumption made about the waves is that they are slowly varying in space and time. The effect of the horizontal particle velocity, u_l , of the long wave is assumed equivalent to that of a time varying current.

For such a case, the kinematic conservation equation for the short wave motion can be expressed as

$$\frac{\partial k_s}{\partial t} + \frac{\partial (c_s + u_l) k_s}{\partial x} = 0 \tag{6}$$

where k_s is the wavenumber of the short waves, c_s , the short wave celerity and u_l is the orbital velocity under the long wave. The equation for the evolution of the wave averaged short wave energy density is given by (see Phillips, 1980)

$$\frac{\partial \mathcal{E}}{\partial t} + \frac{\partial [\mathcal{E} (u_l + c_g)]}{\partial x} + S_{xx} \frac{\partial u_l}{\partial x} = D \tag{7}$$

where c_g is the group velocity for the short wave motion, S_{xx} is the radiation stress and \mathcal{D} is the energy dissipation.

The dispersion relation is given by cnoidal theory in the shoaling region and bore theory in the surf-zone as

$$\frac{c_s^2}{gh} = \begin{cases} 1 + \frac{H}{mh} \left(2 - m - 3 \frac{E(m)}{K(m)} \right) & \text{for } h > h_b \\ 1 + \left(-\frac{3}{2} + 3\delta \right) \frac{H}{h} + \left(\frac{1}{2} - 3\delta + 3\delta^2 \right) \left(\frac{H}{h} \right)^2 \\ + \left(\frac{1}{2}\delta - \frac{3}{2}\delta^2 + \delta^3 \right) \left(\frac{H}{h} \right)^3 & \text{for } h \leq h_b \end{cases} \quad (8)$$

where m is the elliptic parameter, $K(m)$ is the elliptic integral of the first kind, $E(m)$ is the elliptic integral of the second kind, h_b is the depth at breaking and $\delta \equiv \eta_c/H$ with η_c in the surf-zone given by (Hansen, 1990)

$$\delta = 0.5 + [\delta_b - 0.5] \left(\frac{h}{h_b} \right)^2 \quad (9)$$

The short wave averaged energy can be written as

$$\mathcal{E}(x, t) = \rho g H^2 B \quad (10)$$

where B is the shape parameter, which can be expressed outside the surf-zone using cnoidal theory. Inside the surf-zone, the empirical formula suggested by (Svendsen, 1984) is used

$$B = \begin{cases} \frac{1}{m^2} \left[\frac{1}{3} \left(3m^2 - 5m + 2 + (4m - 2) \frac{E}{K} \right) - \left(1 - m - \frac{E}{K} \right)^2 \right] & \text{for } h > h_b \\ B_0(B_{0b}, h_x, \frac{H_0}{L_0}) + \frac{1}{2} \frac{A}{H^2} \frac{c_s}{gT} & \text{for } h \leq h_b \end{cases} \quad (11)$$

where A is the area of the roller, T is the wave period and Hansen's (1990) expression is used for B_0 .

For simplicity, linear theory is used for S_{xx} . The energy dissipation is assumed to be negligible outside the surf-zone and inside the surf-zone can be calculated, using bore theory, as (Svendsen, 1984)

$$\mathcal{D} = -\frac{\rho g H^3}{4hT} \frac{1}{\left(1 + \delta \frac{H}{h} \right) \left(1 + \frac{H}{h} (\delta - 1) \right)} \quad (12)$$

The equations are solved in conservation form using the MacCormack predictor-corrector scheme. The criteria for breaking used in the model is the one given by equation (3). At breaking, a matching condition is required for each of the governing equations. Continuity in frequency and energy flux are used as matching conditions at the break point.

Thus, we are also assuming that the transition from a regular wave to a bore takes place over an infinitesimally small region. Since the break point varies in

time, the matching conditions have to be evaluated at each time step. The model domain extends from the toe of the beach to the location where $\min(h + a_l) = 0$, where a_l is the amplitude of the long wave. The wave envelope, which is the input to the model, is obtained at the toe of the beach using the Hilbert Transform (Melville, 1983). The zero-upcrossing points at the toe of the beach are also input to the model.

7. Comparison between model and data.

Figures 9-11 show the results of the comparison between the model results and the experimental data from W06. In each of these figures, the abscissa shows the time and the ordinate shows the location of the measurement, — — is the measured η , ——— is the predicted envelope of $H(x, t)$, - - - - is the predicted speed of the individual waves and \bullet is the upcrossing point of the individual waves.

Figure 9: Comparison between model and W06 in the shoaling region showing η (— —), zero upcrossing point (\bullet), wave location from model (- - - -) and the envelope from model (———).

Figure 10: Comparison between model and W06 shoreward from breaking, showing η (---), zero upcrossing point (\bullet), wave location from model (-·-·-) and the envelope from model (—). Breaking region from data is between $x = 19.10\text{ m}$ and $x = 21.40\text{ m}$ and in model is between $x = 19.48\text{ m}$ and $x = 22.30\text{ m}$.

In this experiment, the groupiness factor at the wavemaker was $\pm 50\%$, the short wave period was 1.6 s and the mean wave height at the wavemaker was 0.1 m . In the shoaling region (figure 9), the wave envelope and the wave speed are predicted extremely accurately by the model.

The results for the breaking region are shown in figure 10. The prediction of the wave envelope is poor in the breaking region, although the prediction seems to improve as the shoreline is approached. It is seen from figure 10 and 11 that in spite of the fact that the wave speed in the model is represented by the bore velocity, the highly nonlinear kinematics, in particular in the inner parts of the surf-zone, is poorly predicted. This may in part be due to errors in predicting the precise breaking region (model predicts breaking between $x = 19.48\text{ m}$ and $x = 22.3\text{ m}$ whereas the analysis of the data gives the breaking region to be between $x = 19.2\text{ m}$ and $x = 21.4\text{ m}$), in part due to the fact that the surf-zone is very wide and the waves near the shoreline are small.

Figure 11: Comparison between model and W06 in the inner surf-zone, showing η (— — —), zero upcrossing point (\bullet), wave location from model (---) and the envelope from model (——).

8. Conclusions.

Experiments were conducted to analyze the behaviour of wave groups in the breaking region and in the surf-zone.

It was found that the location of the individual wave break point is affected by the groupiness of the waves. The altered structure of breaking causes the group structure to be completely different inside the surf-zone. The long wave motion is mainly forced at the group frequency. These long waves can be resolved into a forced wave travelling shoreward and a free standing long wave. The amplitude of the incident forced wave varies along the tank, whereas the standing wave is shown largely to agree with a linear representation of a free standing wave system.

The model is seen to predict the behaviour of the group very well until the breaking region. Inside the surf-zone, the breaking waves interact strongly with each other and with the long wave motion, which the model predicts poorly.

CHAPTER 13

SIMULATION OF PROPAGATING NONLINEAR WAVE GROUPS

Paul de Haas^{1, 2}, Maarten Dingemans¹ and Gert Klopman¹

Abstract

Propagating nonlinear waves can be computed with a time-domain numerical method based on a boundary element method. For the simulation of propagating wave groups a domain decomposition method is used to increase the efficiency of the model and to enable simulation over many wave periods. In the computations described in this paper several nonlinear formulations for an initial wave group signal are used to investigate their ability to describe a wave group of fixed form. A difficulty consists of the imposition of the boundary conditions at the unknown free-surface elevation. The nonlinear contributions to the first-order signal are related to the generation of free waves as computed by the model.

1 Introduction

Long-wave motion is usually split up between a bound part which is due to nonlinear difference interactions between short sea and swell waves and a free part which are waves that move with their own celerity according to an appropriate dispersion relation. It is known that when waves travel over an uneven bottom, energy in the bound component of the long waves is transformed to the free components.

In this paper we present a two-dimensional (2DV) time-domain numerical method, based on a boundary element method, which computes the propagation of waves with the exact nonlinear boundary conditions over an arbitrary bottom geometry. It is therefore able to simulate the generation of free long waves due to an uneven bottom. A model problem used by Dingemans et al. [3], is used as reference for the computations presented here. Different formulations of the nonlinear wavegroup signal are tested for their suitability to describe a wave group of fixed form over a horizontal bottom. Such a signal can then be used

¹Delft Hydraulics, P.O. Box 177, 2600 MH Delft, The Netherlands

²University of Twente, Faculty of Applied Mathematics, P.O. Box 217, 7500 AE Enschede, The Netherlands

as an initial signal for problems with a bottom topography in order to study the generation of free long-wave components.

Because the study of such problems requires large computational effort, the use of efficient numerical techniques is imperative. Here we will present a domain decomposition method which reduces the computational costs of the boundary element method considerably.

This paper is organized as follows. First the numerical method is described in Section 2. In Section 3 the domain decomposition method is described and its efficiency is discussed. In Section 4 some nonlinear formulations of a wave group signal are discussed and used as initial signal for the computations. Finally some conclusions will be stated in Section 5.

2 Numerical method

In the mathematical model for nonlinear water waves considered here, the motion of the water is described by the usual potential-flow equations for inviscid irrotational fluid motion with a free surface on water of varying depth. It is described by the field equation for the velocity potential ϕ (Laplace's equation)

$$\Delta\phi = 0, \quad (1)$$

and the boundary conditions on the free surface $\partial\Omega_{FS}$

$$\left. \begin{aligned} \frac{D\phi}{Dt} &= \frac{1}{2}(\nabla\phi)^2 - gz - \frac{p}{\rho} \\ \frac{D\mathbf{x}}{Dt} \cdot \mathbf{n} &= \frac{\partial\phi}{\partial n} \end{aligned} \right\} \mathbf{x} \in \partial\Omega_{FS} \quad (2)$$

and on the bottom $\partial\Omega_B$

$$\frac{\partial\phi}{\partial n} = 0, \quad \mathbf{x} \in \partial\Omega_B. \quad (3)$$

Appropriate in- and outflow boundary conditions are formulated on the lateral boundaries.

The numerical method consists of a time marching scheme for the evolution of the free surface and its boundary conditions. At every time-step, Laplace's equation for the velocity potential has to be solved. This is done with a boundary element method (BEM). In the BEM, Laplace's equation is solved by writing it as a set of integral equations over the boundary (one equation for every node). These integral equations are first discretized. Then, by using the boundary conditions a system of linear equations is built and subsequently solved. Insertion into equations (2) of the solution obtained in this way, provides the time derivatives which are needed for the time marching scheme.

Boundary element methods are very suitable for solving Laplace's equation on such domains because they only require a discretization of the boundary of the domain. Compared with field discretization methods, the advantages of a BEM are a much smaller amount of grid points and a natural description of the evolution of the free surface. See [1] for a description of a three-dimensional

method. The computations described here were performed with a code developed for two-dimensional simulations based on the work of these authors.

For the computation of large-scale wave problems the solution algorithm for Laplace's equation is the bottleneck. It involves both the discretization of the boundary integral equations and the solution of the resulting system of linear equations. The time marching scheme requires a minor part of the total CPU-time. Furthermore, memory requirements for solving Laplace's equation depend quadratically on the number of grid points. These problems can be reduced considerably by the use of a domain decomposition method.

3 Domain decomposition

3.1 Description

The domain decomposition method described here consists of a division of the computational domain into subdomains (see Figure 1) and an iterative procedure which generates a sequence of solutions on the subdomains that converges towards the solution on the original domain.

Figure 1: Decomposed domain

Every step of the iterative procedure consists of first solving Laplace's equation for the potential ϕ on the separate subdomains simultaneously and secondly formulating new boundary conditions on the subdomain interfaces. In the latter part the subdomain problems are coupled.

There are many possibilities in the way information can be exchanged between the subdomains. We have chosen here to use the so-called DD/NN-scheme. Every odd step of the iterative procedure Dirichlet conditions are imposed on all interfaces. Neumann conditions are imposed at all even steps. These steps are illustrated in Figure 2 for the first two steps of a two-subdomain problem.

This scheme is also known as a Neumann-Neumann preconditioner in the context of domain decomposition methods for field discretization techniques. See e.g. [4]. In the field of time-domain BEM's a similar technique was used by Wang

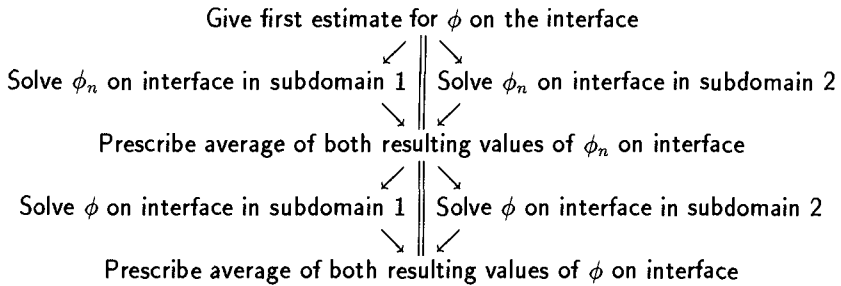

Figure 2: Schematic representation of the DD/NN-scheme

et al. [8]. In their work interfaces are used to formulate a block-structured matrix which is then solved iteratively. For a general impression of work being done in the field of domain decomposition the reader can consult [7].

3.2 Convergence characteristics

The performance of the domain decomposition method is determined here by the convergence of the iterative process. The convergence of the process can be judged by considering the jump across the interface between the solutions on both sides of each interface. The convergence on different interfaces depends on the geometrical form of the subdomains. This aspect has been subject of previous investigations [2] and the main conclusions given there are:

- The convergence of the iterative procedure deteriorates as the length-to-height ratio of the subdomains decreases and if there is more asymmetry near the interfaces due to a disturbed free surface or an uneven bottom.
- Therefore, given a fixed length of the computational domain, the convergence of the iterative procedure deteriorates as the number of subdomains N increases.
- Given a fixed length-to-height ratio of the subdomains, the convergence rate does not change as the number of subdomains increases, in the case of rectangular subdomains of equal size. In applications with a disturbed free surface we have seen that convergence is determined by the interface with the worst convergence. The number of iterations has an upper bound which is independent of N .

3.3 Efficiency

The efficiency of the domain decomposition technique is of course related to the convergence of the iterative method. It can be considered for the two cases mentioned above.

- If for a computational domain with a fixed length the number of subdomains is increased, on the one hand the number of required iterations will increase. On the other hand, the CPU-time to solve Laplace's equation per subdomain decreases, since the subdomains becomes smaller. It appears that there is a certain optimal number of subdomains (with respect to CPU-time) to solve a given water-wave problem. See [2].
- If subdomains are used with a fixed length-to-height ratio, the number of iterations and therefore the computational costs per subdomain, have an upper bound independent of the number of subdomains. This implies that the computational cost per time step depend at most linearly on the size of the computational domain.

In the application of the domain decomposition technique to the time-domain numerical method described here, it is possible to subdivide the domain differently every time step, adjusted to the presence of a wave signal. We have chosen to use a fixed initial subdivision of the computational domain with subdomains of equal size so that no reorganization of data over the subdomains is necessary and the number of grid points in all subdomains is the same.

4 Simulation of some nonlinear wave group signals

4.1 Introduction

In Liu and Dingemans [5] and Dingemans et al. [3] a mathematical model is described for the wave envelope A of a carrier wave signal. In this model third-order equations are derived with a multiple-scales technique for a first-order carrier wave signal given in complex notation by

$$\eta_1(x, t) = \frac{1}{2}(Ae^{i\chi_0} + *) \quad (4)$$

and

$$\phi_1(x, z, t) = \frac{1}{2} \left(-\frac{g \cosh(k_0(z+h))}{\omega \cosh(k_0 h)} i A e^{i\chi_0} + * \right) \quad (5)$$

with $\chi_0 = k_0 x - \omega_0 t$, being the phase function of the carrier wave. The $*$ -symbol denotes the complex conjugate of the preceding term.

From solvability conditions of the third order equations, evolution equations are derived for the envelope A . For a horizontal bottom these equations simplify to a nonlinear Schrödinger (NLS) equation. See also Mei [6]. This equation admits several steady solutions for A which can be used to create an initial signal for a simulation.

In our computations we have chosen a soliton-solution described by the envelope function A as:

$$A(x, t) = a \operatorname{sech} \left(\sqrt{\frac{-\nu_1}{\partial C_g / \partial k_0}} a \cdot (x - C_g t) \right) \exp \left\{ -i \frac{\nu_1 a^2}{2} t \right\} \quad (6)$$

in which a and C_g are the amplitude and the group velocity of the carrier wave. ν_1 is a long expression in terms of characteristic quantities of the carrier wave and is given in Dingemans et al. [3], p. 364. The parameters have been evaluated for $a = 1$ m, $\omega_0 = 2\pi/6$ rad/s and $h = 12$ m. The corresponding wave length L_0 and group velocity C_g according to linear theory are equal to 50.73 m and 5.52 m/s respectively. Based on an elevation $1 \cdot 10^{-3}$ times the maximum elevation, the wave group has a length of approximately 1850 m.

In the computations a known elevation $\eta(x, t)$ is required as the initial disturbance of the free surface. The panel method furthermore requires an initial value of the potential ϕ on the free surface which imposes the initial velocity field on the free surface. In the third-order model it is, just as η , given in terms of the third-order perturbation serie. Because of the large and complex expressions associated with the series, we have tried a number of alternatives and have studied the degree in which they describe a signal that propagates undisturbed over a horizontal bottom. These alternatives will be described next.

4.2 Formulations for free-surface elevation and potential

A difficulty of simulating nonlinear wave signals consists of the imposition of the boundary conditions at the unknown free-surface elevation. In perturbations techniques, one usually expands free-surface elevation and potential around the still-water level $z = 0$ and the potential is evaluated at the still-water level. In the numerical approach, the grid points are located at $z = \eta$ so that evaluations there deviate from those of the perturbation approach. A Taylor expansion for ϕ can be used to account for the location of the free surface at $z = \eta$:

$$\phi(x, z, t)|_{z=\eta} = \phi(x, 0, t) + \eta(x, t) \frac{\partial \phi}{\partial z}(x, 0, t) + O(\eta^2). \quad (7)$$

Besides the first order expressions given in equations (4) and (5) we have used a Stokes' second-order contribution given by

$$\eta_2(x, t) = \frac{1}{2} \left(\frac{1}{4} \frac{k_0 \cosh(k_0 h)}{\sinh^3(k_0 h)} [2 + \cosh(2k_0 h)] A^2 e^{2ix_0} + * \right) \quad (8)$$

and

$$\phi_2(x, z, t) = \frac{1}{2} \left(\frac{3 \omega \cosh(2k_0(z + h))}{8 \sinh^4(k_0 h)} i A^2 e^{2ix_0} + * \right). \quad (9)$$

and a bound long-wave contribution based on the linearized depth-integrated mean-flow equations. See [3]. The free-surface elevation ζ and potential ϕ_{bl} of this wave are given by

$$\zeta(x, t) = \frac{2c_g/c - \frac{1}{2}}{2(c_g^2 - gh)} g \left(|A(-c_g t)|^2 - \langle |A|^2 \rangle \right) \quad (10)$$

and

$$\phi_{bl}(x, t) = \int_{-\infty}^x \frac{\partial \phi}{\partial x'} dx' = \int_{-\infty}^x u dx' = \int_{-\infty}^x \frac{c_g}{h} \zeta dx' \quad (11)$$

$$= \frac{2c_g/c - \frac{1}{2} c_g g}{2(c_g^2 - gh)} \frac{c_g g}{h} \int_{-\infty}^x (|A|^2 - \langle |A|^2 \rangle) dx'. \quad (12)$$

$\langle |A|^2 \rangle$ denotes the mean value of $|A|^2$ over a time interval much longer than the wave group period. For the soliton solution (6), $\langle |A|^2 \rangle = 0$.

4.3 Results

For our computations we have selected a number of formulations which are tabulated in Table 1. These initial signals were used in simulations over 60 wave

Table 1: Initial signal for the various computations

	η	ϕ	using formula (7)
run 1	η_1	ϕ_1	no, ϕ evaluated at $z = \eta$
run 2	η_1	ϕ_1	no, ϕ evaluated at $z = 0$
run 3	η_1	ϕ_1	yes
run 4	$\eta_1 + \eta_2$	$\phi_1 + \phi_2$	no, ϕ evaluated at $z = 0$
run 5	$\eta_1 + \zeta$	$\phi_1 + \phi_{bl}$	no, ϕ evaluated at $z = 0$
run 6	$\eta_1 + \eta_2 + \zeta$	$\phi_1 + \phi_2 + \phi_{bl}$	no, ϕ evaluated at $z = 0$

periods in a computational domain with length 5000 m. Free-surface collocation points were distributed over $z = \eta(x)$ with equal horizontal distances. The resolution of the computational configuration was taken the same for all simulations and is given by $\Delta x = 2.5 \text{ m} \approx L_0/20 \text{ m}$ on the free surface and $\Delta t = T_0/20 \text{ s}$.

The results are illustrated best by showing the free-surface elevation at $t = 45T$ for the different computations. Run 1 has been shown separately in a larger plot in order to show the details better. The result of run 3 is similar to that of run 1, because the vertical profile of ϕ_1 is almost linear in the range $-\eta \leq z \leq \eta$ and differences between the evaluation of ϕ_1 at $z = \eta$ (run 1) and the use of equation (7) (run 3) are hardly discernible. Therefore results of run 3 are not shown here.

A typical feature common to all computations is the generation of small left-going signals. In Figure 3 wave groups with carrier waves with a wave period of approximately 6.0 s (around $x = 200 \text{ m}$) and 3.8 s (around $x = 700 \text{ m}$) can be seen. Their group velocities are equal to 4.4 and 3.1 m/s respectively. Not visible in Figures 3 and 4 is a small left-going *long* wave ($c = 11.1 \text{ m/s}$) which at this point of the computation has already left the computational domain. The left-going signal is the smallest in runs 2 and 5.

There is also a right-going free-long wave (around $x = 4400 \text{ m}$) in all computations. The computed phase velocity of this wave equals 11.1 m/s where as \sqrt{gh}

Figure 3: Surface elevation at $t = 45T$ for run 1

equals 10.85 m/s here. The computations with a contribution of ζ and ϕ_{bl} show a reduction of the amplitude of this wave from 6.0 to 2.5 cm.

At the back of the wave group a smaller wave group evolves consisting of carrier waves with wave period approximately 4.2 s. Its amplitude is smallest in run 4 and 6 which contain the second-order contribution η_2 and ϕ_2 .

In summary it can be said that the differences between the computations presented here can be explained satisfactory by relating them to the contributions to the initial wave signal. However, the second-order contributions in runs 4, 5 and 6 do not prevent the generation of free waves nor do they prevent the generation of a left-going wave signal. At this point it is not clear whether this is due to the imposition of the boundary condition at the actual free surface or to the restriction to only second-order contributions. The use of formula (7) on the second-order part of the wave signal and the use of more higher-order contributions may improve the stationary character of the signal. Nevertheless it is possible to investigate the influence of bottom topography on the generation of free-long waves, but one has to take into account the generation of the spurious waves shown in these computations.

A closer study should also include the effect of the dispersive and dissipative

Figure 4: Surface elevation at $t = 45T$ for: run 2 (upper left), run 4 (upper right), run 5 (down left) and run 6 (down right)

character of the numerical scheme. Although very small for the resolution used, they may become relatively important when smaller contributions to the wave signal are considered.

The simulations over 60 wave periods took about 1.5 hours on a Cray C98 computer at a computational speed of about 125 Mflop/s. The required memory was approximately 56 MByte. The use of a single domain for this simulation would have exceeded the capacity of the Cray computer. Moreover it is questionable whether the system of linear equations in this case is numerically solvable within the required accuracy.

With an eye to larger problems involving a bottom topography it is remarked again that the computational costs per time step depend at most linearly with the size of the computational domain. For comparison with the results of Dingemans et al. [3] on a domain with a length of 15 km, this implies three times as much computational costs per time step. However, a longer simulation time is required for this domain. The computational costs per simulation will then be an additional factor larger than those presented in this paper. Studies including bottom topography will be continued in due time.

5 Conclusions

By using a domain decomposition method in a numerical method for nonlinear waves, it is possible to simulate the propagation of wave groups over large simulation times. For the formulation of a stationary propagating wave group it is important to include higher-order contributions. The release of free waves from the wave group can be explained from second-order contributions to the first-order signal. The question remains however, how to impose an initial signal to obtain a propagating wave group of fixed form over a horizontal bottom.

CHAPTER 14

CROSS-SHORE MOMENTUM FLUX DUE TO SHEAR INSTABILITIES

Ad Reniers¹ and Jurjen A. Battjes

Abstract

Results obtained from a laboratory experiment on shear instabilities in wave-driven longshore currents were used to analyse the cross-shore structure of the shear instability induced momentum flux. As the shear instabilities grew in the downstream direction, a significant cross-shore momentum flux occurred. However, the expected changes in the mean longshore current velocity profile were not observed.

Introduction

In spring 1994 an experiment on the generation of shear instabilities in wave-driven longshore currents was performed in a large wave basin. Shear instabilities were found to occur when using obliquely incident waves to create an alongshore uniform current over a barred beach (Reniers et al., 1994).

Shear instabilities are assumed to cause a cross-shore redistribution of mass and momentum in the surfzone. The redistribution depends on the cross-shore structure of the shear instabilities and the phase coupling between the horizontal velocity components. Numerical studies (Dodd and Thornton, 1990, 1993, Putrevu and Svendsen, 1992) indicate an inflection point in the redistribution of momentum, resulting in a smoothing of the initial longshore current velocity profile. These predictions can now be checked quantitatively.

First a brief layout of the experimental set-up is given. For a more detailed description reference is made to Reniers et al. (1996). Next proof is given of the existence of shear instabilities using a spectral analysis method (MEM) to obtain the frequency wave-number spectrum based on the fact that the shear instability signature is outside the gravity-wave range. This enables us

¹Faculty of Civil Engineering, Delft University of Technology, P.O. Box 5048, Delft, The Netherlands, ad.reniers@wldelft.nl

to establish which energy corresponds to shear instabilities only. Phase coupling between the u and v velocity components results in cross-shore flux of momentum. This is examined in detail using cross-shore spectral analysis to compute the frequency distribution of the momentum flux induced by shear instabilities. The total transfer is obtained by integration over the frequency domain. The results are compared to the other terms in the longshore momentum equation used to compute the longshore current velocity.

Experimental set-up

Figure 1: Left panel: plan view experimental set-up. Instrument positions of alongshore arrays indicated by the '*' signs. Right panel, bottom profile and deployment positions alongshore array indicated by the dashed lines.

The experimental set-up is shown in Figure 1. The left panel shows the plan view of the experimental layout. Incident waves are generated by a multi-paddle wave maker. Given the oblique alignment of the beach with respect to the wave maker the paddles could be operated in phase, generating longcrested waves. The longshore current generated by the waves breaking over the barred profile (right panel Figure 1) was recirculated using a pump system to prevent spurious recirculations in the basin (Visser, 1984, Reniers and Battjes, 1996). To further increase the alongshore uniformity the pumped discharge was redistributed at the inflow opening. The cross-shore distribution of the longshore current velocity profile was measured with instruments attached to the mobile carriage. Two alongshore arrays of six spatially lagged current velocity meters (see left panel Figure 1) were used to measure the velocities up-and downstream respectively and thus the alongshore development of the shear instabilities. Detailed measurements of the cross-shore structure for a particular wave condition, monochromatic waves with a wave height of 8 cm and a 1 s period, were obtained by reposition-

ing the alongshore arrays perpendicular to the beach (see right panel Figure 1). During the repositioning the input wave and flow conditions were maintained. Measurements would restart after the disturbances induced by the repositioning of the instruments had disappeared (estimated duration less than half an hour). Note that instruments could not be positioned at the bar crest given the strong wave breaking induced turbulence.

Shear instabilities

Figure 2: Alongshore development of low-frequency spectral density of alongshore velocity $(\text{m/s})^2/\text{Hz}$ obtained from measurements at $x = 4.5 \text{ m}$, from the inflow opening (upper left panel) to the outflow opening (lower right panel). Distance to the inflow opening given by y .

An example of the downstream development of the low-frequency spectrum of the alongshore velocity, measured with the two alongshore arrays positioned offshore of the bar ($x = 4.5 \text{ m}$), is shown in Figure 2. It clearly shows the strong growth of the energy density in the 0 to .1 Hz frequency band. At this point it is not known whether energy in this frequency band corresponds to shear instabilities.

A spectral analysis technique based on maximum entropy was used to estimate the spectral distribution of energy density with alongshore wave number (k_y) of selected frequencies so as to determine which part of the energy density belonged to the shear instabilities (Reniers et al., 1996). Two results obtained at the downstream end of the basin, offshore of the bar and in the trough respectively, are shown in Figure 3. The zero-mode edge-wave dispersion curve (for a plane beach) is also shown as a reference. It is obvious that all energy density is outside the gravity wave range indicated by the area below the edge wave dispersion line, i.e. belonging to shear instabilities only.

Figure 3: Left panel, $f - k_y$ -spectrum at $x = 4.5m$. Right panel, $f - k_y$ -spectrum at $x = 2.75m$. Zero-mode edge wave dispersion curve denoted by the dashed line.

From the almost linear dispersion lines of the shear instabilities it can be seen that the energy density propagates with approximately the same speed, $c = O(0.35)$ m/s, at both locations.

Cross-shore momentum flux

The momentum flux at the cross-shore measurement locations, denoted by the subscript i , in a single transect may be obtained from:

$$R(x_i) = \rho d(x_i) \langle u(x_i, t)v(x_i, t) \rangle \quad (1)$$

with u and v being the cross-shore and alongshore velocities associated with the shear instabilities, $\langle \rangle$ denotes time averaging, d the local water depth and ρ the water density. The resulting flux depends on the spatial structure, mentioned in the previous paragraph, and the phase coupling between the velocity components. First we have a closer look at the frequency distribution of the momentum flux associated with the shear instabilities using cross-spectral analysis. To that end the velocity time series are written in Fourier series:

$$u(x_i, t) = \sum_n A_n e^{i\omega_n t} + * \quad (2)$$

$$v(x_i, t) = \sum_n B_n e^{i\omega_n t} + * \quad (3)$$

The momentum flux as function of frequency can be obtained from the co-spectral values:

$$R'(x_i, \omega_n) = d(x_i)(A_n B_n^* + A_n^* B_n) \delta \omega \quad (4)$$

The results of the frequency dependent momentum flux at 27,25 m from the inflow opening is shown in Figure 4. The intermediate values have been obtained from linear interpolation in frequency and space. The flux is spa-

Figure 4: Frequency distribution of shear instability momentum flux, R' , at 27.25 m from the inflow opening expressed in $\frac{m^3}{s^2}$ rad/s

tially concentrated at both sides of the bar crest ($x \simeq 3.75$ m), with maximum contributions around the peak shear instability frequency. At the shoreward side of the bar crest ($x < 3.75$ m) the momentum flux seems to be bimodal in frequency space. The frequency where the maximum flux is located decreases with increasing x -values, i.e. going further offshore, indicating that the higher frequencies, having smaller spatial scales, contribute less. The same can be seen going toward the shoreline, though to a lesser extent.

Importance in longshore current modelling

For alongshore uniform steady state conditions the wave averaged longshore momentum equation is given by:

$$\frac{\partial S_{xy}}{\partial x} = \bar{\tau}_{y,b} \quad (5)$$

with the following contributions to the term on the left-hand side due to

waves:

$$\frac{\partial}{\partial x} \rho \int_d \tilde{u} \tilde{v} dz \quad (6)$$

turbulence:

$$\frac{\partial}{\partial x} \rho \int_d u'v' dz = \rho \frac{\partial}{\partial x} \left(d\nu_t \frac{dV}{dx} \right) \quad (7)$$

and shear instabilities:

$$\frac{\partial}{\partial x} \rho \int_d uv dz \quad (8)$$

which are balanced by the alongshore directed wave-averaged bottom shear stress given by the term on the right hand side. In the following the shear instability contribution is compared to the other components in the longshore momentum equation.

The total momentum flux due to the shear instabilities, R , is obtained by integrating R' over all frequencies (see Figure 5). It shows the measured

Figure 5: Total momentum transfer at $y = 27.25$ m from the inflow opening

flux, indicated by the dots, through which a spline has been fitted, in comparison to the horizontal mixing induced by wave breaking turbulence which is estimated from the measurements:

$$R_{\nu_t}(x) = d(x)\nu_t(x) \frac{dV}{dx} \quad (9)$$

using the measured longshore current velocity, V and the measured wave height, H , as input. The turbulent eddy viscosity, ν_t , is obtained from (Batjes, 1975):

$$\nu_t = H(x) \left(\frac{D(x)}{\rho} \right)^{\frac{1}{3}} \quad (10)$$

where the estimated wave dissipation is obtained from the measured wave transformation. It shows a significant contribution of the shear instabilities to the momentum flux at 27.25 m from the inflow opening, though almost everywhere smaller than the estimated horizontal mixing. The cross-shore profile of the momentum flux is not unlike results obtained from linear stability results (Church et al., 1992), though in this case the contribution in the trough seems to be considerably less. Given the fact that the shear instability intensity increases in the downstream direction the corresponding flux also evolves in this direction, which is apparent from the sequence of panels shown in Figure 6.

Figure 6: Alongshore development of total momentum transfer from the inflow opening (upper left panel) to the outflow opening (lower right panel). Distance to the inflow opening given by y .

At the upstream end of the basin little evidence of additional mixing is available, except in the very first panel in the upper left corner, which can be associated with the redistribution of the pumped discharge at the inflow opening. It takes until EMF07, located 19.75 m from the inflow opening, for the cross-shore momentum flux by shear instabilities to become evident.

After that a strong build-up is apparent, though never reaching values as indicated by the wave-breaking induced horizontal mixing. Note that the contribution in the trough stays small all along the beach.

Next we have a look at the cross-shore gradient of the mixing, using the spline, which contributes to the longshore momentum equation in computing the longshore current velocity profile:

$$F = \frac{\partial R}{\partial x} \quad (11)$$

The alongshore directed wave forcing, estimated from the measurements, is included as a reference:

$$F_w = \frac{\partial E_w \sin(\theta) \cos(\theta)}{\partial x} \quad (12)$$

where E_w represents the wave energy (obtained from the measured wave transformation) and θ the angle of incidence (using Snell's law).

Figure 7: Contribution of shear instabilities to the longshore momentum balance at $y = 27.25$ m from the inflow opening (solid line). The alongshore-directed wave forcing is shown as a reference (dashed line)

The results at 27.25 m from the inflow opening, Figure 7, indicate a significant contribution to the longshore momentum balance. Based on this, it is expected that the maximum current velocity will decrease, given the

opposite signs of the contribution by the shear instabilities and wave forcing at the bar crest. Furthermore, the shear instability contribution at the seaward side of the bar indicates a broadening of the longshore current velocity. Only minor differences in the current velocity over the trough are expected to occur.

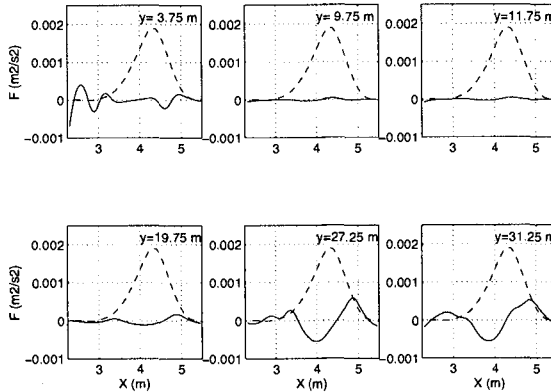

Figure 8: Alongshore development of shear instability contribution to longshore momentum balance (solid lines) from the inflow opening (upper left panel) to the outflow opening (lower right panel). The alongshore-directed wave forcing is shown as a reference (dashed lines)

The alongshore development of the shear instability contribution to the longshore momentum (see Figure 8) is in line with the results previously shown for the momentum flux. In all cases the contribution is considerably smaller than the alongshore directed wave forcing. It is worth to note that the development of the shear instability contribution to the longshore momentum balance stays small in the trough.

Finally we have a look at the measured development of the longshore current velocity (see Figure 9). There is no clear evidence of the effects of the shear instability induced cross-shore mixing on the alongshore development of the mean longshore current velocity profile.

Conclusions

A detailed analysis of the cross-shore momentum flux due to the presence of finite amplitude shear instabilities in a wave-driven longshore current was made based on the measurements obtained during a laboratory experiment.

It showed an alongshore increasing cross-shore flux, becoming of compa-

Figure 9: Longshore current velocity at four different transsects

rable order as the mixing associated with breaking wave induced turbulence at the downstream end of the basin.

However, no significant downstream changes in the mean longshore current velocity profile were detected. This can be explained by the fact that the shear instabilities take only effect near the outflow opening, whereas the wave forcing is present all along the beach.

CHAPTER 15

Modelling Post-Wave Breaking Turbulence and Vorticity.

T.C.D.Barnes, M.Brocchini,[†] D.H.Peregrine[‡] and P.K.Stansby[§]

1. Abstract

A brief review is given of the initial development of two approaches to the modelling of the flow that occurs after a water wave breaks. The first approach aims to model the turbulence generated by a spilling breaker riding on an unsteady wave. The turbulent volume of water in a spiller is modelled as a thin layer.

The second approach is applied to model the region of strong vorticity generated by a plunging breaker. The vorticity is modelled using two-dimensional discrete vortices. The behaviour of both a single vortex and a ‘cloud’ of vortices near a free surface is described.

2. Introduction

Water wave breakers, whether in deep or shallow water are mainly categorized as spilling or plunging breakers with no clear distinction between them. In particular intermediate types certainly exist, where there is a small initial plunging event which initiates tumbling white water as in a spiller. The strongly vortical and turbulent flow which results from all types of breaker is the interest of our studies. We distinguish between the turbulence and the vorticity of the mean flow. For example, a plunging breaker frequently creates a strong vortical flow about a horizontal axis. First steps in using discrete vortices in a two-dimensional model with a fully nonlinear free surface are described in the second part of this paper. The first section describes the modelling of a thin layer of turbulence in a spilling breaker.

3. Turbulence and vorticity in a spilling breaking wave

In their analysis of spilling breakers, bores and hydraulic jumps Peregrine & Svendsen (1978) suggested that the volume of turbulent flow in a spilling breaker resembles a turbulent mixing layer. The roller model in which the turbulent region is modeled as a separate flow region passively riding the wave crest is seen to be only a partial solution as it is evident that the fluid content of the roller itself is continually mixing with the rest of the turbulent fluid in the wave.

Peregrine (1992) also suggests that a spilling breaker may be considered as a quasi-steady system in a frame of reference moving with the wave where deformations of the spiller shape occur at longer time scales than those typical of the motion of water through the turbulent region. The structure of such a quasi-steady breaker is thus an initial mixing layer region, followed by a region beneath the crest of the wave where gravity influences and restrains the turbulent motions near the surface.

This view leads to consideration of a turbulent layer where turbulence is generated at the leading edge (toe of the wave) by shear stresses due to the relative motion between the turbulent wave surface and the water in which the wave propagates. Turbulence, generated near the free surface, propagates within the body of the wave and the turbulent layer evolves from a mixing layer type flow near the leading edge towards a wake type flow where most of the turbulent kinetic energy is dissipated.

This scenario is now documented for a small, quasi-steady spilling breaker, a recent experimental analysis of which is given by Lin & Rockwell (1995). It is found that the breaker originates from a region where the free surface abruptly changes slope (toe of the wave). The magnitude of the velocity is virtually unaltered until the abrupt onset of curvature of the free surface is encountered. At this location, there is a drastic nearly discontinuous reduction in magnitude of the velocity. The change in the velocity field is accompanied by a sudden increase in elevation of the free surface and represents an abrupt transformation from an undisturbed, essentially uniform velocity field to a very low velocity separated region existing beneath the free surface. The essentially discontinuous slope of the surface, in the presence of flow separation beneath it, serves as a source of vorticity giving rise to vorticity concentrations in a separated mixing layer, or shear layer.

We report on modelling of an unsteady thin turbulent layer (to be used in the modelling of a spilling breaking wave). One of the main assumptions is that the vertical extent of turbulent flow is much smaller than its streamwise extent. The motion of the wave is to be modelled by any suitable model for irrotational flows (e.g. boundary integral method) while the turbulent region of the breaker is modelled by a simplified $k - \epsilon$ model for a thin layer of fluid similar to that of Madsen & Svendsen (1983). The main new features of the present model are concerned with the correct representation of stretching, curvature, acceleration and local rotation that the layer of turbulent flow undergoes. Particular care has been put in analyzing the effects of curvature on the turbulent flow in the thin layer.

In figure 1 the global geometry of the present model for a spilling breaking wave is shown. Two regions of turbulent flow are identified. The 'surface layer'

Figure 1: Global geometry adopted in the model for the system wave - turbulent thin layer - surface layer. Frame of video taken at the Fluid Dynamics unit of the University of Edinburgh.

region represents that portion of the turbulent thin layer where the instantaneous free surface fluctuates around the mean free surface. When turbulent eddies cause the interface to splash into the air phase a situation occurs in which space is occupied by two substances which have different properties (e.g. air and water) and can be distinguished from each other (Brocchini & Peregrine, 1997a). Thus, the flow is essentially a two-phase flow. Beneath the 'surface layer' a second layer is found where the flow is still turbulent but single-phase (water). A summary on the modelling of the single-phase turbulent thin layer follows.

Brocchini & Peregrine (1997a) analyses in detail the boundary conditions for a turbulent air-water mixture ('surface layer') occurring at a splashing free surface. In order to obtain conditioned equations for each phase (i.e. air and water) a phase function or intermittency function is introduced such that

$$I(\mathbf{x}, t) = \begin{cases} 1 & \text{probe at } \mathbf{x} \text{ is in the water at time } t \\ 0 & \text{probe at } \mathbf{x} \text{ is in the air at time } t. \end{cases} \quad (1)$$

An integral method has been used to assess the flow equation for the water phase. Exact boundary conditions have been obtained by integrating in the crossflow direction the equations for the water flow. These boundary conditions are com-

plicated and cannot be directly used in simple turbulence models (e.g. $k - \varepsilon$) because they are written in terms of the flow properties in the water phase rather than in terms of the ordinary mean flow variables. Approximations and closure assumptions are made to obtain simpler approximate boundary conditions for use in the modelling of the spilling breaker. The intermittency factor

$$\langle I(\mathbf{x}, t) \rangle = \gamma(\mathbf{x}, t) \quad (2)$$

is the ensemble average of $I(\mathbf{x}, t)$ and is the most important statistical parameter to characterize a specific surface layer. Thus, closure is based on a suitable definition for γ for each flow regime (see figure 2).

Figure 2: The intermittency factor (or residence time) γ for: (a) wavy air-water interface (dashed line), (b) periodically scarified interface (dot-dashed line) and (c) turbulent splashing interface (solid line).

Since the main aim of the modelling is to correctly represent the stretching, curvature, acceleration and local rotation that the layer of turbulent flow undergoes we use the tools of curvilinear tensor analysis to derive the flow equations and derive a more general version of Svendsen & Madsen, (1984) thin, hydrostatic layer for a shallow water flow. Here the underlying irrotational wave motion is supposed to be modelled by an accurate flow solver, such as that of Dold & Peregrine (1986), modified to use the following thin layer equations as a boundary condition.

We start from Euler's equation for a Newtonian, incompressible, perfect fluid

of constant density ρ :

$$\rho \frac{Du_i}{Dt} = \rho F_i - p_{,j}. \quad (3)$$

where the comma refers to partial covariant differentiation. The left hand side of this equation contains the total derivative of the flow velocity. The two contributions on the right hand side are due to the external forces (here only gravity) and to the pressure p . A set of two-dimensional orthogonal coordinates (ξ_1, ξ_2) is defined as follows (Moore, 1978).

Consider a smooth time-dependent two-dimensional curve $\Upsilon(t)$ (see Figure 3) given parametrically by the equation

$$\mathbf{r} = \mathbf{R}(\alpha, t) \quad (4)$$

where t is time and α is an arbitrary parameter. The curve $\Upsilon(t)$ represents either the wave free surface when no breaking occurs or an interface between the irrotational flow region (below) and the region containing turbulent flow (above). Due to the typical entrainment of irrotational flow into the region of turbulence the curve $\Upsilon(t)$ is not a material surface when turbulence is present, i.e. water particles which at time $t = t_0$ are on the surface $\Upsilon(t)$ at a later time $t = t_1$ will not be on the surface any more.

Figure 3: Definitions for geometry and coordinates used for the thin turbulent layer.

With each "convected point" $O_L(\alpha(s), t)$ of the curve we associate a unit tangent vector $\hat{\mathbf{s}}(\alpha(s), t)$ to the curve defined by

$$\hat{\mathbf{s}} = \frac{\partial \mathbf{R}}{\partial s} \quad \text{so} \quad \frac{\partial \mathbf{R}}{\partial \alpha} = \frac{\partial s}{\partial \alpha} \frac{\partial \mathbf{R}}{\partial s} = \frac{\partial s}{\partial \alpha} \hat{\mathbf{s}}; \quad (5)$$

and also a unit normal vector $\hat{\mathbf{n}}(\alpha(s), t)$. For the sake of simplicity much of the following analysis is carried out by referring differential quantities to the arc length s rather than to the convected coordinate α , hence the position of each convected point $O_L(s, t)$ in the fixed frame of reference $\bar{O}\bar{X}\bar{Y}$ is:

$$\mathbf{r} = \mathbf{R}(s, t). \quad (6)$$

For any general point P , which is in the turbulent layer (i.e. above Υ) we assume that it is close enough to Υ that there is only one normal to the curve passing through O_L towards P and the distance $O_L P = n$ is also defined. This is positive if P is on the left hand side of Υ when this is described in the s -increasing direction (i.e. above Υ). Moreover the position of the point P within the thin layer is determined by two coordinates $\xi^1 = s$, $\xi^2 = n$ which form a mobile curvilinear coordinate system.

With this convention the position of P in $\bar{O}\bar{X}\bar{Y}$ is :

$$\mathbf{r}_P(s, n, t) = \mathbf{R}(s, t) + \hat{\mathbf{n}}(s, t)n. \quad (7)$$

The metric tensor g_{ij}^M can be identified more clearly by analysing the infinitesimal distance between two points P and Q and is:

$$ds^2 = d\mathbf{r} \cdot d\mathbf{r} = (1 - \kappa n)^2 ds^2 + dn^2 = g_{ij}^M d\xi_i d\xi_j. \quad (8)$$

where κ is the local curvature.

The model comprises four equations for the mean flow. Mean flow variables are in capital letters (e.g. U, V, P) while turbulent fluctuations are in lower case (e.g. u, v). A first equation states the conservation of mass:

$$\frac{\partial U}{\partial s} + \frac{\partial}{\partial n} [(1 - \kappa n)V] = n \frac{\partial \Omega}{\partial s}. \quad (9)$$

Here two extra terms due to the angular velocity Ω and to the curvature κ influence the mean motion.

The two equations for the conservation of momentum in the streamwise and crossflow direction are respectively:

$$(1 - \kappa n) \frac{\partial U}{\partial t} + (1 - \kappa n) \left[\left(V + \hat{\mathbf{n}} \cdot \frac{\partial \mathbf{R}}{\partial t} \right) \frac{\partial U}{\partial n} + \frac{\partial \langle uv \rangle}{\partial n} \right] + \frac{\partial \langle u^2 \rangle}{\partial s} - 2\kappa \langle uv \rangle \quad (10)$$

$$+ \left(U + \hat{\mathbf{s}} \cdot \frac{\partial \mathbf{R}}{\partial t} - n\Omega \right) \left(\frac{\partial U}{\partial s} - n \frac{\partial \Omega}{\partial s} - \kappa V \right) = (1 - \kappa n) \left(V\Omega + \frac{\partial(n\Omega)}{\partial t} + \hat{\mathbf{s}} \cdot \mathbf{g}' \right) - \frac{1}{\rho} \frac{\partial P}{\partial s},$$

and

$$\frac{\partial V}{\partial t} + \hat{\mathbf{n}} \cdot \frac{\partial \mathbf{R}}{\partial t} \frac{\partial V}{\partial n} + \frac{1}{2} \frac{\partial V^2}{\partial n} + \frac{\partial \langle v^2 \rangle}{\partial n} + \frac{1}{(1 - \kappa n)} \hat{\mathbf{s}} \cdot \frac{\partial \mathbf{R}}{\partial t} \left(\frac{\partial V}{\partial s} + \kappa U \right) + \frac{(U - n\Omega)}{(1 - \kappa n)} \left(\frac{\partial V}{\partial s} + \kappa U \right)$$

$$+ \frac{1}{(1 - \kappa n)} \frac{\partial \langle uv \rangle}{\partial s} + \frac{\kappa \langle u^2 \rangle - \langle v^2 \rangle}{(1 - \kappa n)} = n\Omega^2 - U\Omega + \hat{\mathbf{n}} \cdot \mathbf{g}' - \frac{1}{\rho} \frac{\partial P}{\partial n}. \quad (11)$$

where $\langle \cdot \rangle$ is the average operator and \mathbf{g}' is the 'reduced' gravity factor

$$\mathbf{g}' = \mathbf{g} - \frac{\partial^2 \mathbf{R}}{\partial t^2}. \quad (12)$$

The above are the Reynolds' equations for our two-dimensional mean flow. As usual Reynolds' decomposition of non-linear convective terms introduces Reynolds' stress terms $\langle u_i u_j \rangle$ and isolates the effects of fluctuations on the mean flow.

These equations resemble the equations used in the modelling of a curved thin layer of turbulence (e.g. Gibson & Rodi, 1981). One of the main differences is that in the present case there is interactive coupling (through $\partial \mathbf{R} / \partial t$ and \mathbf{g}') between the motion of the thin layer of turbulence and that of the irrotational wave below.

Finally, modelling of the turbulence may be achieved by means of a simplified $k - \varepsilon$ model in which a first order closure is adopted such that we only solve a transport equations for the turbulent kinetic energy k :

$$\begin{aligned} \frac{\partial k}{\partial t} + \frac{1}{(1 - \kappa n)} \left(U + \hat{\mathbf{s}} \cdot \frac{\partial \mathbf{R}}{\partial t} - n\Omega \right) \frac{\partial k}{\partial s} + \left(V + \hat{\mathbf{n}} \cdot \frac{\partial \mathbf{R}}{\partial t} \right) \frac{\partial k}{\partial n} = \frac{1}{(1 - \kappa n)^2} \frac{\partial}{\partial s} \left(\nu_t \frac{\partial k}{\partial s} \right) \\ + \frac{\partial}{\partial n} \left(\nu_t \frac{\partial k}{\partial n} \right) + (\langle u^2 \rangle - \langle v^2 \rangle) \frac{\partial V}{\partial n} - \frac{\langle uv \rangle}{(1 - \kappa n)} \left[(1 - \kappa n) \frac{\partial U}{\partial n} + \frac{\partial V}{\partial s} + \kappa U \right] - \varepsilon. \end{aligned} \quad (13)$$

Here ε and ν_t are respectively the energy dissipation and the eddy viscosity such that:

$$\varepsilon \approx \frac{k^{3/2}}{\delta}, \quad \text{and} \quad \nu_t \approx \frac{k^2}{\varepsilon} \quad (14)$$

where δ is the thickness of the turbulent layer.

Modelling the dynamics of the thin layer of turbulence provides suitable boundary conditions for the irrotational flow of the wave. The turbulence/wave interaction occurring at lower boundary ($n = 0$) of the turbulent layer is represented by mass entrainment across the boundary and by extra pressure at the boundary. These extra terms are to be incorporated respectively in the kinematic and in the dynamic boundary condition for the irrotational wave along $\Upsilon(t)$. For example the kinematic boundary condition for the irrotational wave is:

$$\hat{\mathbf{s}} \cdot \frac{\partial \mathbf{R}}{\partial t} + \frac{\partial s}{\partial t} = \frac{1}{(1 - \kappa n)} \frac{\partial \phi}{\partial s}, \quad (15)$$

$$\hat{\mathbf{n}} \cdot \frac{\partial \mathbf{R}}{\partial t} = \frac{\partial \phi}{\partial n} + \mathcal{V} \quad (16)$$

where ϕ is the velocity potential for the irrotational flow and \mathcal{V} is the 'entrainment velocity' i.e. the velocity at which the turbulent layer entrains irrotational flow across the boundary $n = 0$. Increasing entrainment is such that the interface $\Upsilon(t)$ is lowered. The velocity \mathcal{V} is parameterized in terms of the local amount of turbulence in the thin layer.

We refer to Brocchini (1996) and Brocchini & Peregrine (1997b) for a detailed description of the derivation of the model equations.

4. Modelling of Waves and Concentrated Vorticity

For large organised vortical motions that are generated by plunging breakers, we add point vortices to the two-dimensional fully nonlinear free surface boundary integral solver for irrotational flow described by Cooker *et al* (1990). The numerical model solves the following equations, the usual equations for inviscid, incompressible and irrotational potential flow with the full nonlinear boundary conditions:

$$\begin{aligned}
 \nabla^2\Phi &= 0 && \text{in fluid} - \{\mathbf{x}_i^v\} \\
 \frac{D\mathbf{x}}{Dt} &= \nabla\Phi && \text{on free surface} \\
 \frac{D\Phi}{Dt} &= \frac{1}{2}|\nabla\Phi|^2 - gy && \text{on free surface} \\
 \frac{\partial\Phi}{\partial n} &= 0 && \text{on solid boundaries}
 \end{aligned} \tag{17}$$

where $\mathbf{x} = (x, y)$, $\Phi(\mathbf{x}, t)$ is the velocity potential and g is the acceleration due to gravity. The velocity potential, Φ is composed of a regular part ϕ_r and a singular part ϕ_s . The singular part is due to a system of point vortices, centres $\{\mathbf{x}_i^v\}$ while the regular part is due to the free surface. The potential due to a single point vortex is augmented by its images in both the bed ($y = -h$) and the line $y = h$ above the free surface, which gives the following expression

$$\begin{aligned}
 \phi_s &= \kappa(\tan^{-1}[\coth[s(x - x^v(t))]\tan[s(y - y^v(t))]] \\
 &\quad - \tan^{-1}[\coth[s(x - x^v(t))]\tan[s(y + y^v(t) + 2h)]])
 \end{aligned} \tag{18}$$

where $s = \pi/4h$, $(x^v(t), y^v(t))$ is the position of the point vortex and κ its strength. The extra images are helpful in giving a singular solution which decays rapidly in space. The circulation around the point vortex is then $\Gamma = 2\pi\kappa$, $\Gamma > 0$ denotes circulation in the counter-clockwise direction. We define a Froude number $Fr = \kappa/\sqrt{(gL^3)}$ where L is some characteristic length scale, usually the distance of a vortex from the free surface. The system is non-dimensionalised with g and L , all results presented are dimensionless.

Tong (1991) computed the evolution of a single point vortex as it interacted with a free surface. He used the two dimensional fully nonlinear free surface potential flow numerical solver which solves the equations shown to model the free surface deformation (Cooke *et al* 1990). A single point vortex modelling the effect of vorticity, moving under the effect of its images and the free surface. We have extended the method to include a system of point vortices in order to model the effect of larger regions of vorticity.

In the extended model each point vortex moves under the influence of the free surface, the other vortices and its images. The free surface moves under the

Figure 4: Stacked free surface deformation due to a single (solid) and 10 (dashed) vortices.

influence of the vortices and gravity. The numerical method which we use time-steps the free surface using a Taylor series expansion truncated at the sixth power of the time-step. The inclusion of the point vortices necessitates the computation of every partial derivative of the vortex potential in every combination of x , y and t up to the third derivative in order to maintain the accuracy of the scheme. The time step criterion must also be modified to include the vortices, as velocities are very high close to the singular core of a point vortex.

We present some preliminary results here: figure 4 shows the free surface deformation and vortex movement due to a single impulsively started vortex (dotted) with strength $\kappa = 0.5$ initial position $(0.5, -1)$, and due to a system of 10 vortices whose strengths are all constant, positive and sum to 0.5, initially grouped around $(0.5, -1)$.

We can see that the two cases are remarkably similar, and give us some hope that the point approximation can model patches of vorticity well. Clearly a very diffuse patch of vorticity will not be well modelled by a point vortex. Our model will allow us to define the limits within which a single point vortex is sufficient

Figure 5: Stacked free surface deformation due to a single (solid) and 10 (dashed) vortices.

to model the free surface deformation due to a patch of vorticity.

We define the centre of the patch of vorticity to be the centroid of vorticity, the point defined by $\mathbf{X}_c^v = \frac{\sum_i \kappa_i \mathbf{x}_i^v}{\sum_i \kappa_i}$. Then the radius of the patch of vorticity is

defined as $R^v = \sqrt{\frac{\sum_i \kappa_i (\mathbf{x}_i^v - \mathbf{X}_c^v)^2}{\sum_i \kappa_i}}$. These definitions are also useful when defining centres and radii of patches of vorticity in experiments.

Figure 4 also shows the individual vortex paths. The thin lines are the paths of the system of 10 vortices, we can see that they co-rotate under their mutual influence, and drift under the influence of the free-surface. The thick line is the path of the single vortex and the centroid of the 10 vortices, which are virtually indistinguishable.

If the patch of vortices are sufficiently diffuse then there are variations from the behaviour in the single vortex case. Figure 5 shows such a case, where the free surface deformation is clearly different in the two cases. However similarities still exist, just outside the limits of the plot the free surface deformation is very

Figure 6: Path of single (solid), five (dashed) and ten (dotted) vortices sum strength 0.1

similar. Also the centre of the system of vortices and the single vortex still move along almost the same path, the thick line.

In certain cases the free surface deformation due to a patch of vorticity and a point vortex appear to be fairly similar. In such cases another interesting feature to study is the longer time evolution of a patch of vorticity which does not induce surface breaking. If the patch is modelled with a single point vortex then, for sufficiently weak vortices, the vortex moves as it would under a rigid wall. The image required to satisfy the rigid wall boundary condition predicts a vortex core velocity of $(-\kappa/2L, 0)$ for a point vortex located at $(x, -L)$. Individual point vortices in a patch of vorticity moving under the influence of the free surface alone will move with different velocities resulting in a diffusion of vorticity. So their interaction with each other and the free surface will determine the evolution of the patch of vorticity.

The solid line graphs in figure 6 show the paths of a single point vortex, strength $\kappa = 0.1$, initial position $(0, -1)$. After an initial transient period the vortex settles down to a constant x -velocity -0.049 with a small varying y -velocity, the rigid wall theory predicts a velocity of $(-0.05, 0)$. Note that the vortex takes some time to reach a steady state, initially sitting almost still. This is in qualitative agreement with the behaviour of vortices which we see in our

experiments (Quinn *et al* 1995 and Haydon *et al* 1996), which appear to take some time to start moving after being left by a plunging breaker.

The dotted and dashed path superimposed on figure 6 show the paths of the centres of systems of five and ten point vortices whose strengths sum to 0.1. We note that even the very small y -variations are fairly similar for all three cases. The radius of the patches is plotted in figure 7.

Figure 7: Radius of the patches in figure 6, five vortices (solid), ten vortices (dashed).

More importantly the free-surface generated in these three cases is also very similar, and rather complicated. It is also worth noting that the computations all fail at similar times due to a lack of points caused by a stretching of part of the free surface. This can be overcome by invoking a regridding procedure, we halt the computation at this point as it seems unlikely to yield any more interesting results.

Finally, we include the variation in the radius of the vortex cloud. Figure 7 shows the variation in the radius of the vortex clouds for the present example. We see that the cloud becomes steadily more diffuse, behaviour which is replicated in all cases which we have tried.

5. Conclusions

The work described in this paper continues. The thin layer model of a spilling breaker is being developed to add to boundary integral methods. The detailed analysis of the toe of the spiller is still in progress.

The discrete vortex system under a free surface is demonstrated to be practicable and may be of value for problems other than plunging breakers. For example the flows over many structures result in vortex shedding, which could be well described using the present methods.

CHAPTER 16

A Turbulent Flow Model For Breaking Waves

Nguyen The Duy¹, Tomoya Shibayama² and Akio Okayasu²

Abstract

This paper presents the formulation and solution of a numerical model for breaking waves on uniform sloping bottoms. The model is based on the two-dimensional vertical (2DV) Reynolds-averaged Navier-Stokes equations. The effect of breaker-generated turbulence is modeled by the Reynolds stress terms in the momentum equations, together with an eddy viscosity model. A transformation technique is utilized to solve numerically the governing equations in a variable grid system. At each time level of computation, it is possible to determine directly the following wave quantities for the surf zone: water surface elevation, pressure field and velocity field. The numerical results are verified with various cases of laboratory data.

1. Introduction

The breaking of waves results in the transformation of irrotational wave motion into turbulent rotational motion, which is characterized by vortex motion of various scales; and due to this turbulent motion, the wave energy transported from the offshore is dissipated throughout the surf zone. It has been known that turbulence generated by breaking waves has important effects on most processes within the surf zone such as wave transformation, diffusion of materials, etc. Therefore, in order to obtain a realistic and reasonable simulation of surf zone processes, it is necessary to include the effect of turbulence in the formulation of the wave equations. In addition, information on the vertical structure of wave variables such as wave pressure and water particle velocities is necessary to solve important problems of the nearshore area. For instance, the vertical profile of wave pressure can be applied to determine acting force used in the design of coastal structures, or the near-bottom velocity can be used as a boundary condition to determine the bed shear stress and to solve the flow inside the bottom boundary layer which, in turn, play an important role in the prediction of beach profile

change due to sediment transport. An useful and effective wave model, therefore, must be capable of computing directly the vertical distribution of wave variables.

Recently, rapid development in the memory capacity and computational speed of personal computers makes it possible to solve the full 2DV Navier-Stokes equations for water waves. The solution of 2DV wave models may be one among preliminary steps to achieve a complete picture of the modeling of coastal hydrodynamics in a near future, when water waves can be simulated by solving the full three-dimensional Navier-Stokes equations.

Petit et al. (1994) computed breaking waves on a submerged bar by applying the Volume of Fluid method to solve the 2DV Navier-Stokes equations. Shibayama and Duy (1994) presented a 2DV model for waves propagating on sloping bottoms and verified it with laboratory data of non-breaking and breaking waves, however, they could not attain reasonable numerical results for the velocity field in the surf zone.

This paper presents a hydrodynamic model for breaking waves on uniform sloping bottoms, in which the effect of breaker-generated turbulence and the depth variation of the wave variables are included in the model.

2. Governing Equations

Figure 1: Definition sketch of coordinates system

For a free surface domain, the 2DV Reynolds-averaged Navier-Stokes equations are written as

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

$$\frac{\partial u}{\partial t} + \frac{\partial(u^2)}{\partial x} + \frac{\partial(uw)}{\partial z} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + M_x \quad (2)$$

$$\frac{\partial w}{\partial t} + \frac{\partial(uw)}{\partial x} + \frac{\partial(w^2)}{\partial z} = -g - \frac{1}{\rho} \frac{\partial P}{\partial z} + M_z \quad (3)$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \int_{z_b}^{\zeta} u dz = 0 \quad (4)$$

where (u, w) : Reynolds-averaged velocity vector; P : Reynolds-averaged pressure; ζ : water surface elevation; z_b : sea bottom elevation; g : gravity acceleration. The

momentum transports due to fluctuating velocity components of turbulent motion (Reynolds stress terms), M_x and M_z , can be expressed as follows, by using eddy viscosity model

$$M_x = 2 \frac{\partial}{\partial x} \left(\nu_T \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial z} \left[\nu_T \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \right] \quad (5)$$

$$M_z = \frac{\partial}{\partial x} \left[\nu_T \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \right] + 2 \frac{\partial}{\partial z} \left(\nu_T \frac{\partial w}{\partial z} \right) \quad (6)$$

where ν_T is the eddy viscosity. In the above equations, since $\nu \ll \nu_T$, the diffusive terms due to molecular viscosity ν are neglected.

In the surf zone, the mean value (time-averaged over one wave period) of ν_T , $\bar{\nu}_T$, has been previously determined by fitting computed currents velocities to measured data. For instance, Longuet-Higgins (1970) simulated longshore currents by using

$$\bar{\nu}_T \approx 0.01h\sqrt{gh} / s \quad (7)$$

where h is the mean water depth and s the beach slope.

On the other hand, in the modeling of cross-shore currents, Okayasu et al. (1988) applied a mean eddy viscosity in the form

$$\bar{\nu}_T = 0.3\sqrt{g(d_t + H)} s z' \quad (8)$$

in which d_t is the depth to wave trough, H the wave height and z' the vertical distance from the bottom, while Svendsen and Hansen (1988) suggested that

$$\bar{\nu}_T = (0.007 - 0.03)h\sqrt{gh} \quad (9)$$

Based on Eq. (9) and the Prandtl-Kolmogorov assumption, Shibayama and Duy (1994) derived approximately a time-varying eddy viscosity for the area outside the bottom boundary layer of the surf zone as follows

$$\nu_T = f_v \sqrt{gh} (\zeta - z_b) \quad (10)$$

In Eq. (10), f_v is a constant and was found to have an average value of 0.125 from the computations of breaking waves. Shibayama and Duy (1994) showed that the use of a fixed value of f_v for all computational cases can produce good agreements between computed and measured wave heights in the surf zone, however, simulated wave profiles and velocity field generally exhibit certain discrepancies compared to measured data, in particular for the near-breaking area. These discrepancies may be caused by the fact that the eddy viscosity commonly increases within certain distance from the breaking point, as shown by laboratory measurements of Okayasu et al. (1988). In order to take into account this effect in the simulation, the constant f_v is slightly modified to become

$$f_v = \begin{cases} 0.03 e^{h_b/h} & \text{if } h_b / h < 1.5 \\ 0.03 e^{1.5} & \text{if } h_b / h \geq 1.5 \end{cases} \quad (11)$$

where h is the still water depth, and h_b the breaking water depth. Eq. (11) expresses a variation range of f_v from a minimum value of 0.082 at the breaking point ($h_b / h = 1$) to a maximum value of 0.134.

Boundary Conditions:

- *Water surface boundary* ($z = \zeta$):

The water surface is a moving boundary in the model. The position of this boundary must be determined at each time level with its own boundary conditions as follows.

For u , a zero shear stress condition is assumed at the water surface

$$\frac{\partial u}{\partial z} = 0 \tag{12}$$

For w , the kinematic boundary condition at a free surface is applied:

$$w = \frac{\partial \zeta}{\partial t} + u \frac{\partial \zeta}{\partial x} \tag{13}$$

and the boundary condition for P is

$$P = 0 \tag{14}$$

- *Bottom Boundary* ($z = z_b$):

A non-slip condition is applied for w :

$$w = 0 \tag{15}$$

In the numerical mesh, the first grid point of u is not located at the bottom (Fig. 2) and therefore, a direct use of the non-slip condition is not necessary. Instead, the boundary condition of u is given implicitly in the form

$$u_{i+0.5,1} + u_{i+0.5,2} = 0 \tag{16}$$

Figure 2: Bottom boundary

Using the continuity equation, Eq. (1), and the non-slip condition, a Neumann boundary condition for pressure is obtained from the z -momentum equation, Eq. (3):

$$\frac{\partial P}{\partial z} = \rho \left[-g + 2\nu_T \frac{\partial^2 w}{\partial z^2} \right] \tag{17}$$

- *Seaward Boundary* ($x = 0$)

The boundary conditions for ζ , u , w and P of incident wave are obtained by applying cnoidal wave theory or Stokes wave theory, depending on the calculated Ursell parameter, Ur , at the seaward boundary (Nishimura et al., 1977):

$$U_r = \frac{HL^2}{h^3} \begin{cases} \geq 25 & : \text{cnoidal waves} \\ < 25 & : \text{Stokes waves} \end{cases} \quad (18)$$

The reflected wave from the domain inside, if existing, will be treated to pass freely and undisturbed through the open seaward boundary. In the model, the actual water surface at each time level t is computed as the sum of the incident and reflected waves.

After determining the water surface elevation $\zeta(t)$, the other variables at the seaward boundary (u, w, P) can be determined approximately by using cnoidal or Stokes wave theory depending on the value of Ursell parameter.

- *Shoreline Boundary* ($x = x_{\max}$)

For u , an absorbing boundary condition is applied at the shoreline boundary (Zienkiewicz and Taylor, 1991):

$$\frac{\partial u}{\partial t} + c \frac{\partial u}{\partial x} = 0 \quad (19)$$

where c is the wave celerity at the shoreline boundary. For outflow at the shoreline boundary, typical boundary condition for w is (Fletcher, 1991)

$$\frac{\partial w}{\partial x} = 0 \quad (20)$$

Assuming that the effect of viscosity in the region adjacent to the shoreline is negligible, a Neumann boundary condition for pressure P can be derived by using the x-momentum equation, Eq. (2), and the absorbing condition, Eq. (19). The resultant equation is

$$\frac{\partial P}{\partial x} = -\rho \left[(2u - c) \frac{\partial u}{\partial x} + \frac{\partial(uw)}{\partial z} \right] \quad (21)$$

- *Breaking Location* ($x = x_b$)

The breaking point is determined by Goda's breaking indices (1975):

$$\frac{H_b}{L_0} = A \left\{ 1 - \exp \left[-1.5 \frac{\pi h_b}{L_0} (1 + 15s^{4/3}) \right] \right\} \quad (22)$$

where H_b : breaking wave height; L_0 : deep water wave length; s : beach slope; and A is an empirical constant taken to be 0.17.

3. Numerical Formulation

In the physical domain, the upper surface is a moving boundary due to wave motion, and the sea bottom also changes in space,

$$\zeta = \zeta(x, t) \quad (23)$$

$$z_b = z_b(x) \quad (24)$$

Figure 3: Physical and computational domain

The generated grid for numerical computation is thus also a moving system in space and time (Fig. 3). It is difficult to solve the governing equations numerically in this moving and curvilinear grid. Therefore, a coordinate transformation is carried out to map the moving grid to a fixed and linear one, in which the boundaries are parallel to the coordinate-axes (Fig. 3). The relationships between the physical domain (x, z, t) and the computational domain (ξ, η, τ) are expressed as follows

$$x = \xi \quad (25)$$

$$z = z_b + f(\eta^*) (\zeta - z_b) \quad (26)$$

$$t = \tau \quad (27)$$

where $\eta^* = \eta / \eta_m$ and η_m is the maximum value of η .

Depending on the form of the function $f(\eta^*)$, different types of numerical mesh can be generated for the physical domain (Fletcher, 1991). To obtain constant vertical mesh intervals in the physical domain, we choose

$$f(\eta^*) = \eta^* \quad (28)$$

The first derivatives of the velocity components, u and w , with respect to x , z , and t are expressed in terms of the new variables ξ , η , τ as follows:

$$\begin{bmatrix} \frac{\partial u}{\partial x} & \frac{\partial u}{\partial z} & \frac{\partial u}{\partial t} \\ \frac{\partial w}{\partial x} & \frac{\partial w}{\partial z} & \frac{\partial w}{\partial t} \end{bmatrix} = \begin{bmatrix} \frac{\partial u}{\partial \xi} & \frac{\partial u}{\partial \eta} & \frac{\partial u}{\partial \tau} \\ \frac{\partial w}{\partial \xi} & \frac{\partial w}{\partial \eta} & \frac{\partial w}{\partial \tau} \end{bmatrix} \begin{bmatrix} \frac{\partial \xi}{\partial x} & \frac{\partial \xi}{\partial z} & \frac{\partial \xi}{\partial t} \\ \frac{\partial \eta}{\partial x} & \frac{\partial \eta}{\partial z} & \frac{\partial \eta}{\partial t} \\ \frac{\partial \tau}{\partial x} & \frac{\partial \tau}{\partial z} & \frac{\partial \tau}{\partial t} \end{bmatrix} \quad (29)$$

where the Jacobian matrix J of the transformation is determined by using Eqs. (25) through (27)

$$J = \begin{bmatrix} \frac{\partial \xi}{\partial x} & \frac{\partial \xi}{\partial z} & \frac{\partial \xi}{\partial t} \\ \frac{\partial \eta}{\partial x} & \frac{\partial \eta}{\partial z} & \frac{\partial \eta}{\partial t} \\ \frac{\partial \tau}{\partial x} & \frac{\partial \tau}{\partial z} & \frac{\partial \tau}{\partial t} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ -\frac{[\eta_m z_{bx} + \eta(\zeta_x - z_{bx})]}{\zeta - z_b} & \frac{\eta_m}{\zeta - z_b} & -\eta \frac{\zeta_t}{\zeta - z_b} \\ 0 & 0 & 1 \end{bmatrix} \quad (30)$$

where ζ_x and z_{bx} denote the derivatives of ζ and z_b with respect to x , respectively.

With the obtained Jacobian matrix J , at each time level the variable physical domain (x, z, t) can be transformed to the fixed computational domain (ξ, η, τ) . The governing equations, Eqs. (1) through (4), in the computational domain are then given as:

$$\frac{\partial u}{\partial \xi} + \eta_x \frac{\partial u}{\partial \eta} + \eta_z \frac{\partial w}{\partial \eta} = 0 \quad (31)$$

$$\frac{\partial u}{\partial \tau} + \eta_t \frac{\partial u}{\partial \eta} + \frac{\partial(u^2)}{\partial \xi} + \eta_x \frac{\partial(u^2)}{\partial \eta} + \eta_z \frac{\partial(uw)}{\partial \eta} = -\frac{1}{\rho} \left(\frac{\partial P}{\partial \xi} + \eta_x \frac{\partial P}{\partial \eta} \right) + M_\xi \quad (32)$$

$$\frac{\partial w}{\partial \tau} + \eta_t \frac{\partial w}{\partial \eta} + \frac{\partial(uw)}{\partial \xi} + \eta_x \frac{\partial(uw)}{\partial \eta} + \eta_z \frac{\partial(w^2)}{\partial \eta} = -g - \frac{\eta_z}{\rho} \frac{\partial P}{\partial \eta} + M_\eta \quad (33)$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} \int_{z_b}^{\zeta} u dz = 0 \quad (34)$$

where

$$M_\xi = 2 \left(\frac{\partial v_T}{\partial \xi} + \eta_x \frac{\partial v_T}{\partial \eta} \right) \left(\frac{\partial u}{\partial \xi} + \eta_x \frac{\partial u}{\partial \eta} \right) + \eta_z^2 \left(\frac{\partial v_T}{\partial \eta} \frac{\partial u}{\partial \eta} + v_T \frac{\partial^2 u}{\partial \eta^2} \right) + 2v_T \left[\frac{\partial^2 u}{\partial \xi^2} + \eta_x^2 \frac{\partial^2 u}{\partial \eta^2} + 2\eta_x \frac{\partial^2 u}{\partial \xi \partial \eta} + \frac{\partial u}{\partial \eta} \left(\frac{\partial \eta_x}{\partial \xi} + \eta_x \frac{\partial \eta_x}{\partial \eta} \right) \right] \quad (35)$$

$$M_\eta = \left(\frac{\partial v_T}{\partial \xi} + \eta_x \frac{\partial v_T}{\partial \eta} \right) \left(\frac{\partial w}{\partial \xi} + \eta_x \frac{\partial w}{\partial \eta} \right) + 2\eta_z^2 \left(\frac{\partial v_T}{\partial \eta} \frac{\partial w}{\partial \eta} + v_T \frac{\partial^2 w}{\partial \eta^2} \right) + v_T \left[\frac{\partial^2 w}{\partial \xi^2} + \eta_x^2 \frac{\partial^2 w}{\partial \eta^2} + 2\eta_x \frac{\partial^2 w}{\partial \xi \partial \eta} + \frac{\partial w}{\partial \eta} \left(\frac{\partial \eta_x}{\partial \xi} + \eta_x \frac{\partial \eta_x}{\partial \eta} \right) \right] \quad (36)$$

The boundary conditions are also transformed to the computational domain in the similar way. The transformed equations and corresponding boundary conditions can be solved numerically by the finite difference method. The numerical computation is carried out on a staggered grid. In this staggered grid, P is defined at the centre of each cell and u, w are defined at the cell faces. In discretizing Eqs. (31), (32), (33), (34), finite difference expressions centered at grid point (i, j) , $(i+0.5, j)$, $(i, j+0.5)$, and (i, j) are used, respectively. These allow all derivatives can be discretised in second-order accuracy with smallest number of involved grid points. The use of the staggered grid also permits coupling of the u, w and P solutions at adjacent grid points. This in turn prevents the appearance of oscillatory

solutions, particularly for P , that can occur if centred differences are used to discretise all derivatives on a non-staggered grid.

A semi-implicit scheme is utilized to solve numerically the discretized forms of Eqs. (31) through (34). At each time step, a main set of linear equations for pressure is solved for the total number of grid points and subordinate sets of linear equations for velocities are solved along the boundaries. The result of pressure distribution is then used to compute the velocity field. For the water surface, two computational steps are necessary to determine this moving boundary at each time step as follows.

(i) At the beginning of a time step $n+1$, an approximate solution for the water surface is obtained by applying an explicit finite difference scheme for Eq. (31), using velocity profiles at the previous time step n . The water surface obtained is then used to evaluate the elements of the Jacobian matrix, and therefore the transformed equations (31) through (34) can be solved in the computational domain.

(ii) At the end of the time step $n+1$, after finishing the velocity computation, an improvement on the water surface computation is achieved by applying the Crank-Nicolson scheme for Eq. (31), using velocity profiles at both time steps n and $n+1$.

4. Numerical results

The total computational time required for the model to get the final results depends mainly on the number of grid points used in the mesh. Using a HP9000/720, it takes approximately 1 hour to complete one simulation for a mesh of 2000 grid points.

A typical illustration of the convergence and stability characteristic of the present model is presented in Fig. 4, which are the computed wave profiles at different sections in the surf zone. With the still water level (horizontal line) is set as the initial condition of the computation, it can be seen that after only about two waves coming from the offshore boundary, the computed wave profile at each section already converts to its final solution. This behavior indicates a rapid convergence characteristic of the model. After the convergence point, the stability of the solution can also be seen through the periodical results of the computed wave profiles.

A typical example of the numerical results of the hydrodynamic model are shown in Figs. 5 and 6. The model results are verified with the laboratory data obtained by Okayasu et al. (1988). In the figures, the variable X denotes horizontal distance from the shoreline of the still water, subscript " b " denotes the breaking point, and z' is the vertical elevation from the bottom.

Fig. 5 shows that the time history of water surface elevation follows an asymmetric pattern: the rise of water surface occurs much faster than the fall one. In general, the model is capable of simulating the highly nonlinear and asymmetric characteristics of wave profiles in the surf zone, as shown through the comparisons with measured data. However, as a common result, large discrepancies between

the computed and measured wave profiles are observed at sections close to the shoreline. These discrepancies may have been caused by the effect of the shoreline boundary. The verifications also show that the present model is capable of

Figure 4: Convergence and stability characteristics of the present model, illustrated through the time series of equi-phase mean water surface elevation ($H_0 = 8.5\text{cm}$, $T = 2\text{s}$, $h_0 = 40\text{cm}$, $s = 1/20$).

(a)

(b)

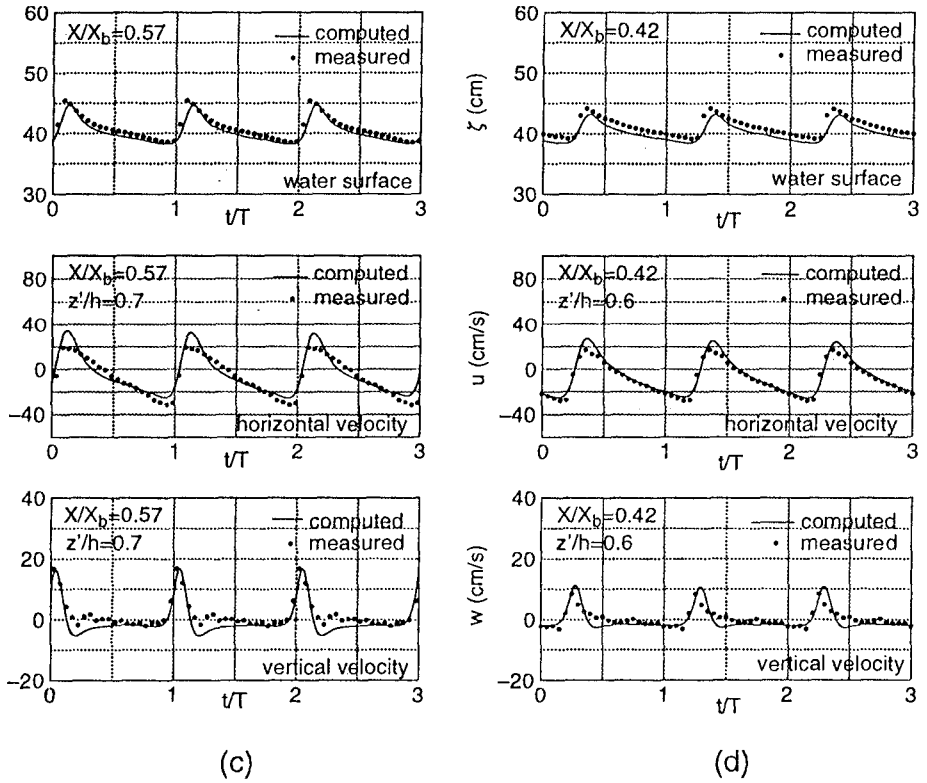

Figure 5: Time histories of water surface elevation ζ , horizontal velocity u and vertical velocity w at different sections and elevations in the surf zone ($H_0 = 8.5\text{cm}$, $T=2s$, $h_0 = 40\text{cm}$, $s=1/20$).

simulating the deformation of the velocity profiles as the wave propagates shoreward and of producing the high nonlinearity and asymmetry of the velocity profiles in shallow water area (Fig. 5). Generally, reasonable agreements, both in magnitude and phase, are obtained between the computed velocities and the laboratory data. In the vicinity of the breaking point, however, the vertical velocity is somewhat underestimated by the model. And at sections close to the shoreline, the model overestimates the peak value of the horizontal velocity. The simulation results also show that, in the surf zone, the vertical velocity magnitude at most elevations is considerable compared to the horizontal velocity magnitude and therefore cannot be neglected in the computation as is done in most existing wave models.

The equi-phase mean velocity vectors in the measured area of the surf zone are plotted in Fig. 6, for different phases in one wave period. A fairly good agreement in the direction and the magnitude between the computed and measured velocity vectors can be observed, but there exist small discrepancies in the near-bottom area. In bottom area, the simulated velocity vectors exhibit smaller values than the measured ones. Small discrepancies between the computed and measured velocity vectors can also be seen in the vicinity of the shoreline. This may be due to the fact that the real shoreline boundary has not yet been simulated perfectly in the model and may cause certain effects on the computed velocity field.

5. Conclusions

- In the present model, the hydrodynamics of breaking waves in the surf zone was investigated based on the governing equations of turbulent flow: the Reynolds-averaged Navier-Stokes equations. The effect of breaker-generated turbulence was included in the model and the vertical distribution of wave variables (P , u , w) can be computed directly by the model. The numerical results agree reasonably well with laboratory data of 2DV velocity field and water surface elevation in the surf zone.
- A time-dependent eddy viscosity was introduced in the present study to solve the 2DV Reynolds-averaged Navier-Stokes equations. The derived eddy viscosity has been verified to be applicable in the modeling of breaking waves. However, this is only one of the possible alternatives in determining the eddy viscosity. The present model may be tested with other solutions of the eddy viscosity in order to seek for possible improvements of the simulation results.
- In the model, it is possible to determine only the vertical distribution of horizontal velocity from the water surface to the first grid point above the bottom. The horizontal velocity profile below this grid point, which is affected by the bottom boundary layer (BBL), has not yet been computed by the model. The inclusion of the effect of the BBL requires a very fine mesh interval, whose order is about $0.1mm$, in order to model the large velocity gradient in the near-bottom area. However, at present, a 2DV hydrodynamic simulation of the entire surf zone, in which the BBL is included, is still not economical in sense of the CPU time required.
- Disagreements between the numerical results and the laboratory data commonly occur in the area close to the shoreline. As already mentioned, these poor agreements may have been caused by the effect of the shoreline boundary. Due to certain technical problems encountered in the formulation of a 2DV model, some assumptions have been made to simplify the implementation of the shoreline boundary conditions such as the absorbing condition for u , the uniform condition for w . These assumptions may not reflect properly the realistic phenomena at the shoreline boundary. Therefore, a more reasonable implementation of the shoreline boundary conditions is necessary to obtain better simulation results in the area close to the shoreline.

Figure 6: Comparison of equi-phase mean velocity vectors in the surf zone ($H_0 = 9.87\text{cm}$, $T = 1.17\text{s}$, $h_0 = 40\text{cm}$, $s = 1/20$).

CHAPTER 17

Turbulence Structures in the Surf Zone.

T.R.Haydon D.B.Hann *, P.Davies † C. A.Greated‡ and T.C.D.Barnes§

Abstract

Turbulence due to breaking waves is an important factor in the ocean as it has a direct effect on coastal erosion, sediment transport and marine life. The laboratory study of this phenomenon is important to produce controlled simulations of processes that occur at sea, and has mainly consisted of temporal point measurements. In this paper the results obtained from using PIV to study the turbulence in the laboratory are presented. PIV is a spatial technique and yields unique information on the turbulence structure in such a flow. Of particular interest in this paper are the evolution of the wavenumber spectra and the form of the turbulent energy decay with time and space. This is used to characterise the decay of turbulence from 2-d to 3-d. Separation of the turbulence from the mean motion is important and the method used here is justified. The main results and conclusions are compared with other research, with similarities and differences emphasised and discussed.

1. Introduction

Little is known about the nature of the turbulence produced by a breaking wave event. It is a very difficult flow to model numerically and equally hard to measure experimentally. The traditional approach to experimental investigation has been to use point measuring techniques such as Laser Doppler Anemometry (LDA) [5, 4]. This does not enable the spatial structures of the flow and the way in which the associated vorticity and energy is dissipated, to be measured. Particle Image Velocimetry (PIV) is a well documented velocity measuring technique, yielding full field instantaneous flow information [12]. The implementation of a high resolution digital camera and an image shifting device allows the problem of measuring multi-directional velocities to be solved, imparting a constant velocity throughout the flow that can be subtracted after analysis.

Previous research on laboratory generated single breaking waves is fairly scarce, however a comprehensive study using LDA was done by Rapp and Melville [5] along with other interesting work from Battjes and Sakai [2]. The results obtained by these researchers will be referenced and comparisons made, with results obtained here. There are two main objectives to be addressed in this paper, firstly the validation of PIV as a technique for studying this type of complex flows, and secondly the exploitation of the advantages inherent in using PIV, to characterise the turbulent flow spatially and temporally.

2. Experimental facility

The experiments described in this paper were carried out in the Edinburgh University wave flume. The flume is 9m long 0.4m wide and 1m deep, with the water depth being 0.75m. The wavemaker is a hinged paddle that has a force feedback mechanism, designed to limit reflections. Breaking waves are formed by the superposition of differing frequencies formed by the paddle which are focussed to create a breaking event. The walls of the flume are glass to allow easy optical access. At the far end of the flume there is an absorbing wedge of foam which disperses the remaining wave energy and limits reflections.

Wavegauges can be used to measure the surface elevations during experimentation and in these experiments four were used, two positioned before breaking and two after. These yield important information on the spectral contents of the wave used in the investigation and also the enable the repeatability of the wavemaker to be verified.

3. PIV

An in depth explanation of PIV is not going to be undertaken in this paper as it has been covered many times before [3]. However there are recent improvements made to the technique that have increased its versatility, which will be outlined here.

Image shifting overcomes the problems that PIV has with measuring multi-directional flows or flows that have a large dynamic range of velocities (for a detailed description see Morrison[6]). The PIV image is obtained through the reflection in a rotating mirror which imparts a constant shift to all the velocities in the flow. It has the effect (when optimised) to shift all the velocities into the range measurable with PIV. The velocity imparted can be removed after the analysis stage, leaving the original flow velocities. There is an added complication, due to the fact that there are differing optical path lengths to the various parts of the mirror, (and hence to the flow region) meaning that the shift velocity is not exactly uniform over the whole flow. However averaging many velocity maps recorded in still water gives the full-field shifting velocity map, which can be subtracted from all measurements.

The use of a high resolution CCD camera for image acquisition has many advantages over the previously used photographic film method. Obviously the primary advantage is the saving in time on the analysis which is done digitally on a PC. Using very large CCD array sizes, however, does create very large image files which fill memory up very quickly. The memory on the frame grabber used in this research was extended to 32mb so that a maximum of seven sequential pictures could be taken, limited only by the frame rate of the camera.

Image analysis is done digitally using an auto-correlation routine which yields the magnitude and direction of the velocity within small areas of the image.

4. Experiments

Both deep water and beach waves were investigated. Four different types of deep water breaker were used, ranging from severe plunging to gently spilling. For the beach experiments a 1:20 beach was built into the flume. Due to the nature of the wavemaker paddle a solitary wave breaking on the beach due to shoaling was not feasible. Therefore the beach waves used broke due to a combination of focusing and shoaling. This was not a huge problem, because the main objective was to see how the shallow water affected the turbulence structures present.

Images of the flow were captured beginning from approximately 3 seconds after the initial breaking event. This was the earliest that the flow could realistically be studied, due to the large amount of aeration that is caused by the breaking. The triggering of the camera was controlled by an external pulse from the wavemaking software which triggered the image-shifter, which in turn triggered the camera at the precise moment the mirror has rotated to an angle of 45° to the line of the flume. The choice of shift velocity was dictated by a number criteria. Firstly the limitation that the same shift had to be used for all images acquired in one sequence, meant that it had to be of a sufficient velocity to shift the earliest flow field into the analysable range of velocities. It is however generally advantageous to use as small a shift as possible, so the loss of resolution is kept to a minimum.

For each different wave used in this experiment a number of different positions of the camera were used in order to cover the full extent of the turbulence and vorticity produced by breaking, which was generally spread over quite a large area. This tends to be split into distinct separate patches of turbulence, which become more merged together as the wave goes from plunging to spilling.

5. Results

Figures 1-6 show vorticity information, on the same scale, derived from a sequence of PIV velocity fields obtained after breaking. These show the evolution of a dominant vortex patch which appears to consist of two counter rotating vortices. The vorticity is shown to be concentrated and fairly focussed soon after breaking. The patch becomes visibly weaker, deepens slightly and occupies a slightly larger area. A notable feature

is that the structures do not seem to translate significantly across the flow. The area shown in these plots are about 60cm wide and 50cm deep.

The vorticity maps give a visual representation of the post-breaking flow, showing a number of significant features. However, in order to make comparisons with the results of other experimenters it was necessary to compute more detailed properties of the turbulence.

The wavenumber spectra for the turbulent velocities obtained at two different times 4s and 17s after breaking are shown in figure 7. The information is shown on a log/log plot with a k^{-3} and a $k^{-5/3}$ line shown for comparison. This can be related to theories on 2-d and 3-d turbulence originally conjectured by Kraichnen [8] and further reviewed by Kraichnen and Montgomery [7] and Lesieur [10]. The proposed slope of the wavenumber spectrum for two-dimensional turbulence is k^{-3} . This seems to suggest that after breaking the flow is dominated by two-dimensional turbulence which decays to three-dimensional turbulence as the structures become smaller and less coherent. This supports the work of Lemmin and George *et al* [9, 11], who also note this spectral change.

The flow measured using PIV cannot be said to be a solely turbulent flow, as it contains a mixture of mean and turbulent components. A simple method of local averaging was used in order to separate out these two components. Each velocity point was averaged using the nearby velocities, with this average then subtracted from the central velocity value. All turbulent information was obtained using this method.

Figure 8 shows the decay of turbulent energy with time for a deep water post breaking field averaged over four repeats. This is shown for two separate positions after breaking, position 2 being closer to the breaking point. The reciprocal of the mean square turbulence level at position 2 appears to decay approximately in proportion to time. This is analogous to the way in which grid generated turbulence decays with the distance behind the grid. Position 1 does not show such a decay relationship, probably because it is close to breaking where the structures are moving forward more than at subsequent positions, hence leading to a significant flow of turbulent energy out of the region.

Figures 9 and 10 show some examples of turbulent energy depth profiles, averaged across each line of velocities at each depth for a deep water breaker and a beach wave. The essential features of the two cases are that in deep water there is a strong decay of the turbulence level with depth, whereas the turbulence in the beach case is spread out more evenly, with only a slight decay with depth. The two instances in figure 9 correspond to the vorticity plots shown in figures 1 and 2. The spike in turbulence between 20 and 30cm depth clearly falls from the first instant to the second.

6. Conclusions

PIV has been effectively applied to the complex turbulent flow generated by breaking waves, producing a visual representation of the structures and the way in which they decay and dissipate. The characterisation of the turbulence in order to make direct comparisons with the work of others has been attempted and early results suggest a good agreement. Further analysis to examine the mixing process in more depth is planned for both the deep and beach waves.

CHAPTER 18

Experiments on Design Wave Height in Shallow Water

J. William Kamphuis, M. ASCE.¹

Abstract

Traditional depth-limited criteria for design of structures in shallow water were found not to be valid in hydraulic model tests with irregular waves. An extensive series of experiments showed that in addition to the height of the short period waves and the depth at the structure, the design wave height is a function of long wave action and wave setup at the structure. The additional effects are related to incident wave height and they result in an increase in depth at the structure. Thus, a simple design expression was developed by introducing a depth modification into a standard depth-limited design equation.

1. Depth-Limited Design

For many years, the design wave for structures in shallow water has been considered to be depth limited, meaning that the design conditions are controlled by the water depth at the structure. The maximum breaking wave reaching the structure is considered to be the design wave height. It is approximated by the wave that breaks exactly on the structure. Any wave breaking further offshore is expected to have lost enough energy that it results in a smaller breaking wave at the structure. Any wave that has not broken by the time it arrives at the structure is by definition smaller than the breaking wave and will result in smaller “non-breaking” wave forces. The design wave (H_{des}) may thus be approximated by the maximum breaking wave height at the toe of the structure, $(H_b)_{max,T}$, which is a function of the water depth at the toe (d_T).

$$H_{des} = (H_b)_{max,T} = \gamma d_T \quad (1)$$

¹ Prof. of Civil Eng., Queen’s Univ., Kingston, Ontario, Canada, K7L 3N6; Kamphuis@civil.queensu.ca.

Equation 1 was developed for regular waves. With irregular waves, a wave height distribution (normally assumed to be Rayleigh) needs to be introduced. The entire Rayleigh distribution is commonly represented by the Significant Wave Height (H_s) as determined by time domain (Zero Crossing) analysis or the Zero Moment Wave Height (H_{m0}) as determined from frequency domain (Wave Spectrum) analysis. Introducing these into Eq 1 yields:

$$H_{des} = (H_{s,b})_{max,T} = (H_{m0,b})_{max,T} = \gamma d_T \quad (2)$$

where γ is normally defined as a constant, which may vary from 0.78 down to values as low as 0.4, depending on the wave height definitions used.

This type of depth-limited calculation has been used in practice for many years and the adequacy of Eq 1 was repeatedly demonstrated to the undergraduate students at Queen's University through a final year project that ended with the design and hydraulic model testing of a rubblemound breakwater section. However, when this exercise was "updated" using irregular waves, Eq 2 was found not to be valid. The following difficulties were identified:

- a. H_{des} was not only a function of water depth at the structure, but increased with incident wave height. Damage to the structure increased with wave height, even when the incident wave broke a long distance offshore.
- b. The use of H_s or H_{m0} is not correct for design when structure damage is cumulative.

The inadequacy of Eq 2 was first investigated with several short experiments, but every one of these indicated that the problem was not simple and that the solution required more thorough investigation. Thus, a comprehensive set of tests was finally embarked upon to try to solve what everyone thought had been solved long ago. This paper provides a summary of these tests, examples from the initial analysis of the results and a simple design expression.

2. Experiments

Experiments were carried out in the 2 m wide irregular wave flume at the Queen's University Coastal Engineering Research Laboratory (Fig 1). The model was 0.6 m wide; the remaining width of the flume was reserved to minimize reflection of long wave action in the flume. The model consisted of a 1:50 plywood slope with a rubble mound breakwater at the end. Water level fluctuations were measured at 64 locations on the ramp for each incident wave height. Each test consisted of 6 to 11 different incident JONSWAP spectra with offshore wave heights (H_{m0}) varying from 0.04 to 0.18 m. Sixteen tests were performed (Table 1), resulting in some 7000 records of water level fluctuation. The results for Test 7 will be used to provide a consistent example in Figs 3 to 6. All other results were very similar to Test 7.

Figure 1 Experimental Setup

TABLE 1
Test Numbers for the Various Combinations of Water Depth and Wave Period

Wave Period (sec)	Depth of Water at Toe (m)			
	0.04	0.05	0.064	0.08
0.8	6	2	9	10
1.0	4	3	1	11
1.2	5	7	8	12
1.5	13	14	15	16

3. Initial Analysis

Each record was analyzed in frequency domain (Wave Spectrum Analysis) and some records were analyzed in the time domain (Zero-Crossing Analysis). Significant wave height (H_s) was virtually identical to H_{m0} everywhere but very close to the toe of the structure, where H_s is smaller than H_{m0} , as shown in Fig 2. The difference was a function of d_T . All wave heights quoted in this paper are zero moment wave heights (H_{m0}), derived from the frequency analysis. An example of wave heights calculated from the records is given in Fig 3. If the concept of depth-limited design as expressed in Eq 2 were valid, then H_{m0} at the structure should decrease (or at least remain the same) as the offshore wave height increases and the breaker moves

Figure 2 H_s as a Function of H_{m0} at the Structure Toe for Test 7

Figure 3 Profile of H_{m0} with Distance for Test 7

Figure 4 Growth of Long Wave Components for Test 7

further offshore. Figure 3 shows that H_{m0} at the toe of the structure is almost depth limited, but there is clearly a small increase with the incident offshore wave height as mentioned in Point a) of Section 1. Figure 3 also shows an unexpected sudden increase in H_{m0} near the structure toe.

During the tests, visual observations indicated that, in addition to the incident short wave action, which decayed as it travelled from the breaking point to the structure, substantial long wave activity and wave setup existed, which increased from the breaking point to the structure. Both the short wave and long wave action could be clearly identified both by time domain and frequency domain analysis. Zero-Crossing Analysis of both long wave and short wave components indicated that both were essentially Rayleigh distributed, even at the toe of the structure. Wave Spectra at three locations for a medium height wave of Test 7 are shown in Fig 4. The long wave component clearly grows as the wave approaches the structure, while the energy of the short wave component decreases. The complicated wave spectrum at 1.72 m indicates, however, that this transformation is not simple and involves major re-organization of wave energy. Figure 4 also shows a minimum spectral density near $f=f_p/2$, where f_p is the peak frequency of the offshore spectrum. This minimum occurred in all the tests and was used to separate long wave and short wave energy for all results, providing H_{m0} values for the long wave component ($f < f_p/2$) and the short wave component ($f > f_p/2$). In addition to the long waves and short waves, there is substantial wave setup at the structure.

Figure 5 shows some profiles of the short wave component of Test 7. The sudden increase in H_{m0} near the structure, shown in Fig 3 has now disappeared, indicating it to be the effect of the long wave component, which is largest near the structure. A credible explanation for the wave height profile with distance of the short wave component is also shown in Fig 5. The simulation proposed by Kamphuis (1994) was used. Rakha and Kamphuis (1995) also show this method to be valid. The wave was shoaled up to the breaking point, using linear shoaling and friction. The breaking point was defined using either the depth-related breaker criterion:

$$\frac{H_{s,b}}{d_b} = \gamma_{s,b} = 0.56 e^{3.5m} \quad (3)$$

or the wave steepness-related breaker criterion:

$$\frac{H_{s,b}}{L_{p,b}} = 0.095 e^{4.0m} \tanh\left(\frac{2\pi d_b}{L_{p,b}}\right) \quad (4)$$

developed by Kamphuis (1991). Here $H_{s,b}$ is the significant height of the breaking waves, $L_{p,b}$ is the wave length of the breaking waves, calculated using the peak frequency and m is the beach slope offshore of the breaking zone. The test results

Figure 5 Calculated and Measured Short Wave Profiles for Test 7

Figure 6 Calculated and Measured Long Wave Profiles for Test 7

Figure 7 Depth-Limited Design Using Equation 5

showed that H_s and H_{m0} at breaking were virtually identical. Wave decay after breaking was related to excess wave energy, a concept originally developed by Dally, Dean and Dalrymple (1986) for regular waves and adapted by Kamphuis (1994) for irregular waves. Similar wave height profiles were also obtained using the method of Battjes and Janssen (1978).

Figure 6 shows an initial explanation of the complicated long wave profile. Similar to Shah and Kamphuis (1996), the long wave profile was assumed to consist of a shoaling, incident bound long wave, that becomes a shoaling, free long wave upon breaking. This wave is partially absorbed and partially reflected, with an antinode at the structure. It is important to note that seiche at the natural frequency of the wave flume was not (and did not need to be) included in this computation. The transition from the bound long wave to the free long wave is gradual through the breaking zone and involves a 180° phase shift of the long wave energy, relative to the wave groups. Offshore, the highest short waves in the wave group accompany the trough of the bound long wave, but at the structure the highest short waves travel on the crest of the free long wave.

4. Waves at the Toe of the Structure

Analysis of the complete data set to determine of the transformation of H_{m0} approaching a structure is underway. The purpose of the present paper is to provide a design expression for structures in shallow water and including the complete wave transformation would be too cumbersome. Therefore the remainder of this paper will concentrate on the waves at the toe of the structure. Two wave gauges were located at the toe for each test. The long waves calculated from both records were virtually identical. The short wave heights showed small differences, that were not systematic. The wave heights quoted at the structure toe are therefore the averaged values of the two measurements.

The long wave influences certain design aspects directly, such as, crest elevation and wave overtopping, which involve water levels. For design parameters involving velocities and accelerations, such as stability of rubble mound armour or of a vertical breakwater, however, it may be assumed that the long wave does not generate large enough fluid velocities and accelerations to influence stability. Although the long wave may influence the actual short wave heights slightly, this paper concentrates on the all-important short wave design component.

Figure 3 indicated that the depth-limited design concept does not quite apply, but it is clear that the effect of increasing offshore wave heights is only of second order. Therefore we propose to work with the depth-limited design equation (Eq 2) and modify it.

Applying strict depth-limited design for the moment and ignoring Point b) from Section 1, Eqs 2 and 3 can be combined to estimate the design wave height as:

$$H_{des} = (H_{mo,b})_{max,T} = 0.56 d_T e^{3.5m} \quad (5)$$

Fig 7 plots all the measured values of H_{mo} for the short waves at the structure toe, against depth at the structure toe. It shows that Eq 5 describes the trend correctly but underpredicts the maximum values. Figure 8 indicates that both the underprediction and some of the scatter may be approached through a relatively simple, linear relationship with wave height. To provide the most accurate representation of the changing incident wave height, the breaking wave height as calculated by Eqs 2 to 4 was chosen here, in lieu of the offshore wave height. The bias and part of the scatter in H_{mo} at the toe of the structure are, in fact, the result of:

- wave setup
- the incoming bound and free long waves
- the antinode of the reflected long wave.

All three of these influences in this complicated, interactive system add to the depth of water at the structure and all are more or less proportional to incoming wave height. Since the influence of the above causes is relatively small, it is possible to use Eq 5 with a modified depth:

$$d_T' = d_T + \alpha H_{s,b} = d_T + \alpha H_{mo,b} \quad (6)$$

The experiments showed the best-fit value of α to be 0.1 and hence the revised design expression is:

$$H_{des} = (H_{mo,b})_{max,T} = 0.56 d_T' e^{3.5m} = 0.56 (d_T + 0.1 H_{mo,b}) e^{3.5m} \quad (7)$$

Figure 9 shows that the best-fit coefficient is 0.52, but that Eq 7 is a better design expression since it represents the maximum values of H_{mo} . Another design formula, based on Eq 4, is shown in Fig 10. It is:

$$H_{des} = (H_{mo,b})_{max,T} = 0.095 L_{p,b} e^{4.0m} \tanh\left(\frac{2\pi (d_T + 0.1 H_{mo,b})}{L_{p,b}}\right) \quad (8)$$

5. Design Wave

Equations 7 and 8 give H_{des} , corresponding to H_{mo} , at the toe of a breakwater, but this does not take into account Point b) of Section 1, which addresses cumulative damage. Because the waves impacting a structure in shallow water are basically

Figure 8 Effect of Wave Height

Figure 9 Modified Depth-Limited Design Using Equation 7

Figure 10 Modified Depth-Limited Design Using Equation 8

depth limited, design return period exerts only a minor influence on H_{des} . Table 2 presents an example for $m=0.02$ and a design return period of 50 yrs. It is seen that Eq 7 increases H_{des} by 10 % (forces increase by 33%) over Eq 5. Table 2 also shows that H_{des} varies only slightly with return period. This means that wave heights very close to the 50 year return period wave height will occur often during the structure lifetime.

Table 2
Wave Height as a Function of Return Period

Return Period (yrs)	Breaking Wave Height (m)	Depth at Structure (m)	Modified Depth (m)	H_{des} Eq (7) (m)	H_{des} Eq (5) (m)
50	4.0	4.0	4.40	2.64	2.40
1	3.5	4.0	4.35	2.61	
0.1	3.0	4.0	4.30	2.58	

Thus it becomes necessary to distinguish between design parameters that, when exceeded, do not result in cumulative damage (such as wave overtopping, breakwater crest height, etc.) and design parameters that, when exceeded, result in damage that is added to any earlier damage (such as damage to rubble mound armour layers and sliding of a vertical structure). Non-cumulative damage may be related to H_{mo} or H_s , which represents a rather high wave and which comes directly from the available long term data. Equations 7 and 8 may be used directly.

For cumulative damage, however, it is absolutely necessary to design for zero damage, each time the design wave occurs (or almost occurs). Therefore design must be for the highest possible waves, which may be defined by:

$$(H_{max}) = K_H (H_{mo}) \quad (9)$$

If the wave height distribution is Rayleigh, K_H is a function of storm duration and may be approximated by values in excess of 2. Goda (1985) uses 1.8. Rakha (1995) found $K_H=1.5$ for stable, irregular breaking waves on a horizontal slope and $K_H=1.7$, when the stable waves are reflected. For waves breaking a substantial distance offshore and travelling over a slowly sloping bottom toward a rubble mound structure, $K_H=1.5$ is probably realistic; For vertical breakwaters, $K_H=1.7$ is probably better. Thus the design wave may finally be defined as:

$$H_{des} = 0.56 K_H e^{3.5m} (d_T + 0.1H_{mo,b}) \quad (10)$$

or

$$H_{des} = 0.095 K_H L_{p,b} e^{4.0m} \tanh \left(\frac{2\pi (d_T + 0.1 H_{m0,b})}{L_{p,b}} \right) \quad (11)$$

where

$$(K_H)_{\text{damage not cumulative}} = 1.0 \quad \text{and} \quad (K_H)_{\text{damage cumulative}} = 1.5 \text{ to } 1.7 \quad (12)$$

6. Discussion

Equations 10 to 12 are based on recordings taken in a wave flume at the toe of a rubble structure. Do they apply to other structures such as vertical breakwaters or sloping seawalls? Wave setup at the toe of a structure is a function of the breaking wave height and the bottom slope. Thus the shape of the structure has only a small influence on wave setup. Only the reflected portion of the long wave is affected by the reflectivity of the structure. Since the rubble mound reflected much of the long wave energy, the shape of the structure is again not expected to exert a major influence on the results. Incident wave angle must of course be taken into account in the usual manner. The perpendicular angle of wave approach in a wave flume obviously results in the maximum effect and a mitigating term related to the cosine of the incident wave angle needs to be introduced. Thus, Eqs 10 to 12 are expected to be robust and applicable to a variety of design conditions and structures.

Equations 10 to 12 also provide a physical basis for determining the design parameters. This is much to be preferred over other, rather subjective adjustments found in the literature, such as an arbitrary increase from H_s to a higher wave height definition for different structures, providing different "damage coefficients" for breaking and non-breaking waves, or basing the design on the estimated number of waves that impact the structure during its lifetime.

Figures 3 and 6 show that analysis of the wave record without due regard for long and short wave components will lead to incorrect results, particularly near the structure. Figure 6 also demonstrates that the common laboratory practice of measuring the waves in a model without the structure in place, misses any influence from reflected long wave action entirely.

7. Summary

- The simple concept of depth-limited design was originally developed for regular waves.
- It was shown not to be correct for irregular waves.
- The design wave increases as incident offshore wave height increases (Fig 3).

- The complete system involves wave setup and the transformation of both long waves and short waves (Figs 5 and 6).
- The analysis of the short wave and long wave profiles, as the waves approach a structure is underway.
- It was possible to develop a relatively simple modification of the depth-limited design equations to incorporate the influence of wave setup and long waves.
- The wave setup and the incident and reflected long waves that accompany a train of irregular waves increase as they approach the structure. They effectively increase the depth at the structure.
- The depth increase may be related to incident wave height, using a modified depth (Eq 6).
- The design wave height can be rather simply related to the modified depth of water at the toe of the structure, which is introduced into existing breaking criteria and depth-limited design expressions (Eqs 7 and 8).
- The design wave height is also a function of whether or not exceedence of the design criterion causes cumulative damage (Eqs 10 and 11).

CHAPTER 19

TIME-DEPENDENT QUASI-3D MODELING OF BREAKING WAVES ON BEACHES

Entin A. Karjadi¹ and Nobuhisa Kobayashi²

ABSTRACT: A time-dependent quasi-3D numerical model is developed to predict the temporal and cross-shore variations of the free surface elevation and fluid velocities in the surf and swash zones under obliquely incident waves. This model, which includes the dispersion due to the vertical variations of the instantaneous horizontal velocities, is an extension of the two-dimensional model of Kobayashi and Karjadi (1994, 1996). The developed model is compared with available laboratory and field data for planar beaches as well as field data for a barred beach. For planar beaches, the dispersion effects on the longshore current are significant for regular waves but secondary for irregular waves. For a barred beach, the model under the assumption of alongshore uniformity cannot predict the broad peak in the longshore current profile. The small alongshore variation of wave setup induced by a small alongshore variation of obliquely incident irregular waves is shown to significantly modify the driving force and longshore current profile in the bar trough region. On the other hand, for planar beaches, the alongshore current profile is shown to be insensitive to the small alongshore variation of obliquely incident waves. This may explain why existing longshore current models based on the assumption of alongshore uniformity were regarded to be adequate before their comparisons with the barred beach data.

INTRODUCTION

The time-averaged quasi-3D nearshore currents below the wave trough level have been modeled by various researchers (*e.g.*, DeVriend and Stive 1987; Svendsen and Lorenz 1989). These time-averaged models assume that the oscillatory wave motion is known, although no realistic model is available to predict the velocity field of breaking waves on beaches. Alternatively, a time-dependent quasi-3D numerical model, which runs on a workstation, is developed herein to predict the oscillatory and mean components of the 3D velocity field of obliquely incident breaking waves on beaches. This model is an extension of the time-dependent two-dimensional model of Kobayashi and Karjadi (1994, 1996) which is simply referred to as KK hereafter.

¹Department of Civil Engineering, Bandung Institute of Technology, Jalan Ganesha 10, Bandung 40132, Indonesia. E-mail: entin@coastal.udel.edu

KK neglects the dispersion due to the vertical variations of the horizontal velocities although wave breaking produces vertical variations in the horizontal velocity and resulting energy dissipation. As a result, KK cannot reproduce the longshore current profile induced by regular waves breaking on planar beaches because it does not model the transition zone and lateral mixing. In this paper, KK is expanded to include the dispersion due to vertical variations of the horizontal velocities. Very little is known of the dispersion effects on surf zone hydrodynamics apart from the analysis of Svendsen and Putrevu (1994) that showed the importance of the dispersion effect due to the nonlinear interaction of cross-shore and longshore currents in explaining the measured cross-shore variations of long-shore currents induced by regular breaking waves. They used linear wave theory with depth-limited breaker height to describe the wave motion. The present analysis deals with the vertical variations of instantaneous horizontal velocities.

The dispersion terms due to the vertical variations of the horizontal velocities express additional cross-shore and alongshore momentum fluxes in the depth-integrated momentum equations. To predict these unknown momentum flux corrections, two new equations are derived from the corresponding three-dimensional shallow-water momentum equations using a method of moments. The quasi-3D model is compared with the same regular and irregular wave data for planar beaches as KK and with the field data of Smith *et al.* (1993) for a barred beach. The measurements of longshore currents on the barred beach during the DELILAH experiment generally indicated a broad peak in the bar trough region. Under the assumption of alongshore uniformity, the 3D model cannot explain this data. Low-frequency components and alongshore variations of incident irregular waves are examined to explain the broad peak of the longshore current. The longshore current profile on the barred beach is then shown to be sensitive to the alongshore variability unlike the longshore current profile on the planar beaches.

NUMERICAL MODEL

Figure 1: Definition sketch.

The approximate continuity and momentum equations used in this paper is derived from the three-dimensional continuity and Reynolds equations (Karjadi 1996) in a manner similar to the derivation for the two-dimensional case presented by Kobayashi and Wurjanto (1992). The symbol used in the derivation are depicted in Figure 1 where the prime indicates the physical variables that will be normalized later; x' =horizontal coordinate normal to the shoreline and positive landward; y' = horizontal coordinate parallel to the shoreline and positive in the downwave direction; z' = vertical coordinate and positive upward with $z' = 0$ at the still water level (SWL); z'_b =elevation of the seabed which is assumed to be impermeable and fixed; η' = free surface elevation

above SWL; h' =total water depth given by $h' = (\eta' - z'_b)$; u' =cross-shore velocity; v' =alongshore velocity; w' = vertical velocity; and g =gravitational acceleration. Limiting to waves in shallow water, the coordinates x' , y' , and z' are normalized by $\sigma H'$, $\sigma H'/\theta_c$ and H' , respectively, where $\sigma = T' \sqrt{g/H'}$, whereas T' , H' , and θ_c are the characteristic wave period, height and incident angle in radian used for the normalization. The corresponding fluid velocity components u' , v' , and w' in the x' , y' , and z' directions are normalized by $\sqrt{gH'}$, $\theta_c \sqrt{gH'}$ and H'/T' , respectively. The normalized continuity and momentum equations are then simplified under the assumptions of $\sigma^2 \gg 1$ and $\theta_c^2 \ll 1$ for shallow water waves with small angles of incidence. The simplified equations are integrated from $z = z_b$ to $z = \eta$ using the kinematic boundary conditions at $z = z_b$ and η and the boundary conditions of zero tangential stresses at $z = \eta$. The derived continuity and horizontal momentum equations for $\sigma^2 \gg 1$ and $\theta_c^2 \ll 1$ are expressed in the following normalized forms (Kobayashi *et al.* 1997, Karjadi 1996)

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(hU) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(hU) + \frac{\partial}{\partial x}(hU^2 + m) = -h \frac{\partial \eta}{\partial x} - \tau_{bx} \tag{2}$$

$$\frac{\partial}{\partial t}(hV) + \frac{\partial}{\partial x}(hUV + n) = -h \frac{\partial \eta}{\partial y} - \tau_{by} \tag{3}$$

with

$$m = \int_{z_b}^{\eta} (u - U)^2 dz \quad ; \quad n = \int_{z_b}^{\eta} (u - U)(v - V) dz \tag{4}$$

in which t = time, U = depth-averaged cross-shore velocity; V = depth-averaged alongshore velocity; τ_{bx} = cross-shore bottom shear stress; τ_{by} = alongshore bottom shear stress. The dispersion terms m and n defined in (4) express the cross-shore and alongshore momentum fluxes due to the vertical variations of u and v , respectively. The dispersion terms result from the vertical integration of the horizontal momentum equations.

The normalized variables without the primes in these equations are defined as

$$t = \frac{t'}{T'} \quad ; \quad x = \frac{x'}{\sigma H'} \quad ; \quad y = \frac{y'}{\sigma H'/\theta_c} \quad ; \quad z = \frac{z'}{H'} \quad ; \quad z_b = \frac{z'_b}{H'} \quad ; \quad \eta = \frac{\eta'}{H'} \tag{5}$$

$$h = \frac{h'}{H'} \quad ; \quad u = \frac{u'}{\sqrt{gH'}} \quad ; \quad v = \frac{v'}{\theta_c \sqrt{gH'}} \quad ; \quad U = \frac{U'}{\sqrt{gH'}} \quad ; \quad V = \frac{V'}{\theta_c \sqrt{gH'}} \tag{6}$$

$$\nu_t = \frac{\nu'_t}{H'^2/T'} \quad ; \quad \tau_{bx} = \frac{\tau'_{bx}}{\rho \sqrt{gH'} H'/T'} \quad ; \quad \tau_{by} = \frac{\tau'_{by}}{\rho \theta_c \sqrt{gH'} H'/T'} \quad ; \quad \sigma = \frac{T' \sqrt{gH'}}{H'} \tag{7}$$

in which ρ = fluid density; ν_t = normalized eddy viscosity used to express the turbulent stresses $\tau_x = \nu_t \partial u / \partial z$ and $\tau_y = \nu_t \partial v / \partial z$; and the parameter σ defined in (7) is the ratio of the cross-shore and vertical length scales. It is noted that the pressure is assumed to be approximately hydrostatic and the lateral turbulent stresses can be shown to be negligible for shallow-water breaking waves (Karjadi 1996).

For obliquely incident waves with $\theta_c^2 \ll 1$, the cross-shore fluid motion governed by (1) and (2) with $m = 0$ is the same as that for normally incident waves

obtained by Kobayashi and Wurjanto (1992). Furthermore, the variations in the y -direction appear only in the term $\partial\eta/\partial y$ in (3) and along the seaward boundary of the computation domain.

In this model, the bottom boundary layer is not analyzed explicitly and the bottom stresses for $\theta_c^2 \ll 1$ are expressed as

$$\tau_{bx} = f_b |u_b| u_b \quad ; \quad \tau_{by} = f_b |u_b| v_b \quad ; \quad f_b = \frac{1}{2} \sigma f'_b \quad (8)$$

in which u_b and v_b are the cross-shore and alongshore velocities immediately outside the bottom boundary layer, respectively, and f'_b = bottom friction factor which is assumed constant. KK assumes that $m = 0$, $n = 0$, $u_b = U$ and $v_b = V$.

In this quasi-3D model, the equations for m and n are derived from the three-dimensional momentum equations using the algebraic procedure which may be called a method of moments. The resulting equations for m and n can be shown to be expressed as (Kobayashi *et al.* 1997, Karjadi 1996)

$$\frac{\partial m}{\partial t} + \frac{\partial}{\partial x} (3mU + m_3) = 2 \left(U \frac{\partial m}{\partial x} - \tilde{u}_b \tau_{bx} - D_B \right) \quad (9)$$

$$\frac{\partial n}{\partial t} + \frac{\partial}{\partial x} (nU + mV + n_3) = V \frac{\partial m}{\partial x} - n \frac{\partial U}{\partial x} - \tilde{v}_b \tau_{bx} - \tilde{u}_b \tau_{by} - 2D_n \quad (10)$$

with

$$\tilde{u}_b = u_b - U \quad ; \quad \tilde{v}_b = v_b - V \quad (11)$$

$$m_3 = \int_{z_b}^{\eta} (u - U)^3 dz \quad ; \quad n_3 = \int_{z_b}^{\eta} (u - U)^2 (v - V) dz \quad (12)$$

$$D_B = \int_{z_b}^{\eta} \nu_t \left(\frac{\partial u}{\partial z} \right)^2 dz \quad ; \quad D_n = \int_{z_b}^{\eta} \nu_t \frac{\partial u}{\partial z} \frac{\partial v}{\partial z} dz \quad (13)$$

The thickness of the bottom boundary layer is assumed to be much smaller than the water depth $h = (\eta - z_b)$, and the lower limit z_b of the integrations in (12) and (13) should be interpreted at the elevation immediately outside the bottom boundary layer. The contributions of the boundary layer flow, which needs to satisfy $u = 0$ at the bed, to the second moments m and n in (4) and the third moments m_3 and n_3 are assumed to be negligible. The normalized energy dissipation rate D_B due to the vertical variations of τ_x and u outside the boundary layer is the same as the dissipation rate due to breaking of normally incident waves used by Svendsen and Madsen (1984). The energy dissipation rate inside the bottom boundary layer corresponding to D_B is estimated as $u_b \tau_{bx}$ (Kobayashi and Wurjanto 1992) and is taken into account in (9). The boundary layer contribution corresponding to D_n is assumed to be given by $v_b \tau_{bx}$ and accounted for in (10) where $u_b \tau_{by} = v_b \tau_{bx}$ by use of (8).

To obtain h , U , V , m and n using (1)–(3), (9) and (10), u_b , v_b , m_3 , n_3 , D_B and D_n need to be expressed in terms of the five unknown variables. As a first attempt to deal with this closure problem, the horizontal velocities u and v outside the bottom boundary layer are assumed to be expressed as

$$u = U + \tilde{u}_b F(\zeta) \quad ; \quad v = V + \tilde{v}_b F(\zeta) \quad ; \quad \zeta = (z - z_b)/h \quad (14)$$

in which F is assumed to be a function of ζ only with $\zeta = 0$ at the bottom and $\zeta = 1$ at the free surface. The definitions of \tilde{u}_b and \tilde{v}_b in (11) require $F = 1$ at $\zeta = 0$. Furthermore, the turbulent eddy viscosity ν'_t is assumed to be given by $\nu'_t = (C_\ell h')^2 |\partial u' / \partial z'|$ outside the bottom boundary layer where the turbulence measurements by Cox *et al.* (1994) indicate that the mixing length parameter C_ℓ is on the order of 0.1. Accordingly, the normalized eddy viscosity ν_t is expressed as

$$\nu_t = \sigma C_\ell^2 h^2 \left| \frac{\partial u}{\partial z} \right| \tag{15}$$

Substitution of (14) and (15) into (4), (12) and (13) yields

$$m = C_2 h \tilde{u}_b^2 \quad ; \quad n = C_2 h \tilde{u}_b \tilde{v}_b \quad ; \quad C_2 = \int_0^1 F^2 d\zeta \tag{16}$$

$$m_3 = C_3 h \tilde{u}_b^3 \quad ; \quad n_3 = C_3 h \tilde{u}_b^2 \tilde{v}_b \quad ; \quad C_3 = \int_0^1 F^3 d\zeta \tag{17}$$

$$D_B = C_B \sigma C_\ell^2 |\tilde{u}_b|^3 \quad ; \quad D_n = C_B \sigma C_\ell^2 |\tilde{u}_b| \tilde{u}_b \tilde{v}_b \quad ; \quad C_B = \int_0^1 \left| \frac{dF}{d\zeta} \right|^3 d\zeta \tag{18}$$

in which the constants C_2 , C_3 and C_B can be found for the specified functional form of F . To find \tilde{u}_b using $m = C_2 h \tilde{u}_b^2$ for given $h \geq 0$ and $m \geq 0$, it is assumed that $\tilde{u}_b \leq 0$ for $U \geq 0$ and $\tilde{u}_b > 0$ for $U < 0$ to ensure $|u_b| \leq |U|$ where $u_b = (U + \tilde{u}_b)$ is the near-bottom cross-shore velocity used in (8). After \tilde{u}_b is obtained, $\tilde{v}_b = n / (C_2 h \tilde{u}_b)$, $v_b = (V + \tilde{v}_b)$, and (17) and (18) yield m_3 , n_3 , D_B and D_n .

Finally, the function F needs to be specified. Svendsen and Madsen (1984) assumed a cubic profile for their analysis of a single turbulent bore on a beach. For regular and irregular breaking waves on beaches, the following cubic profile is tentatively assumed:

$$F = 1 - (3 + 0.75a)\zeta^2 + a\zeta^3 \quad \text{for } 0 \leq \zeta \leq 1 \tag{19}$$

in which a = cubic velocity profile parameter. Comparison of (19) and the cubic profile assumed by Svendsen and Madsen (1984) suggests that a is about 3. The shear stresses at the surface are zero only if $a = 4$. For the range $a = 3-4$, F is not very sensitive to a , $C_2 = 0.49-0.55$, $C_3 = -0.07-0.00$, and $C_B = 12.3-15.2$ (Johnson *et al.* 1996). The computed results using $C_\ell = 0.1-0.2$ in (15) and $a = 3-4$ in (19) are found to be very similar. The typical values of $C_\ell = 0.1$ and $a = 3$ are hence employed for the computed results presented in this paper.

The numerical method used in the quasi-3D model is an extension of the numerical method devised in KK to solve (1)-(3) with $m = 0$ and $n = 0$. The computer program developed for the quasi-3D model solves (1)-(3), (9) and (10) along with (8), (11) and (16)-(18) using the MacCormack method (MacCormack 1969). The procedure is described in detail in Karjadi (1996).

COMPARISON WITH AVAILABLE DATA

1 Comparison with Laboratory and Field Data for Planar Beaches

The comparisons of the 2D model of KK and the quasi-3D model with the laboratory experiments 2-5 of Visser (1991) and the field data of Thornton and Guza (1986) on February 5 and 6, 1980 are presented in Kobayashi *et al.*

(1997). The 3D computations are made in the same way as the corresponding 2D computations presented in KK. For regular waves, the dispersion term n in the alongshore momentum equation (3) definitely improves the prediction of the cross-shore variation of longshore current. The bottom friction factor f'_b in (8) is adjusted somewhat for experiments 4 and 5 to obtain better agreement. The alongshore bottom shear stress τ_{by} in (3) is important in determining the magnitude of \bar{V} but modifies its profile little as expected from the previous work (*e.g.*, Longuet-Higgins 1970).

For irregular waves, the dispersion term n improves the agreement somewhat if the bottom friction factor f'_b is reduced to $f'_b = 0.01$ from $f'_b = 0.015$ used for the 2D model. Moreover, the dispersion effects on the longshore currents induced by breaking irregular waves are secondary in comparison to breaking regular waves. To confirm this conclusion, the time-averaged alongshore momentum equation corresponding to (3) is expressed as

$$\frac{\partial}{\partial x} S_{xy} + \frac{\partial \bar{\eta}}{\partial x} + \bar{h} \frac{\partial \bar{\eta}}{\partial y} + \frac{1}{2} \frac{\partial}{\partial y} \overline{(\eta - \bar{\eta})^2} = \bar{\tau}_{by} \quad (20)$$

in which $S_{xy} = \overline{hUV}$ is the alongshore radiation stress based on U and V . The third and fourth terms in (20) are zero for the case of alongshore uniformity. The computed cross-shore variations of dS_{xy}/dx and $d\bar{\eta}/dx$ for regular and irregular waves are presented in Kobayashi *et al.* (1997). For regular waves, the term $d\bar{\eta}/dx$ included in the 3D model decreases the force driving the longshore current near the breaker point but increases this force near the shoreline. On the other hand, for irregular waves the term $d\bar{\eta}/dx$ is secondary in the alongshore momentum equation (20).

2 Comparison with Field Data for A Barred Beach

On a barred beach, conceptually, waves will break on the bar, reform and break again on the beach face producing two peaks in the longshore current distribution. Contrary to this concept, the measurements of longshore currents on a barred beach obtained during the DELILAH experiment (Smith *et al.* 1993) generally indicated a broad peak in the bar trough region. Existing time-averaged models for longshore currents, which couple four governing equations for the wave height, wave angle, mean water surface elevation, and longshore current, have not been able to predict these broad peak longshore current data (Smith *et al.* 1993).

Smith *et al.* (1993) developed a one-dimensional time-averaged numerical model for longshore current that included the effect of turbulence due to wave breaking through a general transport equation for the mean turbulent kinetic energy. Their model produced an unrealistic high peak on the beach face. Church and Thornton (1993) developed a model using a spatially varying bottom friction coefficient based on a one-dimensional turbulent kinetic energy equation associated with the breaking-wave induced turbulence. However, this model was unable to satisfactorily predict the broad peak of the longshore current distribution observed in the DELILAH experiment. Momentum fluxes associated with mass transport above the trough level of broken waves, which were ignored in the other models, were included in the model developed by Kuriyama (1994). His model with additional empirical coefficients was compared with field data

in Japan. At present, there is no model available to predict the broad peak of the longshore current on a barred beach in a physically satisfactory manner.

To assess whether the developed model including the dispersion effects is capable of predicting the longshore current on a barred beach, the 3D model is compared with the DELILAH field data of Smith *et al.* (1993) on October 14, 1990 at 1900 EST which included the cross-shore variations of the measured root-mean-square wave height and longshore current. The frequency spectrum measured at the 8 m water depth was narrow banded in frequency with symmetric directional distributions about a mean oblique wave direction. The wave conditions at the 8 m depth were: the root-mean-square wave height $H'_{\text{rms}} = 0.83$ m; the spectral peak period $T'_p = 12.0$ sec; and the dominant incident wave direction $\theta_i = 18^\circ$. The bathymetry was nearly uniform in the alongshore direction.

The seaward boundary of the numerical model based on the assumption of shallow water waves is taken at the water depth $d' = 3.64$ m below the still water level where the measured root-mean-square wave height H'_{rms} was 1.02 m. The measured frequency spectrum at $d' = 8$ m is used to estimate the assumed unidirectional frequency spectrum and the predominant incident wave direction at $d' = 3.64$ m using the computer program RESHOAL developed by Poff and Kobayashi (1993) as explained briefly in the following.

RESHOAL assumes a straight shoreline with parallel bottom contours. For a given incident directional random wave spectrum at a deeper water depth, RESHOAL computes the directional random wave spectrum at a specified shallow water depth using linear finite-depth wave theory for directional random wave shoaling and refraction (LeMéhauté and Waug 1982). The incident directional random wave spectrum at the deeper water depth $d' = 8$ m is assumed to be given by the product of the TMA frequency spectrum and the Mitsuyasu-type directional spreading function. The input parameters for RESHOAL at the deeper water depth $d' = 8$ m are: H'_{mo} = spectral estimate of significant wave height; T'_p = spectral peak period ($T'_p = 12$ s for this data); γ = spectral peak enhancement factor; θ_i = dominant incident wave direction ($\theta_i = 18^\circ$); s_{max} = maximum value of the spreading parameter. RESHOAL computes the directional spectrum, frequency spectrum and directional spreading function at the shallower water depth $d' = 3.64$ m. The parameters H'_{mo} , γ , and s_{max} need to be calibrated such that the root-mean-square of wave height at the 3.64 m depth is equal to the measured value of $H'_{\text{rms}} = 1.02$ m and the assumed incident directional wave spectrum at the 8 m water depth is similar to the measured spectrum. The calibrated values are $H'_{\text{mo}} = 1.35$ m; $\gamma = 5$; and $s_{\text{max}} = 120$ at the 8 m water as shown in Figure 2. It is noted that the assumption of $H'_{\text{rms}} = H'_{\text{mo}}/\sqrt{2}$ yields $H'_{\text{rms}} = 0.95$ m for $H'_{\text{mo}} = 1.35$ m, which is slightly larger than the measured value $H'_{\text{rms}} = 0.83$ m. This might indicate wind effects on wind waves between the 8 m and 3.64 m water depths.

Figure 2 shows the measured and fitted frequency and directional spectra at the 8 m water depth and the computed frequency and directional spectra at the seaward boundary $d' = 3.64$ m. The fitted directional spectrum at the 8 m depth is the TMA frequency spectrum with $\gamma = 5$ and $H'_{\text{mo}} = 1.35$ m with the Mitsuyasu-type directional spreading function with $s_{\text{max}} = 120$. The computed frequency spectrum with $T'_p = 11.9$ s at $d' = 3.64$ m is used to compute the incident wave trains at the seaward boundary required as the input to the 3D

model. This incident frequency wave spectrum does not include low-frequency wave components as shown in Figure 2. The computed dominant incident wave direction is $\theta_i = 12^\circ$ at $d' = 3.64$ m as may be seen from the computed directional spectrum at $d' = 3.64$ m in Figure 2 which suggests that the assumption of unidirectional random waves may be reasonable.

Similar to the computations made in KK, the normalized computation duration is taken as $t_{\max} = 500$ corresponding to $t'_{\max} \simeq 99$ min. The sampling rate $\Delta t'_s$ is taken to be the same as the sampling rate of the field data, $\Delta t'_s = 0.125$ s. The bottom friction factor is assumed to be $f'_b = 0.015$. The computed results presented in the following are based on the normalization using the wave conditions at the seaward boundary of $d' = 3.64$ m, *i.e.*, the measured root-mean-square wave height $H' = H'_{\text{rms}} = 1.02$ m; the computed spectral peak period $T' = T'_p = 11.9$ sec; and the computed dominant wave direction $\theta_i = 12^\circ$. Correspondingly, $\sigma = T'(g/H')^{1/2} = 37$ and $\theta_c = \theta_i = 0.21$ in radians. The assumptions of $\sigma^2 \gg 1$ and $\theta_c^2 \ll 1$ are satisfied for this data. The normalized grid spacings are taken as $\Delta x \simeq \Delta y = 0.0106$ corresponding to the dimensional cross-shore and alongshore grid spacings of $\Delta x' = 0.40$ m and $\Delta y' = 1.91$ m, respectively.

Figure 3, with the parameter $\delta_\eta = 0$ for the case of uniform incident wave conditions in the alongshore direction, shows the comparisons between the measured and computed cross-shore variations of the local root-mean-square wave height H_{rms} and the longshore current \bar{V} together with the measured bottom profile. The computed temporal variation of η for $200 \leq t \leq 500$ is used to obtain H_{rms} based on the zero-up crossing method whereas the computed longshore current \bar{V} is obtained by averaging the temporal variation of the depth-averaged alongshore velocity V for the duration $200 \leq t \leq 500$. Figure 3 with $\delta_\eta = 0$ shows that the 3D model without the incident low-frequency wave components underpredicts the root-mean-square wave height in the bar trough region. Moreover, the model predicts a peak in the longshore current at the seaward edge of the bar crest in contrast to a broad peak in the bar trough region.

As a first attempt to explain the broad peak in the longshore current distribution, the effects of incident low-frequency waves on the cross-shore distribution of longshore current are examined because incident low-frequency waves might modify the wave breaking on the bar crest and resulting longshore current profile. The incident wave spectrum at the seaward boundary shown in Figure 2 does not include low-frequency components. As a first approximation, uniform low-frequency components are added to the incident wave spectrum to examine the effects of these low-frequency components to the longshore current profile. The additional low-frequency components are found to modify the longshore current profile little (Karjadi 1996). Consequently, the broad peak of the longshore current in the bar trough cannot be explained by incident low-frequency waves.

The effect of alongshore non-uniformity on the longshore current profile is examined in the following. Longshore currents have been primarily modeled assuming alongshore uniformity, although it has been known that alongshore non-uniformities affect longshore currents (*e.g.*, Putrevu *et al.* 1995). To study the effect of the alongshore variation of incident wave conditions within the limitation of the 3D model based on three cross-shore lines as discussed in KK,

Figure 3: Measured and computed cross-shore variations of H_{rms} and longshore current \bar{V} together with normalized bottom profile for DELLAH experiment with $\delta_\eta \geq 0$.

Figure 2: Measured and fitted frequency and directional spectra at depth $d' = 8$ m and the shoaled and refracted frequency and directional spectra at $d' = 3.64$ m.

the incident wave trains η_i specified as new input to the model are modified as follows:

$$\begin{aligned} \text{Line 1: } & \text{new } (\eta_i)_1 = \text{old } (\eta_i)_1 \\ \text{Line 2: } & \text{new } (\eta_i)_2 = \text{old } (\eta_i)_2 \times (1 - \delta_\eta) \\ \text{Line 3: } & \text{new } (\eta_i)_3 = \text{old } (\eta_i)_3 \times (1 - 2\delta_\eta) \end{aligned}$$

where the old time series $(\eta_i)_1$, $(\eta_i)_2$ and $(\eta_i)_3$ have been computed for incident unidirectional random waves of alongshore uniformity. The distance between two adjacent lines is $\Delta y' = 1.91$ m. The dimensionless parameter δ_η is taken to be much less than unity to satisfy the assumption of gradual alongshore variation. The incident wave intensity decreases or increases in the down-wave direction depending on $\delta_\eta > 0$ or $\delta_\eta < 0$, respectively.

The computed results using these new incident wave trains are shown in Figures 3 and 4 for the cases of $\delta_\eta = 0, 0.0005$ and 0.001 and for the cases of $\delta_\eta = 0$ and -0.001 , respectively. The root-mean-square wave height changes very little since the specified change in the incident wave train is very small. For the wave intensity decreasing in the down-wave direction, the longshore current profile increases almost uniformly across the shoaling region and over the bar crest. The increase in the longshore current is larger in the bar trough region, whereas the increase is smaller in the swash zone. The broad peak in the bar trough region in Figure 3 is similar to the broad peak observed in the field. For the wave intensity increasing in the down-wave direction as shown in Figure 4 the longshore current in the bar trough region is decreased significantly and becomes negative.

To explain the computed results shown in Figures 3 and 4, Figure 5 shows the cross-shore variations of the driving forces on the left hand side of (20) for the cases of $\delta_\eta = 0.001$ and -0.001 . The terms of $\partial\bar{\eta}/\partial x$ and $\frac{1}{2}\partial(\overline{\eta - \bar{\eta}})^2/\partial y$ are on the order of 0.005 or less in the bar trough region and secondary in comparison to the other two terms plotted in these figures. For both cases, the cross-shore gradient of the alongshore radiation stress, $\partial S_{xy}/\partial x$, driving the longshore current is very small in the bar trough region. The additional term $\bar{h}\partial\bar{\eta}/\partial y$ associated with the alongshore wave setup gradient modifies the driving force significantly in the bar trough region where the incident wave intensity and resulting wave setup decrease or increase in the down-wave direction depending on $\delta_\eta > 0$ or $\delta_\eta < 0$, respectively.

To examine the effects of the alongshore non-uniformity on planar beaches, the modified incident wave trains for the cases of $\delta_\eta = 0.0005$ and 0.001 are also specified for the computations for the regular wave experiment 2 of Visser (1991) and the irregular wave data of Thornton and Guza (1986) on February 5. For the planar beaches as shown in Figure 6, the longshore current increases almost uniformly in the shoaling and surf zones except in the swash zone. Contrary to the computed results for the barred beach shown in Figure 3, the longshore current profile shape on the planar beaches is not sensitive to the alongshore non-uniformity. To explain this difference, Figure 7 shows the cross-shore variations of the driving forces in the time-averaged momentum equation (20) for the regular and irregular waves on the planar beaches. The additional driving force terms $\bar{h}\partial\bar{\eta}/\partial y$ and $\frac{1}{2}\partial(\overline{\eta - \bar{\eta}})^2/\partial y$ due to the alongshore variations are small

Figure 5: Computed cross-shore variations of driving forces in time-averaged alongshore momentum equation (20) for a barred beach.

Figure 4: Measured and computed cross-shore variations of H_{rms} and longshore current \bar{V} together with normalized bottom profile for DELILAH experiment with $\delta_\eta \leq 0$.

Figure 6: Effects of alongshore decrease of incident wave intensity on the longshore current profile for planar beaches.

Figure 7: Computed cross-shore variations of driving forces in time-averaged alongshore momentum equation (20) for planar beaches.

in comparison to the main driving force, $\partial S_{xy}/\partial x$, causing the almost uniform increase in the longshore current without changing its shape as shown in Figure 6. It is noted that the term $\partial \bar{\eta}/\partial x$ in (20) is important for regular waves as discussed in relation to (20).

The computed results discussed above imply that the broad peak of the longshore current on a barred beach can be caused by the very small alongshore variation of wave height and setup. This may explain why existing longshore current models based on the assumption of alongshore uniformity were regarded to be adequate before their comparisons with the barred beach data. For planar beaches, the effect of alongshore non-uniformity, even if it exists, can be accounted for by adjusting the constant bottom friction factor which changes the longshore current profile shape little. On the other hand, for barred beaches, the very small alongshore variation of wave height and setup modifies the longshore current profile shape which cannot be changed much by adjusting the constant bottom friction factor.

CONCLUSIONS

A time-dependent quasi three-dimensional numerical model is developed to predict the temporal and cross-shore variations of the free surface elevation and fluid velocities in the surf and swash zones under obliquely incident waves. This model is used to clarify the dispersion effects due to the vertical variation of the horizontal velocities in the surf zone. For planar beaches, the dispersion effects on the cross-shore variations of the wave height and setup are shown to be minor, indicating that the cross-shore dispersion term m may be neglected in the depth-integrated cross-shore momentum equation (2) as anticipated by Kobayashi and Wurjanto (1992). On the other hand, the dispersion effects on the longshore current profile are significant for regular waves but secondary for irregular waves, especially in view of the uncertainties associated with the bottom friction factor.

The 3D model is also compared with the DELILAH field data for a barred beach (Smith *et al.* 1993). Under the assumption of alongshore uniformity, the model cannot explain the observed broad peak in the longshore current in the bar trough region. Small alongshore variations of the incident wave intensity and resulting wave setup are shown to modify the longshore current profile in the bar trough region significantly. The cross-shore gradient of the alongshore radiation stress driving the longshore current is very small in this bar trough region. The alongshore gradient of wave setup is shown to alter the force driving the longshore current significantly in this region and produces a broad peak in the longshore current. Contrary to the computed results for the barred beach, the longshore current profile on planar beaches is found to be insensitive to the alongshore variations of the incident wave intensity and resulting wave setup. As a result, the prediction of the longshore current profiles on barred beaches will require the knowledge of small alongshore variability that is very difficult to measure accurately.

CHAPTER 20

Models of Wave Height and Fraction of Breaking Waves on a Barred Beach

Yoshiaki Kuriyama¹

Abstract

Models for wave height and the fraction of breaking waves were developed; the models employ a wave-by-wave approach, in which the shoaling, breaking and reforming of individual waves are calculated. The performance of the models calibrated with experimental data was not satisfied; the fractions of breaking waves estimated by the models were smaller than the values measured over troughs in the field. The models therefore were calibrated and verified with the field data. Furthermore, the validity of the models calibrated with the field data was confirmed by comparison with large-scale experiment data.

Introduction

The fraction of breaking waves, defined as the ratio of the number of breaking/broken waves to the total number of waves, strongly affects various phenomena in the surf zone, such as nearshore currents, sediment suspension, and morphology changes. This is because various surf zone phenomena are mainly caused by turbulence, mass flux and momentum flux induced by breaking/broken waves, which are much greater than those induced by non-breaking waves. For example, Kuriyama (1994) carried out numerical simulations to show that the longshore current distribution over a longshore bar and trough is dependent on the cross-shore distribution of the fraction of breaking waves. Hence, to predict longshore current velocities as well as undertow velocities, suspended sediment concentrations and topography changes, it is essential to estimate accurately the fraction of breaking waves Q_b .

Several models have been proposed to estimate Q_b and wave height H . Battjes and Janssen (1978) simulated variations in H within the surf zone, assuming a modified Rayleigh distribution truncated at the breaking wave height H_b , where breaking and broken waves have the same value of H_b . According to the assumption, the value of Q_b is estimated with the root-mean-square wave height H_{rms} and H_b . Battjes and Stive (1985), Roelvink (1993) and Southgate and Nairn (1993) compared Q_b estimated by Battjes and Janssen's model with results of field and laboratory measurements on

1) Senior Research Engineer, Marine Environment Division, Port and Harbour Research Institute, Ministry of Transport, Nagase 3-1-1, Yokosuka, Kanagawa 239, JAPAN

planar beaches. Although the estimated values of Q_b were smaller than those measured, the estimated cross-shore distributions of Q_b qualitatively agreed with the measurements.

Thornton and Guza (1983) improved Battjes and Janssen's model; an unmodified Rayleigh distribution, not truncated at the breaking wave height, was assumed at every location inside and outside the surf zone and wave breaking was allowed to occur at any wave height. The value of Q_b was taken to be a function of H , H_{rms} and water depth h . They measured Q_b on a planar beach in the field, and found that Q_b calculated by their model agreed well with the measured values.

Recently, Dally (1992) simulated variations in wave height by applying another algorithm, a wave-by-wave approach, in which the shoaling, breaking and reforming of individual waves are calculated. Because the mode of wave breaking of an individual wave (breaking, broken, or non-breaking) is clarified at any point through the calculation for the individual wave, Q_b can be directly estimated as the ratio of the number of breaking/broken waves to the total number of waves. By comparing calculated results with those measured over a longshore bar in the field by Ebersole (1987), Dally showed that Q_b calculated at the seaward slope of the bar correlated well with measured values, though the calculated values were smaller than the measured values.

The models reviewed above accurately predicted the cross-shore distributions of Q_b quantitatively or at least qualitatively on planar beaches and on the seaward slopes of longshore bars. Over troughs, however, the models could not predict the distributions of Q_b even qualitatively. Rivero et al. (1994) as well as Southgate and Nairn (1993) compared Q_b estimated by Battjes and Janssen's model with the values measured in experiments, and showed that Battjes and Janssen's model considerably underestimated Q_b over troughs. Dally's model also significantly underestimated Q_b over a trough (Dally, 1992; Nishi, 1994). Although Thornton and Guza's model has not been compared with measurements over troughs, their model is expected to have the same problem because it considers only wave breaking and not wave reforming.

To overcome the weakness of these models, Southgate and Wallace (1994) introduced the "persistence length" into Battjes and Janssen's model; beyond the persistence length, a broken wave reforms regardless of the wave condition. This length was assumed to be proportional to H_b , where the coefficient of the proportionality was determined by fitting the model results to Q_b measured in large-scale experiments. The use of the "persistence length" improved the accuracy of determining Q_b over troughs (Southgate and Wallace, 1994). The values of Q_b over troughs, however, were still underestimated. To predict the fraction of breaking waves more precisely, a more reliable criterion for wave reforming is required.

In this study, I hence develop two models for predicting H and Q_b that include a criterion for wave reforming proposed on the basis of field data. The models are calibrated and verified with both field and large-scale experiment data.

Formulation of models

The two models developed here employ a wave-by-wave approach in the manner of Dally (1992); the shoaling, breaking and reforming of individual waves are calculated. The values of significant wave height $H_{1/3}$ and Q_b are estimated using the simulation results of individual waves. The only difference between the two models is in the estimation of wave energy dissipation due to wave breaking. One, called Model 1, contains a periodic bore dissipation sub-model used by Thornton and Guza (1983), while the other, called Model 2, uses a dissipation sub-model developed by

Dally et al. (1985), in which stable wave height is included.

(1) Model 1

The shoaling of a wave is calculated with a shoaling coefficient proposed by Shuto (1974); the coefficient has been derived under the consideration of wave nonlinearity.

As a criterion for wave breaking, Model 1 adopts a formula proposed by Seyama and Kimura (1988), who experimentally measured wave height deformation of individual, irregular waves in the surf zone, and investigated the wave height-water depth ratio at wave breaking H_b/h_b . The formula is expressed in terms of beach slope $\tan \beta$ and the ratio of breaking water depth to the offshore wavelength h_b/L_0 as

$$\frac{H_b}{h_b} = 0.16 \frac{L_0}{h_b} [1 - \exp(-0.8\pi \frac{h_b}{L_0} (1 + 15 \tan^4 \beta))] - 0.96 \tan \beta + 0.2. \quad (1)$$

Because the experiment data of Seyama and Kimura (1988) are scattered around the values predicted by Eq.(1) with a standard deviation of $0.08H_b/h_b$, the values of H_b/h_b in Model 1 are assumed to distribute around those predicted by Eq.(1) with a normal distribution having a standard deviation of $0.08H_b/h_b$.

After wave breaking, the energy dissipation of a wave of frequency f , energy E and group velocity C_g is evaluated using

$$\frac{\partial(EC_g)}{\partial x} = \frac{1}{4} \rho g f \frac{(BH)^3}{h}, \quad (2)$$

where x is the cross-shore coordinate directed positive offshore, ρ is the density of sea water, g is the acceleration of gravity, and B is a dimensionless coefficient.

Thornton and Guza (1983) used Eq.(2) to calculate the total wave energy dissipation applying the same value of B to all waves irrespective of wave heights. By comparing H_{rms} measured in the field with the values estimated by Eq.(2), they determined that $B=1.5$. Model 1, however, predicts variations in H of individual waves, for which $B=1.5$ has not been proved to be optimum. The optimum B for individual waves has therefore been investigated with Seyama and Kimura's experimental results on wave deformation in the surf zone (1988), and has been found to be

$$B = 1.6 - 0.12 \ln(H_0/L_0) + 0.28 \ln(\tan \beta). \quad (3)$$

Wave reforming is judged by a formula proposed by Kuriyama and Ozaki (1996) on the basis of field data. They measured water surface elevations and the modes of wave breaking (non-breaking, breaking, or broken) of individual waves over longshore bars and troughs at the Hazaki Oceanographical Research Station (HORS), which is a 427 m long field observation pier on the Kashima-nada coast of Japan facing the Pacific Ocean, and investigated the wave height-water depth ratio at wave reforming H_r/h_r . The formula proposed is expressed as

$$H_r/h_r = -0.0624 \ln(h_r/L_0) + 0.142. \quad (4)$$

Because the field data are scattered around the values predicted by Eq.(4) (Kuriyama and Ozaki, 1996), H_r/h_r in Model 1 are assumed to distribute randomly in the region between Eq.(4)-0.2 and Eq.(4)+0.2.

While wave reforming is determined on the basis of Eq.(4), a transition zone where a broken wave does not reform even though the wave height-water depth ratio is less than that estimated by Eq.(4) is introduced in the model for the following reason. After wave breaking, a bore gradually develops on the front of a broken wave. Bore development appears to be strongly influenced by the wave condition at the wave breaking point, whereas it appears to be only slightly influenced by the wave condition shoreward of the wave breaking point. Consequently, even though $H < H_r$, the bore under development is supposed to advance toward the shore without vanishing.

The length of the transition zone l is determined based on experimental data of Seyama and Kimura (1988); they reported that the variation in H within the surf zone consists of three phases: an increase in H immediately after wave breaking, a sharp decrease in H after reaching the maximum wave height and a moderate decrease in H from the middle of the surf zone to the shoreline. The length l is assumed to be equal to the distance between the point of the maximum wave height and the point where a change occurs in the rate of decrease of H/H_b versus h/h_b , because bore development is supposed to end at the latter point; Seyama and Kimura (1988) reported the appearance of stable bores at the latter point. The length of l is expressed accordingly as

$$l = \frac{h_b}{\tan\beta} \left[1 - 0.93 \exp(-9.21 \tan\beta) - \frac{0.02}{0.72 \exp(6.11 \tan\beta)} \right]. \quad (5)$$

The transition zone introduced in Model 1 seems to be equivalent to the persistence length proposed by Southgate and Wallace (1994). However, these are slightly different; Model 1 assumes that a broken wave cannot reform if $H > H_r$, regardless of wave position, whereas Southgate and Wallace's model assumes that a broken wave must reform beyond the persistence length, regardless of wave condition.

Naturally, wave shoaling is calculated again after wave reforming.

(2) Model 2

Because Model 2 uses the same methods as Model 1 to calculate shoaling, wave breaking and wave reforming of an individual wave, only the method for estimating the wave energy dissipation due to wave breaking is described here.

Wave energy dissipation is estimated by the following equation, proposed by Dally et al. (1985),

$$\frac{\partial(EC_g)}{\partial x} = (EC_g - E_s C_g) \frac{K}{h}, \tag{6}$$

$$E_s = \rho g H_s^2 / 8, \quad H_s = \Gamma h,$$

where K and Γ are dimensionless coefficients, and H_s represents the stable wave height, defined as the value of H at which wave breaking ends on a shelf beach composed of an upward sloping bottom and a flat bottom. Dally et al. (1985) showed that by setting $K=0.15$ and $\Gamma=0.4$, H could be estimated in good agreement with the experimental data by Horikawa and Kuo (1966).

Since H_s represents the height of a stable wave, which is non-breaking after reforming, Γ can be considered as the wave height-water depth ratio at wave reforming. In this model, hence, Γ is replaced by a value estimated by Eq.(4), while $K=0.15$ is maintained as a constant.

Calibration

The values of $H_{1/3}$ and Q_b estimated by Models 1 and 2 were compared with 11 sets of field data obtained at HORS (Kuriyama and Ozaki, 1996). The offshore boundaries in the calculations were set at the most seaward measurement points where few waves were broken. Figure 1 shows four examples of the comparisons of $H_{1/3}$ and Q_b measured in the field with values estimated with Model 1 and Model 2. Table 1 lists the wave conditions for the measurements shown in Figure 1.

Table 1 Wave and wind conditions during the measurements: significant wave heights in deep water ($H_{1/3}0$), significant wave periods in deep water ($T_{1/3}0$), and the wave directions visually observed at the bar crests θ_b , which are defined relative to the shoreward direction and are positive counterclockwise.

Case	Time	$(H_{1/3})_0$ (m)	$(T_{1/3})_0$ (s)	θ_b (deg.)
1	Mar. 3, 1994, 13:20-14:50	1.28	11.2	10
2	Mar. 10, 1994, 13:10-14:40	2.27	9.5	5
3	June 14, 1994, 13:20-14:40	1.50	9.2	-5
4	Nov. 22, 1994, 10:10-11:40	1.68	7.0	0

Good agreements exist between the results of Model 1 and Model 2 for Q_b and $H_{1/3}$. The values of Q_b estimated by the models are, however, smaller than the measured values over the troughs, and even over the seaward slopes of the longshore bars. Furthermore, $H_{1/3}$ estimated by the models are smaller than the measured values over the troughs. These results show that waves simulated in the models tend to break less and decay more than actual waves in the field. I attribute this tendency of the waves in the models to a scale effect; all coefficients in the models, except those of the wave reforming criterion, were determined on the basis of experimental data.

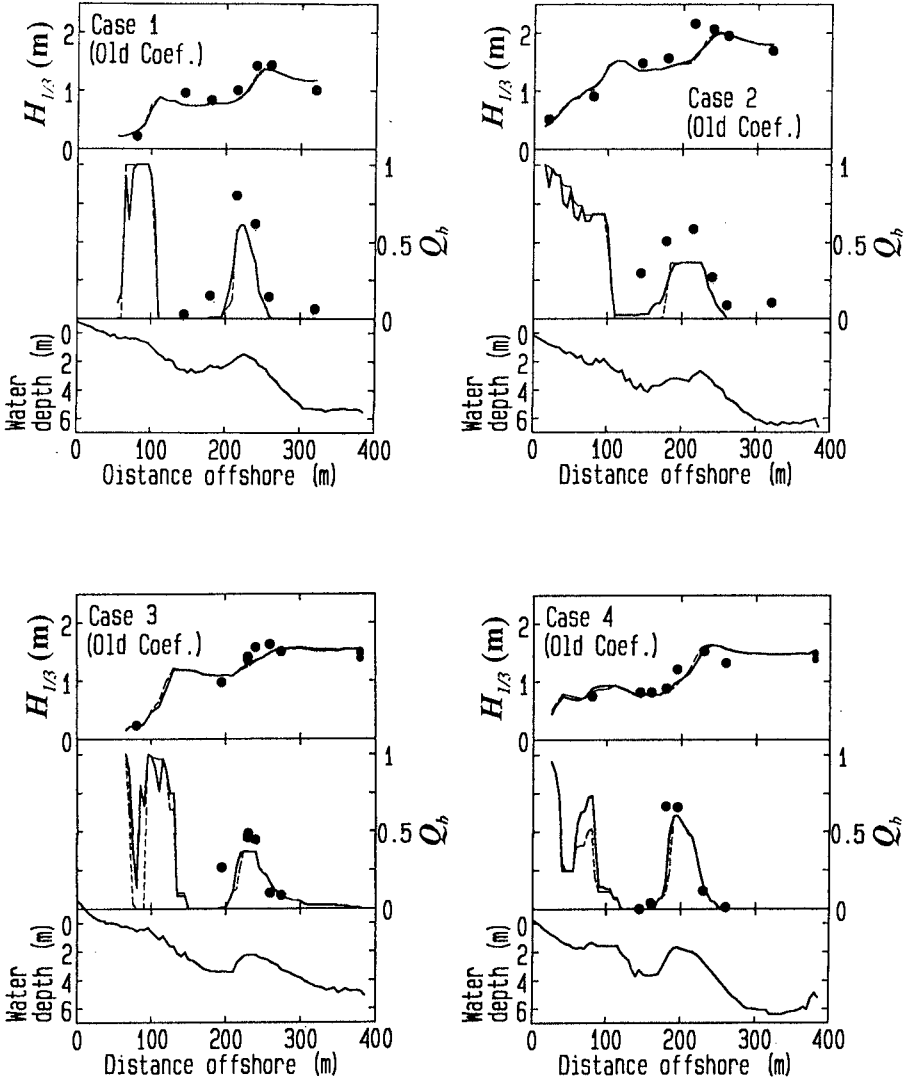

Figure 1 Comparison of $H_{1/3}$ and Q_b measured in the field (solid circles) with those estimated by Model 1 (thick solid lines) and Model 2 (thin dashed lines).

Hence, new coefficients were introduced and the models were calibrated with the field data.

Instead of Eq.(1), which is the criterion for wave breaking in the models, the following equation with a dimensionless coefficient C_{br} was introduced.

$$\frac{H_b}{h_b} = C_{br} (0.16 \frac{L_0}{h_b} [1 - \exp(-0.8\pi \frac{h_b}{L_0} (1 + 15 \tan^4 \beta))] - 0.96 \tan \beta + 0.2). \quad (7)$$

Equation (3), used for the calculation of wave energy dissipation in the Model 1, was replaced by

$$B = C_B (1.6 - 0.12 \ln(H_0/L_0) + 0.28 \ln(\tan \beta)), \quad (8)$$

where C_B is a new dimensionless coefficient.

A calibration for Model 1 was conducted by varying the values of C_{br} and C_B , and by determining the optimum values that minimize errors between predicted and measured values of $H_{1/3}$ and Q_b ; the value of C_{br} was varied from 0.8 to 1.1 at intervals of 0.05, and C_B was varied from 0.5 to 1.2 at intervals of 0.1. An error index $\epsilon(C_{br}, C_B)$ was defined to determine the optimum coefficients. This error index was calculated according to the following procedure.

1) The error in $H_{1/3}$ for all data sets, denoted as $\epsilon_H(C_{br}, C_B)$, and that in Q_b , denoted as $\epsilon_Q(C_{br}, C_B)$, are given by

$$\begin{aligned} \epsilon_H(C_{br}, C_B) &= \sum_{i=1}^{N_s} \sqrt{\sum_{n=1}^{N_{H,i}} ((H_{1/3,p})_n - (H_{1/3,m})_n)^2 / N_{H,i} / N_s}, \\ \epsilon_Q(C_{br}, C_B) &= \sum_{i=1}^{N_s} \sqrt{\sum_{n=1}^{N_{Q,i}} ((Q_{b,p})_n - (Q_{b,m})_n)^2 / N_{Q,i} / N_s}, \end{aligned} \quad (9)$$

where $N_{H,i}$ and $N_{Q,i}$ are the numbers of values of $H_{1/3}$ and Q_b in the i -th data set, and N_s is the number of the data sets. The subscripts p and m denote the values predicted and measured, respectively.

2) If ϵ_H and S_H are the mean and the standard deviation of $\epsilon_H(C_{br}, C_B)$ at $0.8 \leq C_{br} \leq 1.1$ and $0.5 \leq C_B \leq 1.2$, and ϵ_Q and S_Q are those of $\epsilon_Q(C_{br}, C_B)$, then the error index $\epsilon(C_{br}, C_B)$ is defined as

$$\epsilon(C_{br}, C_B) = \frac{(\epsilon_H(C_{br}, C_B) - \bar{\epsilon}_H)}{S_H} + \frac{(\epsilon_Q(C_{br}, C_B) - \bar{\epsilon}_Q)}{S_Q}, \quad (10)$$

In a calibration for Model 2, an error index $\epsilon(C_{br}, K)$ was similarly defined; C_{br} was varied from 0.8 to 1.1 at intervals of 0.05, and K was varied from 0.025 to 1.5 at intervals of 0.025.

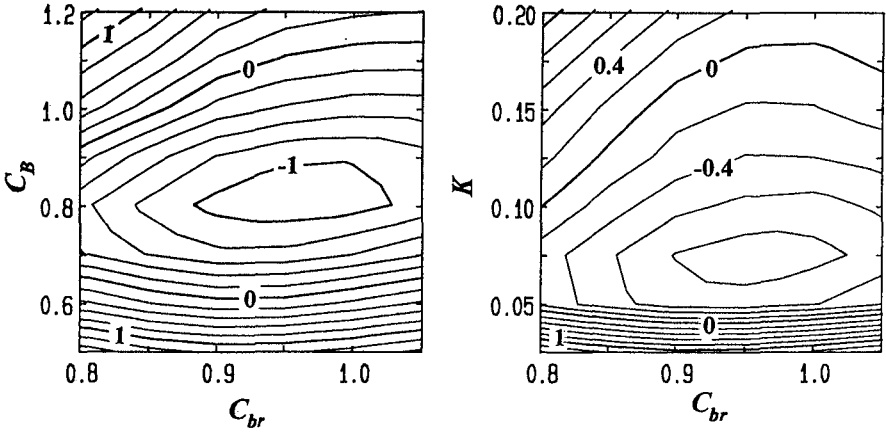

Figure 2 Contour plots of $\epsilon(C_{br}, C_B)$ and $\epsilon(C_{br}, K)$.

Figure 2 shows contour plots of $\epsilon(C_{br}, C_B)$ and $\epsilon(C_{br}, K)$. The optimum values of the coefficients were found to be $C_{br}=0.95$ and $C_B=0.8$ for Model 1, and $C_{br}=0.95$ and $K=0.075$ for Model 2.

I compared $H_{1/3}$ and Q_b measured in the field with those calculated with Models 1 and 2 containing the new coefficients, and show the results in Figure 3. The shortcomings of the models containing the old coefficients were lessened; the accuracy of Q_b estimated with the new coefficients increased. The values of Q_b estimated by the models containing the new coefficients agree with the field data over the longshore bars as well as over the troughs.

The differences between Q_b as estimated by the two models are small, but Q_b estimated by Model 2 decrease more over the troughs toward the shore and are more sensitive to the change in water depth near the shorelines than those estimated by Model 1.

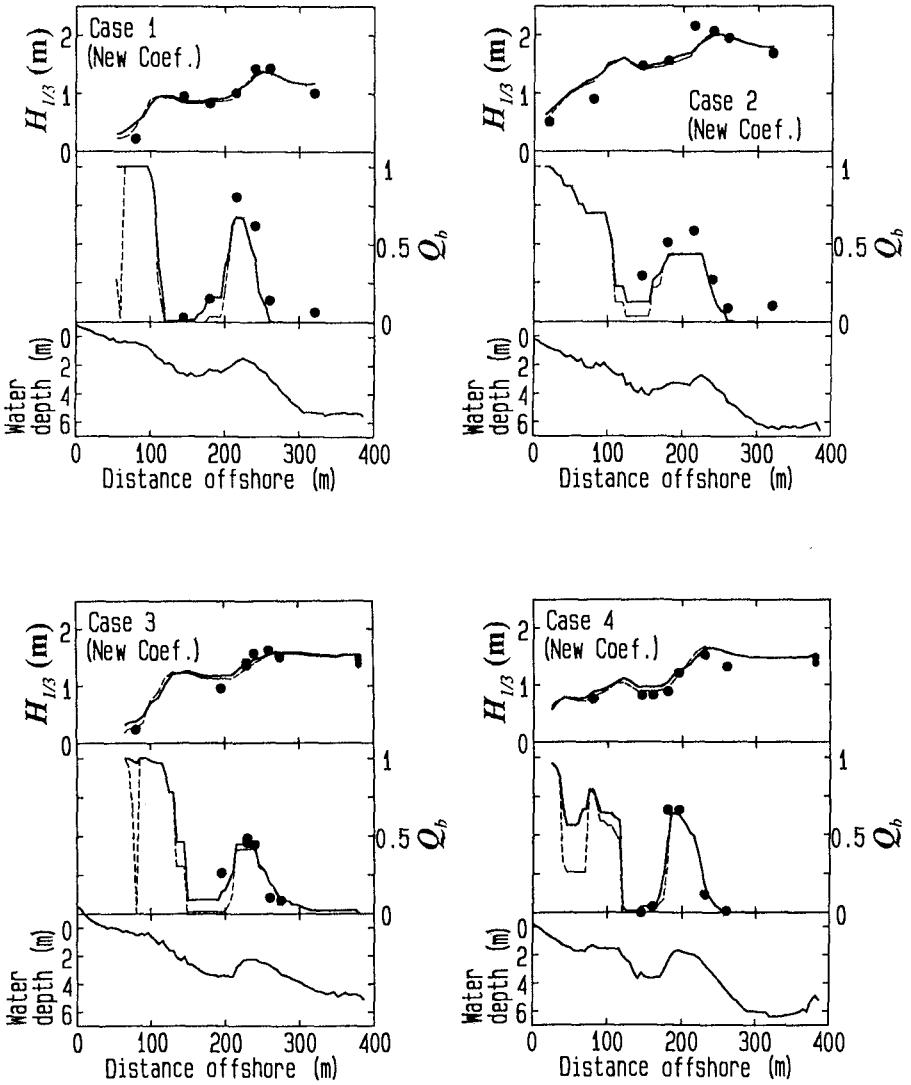

Figure 3 Comparison of $H_{1/3}$ and Q_b measured in the field (solid circles) and those estimated by the newly calibrated Model 1 (thick solid lines) and Model 2 (thin dashed lines).

Verification

The models were then compared with large-scale experiment data of the Delta Flume '93 Experiments (Rivero et al., 1994). The data shown by Rivero et al. (1994) are Q_b and H_{m0} , defined as

$$H_{m0} = 4.004 \eta_{rms}. \quad (11)$$

The present models cannot predict H_{m0} because that variable is estimated from a series of water surface elevation, which the present models cannot predict. Thus, a relationship between η_{rms} and $H_{1/3}$ is required to compare the results of the present models with those of the large-scale experiments.

Outside the surf zone, using field data, Goda (1983) has investigated the relationship between $H_{1/3}/\eta_{rms}$ and a wave nonlinearity parameter $\pi_{1/3}$, defined as

$$\pi_{1/3} = \frac{H_{1/3}}{L} \left(\tanh \frac{2\pi h}{L} \right)^{-3}, \quad (12)$$

where L is the wavelength at the water depth of h . He reported that $H_{1/3}/\eta_{rms}$ increases with increasing $\pi_{1/3}$ when $\pi_{1/3} \geq 0.1$, while $H_{1/3}/\eta_{rms}$ is constant and about 3.8 when $\pi_{1/3} < 0.1$.

Although the relationship between $H_{1/3}/\eta_{rms}$ and $\pi_{1/3}$ for waves out of the surf zone was investigated, no relationship between them for waves in the surf zone has been reported. Hence, I investigated this relationship with the field data for the 11 cases mentioned above, and show the results in Figure 4.

Figure 4 Relationship between $H_{1/3}/\eta_{rms}$ and $\pi_{1/3}$. The solid line shows the relationship obtained with the method of least squares, and the dashed line shows $H_{1/3}/\eta_{rms} = 3.8$.

The value of $H_{1/3}/\eta_{rms}$ in the surf zone increases with increasing $\pi_{1/3}$ when $\pi_{1/3} \geq 0.1$, while $H_{1/3}/\eta_{rms}$ is remaining constant at about 3.8 when $\pi_{1/3} < 0.1$. Thus I assumed that

$$\begin{aligned} H_{1/3}/\eta_{rms} &= 0.349 \ln \pi_{1/3} + 4.648, & \pi_{1/3} \geq 0.1, \\ H_{1/3}/\eta_{rms} &= 3.8, & \pi_{1/3} < 0.1. \end{aligned} \tag{13}$$

The upper equation of Eq.(13) for $\pi_{1/3} \geq 0.1$ was obtained by the method of least squares.

With the relationship expressed as Eq.(13), $H_{1/3}$ predicted by Model 1 and 2 were translated to H_{m0} , and the translated H_{m0} and the predicted Q_b were compared with the values measured in cases 1A, 1B, and 1C of the Delta Flume '93 Experiment (Rivero et al., 1994). The comparisons are shown in Figure 5. In all cases, the values of H_{m0} predicted by Model 1 are almost equal to those predicted by Model 2, and both agree with the measured values quite well. Hence, the discussion is focused on the fraction of breaking waves. On the planar beach of case 1A, the predicted Q_b agree with the measured values although the predicted values are somewhat smaller. On a barred beach of case 1B, Q_b predicted over the trough do not decrease toward the shore, and agree with the measured values, while the present models overestimated Q_b out of the trough. On another barred beach, case 1C, although the predicted values of Q_b decrease slightly toward the shore over the trough, the predicted Q_b agree with the measured values. Out of the trough, the present models also overestimated Q_b . Compared with Q_b predicted by Southgate and Wallace (1994) for cases 1A, 1B and 1C, Q_b predicted by the present models are insensitive to the change in water depth over the troughs, and Q_b variations predicted by the present models are smooth.

Discussion

The models developed in this study incorporate the wave reforming criterion proposed on the basis of field data and the coefficients calibrated with the field data. Through the calibrations of the models, scale effects were recognized in H_b/h_b and in the rate of wave energy dissipation due to wave breaking. In the field, values of H_b/h_b and the energy dissipation seem to be smaller than those in small-scale experiments.

While the cause of the scale effects on H_b/h_b is unknown, the scale effects on wave energy dissipation are considered to be due to the size of the vortex and turbulence generated by wave breaking. Differences in the size of the vortex and turbulence probably results in difference in the energy dissipation process.

Although scale effects on wave energy dissipation due to wave breaking, which strongly influence wave height variation in the surf zone, were recognized in this study, a comparison of wave height variations at different scales on planar beaches (Stive, 1985) revealed that scale effects on wave height variations in the surf zone were negligible. On a planar beach, waves continuously break and few waves reform. On the other hand, at a trough on a barred beach, few waves newly break and some waves reform. The difference in wave conditions seems to result in the difference in the appearance of scale effects.

Although the present models predict well $H_{1/3}$ and Q_b in the surf zone, models employing the wave-by-wave approach, like the present models, have a serious limitation; changes in wave period due to wave decomposition cannot be predicted

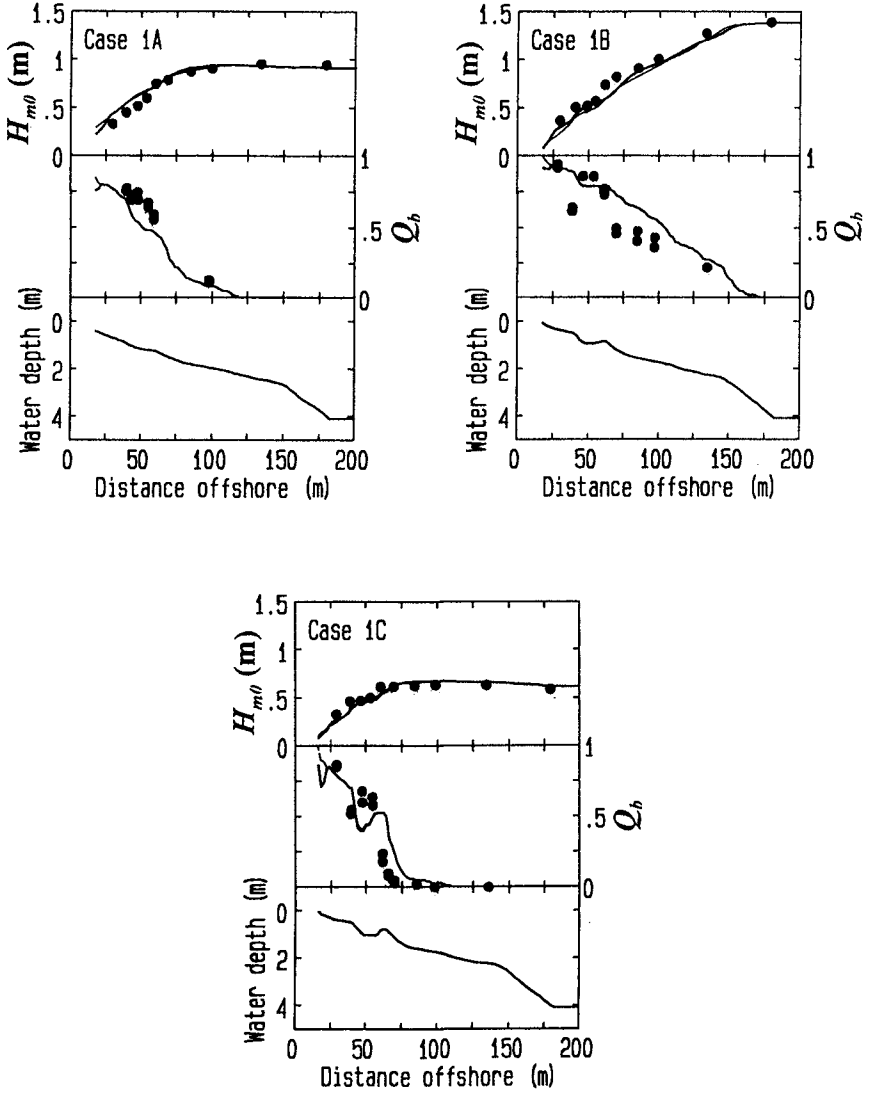

Figure 5 Comparison of H_{m0} and Q_b measured in large-scale experiments (solid circles) and those estimated by Model 1 (thick solid lines) and Model 2 (thin dashed lines).

because the models assume the number of waves to be constant. Wave decomposition frequently occurs over longshore bars, and results in a decrease in wave period. Future improvement of the models will be required to overcome this limitation.

Summary and Conclusions

Models for calculating $H_{1/3}$ and Q_b employing a wave-by-wave approach were developed. The performance of the models containing sub-models for wave breaking and energy dissipation calibrated with experimental data was not satisfactory; Q_b values estimated by these models were smaller than those measured over troughs. New coefficients were therefore introduced, and the models were calibrated with the field data. The models calibrated with the field data predict $H_{1/3}$ and Q_b well over the longshore bars as well as over the troughs. The validity of the models was also verified by comparison with large-scale experiment data.

CHAPTER 21

A Parametric Model for Random Wave Deformation by Breaking on Arbitrary Beach Profiles

Hyuck–Min Kweon¹ and Yoshimi Goda²

Abstract

The process of wave energy dissipation after breaking has been investigated with a number of random wave tests. To obtain the data for wave breaking and its deformation, experiments have been conducted by utilizing a horizontal step adjoining to a combined slope of 1/20 and 1/10.

After breaking, the wave height decreases by dissipation but attains a certain value at some distance from the breaking point. Experimental results show that the stable wave height is not constant but affected considerably by the wave period. The study has yielded a general formulation of stable wave height due to the random wave breaking.

A new one-dimensional random wave deformation model is proposed, being coupled with nonlinear shoaling coefficient formula before wave breaking and the new energy dissipation term after breaking. The model is compared with the experimental data, large wave tank data, and field data. It predicts well the wave height deformation and the change of mean water level before and after wave breaking on arbitrary bottom profiles.

1 Introduction

Random wave breaking is one of the most important phenomena in coastal engineering. Since around 1970, various models have been proposed to predict wave height variations in the surf zone. Many models assume planar beach profiles. However, in the natural sea there are step type beach profiles, and longshore bars appear in the breaking zone. Thus, a workable model applicable to arbitrary beach profiles is needed.

The difference among existing models lies on how to express the dissipation

1) Researcher, TETRA Co., Ltd., 2-7 Higashi Nakanuki, Tsuchiura, Ibaraki, 300, Japan

2) Professor, Department of Civil Engineering, Yokohama National University, 79-5 Tokiwadai, Hodogaya-ku, Yokohama, 240 Japan

term. Takayama et al. (1991) proposed a model that calculates the dissipation term with a modified Rayleigh distribution. Battjes and Janssen (1978) represented it with a bore model. The concept of stable wave height after wave breaking was introduced by Dally et al. (1985). That is, after breaking, the wave height decreases by dissipation but attains a stable value at some distance from the breaking point. However, existing models have certain problems. Some models are applicable to plane beaches only, some requires clumsy computation for a joint probability density of wave heights and periods, and some others need calibration with individual wave data in the field.

The present study gives a formulation of the stable wave height due to the random wave breaking and aims at presenting a model simple enough but reasonably accurate.

2 Experiments

2-1 Experimental conditions

Tests were conducted in a glass walled tank of 17 m long, 0.5 m wide, and 0.55 m as shown in Fig. 1. A horizontal step of 6 m long was set, adjoining to the combined slopes of 1/10 with the length 2.0 m and 1/20 with the length 1.0 m. The motion of the wave generator was controlled to absorb waves reflected from slopes. The crushed stone slope of 13/100 was built at the end of horizontal step. Buoyant artificial material was also used as a dissipater together with the crushed stone. The height of horizontal step was 25 cm.

Fig. 1 Experimental section and measuring points for obtaining stable wave height

The wave profiles were recorded at 14 points. Measurements were made at 8 points simultaneously. Gauge #1 was fixed at the distance 3 m from the wave paddle and gauge #2 changed its location depending on the wave period for separation of incident and reflected waves utilizing the Goda and Suzuki (1976) method. Gauge #5 was set at the tip of horizontal step. On the horizontal step, 9 wave gauges from gauge #6 to #14 were set with the interval of 60 cm each.

Experiments are divided into two groups. One is for estimation of the bottom friction effect. The other is for obtaining fundamental data of wave height decay.

Firstly, nonbreaking waves were utilized for the estimation of wave attenuation due to bottom friction on a horizontal step. In total, 18 cases were tested with the water depth on the step of 9 cm and 11 cm, 3 types of spectrum, and 3 combinations of wave periods and heights.

Secondly, wave profiles were measured for obtaining the data of wave height decay by breaking and stable wave height. With 3 different shapes of spectrum, 2 water depths, 3 periods, and 3 wave heights, a total of 54 cases was tested. Wave heights were measured at 14 points as shown in Fig. 1. The sampling interval was 0.05 sec and 8192 data were collected at one run. Wave heights were determined from the surface elevation records using the zero down-crossing method.

2-2 Analysis of wave data

Investigation of wave spectra at gauges #1 or #2 indicated a presence of appreciable low frequency energy. However, there was a noticeable drop of spectral density between the main wave component and the low frequency components. The frequency of spectral density drop was indentified for each case, and the wave components lower than that frequency was filtered out. The filtered wave profiles were produced by the inverse FFT technique.

The frequency range for separating incident and reflected waves was from 0.6 to 3 times the peak frequency. The magnitude of wave attenuation in wave height due to friction was estimated with the data of nonbreaking waves. The wave profiles obtained from gauges #5 to #14 on the horizontal step were analyzed by the FFT method for the Fourier coefficients.

Iwagaki et al. (1965) derived the solution of wave attenuation by bottom friction based on the laminar flow theory. The solution was used to yield the following formula for wave amplitude correction.

$$a_{cor} = a_{mes} \exp(-C_{amp} \epsilon_{b+w} x/L) \quad (1)$$

where

$$\epsilon_{b+w} = (4\pi^2/\beta L)(1 + 1/\psi_0)(\sinh 2kd_0 + 2kd_0) \quad (2)$$

$$\beta = (\pi/\nu T)^{1/2} \quad (3)$$

$$\psi_0 = k B/\sinh 2kd_0 \quad (4)$$

in which a_{cor} is the amplitude of corrected Fourier coefficient, a_{mes} the amplitude of measuring data, C_{amp} (≥ 1.0) an amplifier coefficient, x the distance from the initiation of horizontal step, L the wave length at a local point, T the wave period, k the wave number, d_0 the still water depth, ν the kinematic viscosity of water, and B the width of a water tank. The value of C_{amp} was estimated with nonbreaking waves corresponding to different shapes of spectrum. The results were 1.48 for the JONSWAP-type spectrum with $\gamma=1.0$, 1.74 for the spectrum with $\gamma=3.3$, and 2.19 for an extremely high concentrated spectrum with $\gamma=10.0$, respectively.

The decomposed Fourier amplitudes were corrected for the bottom friction

effect with eq. (1). Then, all the corrected amplitudes were utilized in the inverse FFT method to reproduce wave profiles. Wave heights were determined from the reproduced profiles.

3 Estimation of Stable Wave Heights after Random Wave Breaking

The stable height at some distance from the breaking point is proportional to the local water depth. In the experiments of Horikawa and Kuo (1966) the test bottom profile consisted of a steep slope section of 1 to 5 followed by a less steep slope (up to 1 to 20) or a horizontal section. The incident waves were forced to break at the end of the steep slope section and the wave height decay after breaking was monitored. It was fitted by exponential functions toward a stable wave height that is equal to about 0.4 times of the local water depth (d_0) for all conditions. The results of Horikawa and Kuo were interpreted by Dally et al. (1985) in terms of a wave height stabilizing at a constant value (cessation of breaking) lower than that related to the initiation of breaking.

The present study re-analyzed the Horikawa and Kuo (1966) data, by fitting the following exponential function:

$$H = H_0 \exp(-\varepsilon_{b+w}x/d_0) + H_S \tag{5}$$

where H_0 is the wave height at the initiation of the horizontal step. The stable wave height H_S was estimated with a bisection method.

All the stable wave heights were classified by water depth and wave period of 20 groups. Dally et al (1985) assumed that the stable height is proportional of water depth only. However, the height-to-depth ratio is not constant but affected considerably by the wave period as shown in Fig. 2 for the cases of regular waves. As shown in Fig. 2, the longer the wave period is, the higher the stable wave height is.

Fig. 2 The effect of wave period to a stable wave height

With the same procedure, the stable wave heights after random wave breaking

were estimated. In the random wave system, however, the stable wave heights have different levels corresponding to the definition of representative wave heights such $H_{1/3}$ and H_{rms} . The experimental results are plotted in Fig. 3.

Figure 3 indicates that the stable wave height is a function of the relative water depth d_0/L_0 . For the experimental data, the following formulation has been applied in an analogy to Goda's breaker index:

$$H_s = \Gamma d \quad (6)$$

where

$$\Gamma = A(d_0/L_0)^{-1} [1 - \exp(-1.5\pi d_0/L_0)] \quad (7)$$

$$d = d_0 + \bar{\eta} + \bar{\xi} \quad (8)$$

in which A is the coefficient for stable wave height. The symbol d_0 refers to the still water depth, L_0 the deep water wave length corresponding to the significant wave period, $\bar{\eta}$ the wave set-up, and $\bar{\xi}$ the representative amplitude of surf beat.

The curves in Fig. 3 represents the computation with eqs. (6) to (8).

Fig. 3 The general form of stable wave heights due to breaking of random wave

The total water depth including the representative surf beat amplitude was assumed as below.

$$d_0 + \bar{\eta} + \bar{\xi} = d_0 + \chi \bar{\eta} \quad (9)$$

By assuming the value of χ at 1, 2, and 3, the least square method was applied for the relationship between the ratio of the significant wave height to the total depth and the relative water depth. It was found the linear fitting has the least value when χ is equal to 2. That means, it is best to set the representative surf beat amplitude $\bar{\xi}$ equal to the

wave set-up $\bar{\eta}$.

Table 1 lists the best fitted values of stable wave height coefficient A in eq. (7), for various representative wave heights.

Table 1 The stable wave height coefficients of A for various representative waves.

H	mean	rms	1/3	1/10	max
A	0.072	0.083	0.122	0.145	0.188

4 Modeling of Random Wave Deformation

4-1 Governing equation

Dally et al (1985) proposed a model to describe wave decay in the surf zone assuming that the energy dissipation per unit surface area due to breaking is proportional to the excess energy flux relative to a stable energy flux, which is depth dependent.

$$\frac{\partial EC_g}{\partial x} = -\frac{K_d}{d_0} \left[EC_g - (EC_g)_s \right] \quad (10)$$

where E is the energy density, C_g the group velocity, x the onshore coordinate, K_d the wave decay coefficient, and d_0 the still water depth. The energy density and group velocity are given by the linear theory relationships.

Rewriting eq. (10) in terms of wave height, it becomes as below:

$$\frac{\partial [H^2 C_g]}{\partial x} = -\frac{K_d}{d} C_g [H^2 - H_s^2] \quad (11)$$

where $H_s = \Gamma d$.

The present model adopts eq. (11) as the basis of computation and employs the stable wave height expressed by eq. (7). The wave decay coefficient K_d is specified with a gradually varying value, the treatment of which is discussed in detail in the next section.

The wave-induced set-up and set-down are determined from the time-averaged momentum balance equation neglecting inertial effects and bed-shear stress, as follows :

$$\frac{d\bar{\eta}}{dx} = -\frac{1}{\rho g(d + \bar{\eta})} \frac{dS_{xx}}{dx} \quad (12)$$

in which S_{xx} is the onshore radiation stress. The radiation stress component S_{xx} for the organized wave motion is calculated by the linear theory as

$$S_{xx} = \frac{1}{16} \rho g H_{rms}^2 \left[1 + \frac{4kd}{\sinh 2kd} \right] \tag{13}$$

where ρ is the density of water, g the acceleration due to gravity, k the wave number, and d the total water depth ($d = d_0 + \bar{\eta} + \bar{\xi}$).

4-2 Treatment of wave decay coefficient

The dissipation term with the wave decay coefficient K was originally proposed by Dally and Dean (1985) who gave a constant value. For the analysis of random wave deformation, however, a modification is made on the decay coefficient in such a way that its value gradually increases over some distance.

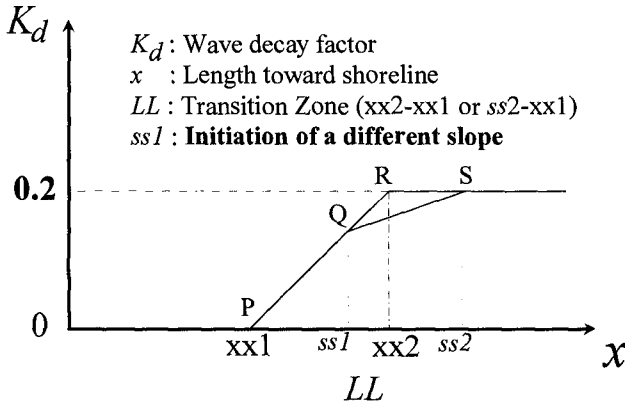

Fig. 4 Treatment of wave decay coefficient, K_d

The modification reflects the fact that waves have the different locations of initiation of breaking in a random wave system. Figure 4 shows the treatment of wave decay coefficient. For a single slope, K_d rises along the line PR over the locations between $xx1$ and $xx2$ and then takes a constant value of 0.2. The distance between $xx1$ and $xx2$ is calculated as the horizontal length corresponding to the change in water depth equivalent to the vertical distance of H_0' . If the slope becomes milder at the location $ss1$, then K_d follows the line QS. By introducing such a gradually varying wave decay coefficient, it becomes possible to calculate the wave decay successfully with the representative waves of a random wave system. It is also possible to analyze the wave deformation across beaches of arbitrary shapes.

The model has been calibrated with the Goda model (1975) for random wave breaking on a plane beach. The maximum value for the wave decay coefficient K_d and the transition length LL are calibrated to yield the best agreement between the present and Goda models. The comparison of the present and Goda model is shown in Fig. 5.

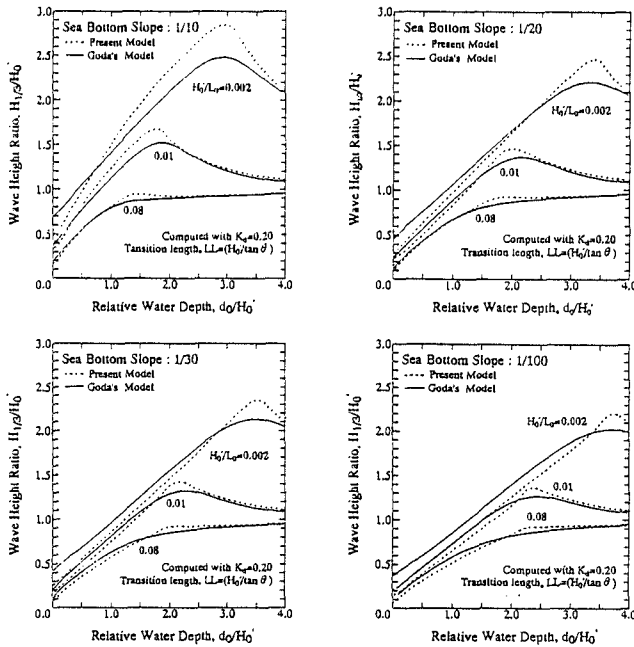

Fig. 5 Comparison of the present model with $K_d=0.2$ and the Goda model on plane beach

4-3 Procedure of calculation

Calculation is proceeded by a forward-difference numerical solution scheme from the offshore end of the numerical grid. The incident wave conditions of the model are the representative wave heights and the significant wave period. The non-linear wave shoaling is considered in the model.

Because eq. (11) produces a linear wave shoaling before wave breaking, the resultant wave height is amplified by the factor β of the following

$$\beta = K_s / K_{s0} \tag{14}$$

where

$$K_s = K_{s0} + 0.0015(d_0 / L_0)^{-2.87} \left(H_0' / L_0 \right)^{1.27} \tag{15}$$

in which K_s is a nonlinear shoaling coefficient, K_{s0} the linear shoaling coefficient, and H_0' the equivalent deep water significant wave height. The nonlinear shoaling coefficient of eq. (14) is obtained by the trial and error method as an approximation to Shuto's (1974) shoaling coefficient for non-breaking nonlinear wave based on cnoidal wave theory.

For initiation of wave breaking, Goda's breaking index of the following is adopted:

$$H_b = \Gamma_b d \quad (16)$$

where

$$\Gamma_b = A(d_0/L_0)^{-1} \left\{ 1 - \exp \left[-1.5 \frac{\pi d_0}{L_0} \left(1 + 15 \tan^{4/3} \theta \right) \right] \right\} \quad (17)$$

in which H_b refers to the respective breaker heights of representative waves such as $H_{1/3}$ and A is the coefficient listed in Table. 1.

After wave breaking is initiated, the wave decay coefficient K_d in eq. (11) is assigned the value which rises up following the path PR or PQS and the energy dissipation is evaluated. For the calculation of nonlinear wave decay height, the stable wave height is modified as

$$(H_s)_A = \frac{1}{1 + \beta_b} (H_s)_F \quad (18)$$

where $(H_s)_A$ is the linear stable wave height, $(H_s)_F$ the non-linear stable wave height which was attained by experiments as in eq. (6), and β_b is the amplification factor of shoaling coefficient ratio at the initiation point of breaking.

After wave breaking has occurred, a check is always made for the possibility of wave reformation. That is, if the calculated wave height falls below the stable wave height even though the K_d does not attain the maximum value of 0.2, K_d is reset as zero at that point. Then calculation starts again in the process of shoaling change.

Calculation of radiation stress by eq. (13) is needed before that of wave set-up by eq. (12). The root-mean-square wave height is calculated from $H_{1/3}$ with the assumption of Rayleigh distribution.

$$H_{rms} = H_{1/3}/1.416 \quad (19)$$

The computation of wave height and set-up is carried out twice. In the first run, the wave set-up at the shoreline where the still water depth is zero is linearly extrapolated from the adjacent two grid points. In the second run, the wave set-up and representative surf beat amplitude are added to the still water depth to yield the total depth. The present model finishes the calculation for all points at the second run because the difference of wave set-up between the 2nd and 3rd runs becomes below 2%.

5 Verification of the Model

5-1 Laboratory tests on a horizontal step adjoining to slope

Figure 6 shows the comparison of the model calculation and experimental data obtained from the present study. The increment of x in the calculation is 5 cm. The data with the JONSWAP-type spectrum ($\gamma=3.3$) are selected for comparison. Three

sets of data in which the wave steepness is almost the same but the water depth is different are shown here. As seen in Fig. 6, even when the water depth is extremely shallow, the model predicts the wave decay height quite well.

Fig. 6 Comparison of the model and experimental data on a horizontal step adjoining to slopes

5-2 Laboratory tests on a bar type beach profile

For obtaining data in a bar type beach profile, experiments were conducted with the section shown in Fig. 7. The wave profiles were measured at 14 points. Waves were expected to break between gauges #3 to #5 and to attain stable wave height between gauges #9 to #11. After waves become stable, waves start a shoaling change and re-break around gauges #12 to #13. Gauges #4 to #13 were set with the interval of 50 cm. The distance between gauges #13 and #14 was changed depending on wave period from 50 cm to less than 50 cm. The wave conditions included 3 diffe-

Fig. 7 Experimental setup for bar type beach profile

rent shapes of spectrum, 2 water depths, 3 wave periods, and 3 wave heights, and 54 cases were tested totally. The water depth in front of the wave paddle was $h_1=39$ cm and the depth on top bar was $h_2=9$ cm.

A selected set of experimental data with the JONSWAP-type spectrum ($\gamma=1.0$) is compared with the model calculation in Fig. 8. As shown in Fig. 8, the significant wave height (closed circles) shows good agreement except for the case with the largest wave steepness (top figure). However, the root-mean-square wave height (closed triangle) is predicted well by the model. During the wave decay height, it arrives a stable wave and increase with shoaling change. And it breaks again and decays toward the shoreline

Fig. 8 Comparison of the model and data on a bar type profile

Moreover, variation of wave set-up (open boxes) is predicted quite well by the present model. Though not presented in this paper, experimental data with other spectral shapes have also shown good agreement with the calculation by the present model. Thus, the model is applicable broadly to different shapes of spectrum.

5-3 SUPERTANK data

Four cases from the SUPERTANK Data Collection Project (Kraus et al. 1992) were selected to validate the random wave deformation model for normally incident waves under controlled conditions. SUPERTANK was conducted to investigate cross-shore hydrodynamic and sediment transport process using the large wave tank at Oregon State University, Corvallis, Oregon. In this study, the statistical data are utilized and no spectral information is used.

In the case A0517A, a pronounced bar was present with the crest located at a water depth of about 0.6 m. Case A0914A belongs to the same run as the previous case, but the bar was located further offshore. In the case S0913A a narrow-crested mound was constructed. A broad-crested mound was built in the offshore in the case S1208B.

Table 2 Wave conditions for compared SUPERTANK data

Run Number	Case number	Incident wave height		Wave period (sec)
		<i>rms</i> (m)	$H_{1/3}$ (m)	
ST10	A0517A	0.56	0.79	2.9
ST10	A0914A	0.51	0.71	3.8
STJ0	S0913A	0.45	0.63	2.8
STK0	S1208B	0.45	0.64	2.7

The data of $H_{1/3}$, H_{rms} and $\bar{\eta}$ are plotted in Fig. 9 with the symbols of closed boxes, closed circles, and open circles, respectively. The computed results are shown by the dash-dot lines, continuous lines, and dashed lines, respectively.

In the case A0517A, the wave breaking by computing starts prior to the data. The significant wave height is predicted well by the model. Case A0914A belongs to the same run as previous case but has longer wave period. The decay in H_{rms} and $H_{1/3}$ through the surf zone are well produced. However, it seems that the wave height nearest to the bar is affected by concentrating of wave breaking. The starting of set-up is affected by the initiation of breaking points.

In the case S0913A, the decays in H_{rms} and $H_{1/3}$ are faithfully produced by the model. However, the wave set-up is lower than the computation. In the case S1208B which has the broader bar, the model overestimates the wave heights around crest of the bar. It seems that on the crest the waves are not strongly affected by the wave nonlinearity.

5-4 Field data

Hotta and Mizuguchi (1980) carried out field measurements in 1978 at Ajigaura beach facing the Pacific Ocean located at the southern end of Tokai coast about 200 km from Tokyo. A breaker bar was present in the surf zone as shown in Fig. 10. In the nearshore zone, about sixty poles were placed on the sea bed at intervals of about 2 m normal to the shore over a total distance of 120 m. The significant wave at the latter pole was about 0.8 m in height and 9.4 sec in period.

Figure 10 shows the measured and computed wave heights. The computed wave heights before breaking are greater than the measured ones. The measured wave heights do not increase much in the zone between 120 to 100 m. The reason is not quite clear. It may be related to the bathymetry of the field. Dally and Dean(1986) also made comparison of their model and the data. Their prediction shows underestimation of the data because they used the linear shoaling.

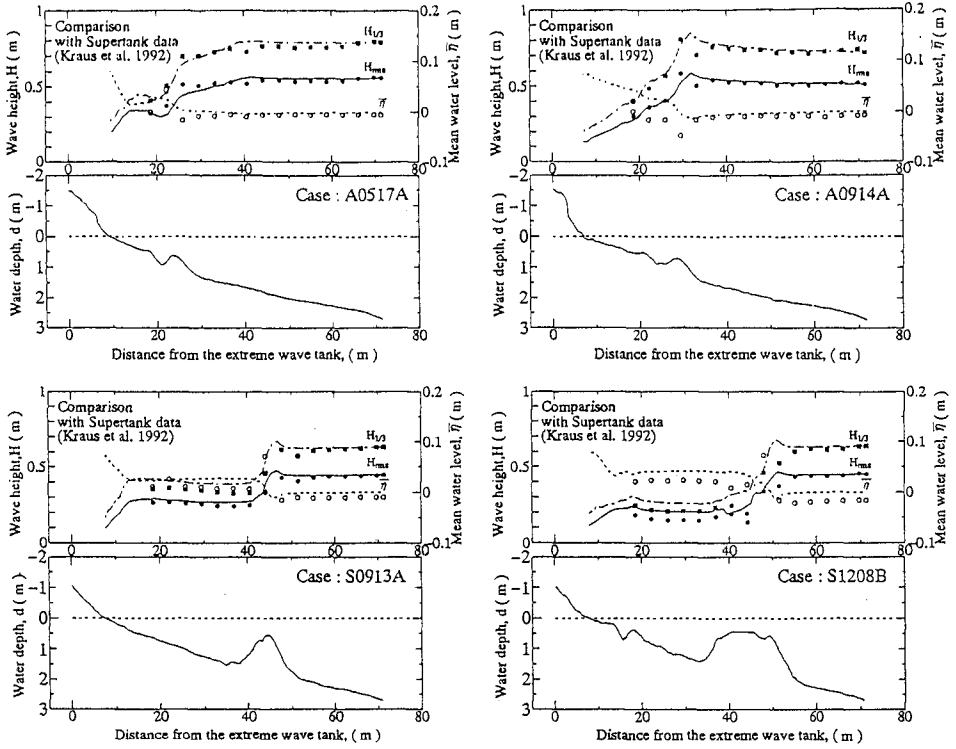

Fig. 9 Comparison of the model and SUPERTANK data

Fig. 10 Comparison of the model and field data

6 Conclusion

The merits of the present model are summarized as follows:

- 1) The model is applicable to any shapes of bottom profiles.
- 2) It requires the input data of incident wave heights and periods only without necessity of coefficient calibration with field data.
- 3) Its computation time is minimal because it deals with representative waves directly.

In addition, the model can easily be programmed as a subroutine for a large scheme to drive numerical models of nearshore circulation and sediment transport problems.

Acknowledgment

The authors would like to thank Dr. Kraus, Dr. Smith and all the members who participated the SUPERTANK project. They offered valuable data for verification of the present model.

CHAPTER 22

Generation Characteristics of Wave Sounds as a Factor of Beach Amenity

Hitoshi Murakami¹, Sadahiko Itoh², Yoshihiko Hosoi³,
Hideo Araki⁴ and Tsuyoshi Koyabu⁵

Abstract

This study deals with the comfortableness of wave sounds from physiological and psychological aspects. Firstly, the difference of wave sound generation mechanism between plunging and spilling breakers is discussed on basis of the variation characteristics of sound pressure level and the volume of air bubbles in water. Secondly, the comfortableness of wave sounds is investigated based on the generation characteristics of the brain wave and the result of questionnaire surveys of auditory test.

Introduction

Many artificially nourished beaches have been created as part of the improvement works related to coastal environment. The visual, auditory and olfactory factors are considered important factors of beach amenities.

Recently, much importance has been attached to the roles of desirable sounds in environment. The term "Sound Scape" named by R.M.Schafer(1977) has been used in much the same way as the term "Land Scape". More attention must be paid to the sound environment of the coastal zone.

As a matter of fact, the sensory tests on psychological responses to wave sound

have shown that the auditory factor such as breaking wave sounds is one of the most important factors affecting the amenities of the beach environment just as much as visual and olfactory factors(Nadaoka et al,1991a,b. Murakami et al, 1991). Authors have also investigated the characteristics of breaking wave sounds in laboratory tests and field observations(Murakami et al,1993). However, the exact physical mechanism of sound generation due to wave breaking remains under debate.

The purpose of this study is to investigate fundamental characteristics of the wave sound generation and to examine the difference of the sound generation mechanism in two types of wave breaking, the plunging and spilling breakers. Furthermore, the relationship between wave sound and its comfortableness is discussed from physiological and psychological aspects.

Characteristics of Wave Sound Generation of Air Bubbles in Wave Breaking

1) Experimental Methods

A wave tank with a pendulum-type wave generator at one end, which was 30m long, 1m wide and 0.9m deep, was used as shown in Fig.1. The bottom slopes θ were 1/10 and 1/15, and 45 kinds of waves which had different surf similarity parameters ξ_0 were induced.

Fig.1 Experimental Apparatus

Table 1 Experimental Conditions

beach slope $\tan\theta$	wave period T (sec)	equivalent deepwater waveheight H_0' (cm)	surf similarity parameter ξ_0
1/10	0.8~2.0	1.8~13.4	0.397~2.045
1/15	0.8~2.0	2.9~13.3	0.214~0.894

Wave sounds were recorded by a sound level meter at the upper point 30cm from still water surface. The video pictures of breaking waves were taken simultaneously at the distance of 1.5m from the side wall of wave tank to observe air bubbles in water induced by wave breaking. The water depth h was kept at a constant of 35 cm. The wave period T was changed from 0.8 to 2.0 sec.

Experimental conditions of wave breaking were shown in Table 1.

The surf similarity parameter ξ_0 as a breaker type index is defined as follows(Battjes,1974):

$$\xi_0 = \tan \theta / \sqrt{H_0'/L_0}$$

Spilling breaker, if $\xi_0 < 0.5$. Plunging breaker, if $0.5 < \xi_0 < 3.3$. Surging breaker, if $\xi_0 > 3.3$. In which, H_0' ; equivalent deepwater wave height, L_0 ; deepwater wave length. ξ_0 in this study are in the range of 0.2-2.0 . This means the experiments include both spilling and plunging breakers.

2) Characteristics of Generation of Air Bubbles and Wave Sounds

Fig.2 shows an example of the wave breaking process and air bubble generation during a wave period for the plunging and spilling breaker, respectively. Nondimensional phase $t/T=0$ means the onset of wave breaking. Generally, the behavior of wave breaking is divided into the following four phases; breaking , plunging, run-up and backwash.

For the plunging breaker, the wave begins to break and folds over air at the breaking phase. At the plunging phase, a large quantity of air bubbles are generated.

(1) plunging breaker

($H_0'/L_0=0.01, \tan \theta =1/15$)

(2) spilling breaker

($H_0'/L_0=0.12, \tan \theta =1/15$)

Fig.2 Breaking Process and Air Bubble Generation

Subsequently air entrainment occurs and the air bubble cloud reaches the sea bottom. After that , the air bubble cloud spreads out gradually to create the patch of foam at the run-up and backwash phases.

On the other hand, for the spilling breaker , the air bubble cloud induced by the former wave breaking remains without appearance over a wide area, even when a new wave begins to break at the wave crest in the breaking phase. The air bubble cloud near the wave crest spreads radially in every direction at the breaking and plunging phases. Finally, it combines with the former air bubble cloud .

From this experiment, the difference of generation and disappearance mechanism of air bubbles for the two types of wave breaking was revealed to

Fig.3 Relationship between B_{av} and H_b

Fig.4 Relationship between P_{av} and B_{av}

some degree. The volume of air bubbles, however, depends on the breaking wave height. In addition, the wave sound must be related to the volume of air bubbles.

Fig.3 shows the relationship between the average volume of air bubbles per one wave B_{av} and a breaking wave height H_b in the case of the bottom slope 1/15. It is difficult to measure directly a volume of air bubbles. The volume of air bubbles B at an arbitrary phase of wave is conveniently defined so that B can be obtained by multiplying a bubble cloud cross section area projected on the glass wall of wave tank with a wave tank width. An average volume of air bubbles B_{av} was obtained from the average value at the 5 different wave phases in a one wave period.

It can be seen that B_{av} increases with an increase of H_b . However, it shows a partially opposite tendency in the spilling breaker's long period wave. The relationship between an average sound pressure level P_{av} and B_{av} is shown in Fig.4. P_{av} increases with an increase of B_{av} regardless of the breaking type. The rate of increase of P_{av} , however, is more distinct with a steeper bottom slope.

The sound pressure level is also closely related to the volume of air bubbles.

Furthermore, let us consider the correlation between

(1) plunging breaker ($H'_0/L_0 = 0.01, \tan\theta = 1/15$)

(2) spilling breaker ($H'_0/L_0 = 0.12, \tan\theta = 1/15$)

Fig.5 Temporal fluctuation of P and B

the variation of sound pressure level P and the volume of air bubbles B in time in order to clarify the sound generation mechanism .

Fig.5 shows the temporal fluctuations of P and B for two types of wave breakers. Let us first consider the variation characteristics of P for the plunging breaker. P takes the maximum value in the middle of breaking and plunging phases. P decreases rapidly at the run-up and backwash phases. On the other hand, B takes the maximum value in the middle of run-up and backwash phases. It is significant that the maximum sound is not generated when the volume of air bubbles is at a maximum . It means a dominant sound is generated only in the short time when a water wave plunges on to the water surface, however, air bubbles are only slightly generated. Subsequently, even if the volume of air bubbles increases gradually after breaking, these bubbles are not an important factor in the generation of dominant sounds.

Secondly, let us consider the characteristics of the spilling breaker. P does not fluctuate so noticeably, though it increases slightly at the breaking phase in comparison with other phases. The fluctuation of B is smaller than that of P . It can be recognized that the mechanism of wave sound generation for the spilling breaker is attributed to the strong turbulence and bursting of air bubbles in the vicinity of the water surface.

Comfortableness of Wave Sounds due to Auditory Tests

1) Experimental Methods

In order to investigate the comfortableness of wave sounds, the brain wave test and questionnaire surveys were carried out simultaneously with 8 students of the University of Tokushima being the subjects.

Fig.6 shows an outline of brain wave measurement . First of all, a subject listened to various kinds of recording tapes of wave sounds on the headphones. The brain waves at the central zone Cz and occipital one Oz were measured and recorded in the FM data recorder whilst the subject's eyes were open for 3-6 min. The brain

Fig.6 Outline of Brain Wave Measurement

Table 2 Experimental Conditions of Auditory Tests

sound factor	wave sound		subject
	kind	condition	
strength	field observation sounds	$P_{av}(dB)$ 54,62,74	students male4,female1
wave period	artificial sound	$T(sec)$ 4,6,8,10,12	male7
sound tone	field observation sounds	$f^{-1/2}, f^{-1}$	male8

wave spectrum was obtained by a spectrum analyzer. In addition, the questionnaire surveys were conducted to find the most desirable sound by the same subjects.

The experimental conditions used in the brain wave tests and questionnaire surveys are shown in Table 2. Field observation wave sounds and artificial sounds made from white noise by FM radio were used as wave sounds in the tests. The effects of sound strength, sound wave period and sound tone as physical sound factors on the comfortableness of wave sounds were examined. The sound tone spectra at the backwash phase used here is shown in Fig.7. One is having minus 1/2 power of frequency f at the higher frequency region. The other is having minus 1st power of frequency f .

Fig.7 Sound Tone Spectra at Backwash Phase

2) Effects of Wave Sound Strength on Comfortableness

Fig.8 shows the relationship between the average power of α -wave(8-13Hz) P_w and an average sound pressure level SP_{av} over 6 min. Sign N in the transverse axis means non-sound. P_w decreases slightly with an increase of SP_{av} at the central zone Cz. On the other hand, P_w at the occipital zone Oz has the maximum value for the 62 dB sound. Especially, it should be noted that the power of α -wave for the 74 dB sound is smaller than that for the two others.

Fig.9 shows the result of a questionnaire survey on the relationship between the

Fig.8 Relationship between P_w and SP_{av}

comfortableness and the average sound pressure level P_{av} . The vertical axis indicates the number of persons, who gave the most suggestive response from the three sounds. From this test, the 62dB sound is the most comfortable of the three which corresponds to as the tendency of the brain wave tests at Oz. No one felt any comfortableness from on the 74dB sound to the subjects. The 74dB sound seemed to be felt as if it were stormy sea.

Fig.9 Effect of SP_{av} on Comfortableness

3) Effects of Sound Wave Period on Comfortableness

The authors have already pointed out from the questionnaire survey of the 67 students that the subjects feel the comfortableness for 6-8 sec of the sound wave period, but do not feel the comfortableness under 6 sec of the wave period. It has been pointed out this desirable value is nearly equivalent to the period of our breathing(Murakami et al,1992).

Fig.10 shows the effect of the sound wave period on the brain wave. The power of α -wave P_w has the muxmum value in 8 -10 sec of wave period in both figures. In the case of the wave period being under 6 sec, P_w has less than the power at non-sound.

Fig.10 Relationship between P_w and T

Fig.11 shows the results of the points obtained from the questionnaire survey of the five grade estimations with a score of 5 to 1 points for each wave period. The tendency in this figure is similar to the result of brain wave tests, though the tendency of the two in 12 sec of the wave period is different.

Fig.11 Effect of T on Comfortableness

Fig.12 Effect of Power Spectrum Shape on Comfortableness

4) Effects of Sound Tone on Comfortableness

The subjects listened to wave sounds which had two kinds of sound tone spectra as shown in Fig.7.

Fig.12 shows the effects of wave sound tone on the α -wave power. As a result, it can be seen that the power on sw2 is only slightly bigger than that on sw1. It is widely noted the α -wave power increases in the case of sound tone with the minus 1st power of frequency at a higher frequency region.

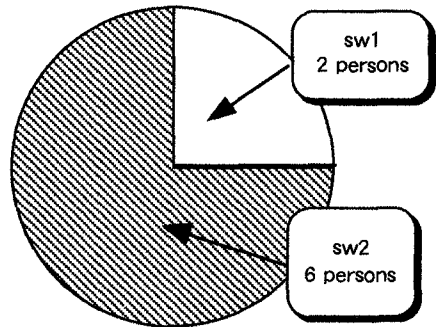

Fig.13 Comfortableness of Sound Tone

Fig.13 shows the comparison of the comfortableness of two kinds of sound tone on the basis of the questionnaire survey. The sound tones with sw2 and sw1 are in the ratio 6:2. This is the same tendency as the result of the brain wave test.

Conclusion

The generation mechanism of wave sound for two types of wave breakers was discussed on the basis of measurement of sound pressure level and volume of air bubbles. The effects of sound factors on comfortableness were examined from the physiological and psychological aspects. As a result, the wave sounds should be emphasised as being one of the most important factors of beach amenities. The

results are summarized as follows.

1) The difference of the sound generation mechanism between the plunging and spilling breakers was clarified. It was confirmed the behavior of air bubbles generated by wave breaking was closely connected with the characteristics of wave sounds.

2) It was proved that the comfortableness of wave sounds was affected by the factors of sound pressure level, sound wave period and sound tone and so on through the power of α -wave in the brain wave test and questionnaire surveys.

CHAPTER 23

Measurements of Wave Breaking in the UK Coastal Research Facility

Howard N Southgate¹ and Stuart Stripling¹

Abstract

Many experiments have been carried out on wave breaking in the past, but these have mainly been for regular, normally-incident waves. This paper describes experiments in the UK Coastal Research Facility in which over a hundred separate tests were carried out, covering regular, random, normally-incident, angled and multidirectional waves. Measurements were made of wave parameters as the waves underwent breaking in shallow water on a 1:20 slope. Analysis of the data to determine the wave breaking criterion, γ , for three random wave categories is presented.

Introduction

The criteria for values of wave height and water depth at which waves start to break in shallow water are an essential part of most computational models of nearshore wave propagation, and hence of many types of coastal engineering projects. A recent review (Southgate, 1995) has collated a large number of theoretical studies, laboratory experiments and field data sets which provide information for determining these criteria. Despite the large amount of work carried out, there remain important gaps in our understanding of the factors that influence breaker height criteria, with consequent uncertainties in the expressions used in wave prediction models. In particular, more information is required on breaker height criteria for random, angled and multidirectional waves.

This paper describes experiments carried out in the UK Coastal Research Facility (hereafter referred to as the CRF) to provide data for this purpose and for other aspects of wave propagation in shallow water regions where waves are breaking. About 100 tests were done in total, and five categories of wave were

¹HR Wallingford Ltd., Wallingford, Oxon, OX10 8BA, U.K..

investigated. These were:

- 1) Regular waves, normal incidence
- 2) Regular waves, 25 degrees to the normal
- 3) Random long-crested waves, normal incidence
- 4) Random long-crested waves, 25 degrees to the normal
- 5) Multi-directional waves, mean direction at normal incidence

These tests were designed so that, as far as possible, equivalent average input wave heights and periods were tested in each category. This has enabled a direct comparison of trends in wave behaviour across the different categories to be made.

In addition, this paper presents an initial evaluation of breaker height criteria for three categories of random waves (random at normal incidence, random at 25° incidence, and multidirectional waves).

Experimental Arrangement

Figure 1. Layout of the CRF

The CRF is a state-of-the-art shallow-water wave basin constructed at HR Wallingford. The basin measures 36m by 27m and has a working area of about 20m by 15m. The wave-maker is 36m long and consists of 72 independent paddles capable of generating regular, random or multidirectional waves at normal or

oblique incidence. In front of the wave-maker is a flat area followed by a 1:20 smooth concrete slope parallel to the wave-maker. The depth of water in the flat area is 0.5m. The overall layout is shown in Figure 1, and the main features of the CRF are described in more detail in Simons et al (1995).

For each test, wave conditions were measured at 14 locations along a line perpendicular to the coastline roughly midway between the two side boundaries of the basin. Measurements were made with twin-wire resistance probes. Most of the probes were clustered within and just offshore from the breaking region, giving a high spatial resolution in this region. Three probes were also positioned a short distance in front of the wave-maker in order to make measurements of the input wave conditions. These probes were positioned on a line parallel to the wave-maker, with the central probe on the same cross-shore line as the inshore cluster of probes.

Figure 2. Cross-Shore Locations of Pressure Tappings

In addition to measurements of wave conditions, data was obtained on set-up of the water level caused by the breaking of waves. To measure the set-up, holes (known as pressure tappings) were drilled at spatial intervals into the basin floor along the cross-shore line (see Figure 2). These holes were connected via smooth nylon hydraulic tubes to individual stilling pots. Measurements of the water levels in each pot were made using the same type of twin-wire probes as for the wave measurements. This system of pressure tappings and stilling pots was installed specifically for this study and is now a permanent feature of the CRF. In all, 38 pressure tappings and stilling wells were installed, but only a subset of these were

used in each test. For identification, each pressure tapping is given a number, with 1 closest inshore and 38 furthest offshore. Wave probe positions were selected to be coincident with a pressure tapping location so that corresponding values of wave parameters and water level set-up could be obtained.

A range of input wave heights from 0.03m to 0.1m was tested. Obviously, the higher waves broke further offshore and had a wider surf zone than the smaller waves. Therefore, in order to get the best spatial coverage and resolution, the locations of the probes needed to be changed according to the input wave height (the probes would need to be more spaced out for the higher waves). However, too much moving around of the probes would use up valuable experimental time, so a compromise was adopted in which there were two arrangements of probes. The first arrangement had the probes closely bunched near the waterline, and was used for low wave conditions (input wave height between 0.03m and 0.08m). The second arrangement had the probes more widely spaced, and was used for high wave conditions (input wave height of 0.09m and 0.1m). In each case every probe was located over a pressure tapping point. Figure 3 shows the relative locations of the probe positions for 'low' and 'high' wave conditions (the West Wall is the basin wall behind the beach, and the bed elevation is relative to the flat area in front of the wavemaker). Further details on the experimental arrangements can be found in CRF test report (Beresford and Channell, 1995)

Figure 3. Locations of wave probes

Test Programme

A total of 125 tests was planned. Due to time constraints, only 108 tests were actually carried out. Of these, data from seven tests were found to be corrupted as a result of a hardware problem in the logging computer. Therefore, a total of 101 tests produced data successfully for subsequent analysis.

The following procedure was adopted in carrying out the test programme. Firstly, the water was allowed to settle to a quiescent state and then 'zero levels' (ie the digital readings corresponding to the still water level) for each probe were logged. The waves were started and run until transient effects had died away. This was checked by monitoring up to four of the probes online. After this, data collection for the first test started, and tests continued in sequence for about two hours. The wave-maker was then switched off, and the water allowed to settle. New zero readings were taken and testing was restarted.

The regular wave tests were performed first. The duration of these tests was the equivalent of 100 wave periods or 180 seconds, whichever was the longer. The two wave directions tested were at 0 degrees and 25 degrees to the normal to the shoreline. At the end of each test, the data quality was assessed. The data from the three offshore probes was analysed (by a wave counting method) and the average wave height over the three probes was calculated. The test was accepted if this wave height was within 10% of the target wave height. If not, the test was discarded and then repeated.

The random and multidirectional wave tests were then performed. For all the tests, the frequency spectrum was based on the JONSWAP formulation (Hasselmann et al., 1976), with a peak enhancement factor equal to 3.3. As with the regular wave tests, the directions tested were 0 degrees and 25 degrees. For the multidirectional wave tests, the directional spectrum used a standard Cos-squared spreading function centred on 0 degrees. The length of each random wave test needed to be considerably longer than the regular wave tests to ensure that there were a sufficient number of the longest period waves in the spectrum for reliable statistical analyses to be carried out. Accordingly the length of each random wave test was set at 1200 seconds. The procedure for carrying out the random wave tests was the same as the regular wave tests, but a more stringent data quality criterion was applied. One of the main purposes of the experiment was to compare results of different wave categories for equivalent wave input (ie waves with the same average wave height and period). A random test was repeated if its input root-mean-square wave height differed by more than 5% from the input wave height in the equivalent regular wave test.

For all the tests, signals from all the 30 probes were sampled at a rate of 30 Hz. This is sufficient to determine maximum wave heights by wave counting analysis to an accuracy of better than 0.5% (Tayfun, 1993). This rate is more than

is necessary for spectral analysis, but does not adversely affect the analysis.

Table 1 below summarises the numbers of tests carried out for each wave category.

Wave Run Category	Wave Height Range (cm)	Steepness Range	Wave Period Range (sec)	Number of Performed Runs	Number of Successful Runs
Regular Waves. Normal Incidence	3 - 10	0.005 - 0.055	1 - 3	25	23
Regular Waves. 25 Degrees Incidence	3 - 10	0.005 - 0.055	1 - 3	25	25
Random Waves. Normal Incidence	6 - 10	0.015 - 0.055	1 - 3	20	20
Random Waves. 25 Degrees Incidence	6 - 10	0.015 - 0.055	1 - 3	18	15
Multi-Dir Waves. Normal Incidence	6 - 10	0.015 - 0.055	1 - 3	20	18
Totals	-	-	-	108	101

Table 1. Summary of Tests Performed for each Wave Category

Within each category, input wave height and steepness values were chosen systematically within the ranges 0.03m to 0.1m for wave height, and 0.005 to 0.055 for wave steepness. Pairs of values were chosen to give wave periods between 1s and 3s. These ranges of wave height and period represented the allowed operating ranges of the wave-maker. The random wave parameters that are designed to be matched to the equivalent regular waves are the *root-mean-square* wave height, and the *peak* period.

A feature of the wave-maker software for random and multidirectional waves normal to the shoreline is set-down compensation. Set-down is a natural feature in random (but not regular) seas that refers to the raising of the water level under groups of lower waves and lowering of the water level under groups of higher waves. The software allows the movement of the paddles to be modified to ensure that the set-down propagates correctly without unwanted second-order wave effects. For the normal-incidence random and the multidirectional wave tests, the set-down compensation was switched on. However, for both wave categories an extra test was done with the set-down compensation switched off, in order to assess the differences in the final results. In both cases the differences turned out to be very minor, and substantially less than differences between equivalent runs for different wave categories. The random wave tests at 25 degree incidence were done

without set-down compensation (the software at the time was only applicable to normally incident waves). Further details of the design input conditions for each test are given in Southgate et al (1996).

Spectral Analysis of Data

The CRF data has been analysed spectrally, and all the results in this paper are based on this analysis. The software uses a fast Fourier transform (FFT) algorithm, which requires the data to consist of exactly 2^n values, where n is a positive integer. Accordingly the data series for each probe in each run were truncated to 2^{12} (=4096) for the regular wave tests, and 2^{15} (=32768) for the random and multidirectional wave tests. One potential problem was the presence of a number of spikes in the time series data of water surface elevations. However, the spikes were narrow (usually consisting of only one data point) and few in number. Tests showed that they had a negligible effect on the statistical quantities of the whole time series, and therefore no action was taken to remove them.

The results of the spectral analysis are in two forms: a) frequency spectra (in 32 bands each of width 0.434Hz) for each of the wave probes, and b) statistical data derived from the frequency spectrum for each wave probe and corresponding stilling well probe. These latter data are:

- 1) The root-mean square wave height (H_{rms}), defined as $2\sqrt{2.m_0^{1/2}}$, where m_0 is the zero spectral moment.
- 2) The spectral period (T_m), defined as $(m_0/m_2)^{1/2}$, where m_2 is the second spectral moment.
- 3) The mean water level, derived from the stilling well probe data (the still water level is 0.5m).

Tabulated examples are shown in Southgate et al (1996). In deriving the data for b), the spectrum was truncated at high frequencies and only the first 16 frequency bands were considered (covering wave frequencies between 0Hz and about 7Hz). Wave energy at higher frequencies appeared to be 'noise' and represented only a small contribution to the total. Low-frequency wave energy is included in the analysis. A separate investigation of the low-frequency part of the spectrum would require a reanalysis with smaller band widths.

The spectral analysis has provided results in the form of wave frequency spectra, rms wave heights, spectral wave periods and wave setup at each probe location for each run. An example of the wave height results has been plotted in Figure 4 (diamonds) along with a computational model prediction with a best-fit breaker criterion, γ_{min} (full line). A full set of results for wave height decay and wave setup is shown in Southgate et al (1996).

Figure 4. Random waves, Normal Incidence

From the full set of results some initial observations can be made:

- a) Angled waves are generally slightly lower than normally incident waves. This can be explained by the angled waves undergoing refraction.
- b) Regular waves are generally higher than random waves immediately before breaking and decay to lower values immediately after breaking. This is explained by regular waves breaking over a much narrower zone than random waves. Also the increase in wave height due to non-linear effects immediately before breaking is noticeable.
- c) Multidirectional waves and random normally incident waves show very similar heights and patterns of decay
- d) There is substantial spreading of wave energy to both lower and higher frequencies, and a reduction in the spectral period values as one travels inshore. The effect is particularly strong for regular waves.
- e) Setup caused by regular normal waves starts further landward and reaches higher values than that caused by random normal waves or multidirectional waves.
- f) Setup caused by random normal waves tends to be higher than that caused by random oblique waves or multidirectional waves.

Other plots of this data are possible, for example spectral period vs cross-shore distance, or spectral density vs wave frequency (at each location). Other modes of analysis are also possible, for example wave counting analysis, or spectral analysis using different frequency bands.

Determination of Breaker Height Criterion for Random Wave Categories

This data set has been used to illustrate how to derive an expression for the breaker height criterion, γ , for three categories of random wave (normal incidence, 25 degrees incidence, and multidirectional waves). γ is defined as the ratio of wave height to water depth when waves initially break in shallow water, and is a key input parameter in most computational models of shallow water wave processes. Many experiments have been carried out in the past to derive values of γ , but these have mainly been flume experiments, most commonly with regular waves. The present experiments provide the opportunity to derive expressions for γ for the three types of random wave categories with equivalent input wave conditions. For random waves the wave height in the definition of γ is the rms value.

For random waves, γ has a different interpretation than for regular waves. In the case of regular waves, γ refers to the wave height to depth ratio at initial breaking for *individual waves*. For random waves, γ is a single value representing an average value of wave height to depth ratio at initial breaking for a range of waves of different heights and wavelengths. In parametric surf zone wave models, it needs to be regarded as a parameter in the representation of the average rate of wave decay through the surf zone.

The most extensive previous study of breaker height criteria for random waves was done by Battjes and Stive (1985) who analysed twenty results from three separate laboratory exercises and two field exercises. Their analysis showed no systematic dependence of γ on bed slope, but a dependence on deep-water wave steepness. They used a hyperbolic tangent function to give a best fit to the data:

$$\gamma = 0.5 + 0.4 \tanh(33H_0/L_0)$$

The method of determining γ from the present experiments follows that used by Battjes and Stive. The idea is to use a parametric model of wave decay through the surf zone and repeat the runs for many different trial values of γ . For each run, the rms error of predicted wave height vs measured wave height at all points across the profile for which there are measurements is calculated. The value of γ which gives the minimum error is selected. The model used for this purpose was the wave part of the morphodynamic profile model, COSMOS-2D (Southgate and Nairn, 1993).

Model runs were performed for each experiment in each of the three random wave categories, stepping through a range of values of γ from 0.4 to 1.0 with

Figure 5. rms Error in Wave Height vs γ

increments of 0.01. At each value of γ , the root-mean-square (rms) error between the wave height measurements and the wave height profile predicted by the model at each measurement point was calculated. Figure 5 shows the range of γ values plotted against the rms error between the measured and the predicted wave height profiles. It can be seen that each wave has an optimum value of γ which provides a minimum rms error. This was taken to be the wave breaking coefficient for that wave.

Results

Figure 6 shows a plot of the deep water wave steepness against the optimum γ value, γ_{\min} . To calculate the deep water wave steepness, the average rms wave height and wavelength (calculated by the linear dispersion relation from the peak period) at the three probes in front of the wavemaker were refracted out to deep water using Snell's law. In this plot, r is the correlation coefficient and sd is the standard deviation of the data from the linear regression line obtained using the method of least squares. It can be seen that the normally incident random waves

Figure 6. γ_{min} vs Deep Water Wave Steepness

and the multidirectional waves have quite high values of the correlation coefficient, but that random oblique incident waves have a lower value.

Figure 7 shows a plot of the deep water Iribarren number, I_d , where I_d is the beach slope divided by the square root of the deep water wave steepness. It can be seen here that the correlation coefficients are lower for the random normal and oblique incident waves than for the deep water steepness plotted in Figure 6. The

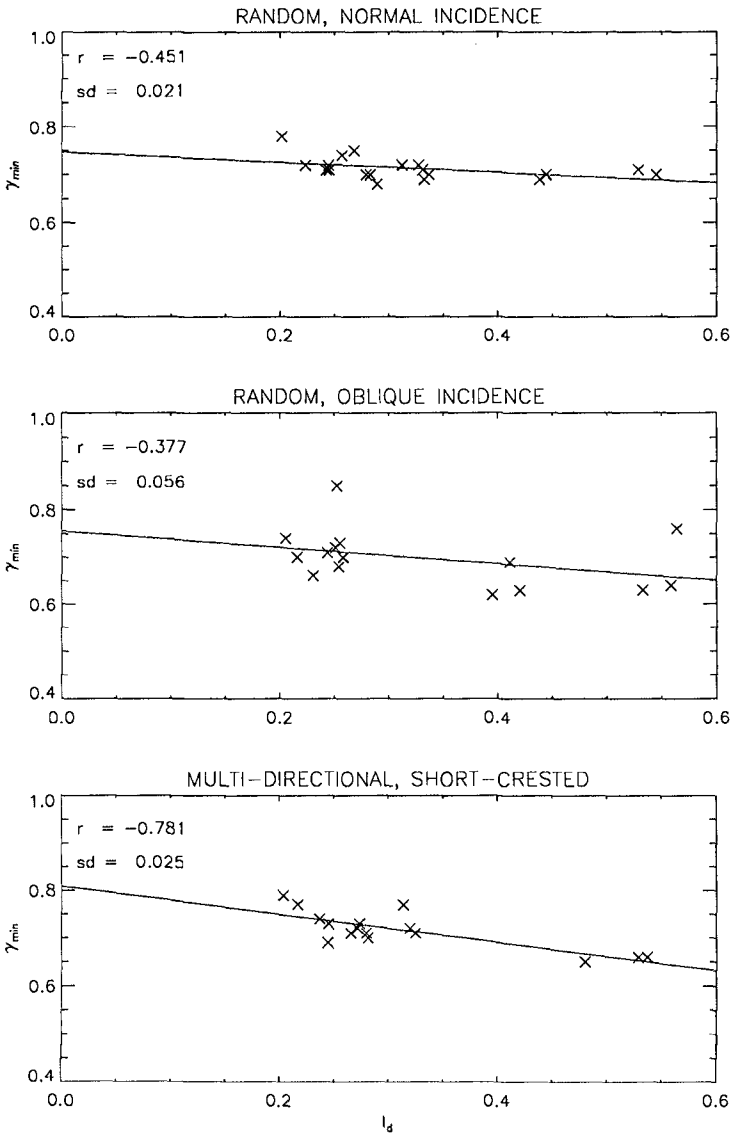

Figure 7. γ_{min} vs Deep Water Irribarren Number

multidirectional waves, however, still have a high correlation coefficient. This suggests that the deep water wave steepness is a more appropriate parameter than deep water Irribarren number to predict γ .

Figure 8 shows the deep water wave steepness regression lines and the trend line of Battjes and Stive (1985). The differences with Battjes and Stive appear

Figure 8. γ_{\min} vs Deep Water Wave Steepness (trend lines)

quite large, but almost all the wave steepness values in Battjes and Stive's data lay between 0.01 and 0.03.

Conclusions

A series of experiments in the UK Coastal Research Facility have been performed to provide data on wave transformation and decay in the nearshore breaking region in a systematic manner using five different categories of input waves. This data has been processed by spectral analysis to provide information suitable for investigating nearshore wave processes and evaluating wave models. An initial, visual comparison of the results across the different wave categories is summarised in the section on spectral analysis. If necessary the data could also be reanalysed using alternative methods. Typical examples of applications of this data set would be:

- a) Criteria for initial breaking of waves
- b) Wave height transformation and decay
- c) Wave setup and the 'transition zone' length (the distance between where waves start to break and where radiation-stress-driven phenomena start to appear, as revealed by wave setup)
- d) Wave energy transfer between frequency spectral components
- e) The fraction of waves breaking at any location (for random and multidirectional runs) determined from analysis of video records.

An analysis of the data for three categories of random wave (normal incidence, oblique incidence and multidirectional) has been carried out to determine breaker height criteria and their functional dependence on deep water wave steepness. However, to establish the most reliable expressions for breaker height criteria, it is recommended that this data set is combined with others, such as those used in Battjes and Stive (1985), so that the overall data set is as large as possible and covers as wide a range as possible of laboratory and field conditions.

CHAPTER 24

A New Type Breaker Forming a Giant Jet and its Decaying Properties

Takashi Yasuda¹, M.ASCE Hidemi Mutsuda², Atsushi Oya³,
Akihide Tada⁴ and Tadashi Fukumoto⁴

Abstract

Experiments in a wave flume(1m × 2m × 65m) with 16 wave gages and numerical simulations using a fully nonlinear BIM(Boundary Integral Method) in a super-computer(VP2600) are conducted to make clear the characteristics and occurrence condition of a new type breaker. Further, its deformation and wave height decay after breaking are investigated. It is shown that the new type breaker forms a giant jet with the size exceeding three times of the maximum jet size of usual type breakers and therefore is very efficient to wave control because of strong turbulence excited by plunging of the giant jet and the resultant remarkable absorption.

1. Introduction

Wave control and shore protection works utilizing artificial reef and submerged breakwater have many advantages over usual coastal structures such as offshore breakwater. However, since most breaking waves caused by the submerged coastal structures are spilling or plunger and they cannot excite sufficiently strong turbulence responsible to the required wave absorption, the problem that the efficiency of wave absorption is insufficient arises from those submerged structures. For that reason, in order to increase the efficiency and develop the artificial reef work to a desirable wave control and shore protection work, it is required to generate a breaker exciting much stronger turbulence and strengthen the absorption due to wave breaking.

However, a good understanding and information of the mechanism for breaker types that are essentially important for the energy absorption are still very limited. Nevertheless, most breaking waves have been supposed to be classified into four breaker types, spilling, plunging, collapsing and surging, based on

the visual observations of periodic waves regarding uniformly sloping bottoms, and accordingly little attention has been given to the possibility of new breaker types.

Cooker et al.(1990) studied the interaction between a solitary wave and a submerged semicircular cylinder, and found that the breaker forms are governed by the extent of the crest exchanges between the incident crest and the 2nd crest excited on the downward side of the cylinder. The results show that the breaker suffering the crest exchange is clearly different from the breaking of nonlinear long waves, in which the higher parts of an incident wave travel faster due to shallow water steepening and finally overturns to eject a jet, and reveals various behaviors and forms dependent on the interaction between the incident crest and the 2nd one.

In order to find out a new type breaker forming a giant jet and being efficient to wave absorption, we have been investigating basically the mechanism and characteristics of the breakers caused by submerged obstacles. As a result, such a breaker forming a giant jet was found to occur when a solitary wave strikes a reef having two steps, referred here to as a double reef. This breaker could be expected applicable to efficient wave control because it excites strong turbulence by plunging of the giant jet. Further, the new type breaker could be generated independently of these kinds of waves and bottom topography, only if the given conditions can be satisfied.

In this study, a solitary wave is made as an incident wave and is allowed to strike reefs having single and two steps with various heights, in order to reduce the number of parameters related to wave breaking as few as possible. Numerical simulations of the overturning of solitary waves on reefs are carried out until the jets ejected from their crests begin to fall, in order to investigate the characteristics of breaking wave profile and jet size and make clear the occurrence condition of the aforementioned new type breaker forming a giant jet. Further, experiments are conducted to verify the generation of the new type breaker in real fluid. At the same time, the accuracy of the simulated results is examined and the properties of wave deformation and wave height decay after breaking is made clear.

2. Method and Condition

2.1 Computations

Numerical computations using a fully-nonlinear BIM irrotational-flow model (Yasuda et al., 1990) are carried out of the overturning of solitary waves on reefs having single and two steps (Fig .1) until the jet-fall initiation, defined as when the overhanging face beneath the jet becomes just horizontal and the maximum

Figure 1: Coordinates and symbols for computations

Figure 2: Wave flume and locations of wave gages

gradient angle θ of the front face at each time step reaches 180° . Here, while a reef shown in Fig.1(a) is referred to as a single reef, a reef having two steps is referred to as a double reef.

The accuracy of the computations was previously examined by comparing a computed solitary wave with its exact solution and further verifying the validity of the computed surface profiles and water particle velocities at the breaking against carefully controlled experiments (Yasuda et al., 1992, 1993).

As an initial condition, a solitary wave represented by the exact solution (Tanaka, 1986) of a fully-nonlinear irrotational flow theory is given over the flat bed of the left-hand side of each reef as illustrated in Fig.1, and is assumed to propagate toward the reef. The numerical computations were undertaken under the condition that the error for energy conservation law is always less than 1%.

2.2 Experiments

Experiments were conducted in a 65m long, 1m wide and 2m high wave flume with a side window. Solitary waves with incident wave heights of 9.15cm \sim 16.90cm were generated using a computer-controlled piston wave maker. The still water depth h_1 was fixed to 31.0cm. Reef models made of steel plate were built on the plane bottom, 30.0m distant from the wave paddle. The height R of a single reef is 26.3cm, and the lower crown height R_2 and the upper one R_1 of a double reef are 13.1cm and 26.3cm respectively. A relative distance X_1 between

the 1st step and 2nd one of a double reef was changed from 0.0cm to 250.0cm. The case of $X_1 = 0.0\text{cm}$ corresponds to the single reef ($R_2 = 0.0\text{cm}$).

16 capacitance wave gages were installed to measure the temporal water surface elevation at each location shown in Fig.2. The gage W01 was placed in front of the reef to measure the incident wave profile and height. A high-speed video camera(unic, HSV-400) with a speed of 200 frames per second was used simultaneously to record the profile and size of the overturning jet.

3. Wave Breaking on a Single Reef

Time evolutions of spatial surface profiles of a solitary wave incident to single reefs with $R/h_1 = 0.4, 0.6$ and 0.9 are introduced here. The evolutions up to jet-fall initiation are illustrated in Fig.3, in which $\Delta t \sqrt{g/h_1}$ indicates the non-dimensionalized time increment of each evolution. The incident wave shown in Fig.3(a) does not accompany the 2nd crest and steepens to eject a small jet from the crest point at the location of $X/h_1 \approx 8$. This breaker therefore could be regarded as a spiller type. In the case of a single reef with a relative crown height of $R/h_1 = 0.6$, the breaker could be regarded as a plunger type because it had a larger jet than that of a spiller type. Further, the 2nd crest is generated from the front face and grows to eject a jet from the crest at the position of $X/h_1 \approx 4$ through the crest exchange with the incident crest, while the incident crest vanishes after having finished the crest exchange. Although this crest exchange is apparently similar with the soliton-soliton overtaking interaction as pointed out by Cooker et al.(1990), more information about it needs to be known. Furthermore, in the case of a single reef with $R/h_1 = 0.9$, the 2nd crest is generated far before the incident crest approaches the step, and then promptly ejects the jet at the position of $X/h_1 \approx 2$ during the crest exchange, while the incident crest keeps a height exceeding the 2nd crest. As a result, the jet seems to be ejected from lower part of the front face of the incident wave and therefore is regarded as a collapsing breaker.

In order to examine the relation of the profile and size of the jet to the relative crown height R/h_1 , comparisons of surface profiles around the jet are made for the solitary waves incident to single reefs with $R/h_1 = 0.25 \sim 0.90$, and their profiles at the breaking limit, defined as an instant that the forward face first becomes vertical and the maximum gradient angle θ just reaches 90° , and the jet-fall initiation are shown in Fig.4. It is found from the surface profiles at $\theta = 90^\circ$ that their horizontal asymmetries correspond well to the crown heights of reefs. It is also noticed that the vertical location of the jet tip at $\theta = 180^\circ$ becomes lower with the increasing of the reef height. However, the size of the jet seems to grow with the increase of the reef height while the profile of the jet keeps similarity.

(a) $R/h_1 = 0.4$

(b) $R/h_1 = 0.6$

(c) $R/h_1 = 0.9$

Figure 3: Propagation process up to overturning of a solitary wave with $H_1/h_1 = 0.5$ on single reefs with $R/h_1 = 0.4, 0.6$ and 0.9

(a) Breaking limit($\theta = 90^\circ$)

(b) Jet-fall initiation($\theta = 180^\circ$)

Figure 4: Comparisons of wave profiles at the breaking limit($\theta = 90^\circ$) and jet-fall initiation($\theta = 180^\circ$)

Further, in order to examine a quantitative relationship between the jet size and the reef height, we first define the horizontal jet length γ and the jet height η_J at the jet-fall initiation ($\theta = 180^\circ$), as illustrated in Fig.5, and further show the correlation under the incident wave heights of $H_1/h_1 = 0.4, 0.5$ and 0.6 between the relative jet size $S = \gamma\eta_J/H_1^2$ and the relative reef height R/h_1 in Fig.6. The relative jet size S is found not to grow monotonically with the increase of the reef height but to have the maximum value dependent on the value of H_1/h_1 . This shows that the breaking waves accompanying the jet of which size exceeds 0.06 under the incident wave heights of $H_1/h_1 = 0.4, 0.5$ and 0.6 never occur on single reefs even if the reef height R increases up to the water depth h_1 .

4. New Type Breaker on a Double Reef

The surface profiles of a new type breaker on a double reef are shown in Photo 1. It is clearly found from the profiles that the new type breaker is characterized by the height of the location ejecting a jet, which is not the crest point and lower-half part of the wave, but is the upper part of the front face, and by the overturning jet form having a triangular crown. Such a breaker can never be categorized by the usual four types defined by Galvin(1968), and therefore, should be recognized as a new type breaker out of doubt. The snapshots further demonstrate the generation of the 2nd crest from the forward face and the formation of a giant jet excited by the coupling of the near-breaking incident crest and the 2nd one. Thus, the new type breaker is characterized by the formation of the giant jet having a triangular crown through the composition of both the crests and therefore is referred to as a composite breaker.

Figure 7 shows time evolutions of the numerically computed spatial surface profile of a solitary wave with $H_1/h_1 = 0.5$ incident to a double reef with $R_1/h_1 = 0.8$, $R_2/h_1 = 0.4$ and $X_1/h_1 = 6.5$, in which the 2nd step is located near the point of breaking of the incident wave caused by the 1st step. The features of the composite breaker demonstrated by the snapshots are clearly found in the computed results. The 2nd crest generated from the forward face grows fast to eject the jet through the crest exchange with the near-breaking incident crest, as found from the distance between the 2nd step and the position of the ejection

of the jet.

The incident crest suffers the decaying effect due to the crest exchange with 2nd crest and the shoaling effect due to the 2nd step, and consequently, its steep profile is strongly held under the nonlinear interaction. This strongly held triangular crest joins up with the 2nd crest to form a giant jet. Thus, the composite breaker is supposed to be generated by the composition of the triangular incident crest strongly held by the reciprocal effects of decaying and shoaling and the overturning 2nd crest.

Figure 8 indicates comparisons of the breaking wave profiles shown in Photo 1 between the results processing from the images captured with the high-speed video camera and the computed ones shown in Fig.7. The computed profiles agree very well with the experimental ones, although the numerical computation was performed under the assumption of irrotational flow in an incompressible and inviscid fluid. The results obtained assure again that the present BIM is applicable for investigating the breaking wave problem without performing any experimental work, and further, verify that a new type breaker forming a giant jet, that is, a composite breaker can be generated on a double reef.

Photo 1 : Snapshots of the composite breaker from the generation of the 2nd crest to the jet-fall initiation

Figure 7: Propagation process of a solitary wave leading to composite breaker on a double reef with $R_1/h_1 = 0.8$, $R_2/h_1 = 0.4$ and $X_1/h_1 = 6.5$.

Figure 8: Comparisons of spatial surface profiles at breaking and jet-fall initiations between the results processed from images captured with a high-speed video camera and the numerically computed ones

(a) Breaking limit($\theta = 90^\circ$) (b) Jet-fall initiation($\theta = 180^\circ$)

Figure 9: Relations of wave profiles at the breaking and jet-fall initiations to the relative step distance X_1/h_1 of the double reef

In order to examine the relation of the profile and size of the jet to the relative step distance X_1/h_1 , comparisons of surface profiles around the jet at the breaking and jet-fall initiations are made for a solitary wave with $H_1/h_1 = 0.5$ incident to the double reefs with $R_1/h_1 = 0.8$, $R_2/h_1 = 0.4$ and $X_1/h_1 = 0.0 \sim 7.3$ and their results are shown in Fig.9. The incident crest turns to reveal triangular form and its height exceeds that of the breaker on a single reef($X_1/h_1 = 0.0$), as the relative step distance X_1/h_1 increases. However, when the value of X_1/h_1 exceeds about 7.0, a small jet is ejected from the incident crest before the incident crest gets to be combined with the 2nd one and then a giant jet is formed. For that reason, the jet size remarkably decreases in $X_1/h_1 = 7.3$ as shown in Fig.9(b).

Further, in order to make clear quantitatively the relation of the jet size S of breakers on double reefs to the relative 1st step height R_2/h_1 and step distance X_1/h_1 , we show the relations under the conditions of $H_1/h_1 = 0.5$, $R_1/h_1 = 0.8$, $R_2/h_1 = 0.3 \sim 0.6$ and $X_1/h_1 = 0.0 \sim 10.0$ in Fig.10. While the jet sizes of usual

Figure 10: Relations of the jet size parameter S of the breaking wave with an incident wave height $H_1/h_1 = 0.5$ caused by double reefs with $R_1/h_1 = 0.8$, $R_2/h_1 = 0.3 \sim 0.6$ and $X_1/h_1 = 0.0 \sim 10.0$.

Figure 11: Overturning process of a composite breaker obtained by image processing

type breakers generated on a single reef can never exceed the maximum value as previously shown in Fig.6, the jet size of the composite breaker generated on a double reef grows with an increase in X_1/h_1 and at last exceeds 0.16, that is, three times of the maximum jet size $S \doteq 0.05$ of usual type breakers introduced in Fig.6 when the location of the 2nd step is close to the breaking point of the incident wave.

5. Deformation and Decay After Breaking

Deformation of wave profile and decay of wave height after breaking are investigated and then their characteristics for composite breaker are made clear, by analyzing the data of water surface elevations at 16 measuring points.

Figure 11 shows the time evolution up to the touch down of the water surface

profiles of a composite breaker captured with the high speed video camera. The surface profile demonstrates that a remarkably large jet is formed by the composite breaker and is ejected from the 2nd crest developed by the coupling with the incident crest.

Figure 12 shows spatial changes of water surface elevations at measuring points from W01 to W16 of composite breakers with $H_1/h_1 = 0.30, 0.42$ and 0.55 on a double reef with $R_1/h_1 = 0.85, R_2/h_1 = 0.43$ and $X_1/h_1 = 8.06$. Each incident wave begins to break near the measuring point of W07. After that, the overturning jet from the 2nd crest touches down on the front face as shown in Fig.11, and further a bore front accompanying strong energy dissipation is formed.

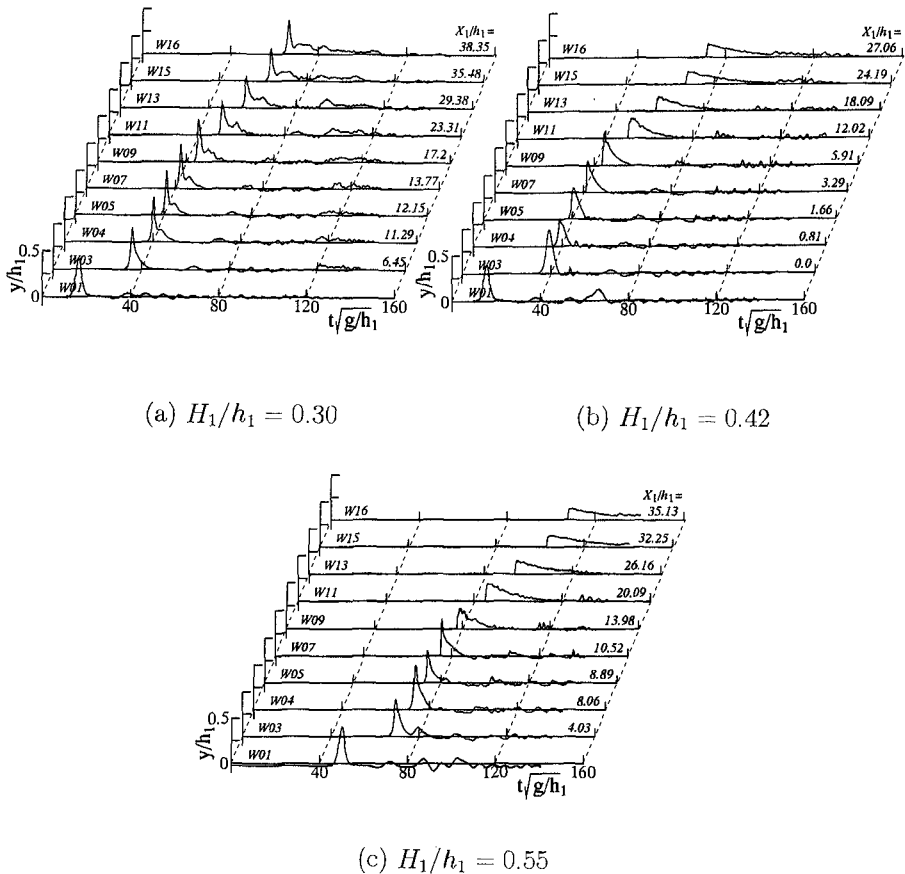

Figure 12: Temporal water surface elevations at representative measuring points of the composite breaker

Figure 13: Wave height decay after breaking of the composite breaker

As a result, wave absorption is pronounced and the breaking wave propagates as bore-like wave while keeping a similar profile.

Figure 13 shows spatial variations of the wave height ratio H/H_{max} of the composite breakers on a double reef shown in Fig.12, together with those of a spilling breaker on a single reef of $R/h_1 = 0.43$ and a plunging breaker on a single reef of $R/h_1 = 0.85$. The value of H/H_{max} strongly depends on breaker type ; the wave height of the composite breaker remarkably decays with the propagation distance after breaking, while those of the spilling breaker and the plunging one reach nearly stable state at $X_2/h_1 \approx 10$ and 20 respectively.

Figure 14 shows the relations of the transmission coefficient K_T and reflec-

Figure 14: Comparisons of the transmission coefficient K_T and reflection one K_R between the composite breaker and plunging one under the same incident wave height H_1/h_1

Figure 15: Relationships between the transmission coefficient K_T and the relative jet size S

tion coefficient K_R to the incident wave height ratio H_1/h_1 . The incident waves break on a double reef as a composite breaker, while they break on a single reef as a plunging breaker. Even if the incident wave is identical and further the crown height R_1 of the double reef is the same with the crown height R_1 of the single reef, both the coefficients K_R and K_T for waves incident to a double reef largely decrease in comparison with those for waves incident to a single reef, respectively by the depth change due to two steps and the generation of the composite breaker on the reef. Thus, by remodelling a single reef with $R_1/h_1 = 0.85$ to a double reef with $R_1/h_1 = 0.85$, $R_2/h_1 = 0.43$ and $X_1/h_1 = 8.06$, it becomes possible to reduce both the values of K_T and K_R by more than 23% against the incident waves with $H_1/h_1 = 0.30 \sim 0.55$.

Figure 15 shows the relationships of the transmission coefficient K_T to the jet size S of various type breakers on single and double reefs. It is clearly found that the value of K_T decreases proportionally to the increase of the jet size and wave height decay after breaking is governed by the jet size itself. This result shows that the generation of the breaker forming a jet with larger size, that is, the generation of the composite breaker is efficient to the improvement of wave absorption.

6. Conclusions

A new type breaker forming a giant jet, referred here to as a composite breaker, is generated by the composition of fast growing 2nd crest and near-breaking incident crest suffering the reciprocal effect; the decaying effect due to the crest exchange with the 2nd crest generated by the 2nd step of a double reef and the shoaling effect due to the 2nd step. The reciprocal effect forms the strongly held triangular crown and produces a giant jet by incorporating the triangular crown into the 2nd crest. Such a breaker has not ever been known and are supposed to excite strong turbulence by its diving and cause the resultant remarkable dissipation. Therefore, development of a new wave control system utilizing a composite breaker could be expected.

CHAPTER 25

WAVE CLIMATE CYCLES AND COASTAL ENGINEERING PRACTICE

Douglas L. Inman,¹ Scott A. Jenkins,¹ M. Hany S. Elwany¹

Abstract

El Niño-Southern Oscillation (ENSO) events are major factors in changing wave climate at coastal sites. These events are triggered by extreme anomalies in the global seasonal climate; and in recent years they have become quasi-predictable from certain antecedent conditions. Judicious application of the global concepts leading to (ENSO) events will improve our understanding and prediction of wave climate.

Introduction

Design of coastal structures and planning for beach remedial systems depend upon statistics determined from the study and measurement of past events and upon models using those statistics as primary inputs. The value of the statistic is usually assumed to depend solely upon the accuracy and duration of the observational series. This leads to common statistics such as a "design wave" height based on a recurrence history that defines the storm of the decade and century, and to shoreline changes based upon simple statistics such as the mean and standard deviation of beach width.

The limitation of our statistic is usually not the quality or resolution of the observations it is based upon, but rather that the statistics do not take into consideration the episodic nature of larger,

¹ Center for Coastal Studies, Scripps Institution of Oceanography, La Jolla, California 92093-0209

controlling systems that govern the intermediate to long-term wave climate and sediment budget. For example, wave climate is an end product of meteorological climate and subject to the cyclicities and uncertainties associated with that subject. Beach width is an end effect of the position within a littoral cell and is subject to all of the factors that influence the littoral sediment budget, including source, transport paths and sinks of sediment, as well as the variability in wave climate. Also, in the case of beaches, there is an element of inertia that causes beach erosion to be influenced more by the successive occurrence of clusters of average storms rather than by the isolated occurrence of a single extreme storm.

Climatic events such as El Niño-Southern Oscillation (ENSO) effect wave climate on a world-wide basis by altering the global atmospheric circulation paths, introducing periods of abrupt chaotic or episodic change. El Niños are harbingers of more intense wave climate along the temperate west coast of the Americas, but result in milder wave climates for the temperate east coasts of the Americas (Inman and Masters, 1994; Neelin et al 1994). El Niños also modify rainfall, causing droughts in some areas and flooding and maximum sediment yield in others. Along the southern California coast decades of relatively stable, mild wave climate are interrupted by El Niño events characterized by groups or clusters of intense storms and heavy rainfall. The El Niño of 1982/83 and its associated cluster storms completely denuded beaches that had been stable for the preceding 30 years. Thus, it is apparent that the usual statistical techniques based upon limited record lengths for predicting beach width and littoral drift rates and directions would lead to conclusions that are invalid for episodic periods of significant wave climate change.

Seasonal Climate: An Introduction to ENSO Events

The seasonal variations in the exposure of the hemispheres to the sun produce interannual changes in the duration of daylight and the angle of the sun's irradiance. These effects modulate solar heating, resulting in the interannual variation of the earth's atmospheric pressure field which in turn introduces seasonal climatic effects. Interannual variations are enhanced by the higher

convective effects of land and the greater concentration of land mass relative to water in the temperate latitudes of the northern hemisphere. In January, a large intense area of high pressure forms over the Asian continent (Figure 1a). This occurs because the convective slopes of Asia are inclined away from the sun with short periods of daylight that shutdown upslope convection, resulting in subsidence of air mass and an increase in pressure at ground level. In July, the convective slopes are inclined towards the sun with longer periods of daylight that increase solar irradiance and fuel upslope convection and lower surface pressure. Note that, in contrast to a rigid-lid system, the free motion of air in the convective atmosphere results in an inverse relation between temperature and pressure.

The northeast monsoons of southern Asia maximize in January, mainly in response to downslope anticyclonic flowing air caused by subsidence under the large area of Asian high pressure (Figure 1a). The cold descending air converges with tropical air to form a wet monsoon. The northeast monsoon in the Indian Ocean is less intense because of lower pressure gradients and the blocking effect of the Asian and African continental mountains. During July, the combination of upslope flow towards the low pressure area over the Himalaya mountains and the cyclonic geostrophic flow generates a strong southwest monsoon over the Indian Ocean (Figure 1b). This brings heavy rainfall over India and the high Ethiopian plateau (Quinn, 1992). The latter causes the Nile River floods that maximize during July. In contrast to the Indian Ocean, the southwestern monsoon is weak and relatively dry over southeast Asia because of lower pressure gradients and blocking by high inland topography.

The ENSO System

Upon occasion the typical seasonal weather cycles discussed above are abruptly and severely modified on a global scale. These intense global modifications are signalled by anomalies in the pressure fields between the tropical eastern Pacific and Malaysia known as the *El Niño/Southern Oscillation* (ENSO) (e.g., Diaz and Markgraf, eds., (1992). The intensity of the oscillation is often

measured in terms of the *Southern Oscillation Index* (SOI), defined as the monthly mean sea level pressure anomaly in mb normalized by the standard deviation of the monthly means for the period 1951-1980 at Tahiti, minus that at Darwin, Australia (Figure 2). A

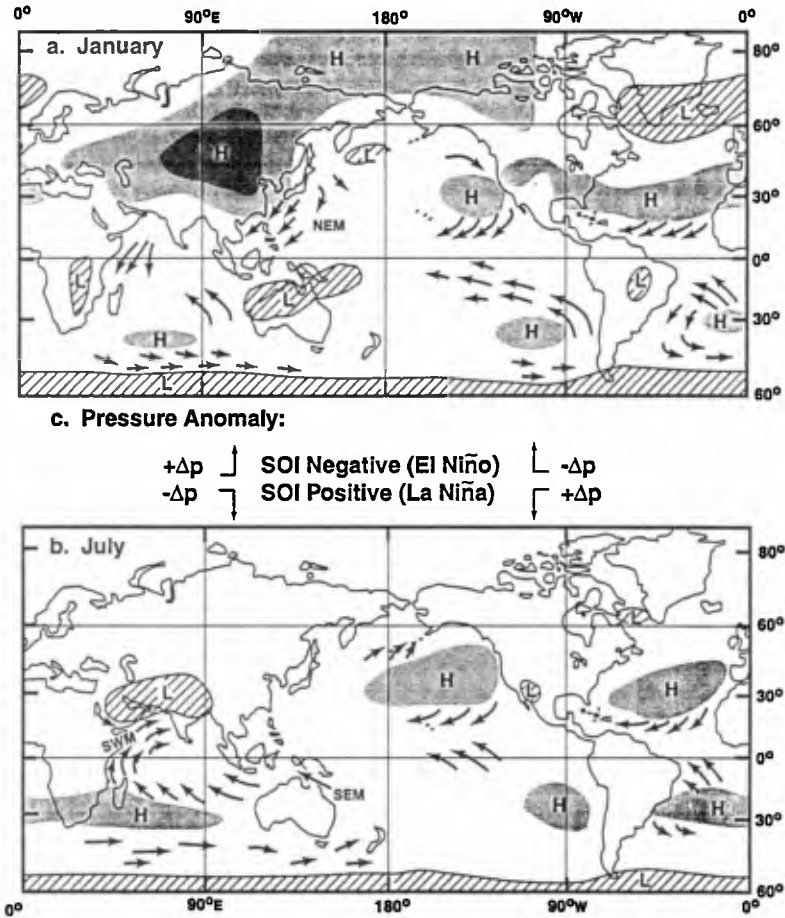

Figure 1. Seasonal pressure and winds for (a) January and (b) July. Contours of 1020 mb and 1000 mb are shown around areas of high (H) and low (L) pressure respectively. Prevailing winds are indicated by arrows: NEM, SEM, SWM designate northeast, southeast and southwest monsoons. (c) The pressure anomaly, Δp centered around longitudes 105° E and 105° W for negative and positive Southern Oscillation Indices (SOI).

Asian low pressure area will be intensified, spinning up a strong southwestern monsoon in the Indian Ocean, causing increased rain in India and over the Ethiopian plateau. In July, the air flow over the northern Indian Ocean is dominated by the large Asian low pressure system centered over Afghanistan. This intensifies the southwesterlies and draws the *intertropical convergence zone* (ITCZ) north over the Ethiopian plateau. The ITCZ is the zone of collision between the converging tradewinds of the northern and southern hemispheres. Its primary features are surface doldrums and vertical convection with considerable cumulus development, rain and thunder storms. For intense La Niñas, the resulting convergence of air masses in the ITCZ brings heavy rainfall that causes floods on the Nile River (Quinn, 1992). Application of $-\Delta p$ anomaly to the southern hemisphere tropics in the vicinity of 105° E lowers the pressure over northern Australia and New Guinea. This modifies the pattern of the southeast monsoon and brings heavy monsoonal rainfall to Australia (e.g., Nicholls, 1992).

Of course, the above suggestions based on an intensified seasonal pattern are vastly oversimplified and tell us nothing about why or when ENSO events occur or how long they will last. However, climatic events characterized by intense El Niños and La Niñas affect wave climates on a world-wide basis in the sense that atmospheric circulation paths are altered globally (Neelin, et. al., 1994; Philander, 1989). Spectral analysis of coral growth rates shows that over the past century El Niño events have occurred with recurrence periods centered approximately on 3 and 7 years with more intense events occurring every decade or so (Cole et al, 1992; 1993). Although the events are not clearly understood, there is evidence that ocean-atmosphere interactions act as an oscillator which drives large-scale ocean waves known as equatorial Kelvin waves. However, this oscillator interacts with Earth's annual cycles, producing nonlinear resonances (Jin et al, 1994; Tziperman et al, 1994). The ENSO cycles jump irregularly among these nonlinear resonances, exhibiting chaotic behavior. Thus, there may be relatively long periods of uniform annual climate response, interrupted by periods of abrupt change.

El Niños are harbingers of more intense wave climates along the temperate west coast of the Americas, but may result in milder

measured in terms of the *Southern Oscillation Index* (SOI), defined as the monthly mean sea level pressure anomaly in mb normalized by the standard deviation of the monthly means for the period 1951-1980 at Tahiti, minus that at Darwin, Australia (Figure 2). A

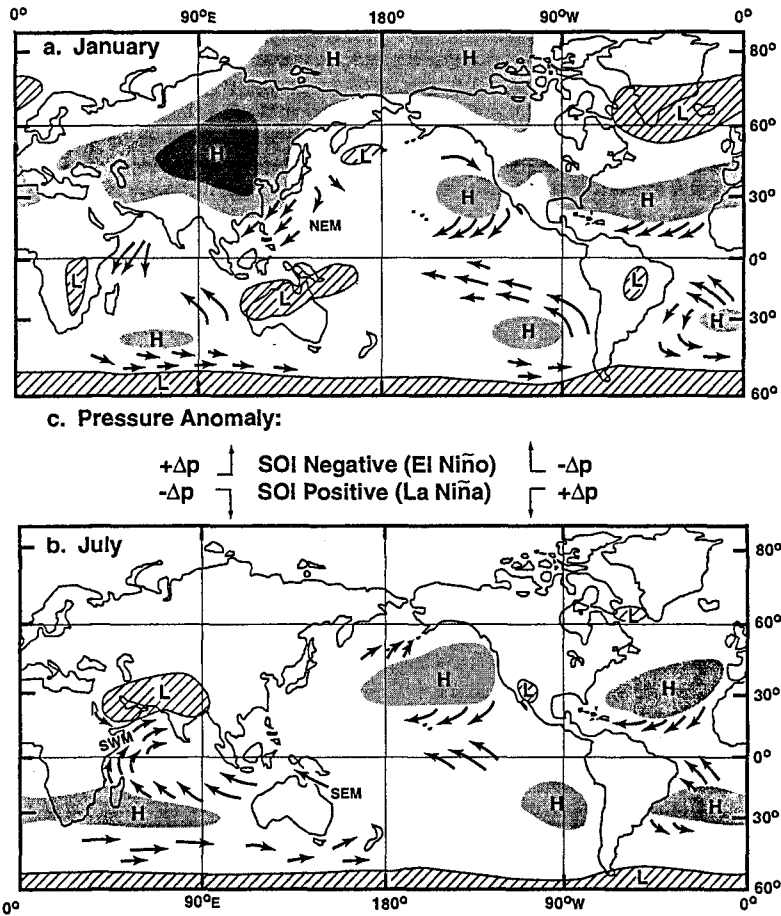

Figure 1. Seasonal pressure and winds for (a) January and (b) July. Contours of 1020 mb and 1000 mb are shown around areas of high (H) and low (L) pressure respectively. Prevailing winds are indicated by arrows: NEM, SEM, SWM designate northeast, southeast and southwest monsoons. (c) The pressure anomaly, Δp centered around longitudes 105° E and 105° W for negative and positive Southern Oscillation Indices (SOI).

negative SOI (lower pressure at Tahiti, higher pressure at Darwin) is known as an El Niño or warm ENSO event, because of the arrival

Figure 2. Global distribution of the correlation coefficient of annual pressure anomalies with simultaneous pressure anomalies at Jakarta (107° E longitude). Redrawn from Berlage (1957) and centered on 180° to show the southern oscillation.

of unusually warm surface water off the coast of Peru at the time of Christmas; hence, the term El Niño. Warm water also occurs along the coast of California and both regions experience unusually heavy rainfall. A positive SOI is known as La Niña and it signals the occurrence of colder than normal surface water in the eastern Pacific, but stronger southwest monsoons in the Indian Ocean with heavy rainfall in India and in the Ethiopian plateau. The latter causes flooding of the Nile River. Thus, the terms warm and wet vs cold and dry ENSO events that accompany El Niños and La Niñas respectively apply to the waters and coastal areas of the tropical-subtropical eastern Pacific Ocean and not necessarily to other parts of the globe.

It has been shown that the pressure changes associated with ENSO events are global in extent, and follow a pattern of alternate positive and negative correlation coefficients centered around

wave climates for the temperate east coasts of the Americas (Dolan et al, 1990 and Seymour, 1996). As El Niño events and groups of intense storms (referred to as "cluster storms") alter the wave climate, models of the nearshore must be adjusted to these changes in order to account for the abrupt and often long-lived coastal changes induced by these events.

The El Niño system

El Niño systems involve a complex set of interactions between the atmospheric and ocean circulation at tropical to middle latitude. The large-scale wind patterns and the companion mid-latitude high pressure systems described previously have a complementary feature in the ocean circulation referred to as "gyres". The gyres are the dynamic equivalent of the mid-latitude highs in the atmosphere, and are the result of an elevated sea level in the center of the ocean basin caused by a convergence of the Ekman drift from the trades and the mid-latitude westerlies. A large pool of warm water is established in the western Pacific which is ultimately regulated by the strength of the tradewind-driven component of gyre circulation.

This warm pool extends from the Philippine Islands south to the mid-Australian coast (Figure 3). Associated with these prevailing conditions is a stationary area of low atmospheric pressure, centered on Darwin, Australia, as compared with the relatively higher sea level pressure in the eastern Pacific from Tahiti to the coast of the Americas. El Niño events are associated with the release to the east of the warm water pool and a reversal of the relative pressure fields at Darwin as compared with Tahiti and the coast of the Americas (Figure 1a,c). These changes in the pressure fields in the lower layers of the atmosphere redirect the upper level jet streams that steer the tracks of traveling storms and markedly alter the wave climate of the world's coastline. The sequences within an El Niño event are illustrated in Figure 3 by numbers (1) through (5). The trade winds setup and confine a pool of warm surface water on the western side of the equatorial Pacific Ocean (1). Fluctuations in the prevailing trade wind intensity may release a series of eastward-flowing pulses of warm water. The warm El

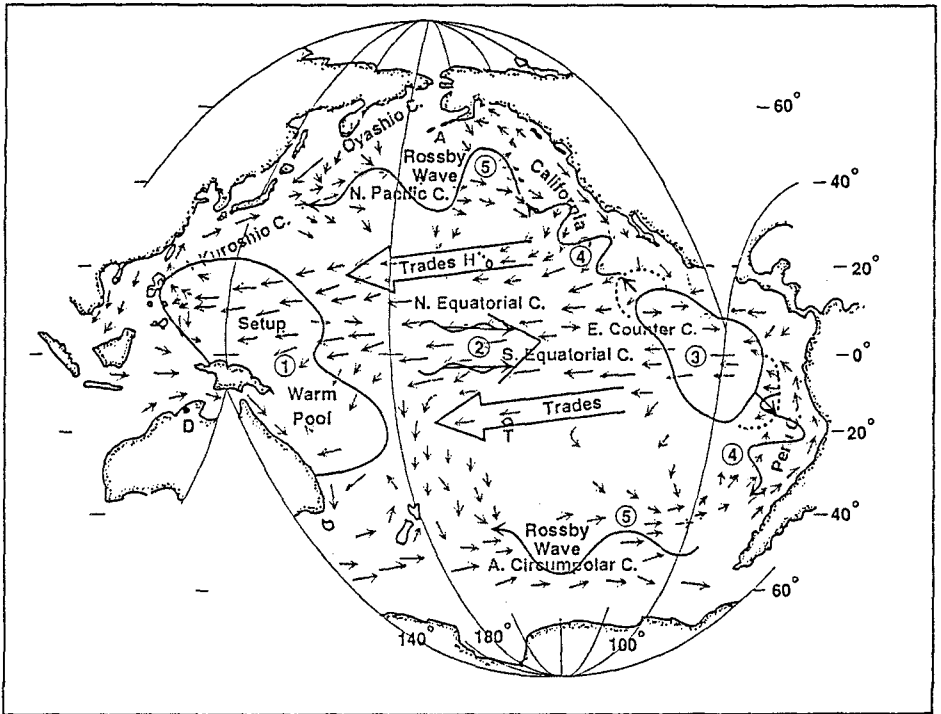

Figure 3. Schematic illustration of the five sequences leading to a fully developed El Niño event. See text for description.

Niño event begins when the trade winds relax and release a large "slosh" from this warm water pool which travels to the east along the equator (2). These sloshes travel as soliton-like internal features that are low-mode, baroclinic Kelvin waves channeled in the equatorial wave guide by the north-south gradients in planetary vorticity. Planetary vorticity is the spin imparted to a fluid particle by the local surface-normal vector component of the earth's angular velocity. These Kelvin waves have a phase speed determined by the density difference, $\Delta\rho$, at the thermocline, such that their phase speed is order:

$$C = [(\Delta\rho/\rho_2)gh_1]^{1/2} = 150 \text{ cm/sec,}$$

where h_1 is the depth of the thermocline. The equatorial Kelvin waves pump warm water into the eastern equatorial Pacific (3),

where it is spread poleward by barotropic Kelvin waves with topographically trapped modes propagating along the continental margins (4). These waves oppose the flow of the California and Peru currents. In turn, the shelf-trapped Kelvin waves appear to excite Rossby planetary waves that propagate slowly to the west against the flows of the North Pacific Current and the Antarctic Circumpolar Current (5). In addition to slowing the ocean current system, the Rossby waves induce sea surface temperature anomalies which modify surface pressures in the lower atmosphere that ultimately decrease the intensity of the westerlies, further slowing the overall circulation of water in the large Pacific gyres.

Sequences (1) through (5) in the El Niño event are all interactive among themselves and with the atmospheric circulation in very complex ways that are poorly understood. The conditions triggering the beginning of an El Niño event or those leading to its demise are not yet known. However, it is clear that, once started, the Kelvin-Kelvin-Rossby sequences all provide positive feedback that enhance each other and work toward a spin-down in the intensity of the prevailing anticyclonic oceanic gyres.

Changing Wave Climate

ENSO events leading to significant changes in seasonal trends of wave climate are usually associated with SOI values greater than about ∓ 0.5 . Figure 4 shows hemispheric contour plots of the pressure height anomalies (meters) for SOI positive (La Niña) and SOI negative (El Niño). Pressure gradients cause winds, and height anomalies show where persistent pressure gradients occur. The strongest pressure gradients occur along the boundaries of the height anomalies. The height anomalies in the figure show the mean location and intensities of the pressure changes during the ENSO events, and their boundaries indicate the likely location of storm paths. Figure 4a (La Niña) shows large areas of high pressure over the North Pacific and eastern North Atlantic. These high pressure areas would enhance storm tracks as shown by the two arrows for waves approaching North America and Europe. The El Niño condition is characterized in Figure 4b by a large area of negative height anomaly over the North Pacific ocean and a

relaxation in intensity but an increase in area of the positive height anomaly in the eastern North Atlantic. Thus, the La Niña/El Niño pattern over the North Pacific is bipolar and would be expected to give distinct changes in the storm track locations for the two conditions. In contrast either extreme would tend to enhance storm tracks approaching the coasts of Europe and the southeastern Mediterranean coast.

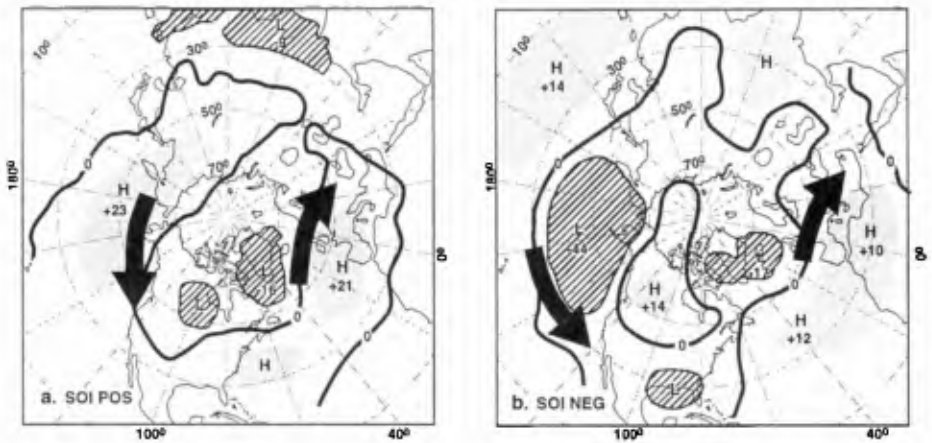

Figure 4. Height anomalies of the 700 mb atmospheric pressure surface derived from averaging winters (October-March) between 1947 and 1992 with preceding June-November for 11 SOI of +0.5 or greater (a) and for 12 SOI of -0.5 or less (b) (data from Redmond and Cayan, 1994). Shading and hatching indicate areas of negative (L) and positive (H) anomalies with maximum departure in meters. Arrows show position of storm-track enhancement associated with the anomalies.

Along many coasts, there are decades of relatively stable weather interrupted by shorter periods characterized by more variable weather, often accompanied by severe storms. The most recent period of mild-stable weather along the southern California

coast occurred during the 30 years between the mid-1940's and mid-1970's when mild La Niña type weather prevailed. Winters were moderate with low rainfall (Figure 5), and winds were predominantly from the west-northwest. The principal wave energy was from Aleutian lows having storm tracks which usually did not reach southern California (Figure 4a). Summers were mild and dry with principal wave energy coming from the southern hemisphere.

Figure 5. Cumulative residual rainfall in San Diego illustrating wet and dry periods that correlate with El Niño trends.

The wave climate in Southern California changed, beginning with the El Niño years of 1979/80 and 1982/83. The prevailing northwesterly winter waves have been replaced by waves approaching from the west (Figure 4b), and the previous southern hemisphere swell waves of summer have been replaced by tropical storm waves from the waters off Central America. The net result appears to be a decrease in the southerly component of the longshore transport of sand that prevailed during the preceding thirty years (Inman and Masters, 1994). Previous southward drift

rates of 200,000 m³/yr. have decreased to 50,000 m³/yr. and have reversed direction for protracted periods of time.

Conclusions

The clue to successful application of time series to engineering practice lies in long record lengths, and in the identification of supposedly anomalous trends. These anomalous trends can be identified by observables that either have intrinsically long record length or correlate with certain cause and effect mechanisms. For example, rainfall records, tree rings, railroad surveys and old newspaper articles can be used to correlate beach width and wave erosion with past El Niño's. Fluctuations in rainfall and wave intensity both follow the ENSO cycle which links them. For the modern records, a number of techniques are available to help elucidate this problem of cause and effect, including spectral and cross-spectral approaches and numerical progressions such as those resulting in cumulative residuals (Figure 5).

CHAPTER 26

STABILITY OF DESIGN WAVE ESTIMATES

Jan Rossouw¹, Josep R Medina²

ABSTRACT

Design wave heights are estimated for the Atlantic coasts of Southern Africa and the Iberian peninsula using the best available recorded data sets from the more exposed sites along these coasts. By spatial integration of the available data for a region and relaxing conditions with respect to independent sampling, stable estimates of design wave heights are obtained. Clear patterns are found in which the predicted design wave heights are strongly correlated with latitude. The recommendations of the IAHR committee on methods for design wave estimation are discussed and reservations are expressed about their recommendation to use only one method for design wave estimation.

INTRODUCTION

The estimation of design wave heights from recorded data is a subject that has received attention from many designers, engineers, statisticians and scientists in the past. Standard procedures for these estimates have however not been established and a variety of methods are presently being used. An international committee appointed by the IAHR, published a recommended procedure for design wave estimation in 1994 (Mathiesen et al, 1994). The committee recommended that only one method should be used. This method fits a three parameter Weibull distribution to data selected by means of a peaks over threshold (POT) sampling method.

This paper describes an alternative approach to design wave estimation favoured by the authors for areas such as the Atlantic ocean off South Africa and the Iberian peninsula. These areas are free of cyclones and similar storm events occur with great regularity during the winter months. Clear patterns in parameters such as the mean and standard deviation of the recorded wave heights exist in these areas. By using the method of moments to fit an Extreme 1 distribution to a total sample from the winter months, stable design wave estimates are obtained. Using this method, a very

¹ Senior Lecturer, Department of Civil Engineering, University of Stellenbosch, Stellenbosch 7600 South Africa

² Professor, Universidad Politecnica de Valencia, 46022 Valencia, Spain

interesting pattern in design wave heights emerges which is compatible with the known weather patterns in the area. Design waves estimated by this method are often much higher than with the method recommended by the IAHR committee.

In this paper an overview of the weather systems responsible for generating large waves in the Atlantic is given. Patterns in recorded wave heights are described and the knowledge of the weather and wave patterns are used to estimate design waves. The results obtained are discussed and compared with the results from studies by the IAHR committee

WAVE CLIMATE OF THE STUDY AREAS

The Atlantic coastlines off South Africa and the Iberian peninsula are free of cyclones as illustrated in Figure 1

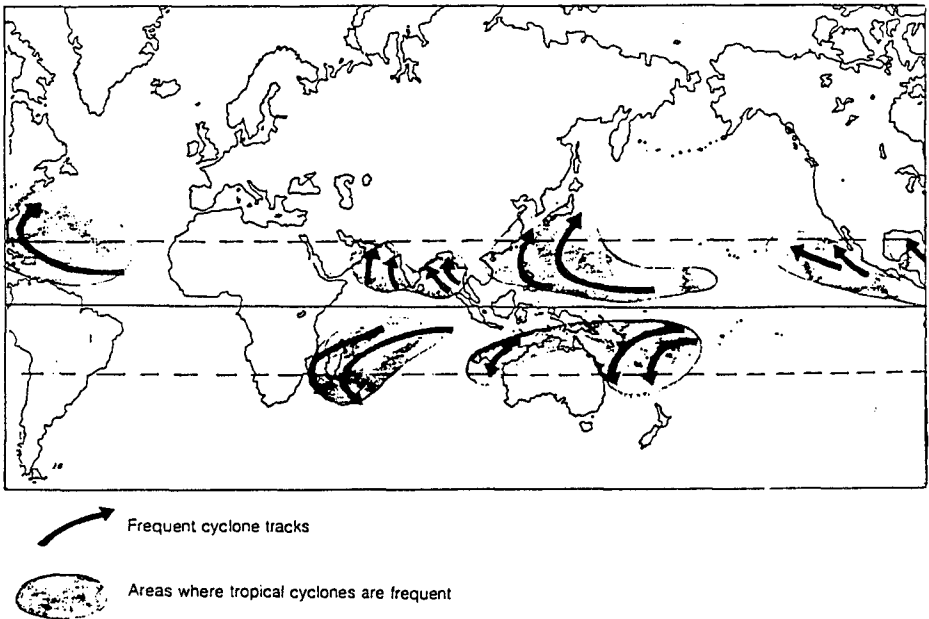

Figure 1: Frequent cyclone tracks of the world

(Hurry and van Heerden, 1982)

All major wave events in these areas are caused by large frontal systems which occur with great regularity during the winter months. Because of the size of the frontal systems and the speed at which they move on their path from west to east towards and past the coastline, similar wave heights are recorded over large coastal areas during major wave events. This is illustrated in Figure 2 for the South African coast for a few events during August 1980.

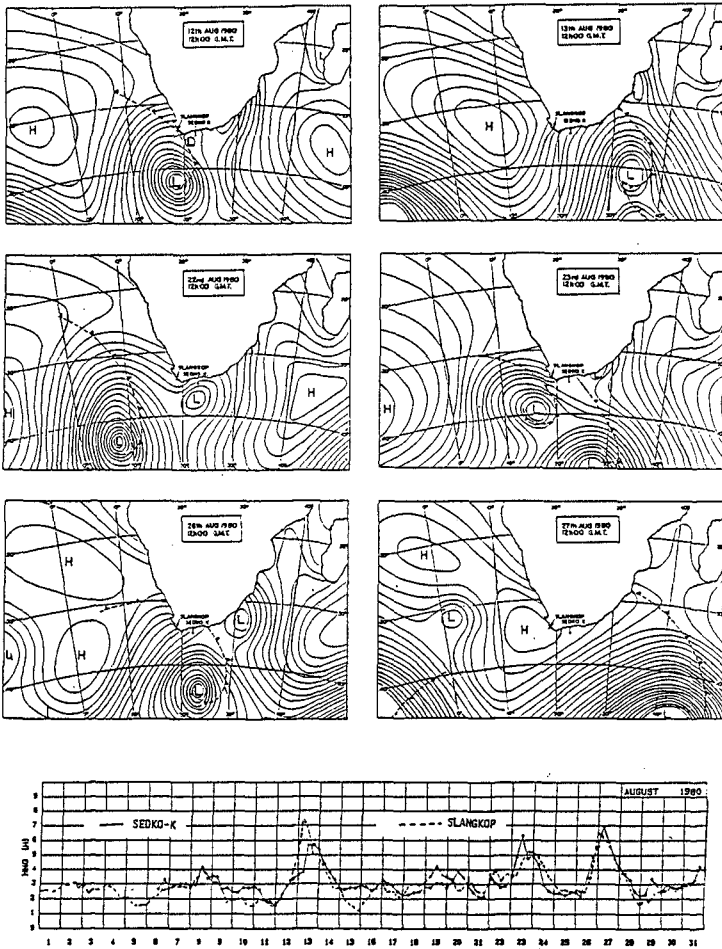

Figure 2: Waves recorded during August 1980

The similarity in wave heights recorded at two stations 300 km apart is apparent from this figure. Not only are the wave heights during major wave events similar over large areas, but the mean and standard deviation of the recorded wave heights over longer periods also show a remarkable similarity. In Figure 3 this similarity for 3 stations off the Iberian peninsula is illustrated.

The seasonal variation in wave height is also apparent from Figure 3. Extreme events can therefore be expected to occur in the winter months. In Figure 4 a comparison is made of the mean and standard deviation of the wave heights recorded in winter at a number of stations in the north Atlantic.

A clear pattern of increasing wave height with latitude is evident as can be expected due to the increasing intensity of the frontal systems at higher latitudes. A similar pattern is evident along the South African Atlantic coast.

Figure 3: Mean and standard deviation of Hmo - Iberian Peninsula

The similarity in extreme and average wave conditions recorded along these coasts, together with the knowledge of the weather systems, lead to the following conclusions related to design wave estimation:

- Extreme waves are invariably caused by similar frontal systems and the extreme wave heights at exposed coastal stations must belong to the same extreme distribution.

- Due to the absence of cyclones and the seasonal variation in wave heights, identical data would be ensured if only data from the stormy winter months are selected
- The paths of the frontal systems are such that their intensity increase towards the higher latitudes. An increase in design wave heights should therefore occur with increasing latitude. Recording stations at similar latitudes should have similar design wave heights.

Figure 4: Mean and standard deviation of H_{mo} - European Atlantic

ESTIMATES BASED ON EXTREME 1 DISTRIBUTION AND TOTAL SAMPLE

The method preferred by the authors for estimating design wave heights, uses the method of moments to fit an Extreme 1 distribution to a total sample from the winter months. In this method the parameters of the distribution are based only on the mean (\bar{H}_{mo}) and standard deviation (σ) of the recorded wave heights in winter. The distribution is given by

$$(\bar{H}_{mo}) = A - B \cdot \ln(-\ln p) \quad \text{with}$$

$$B = 0.78 \cdot \sigma \quad \text{and}$$

$$A = (\bar{H}_{mo}) - 0.5772 \cdot B$$

$$p = \text{probability of non-exceedance of } H_{mo}.$$

A graph of H_{mo} versus $\ln(-\ln p)$ gives a straight line with slope B and a abscissa A as shown in Figure 5.

Figure 5: Extreme 1 distribution

This method makes maximum use of the available data as well as of the clear pattern that exists in the mean and standard deviations of the recorded wave heights

The fit of the data to the Extreme 1 distribution for all the stations along the South African west coast is shown in Figure 6.

The distribution generally fits the data well although deviations occur near the upper tail of the data. The deviations of the data at the upper tail are both above and below the fitted distribution. Although it will be possible to obtain a better fit at individual stations by employing a three parameter distribution, the overall fit is acceptable if the same distribution is used at all the stations along the coast. Inspection of the data shows that the stations where the data at the upper tail exceeds the fitted curves, included the more severe storms recorded on the coast. A downward deviation occur where these storms are not included in the data set. These deviations are considered

to be due to variations in the wave climate and deficiencies in the data rather than variation in the underlying distributions. Too much emphasis on this upper tail will lead to unstable design wave estimates that vary haphazardly from station to station.

Figure 6: Extreme 1 fit to RSA data

The 100 year return period waves (H_{m0}) with a duration of 3 hours are shown in Figure 7 for the south and north Atlantic. Added to the data off the South African and Iberian Atlantic is data off the British isles and Norway.

Figure 7: Design $H_{m0}(100)$ - 3 hour duration

A strong correlation between the design waves and the latitude is evident from this figure.

The 100 year wave as estimated here is compared to the largest waves recorded at various sites in the north Atlantic in Figure 8. The 100 year wave predicted at all the stations exceed the maximum recorded wave height by between 30 and 50 per cent. The maximum difference occur at Haltenbanken where the 100 year wave of 18.5 m exceeds the maximum recorded wave by 6m or nearly 50 per cent. This design wave seems extraordinarily high and is much higher than the 15.0 m predicted by the members of the IAHR committee using the same data (van Vledder, 1993). The question obviously arises whether there should be a physical limit to the height a wave can reach. A wave height (H_s) of 17.4 m was recorded at the Weather Station India in the North Atlantic (Draper, 1986), at a latitude lower than the Haltenbanken site, giving some credibility to this high design height. The probable reason for the large difference between the two methods of design wave estimation in the case of Haltenbanken lies in the difference in emphasis placed on the upper tail of the data by the two methods. This will be further discussed in the next section.

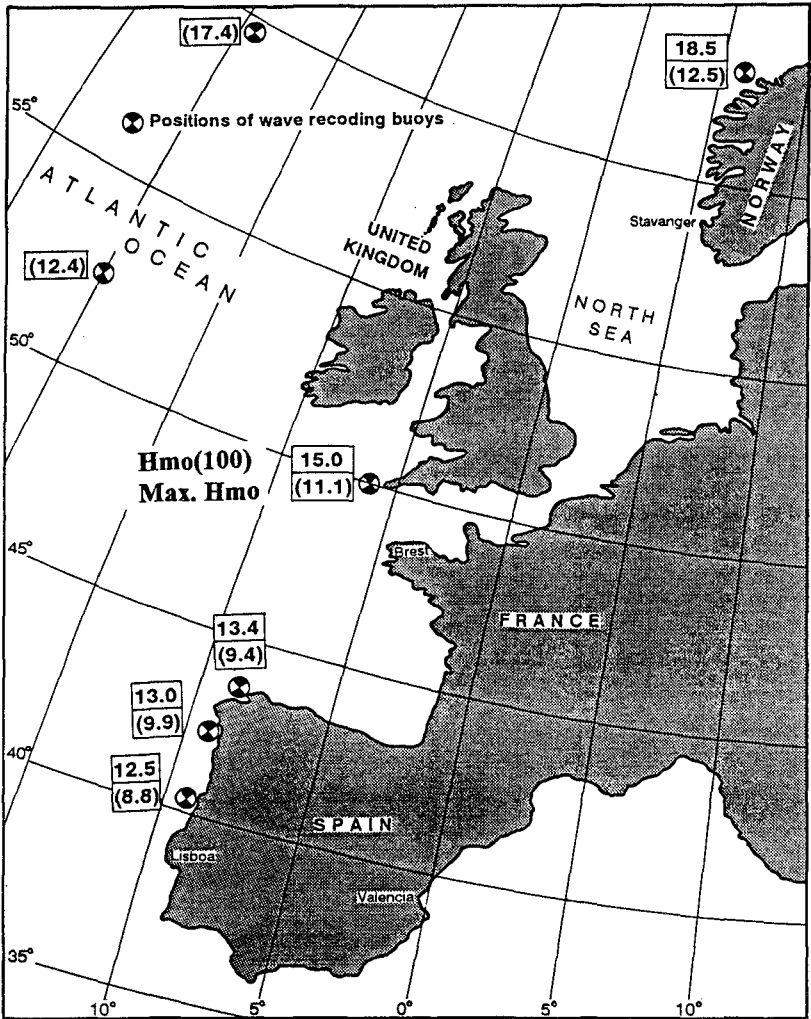

Figure 8: $H_{mo}(100)$ and maximum H_{mo} recorded

ESTIMATES BASED ON 3 PARAMETER WEIBULL DISTRIBUTION AND POT SAMPLING

The method for design wave estimation recommended by the IAHR group, differ from the method described above. To ensure independent and identical data, a peaks over threshold sampling technique is used. The highest wave recorded between the up and down crossing of a chosen threshold (POT) is used as data. A three parameter Weibull distribution is fitted to the selected data. This method inherently places the emphasis on the upper tail of the data in that only the largest storms are included in

the data and that the use of three parameters allows the fit to follow the data deviations at the upper tail.

With the South African data it was found that the two methods described above lead to similar design values in cases where a long data record is available and where the upper tail of the data follows the Extreme 1 distribution. With shorter data sets or in cases where a deviation from Extreme 1 distribution occur at the upper tail of the distribution, large differences occur between the two methods. Because of the emphasis on the upper tail by the IAHR method, much lower design wave heights are predicted when the data deviates downward at the upper tail. This is thought to be the reason for the large differences at Haltenbanken discussed in the previous section. Similarly the IAHR method will predict higher waves where the deviation is upward. The emphasis on the upper tail destroys the clear pattern in design waves illustrated in Figure 6. Copeiro (1978) already warned against placing too much emphasis on the upper tail of the distribution.

APPROPRIATE METHOD

Two methods have been presented which essentially differs in the procedure for data selection and in the choice of extreme value distributions. The question arises as to which procedure is most appropriate.

The advantages of using a total sample from the winter months and a simple two parameter Extreme 1 distribution in areas such as the open coasts of the South African and European Atlantic are:

- Maximum use is made of the available data.
- Design wave estimates are not sensitive to the upper tail of the data. The loss of data during storms and outliers in the data do not influence the estimates unduly.
- Estimates of design waves stabilise after a few years of data. This method is therefore ideal where short data records must be used.
- The Extreme 1 distribution fits the data well if all the data of an area is considered rather than data at individual recording stations
- Maximum use is made of clear spatial patterns that exist in the mean and standard deviation of the recorded wave heights

Criticisms against the method are:

- The data used are not independent. For areas such as the South African and Iberian Atlantic, where storms occur with great regularity, the use of correlated data do not seem to bias the estimates (Rossouw,1988). This method however will only work in areas where one can expect a strong correlation between mean and extreme conditions. It will not work in areas prone to cyclones, semi-protected areas where refraction, diffraction and other shallow water effects will influence the data or in areas where mixed distributions are present.

- The selection of the probability associated with a given return period requires a decision with respect to the duration of the storm peak. This in the opinion of the authors is an advantage since the significant wave height of one hour duration during the peak of the storm can be expected to be higher than the height for three hour duration. This is also the reason why an increase in the peak H_{m0} value can be expected if the recording interval is decreased. Rossouw and Medina (1995) show that the selection of the duration of storm peaks varying from 1 to 6 hours, although affecting the value of the design H_{m0} , does not influence the design H_{max} values.

Advantages of the method recommended by the IAHR committee are as follows:

- The POT method of sampling should ensure independent and identical data.
- The use of a three parameter Weibull distribution allows a good fit to most data sets

Problems with this method are however:

- The POT method of sampling is sensitive to the level of the threshold that is chosen. This was illustrated by the IAHR committee in van Vledder et al (1993).
- There is an emphasis on the upper tail of the distribution. This emphasis increases with increasing threshold values
- The use of a 3 parameter distribution increases the emphasis on the upper tail of the distribution.
- The use of only one data point in each storm makes the method very sensitive to outliers in the data, loss of records near the peak of the storm, the recording interval, etc. Long data records are also required before stable design wave estimates are obtained.

It is concluded that both these methods have their merits. The method recommended by the IAHR committee is expected to be superior in cases where there is a danger of using non identical data. Such areas would be cyclone prone areas, semi protected areas such as inside bays where directionality plays a major role and where mixed systems are present.

The simple method favoured by the authors seem to be applicable to areas where storms of identical origin occur with great regularity. In such areas a correlation between the mean and extreme conditions should exist and the estimate of design waves based on mean wave heights seems reasonable.

For either method the integration of the data over space should help to add stability to the estimates. Knowledge of the generating systems should be incorporated in the integration process.

CONCLUSIONS

The recommendation of the IAHR committee to use only one method for design wave estimation seems unrealistic. Their recommended method will work well in areas where different systems are responsible for wave generation for example in areas where cyclones occur regularly. In areas such as the Iberian and South African Atlantic, the methods used by the authors are preferred, especially at stations with short recording histories. In areas such as the South African east coast where cyclones occur very irregularly, i.e only once every few years, neither these methods are applicable.

Clear patterns exist in the recorded wave data. This is to be expected taking into account the present knowledge of the weather systems over the oceans. Design wave estimates, especially over large bodies of open water, can be improved by the spatial integration of the available data. Efforts to do this in the South African and Iberian Atlantic produces promising results. A global approach and co-operation between the countries involved in wave recording, will enhance our knowledge of extreme wave events and will lead to better estimates of design wave conditions.

CHAPTER 27

AN EVALUATION OF TWO WAVE FORECAST MODELS FOR THE SOUTH AFRICAN REGION

by
M. Rossouw¹, D. Phelp¹

ABSTRACT

The forecasting of wave conditions in the oceans off Southern Africa is important for both offshore and coastal marine operations in the area. The accuracy of wave forecasts for the area from models operated in Europe has, however, not been high. One of the main reasons is that the local measurement of waves has not been taken into account. Since the necessary infrastructure for operational wave forecasting is locally available in South Africa, a decision has been taken to establish a local facility whereby a numerical wave forecast model will be implemented. This paper focuses on the comparison of two operational wave forecast models in order to assist in the selection of an appropriate model for the South African region.

1. INTRODUCTION

The South African ocean route is one of the major shipping routes in the world (approximately 120 million tonnes of oil were transported around the tip of Africa in 1991). In addition, the offshore activities such as oil exploration, diamond mining and also coastal construction operations are increasing.

The Southern African waters are renowned for their treacherous sea, especially during winter. The already established weather forecast service provided by the South African Weather Bureau (SAWB) has up till now depended largely on information obtained from the global forecast model data, especially for wave forecasts. However, the wave conditions are represented relatively poorly as the input data sources are sparse in the Southern Atlantic Ocean where most of the wave energy is generated which reaches the South African coast. Only a few weather data sources are available (a couple of islands and a number of weather buoys).

¹Research Engineers, CSIR, P O Box 320, Stellenbosch, 7599, South Africa

The maritime activities need a reliable and accurate maritime weather forecast service which includes the prediction of the wave conditions. Local input data sources should be incorporated, including the local wave conditions. This information should result in a reduction in the risk of shipping accidents and could improve the planning for offshore exploration and operational activities.

Therefore, an appropriate wave forecast model should be implemented and operated in conjunction with the already established weather forecast service. This paper focuses on the comparison of two operational wave forecast models in order to assist in selecting an appropriate model for the South African region (CSIR, 1995).

2. DATA SOURCES

The data sources used for this exercise included the wave forecast data from the UKMO and WAM numerical wave models, wave data collected by wave recording buoys and also remotely sensed wave height data recorded by the ERS-1 satellite. In a number of cases the synoptic weather charts were also consulted for the identification of weather systems. These data sources are discussed briefly in the following sections.

2.1 Forecast Wave Data

UKMO model

The data of the UKMO model from the British Meteorological Office in Bracknell (UKMO) were received via the South African Weather Bureau (SAWB). Two forecasts per day were received, for 00:00 and 12:00 hours.

The forecasts covered an area delineated by latitudes 20° to 65° S and longitudes 0° to 40° E at a 2,5° grid spacing. The data included the significant wave height (H_{mo}), the significant wave height and wave direction for the swell, and the swell and sea wave period. Each forecast covers 120 hours (five days) at the following intervals:

$$T+0, 12, 24, 36, 48, 72, 96 \text{ and } 120 \text{ hours } (T = 00:00 \text{ and } 12:00)$$

WAM model

The WAM model data were received directly from the Royal Dutch Meteorological Institute (KNMI) in the Netherlands via e-mail. One forecast per day was received, for 12:00 hours.

The forecasts covered an area delineated by latitudes 21° to 60° S and longitudes 9° to 39° E at a 3,0° grid spacing. The data included the significant wave height (H_{mo}) and wave direction, the significant wave height and wave direction for the swell, and the significant wave height and wave direction for the sea component. The forecast covered a period 72 hours (three days) at six hourly intervals.

2.2 Recorded Wave Data

Wave recording buoys

The wave data used in this study were collected by wave recording buoys at locations offshore of Mōwe Bay, Port Nolloth, Slangkop and Durban in water depths of 100m, 100m, 76m and 50m, respectively (Figure 1).

Wave records of approximately 17,5 minute duration were routinely recorded at three-hourly intervals at all these stations. These records were subsequently spectrally analysed and interpreted in terms of the significant wave height and period. However, these records do not contain the wave direction and are therefore omnidirectional.

Remotely sensed data

The only remotely sensed data used in this study were obtained from the ERS-1 satellite. These data, consisting of significant wave height, were used to investigate specific forecasts during the period of interest. It was possible to compare observed and predicted wave heights over a large area.

3. COMPARISON METHODOLOGY

The study used a number of methods to compare the predicted data with that observed. It should, however, be noted that only the significant wave height could be analysed as it was the only parameter common to all three data sets. Although the wave direction parameter is included in the forecasts, it is not part of the suite of wave parameters obtained from the recorded data, as non-directional wave recording buoys were used. The methods of comparison are discussed below.

3.1 Data Processing

Both the UKMO and WAM data were received in a grid format. For comparison with measured data at specific locations, the most appropriate grid points had to be identified in the UKMO and WAM data sets. Therefore, the closest grid points to the wave recording buoy locations were selected as shown in Figure 1. Although two UKMO forecasts per day were available, only the 12:00 hour forecasts were used to compare with the 12:00 WAM forecast and the measured data.

For comparison with the offshore wave data from both models, the measured data had to be adjusted for the shallow water effects. Shoaling was therefore taken into account by applying linear shoaling as described in the Shore Protection Manual (CERC, 1984). However, as no wave directions were available, the refraction-effect could not be considered. The bathymetry in the vicinity of all four locations is fairly uniform and the water depth relatively large, thus wave energy-loss due to refraction will not be significant.

3.2 Time-series Comparisons

In order to establish the effectiveness of a wave forecast over a certain period, one can compare the entire forecast with the observed (measured) wave conditions. If the forecast predicted the actual conditions well enough one would have confidence in that forecast. It should, however, be remembered that there can be some variation in the predictions as these are based on meteorological information that is not always 100 per cent correct. One must, therefore, include an estimation of uncertainties for short-term sea state parameters in the wave forecast.

For the purposes of this study a factor " σ " (normalised standard deviation) was applied to both UKMO and WAM data sets. This factor was taken as $\sigma=0,2$ in accordance with standards for wave predictions (PIANC, 1992). Thus, the following formula was implemented:

$$H_{\min} = H - (H * \sigma) \quad \text{and} \quad H_{\max} = H + (H * \sigma)$$

where H = significant wave height (H_{m0})

These two parameters, H_{\min} and H_{\max} , thus provide a range in which the observed wave height could occur for a satisfactory prediction.

3.3 Specific Timeslots

Another way of comparing the wave forecasts with measured data is to consider specific forecast timeslots. Both the model data sets have predictions for 12, 24, 48 and 72 hours ahead. It was therefore possible to compare the predicted and measured data at the specific timeslots, graphically and statistically.

Scatter plots of the predicted and measured total wave height were prepared at all four locations for the above mentioned timeslots. Statistical parameters such as the correlation coefficient and the root mean square error (RMSe) were also determined for these comparison sets (Khandekar, 1989). The RMSe is given by the following expression:

$$RMSe = \sqrt{\frac{1}{N} \sum (Model - Observed)^2}$$

where:

Model = predicted value; Observed = observed value; N = number of values

3.4 Wave Contours

As mentioned previously both the UKMO and WAM data come in a grid format. It is thus possible to present these data sets in a contour plot. Predicted wave conditions for a large section of the Southern Atlantic Ocean can therefore be presented. These were plotted with the ERS-1 satellite tracks. The predicted wave heights along the satellite tracks could then be compared to wave heights recorded

by the ERS-1 satellite.

Due to the vast number of individual predictions (every timeslot), it is not practical to prepare a contour plot for each of them. Therefore, only a selected number were chosen which could be examined.

4. RESULTS

4.1 Time-series Comparisons

Using the procedure described in Section 3.2, both UKMO and WAM forecasts were plotted with the observed data recorded off Möwe Bay, Port Nolloth, Slangkop and Durban for the period 14 November to 31 December 1994. Examples of the comparisons are presented in Figure 2 for Möwe Bay, Port Nolloth, Slangkop and for Durban.

For the purposes of this study the assumption was made that up to a two-day-ahead (48 hours) and three-day-ahead (72 hours) wave forecasts are practical. The observed values had to fall within approximately 80 per cent of the predicted ranges in each wave forecast in order for the forecast to be deemed satisfactory. This meant that only one prediction value of the UKMO forecasts for both the 48 and 72 hours could be out of range. As the WAM data produced more values, two predictions in 48 hours and three predictions in 72 hours could be out of range and the forecast would still be acceptable. However, if the erroneous prediction values were consecutively out of range, the forecast was rejected.

Based on these criteria, the percentage of satisfactory wave forecasts are presented in Table 1. For each location and for the two models these percentages are given for the 48 hour and 72 hour forecast period. It is evident that the WAM model produced more satisfactory forecasts than the UKMO model for the Möwe Bay, Port Nolloth and Slangkop area. For example, at Möwe Bay 92 per cent of the WAM wave forecasts were satisfactory while 67 per cent of the UKMO forecasts were satisfactory. Both models produced better results over the 48 hour forecast period than over the 72 hour period. The low percentage of acceptable forecasts for the Slangkop location is again addressed in Section 4.2.

TABLE 1: Percentage satisfactory wave forecasts

Location	UKMO model (%)		WAM model (%)	
	48 hour	72 hour	48 hour	72 hour
Möwe Bay	67	64	92	89
Port Nolloth	60	44	81	73
Slangkop	39	11	56	44
Durban	64	51	45	33

4.2 Specific Timeslots

Using the procedure described in Section 3.3, scatter plots were done for both the UKMO and WAM forecasts with the observed data recorded off Möwe Bay, Port Nolloth, Slangkop and Durban for the period 14 November to 31 December 1994.

UKMO data

Two examples of the scatter plots are presented in Figure 3, showing the 24 and 48 hour timeslot results for Slangkop. The solid line also shown in the figures represents the 1-to-1 (1:1) ratio of the predicted versus the observed wave heights. The correlation coefficient and RMSe values for the 24 hour timeslot are given in Table 2.

TABLE 2: UKMO statistics: 24 hour timeslot

Location	Average wave height (m)		Correlation coefficient	RMSe (m)
	Measured	Predicted		
Möwe Bay	1,86	1,84	0,644	0,34
Port Nolloth	2,01	1,82	0,652	0,53
Slangkop	2,22	1,86	0,631	0,69
Durban	1,81	2,00	0,503	0,53

From the results it appears that the values for Möwe Bay, Port Nolloth and Durban locations are distributed fairly symmetrically around the 1:1 line. However, at the Slangkop location there is a definite bias towards under-prediction. This was evident in the scatter plots of all four timeslots. In order to eliminate this bias, linear regression was performed on the 12-hour data set. The regression line should coincide with the 1:1 line if perfect agreement between observed and predicted data exists. In order to eliminate the under estimation of the predicted results, data points were adjusted proportionately to get better correlation between observed and predicted values. The data sets of the other three timeslots (24, 48 and 72 hours) were also adjusted in a similar manner using the 12 hour regression function. These re-analysed results are presented in Table 3. Using this regression function it was possible to improve the comparison of the predicted with the observed wave heights for all four timeslots at Slangkop.

In general the correlation between the observed and predicted values was found to be low. As can be expected, the correlations decreased over time with the 12 hour timeslot having the highest correlations. The average correlation coefficients for the 12, 24, 48 and 72 hour timeslot (for all four locations combined) were found to be approximately 0,6, 0,6, 0,5 and 0,4 respectively. In general, the predictions, therefore, do not compare all that well with the observed conditions. However, by applying the regression function to the Slangkop data, an average coefficient of about

0,8 was found. As was expected, the correlation for 72 hour forecasts was the lowest on average.

TABLE 3: UKMO: Re-calculated Slangkop statistics

Timeslot (hours)	Average wave height (m)		Correlation coefficient	RMSe (m)
	Measured	Predicted		
12	2,35	2,35	0,88	0,45
24	2,22	2,11	0,86	0,40
48	2,20	2,20	0,80	0,45
72	2,21	2,24	0,62	0,65

The RMSeS on the other hand, range from approximately 0,3 m to 0,85 m; the lowest RMSe values being in the 12 hour timeslot. It is also noteworthy that Möwe Bay has the lowest values for all timeslots, on average 0,36 m. This implies the predictions for Möwe Bay were the most accurate of the locations considered. By applying σ (0,2) to the average predicted wave height (Tables 2 and 3), an uncertainty value of 0,38 is determined. Therefore, because this value compares well with the RMSe, one can conclude that the prediction for Möwe Bay should be satisfactory and typically within ± 20 per cent of the actual wave height.

The average RMSe for the Slangkop location was found to be 0,71 m while an average uncertainty value of 0,39 m was calculated. This difference of 0,32 m and the low correlation indicates that the predictions for this location are unsatisfactory. However, following the re-analysis the high correlation coefficient of 0,8 and the average RMSe of 0,49 m suggest reasonable predictions. Based on the average predicted wave height an uncertainty value of 0,45 m was determined. This value therefore compares well with the average RMSe. Thus, the predictions close to the Slangkop location appear to have been reasonable. Satisfactory forecasts can therefore be obtained with some level of calibration.

Durban has the highest RMSe value, 0,84 m (72 hour) with an average value of approximately 0,65 m. Application of σ to the average predicted wave height yields an uncertainty value of 0,41 m which is about 0,2 m less than the average RMSe. Apart from inadequate input data for the wave forecast model, these discrepancies could also be attributed to the effect of the Agulhas Current on wave conditions along the south and south-east coast of South Africa.

The average RMSe at the Port Nolloth location was found to be 0,61 m while the average uncertainty value of 0,4 m was calculated. Therefore, these forecasts for this location could not be rated as satisfactory as a correlation coefficient of 0,6 was obtained.

WAM data

Figure 3 also presents two examples of the scatter plots showing the 24 and 48 hour timeslots for Slangkop. The solid line also shown in the figures represents the 1-to-1 (1:1) ratio of the prediction versus the observed wave heights. The correlation coefficient and RMSe values for the 24 hour timeslot are given in Table 4.

TABLE 4: WAM statistics: 24 hour timeslot

Location	Average wave height (m)		Correlation coefficient	RMSe (m)
	Measured	Predicted		
Möwe Bay	1,84	1,89	0,86	0,23
Port Nolloth	2,00	2,05	0,87	0,33
Slangkop	2,19	2,41	0,77	0,53
Durban	1,77	2,18	0,45	0,76

From the figures it appears that the values for Möwe Bay and Port Nolloth locations are distributed fairly symmetrically around the 1:1 line. However, at the Slangkop location there was also a slight bias towards over-predicting wave heights below 2,5 m and under-predicting wave heights above 2,5 m. In order to eliminate this bias, linear regression was performed on the 12-hour data set, as in the case of the UKMO data (Section 4.2). The data sets of the other three timeslots were also adjusted in a similar manner using the 12 hour regression function. These re-analysed results are presented in Table 5.

TABLE 5: WAM: Re-calculated Slangkop statistics

Timeslot (hours)	Average wave height (m)		Correlation coefficient	RMSe (m)
	Measured	Predicted		
12	2,32	2,32	0,90	0,41
24	2,19	2,18	0,90	0,33
48	2,17	2,17	0,89	0,34
72	2,18	2,15	0,82	0,42

The correlation between the observed and predicted values was found to be quite satisfactory, except for the Durban location. As expected, the correlations decreased over time with the 12 hour timeslot having the highest correlations.

The average correlation coefficients for the 12, 24, 48 and 72 hour timeslots were found to be approximately 0,7, 0,7, 0,7 and 0,6 respectively. The average

correlation coefficients for the Möwe Bay, Port Nolloth, Slangkop and Durban location were found to be about 0,8, 0,8, 0,7 and 0,4 respectively. In general, the predictions, therefore, compare well with the observed conditions except at the Durban location. However, by applying the "regression" function to the Slangkop data, an average coefficient of almost 0,9 was found at this location. As was expected, the correlation of 72 hour forecast was, on average the lowest on average.

The RMSe's on the other hand range from approximately 0,2 m to 0,8 m. The lowest RMSe values being in the 12 hour timeslot. It is also noteworthy that Möwe Bay has the lowest values for all timeslots, on average 0,26 m. By applying σ (0,2) to the average predicted wave height, an average uncertainty value of 0,39 m is determined. Therefore, because this value compares well with the RMSe, and the correlation is good for Möwe Bay, one can conclude that the forecasts are satisfactory.

The average RMSe for the Slangkop location was found to be 0,56 m while an average uncertainty value of 0,47 m was calculated (Section 3.2). Although the difference is quite small and the correlation fair, the re-analysis resulted in a high correlation coefficient of 0,9 and an average RMSe of 0,38 m suggesting satisfactory predictions. Based on the average predicted wave height an average uncertainty of 0,44 was determined. This value therefore compares well with the average RMSe. Thus, reliable wave forecasts close to the Slangkop location can be obtained with some level of calibration.

As in the case of the UKMO forecasts, the Durban location has the highest RMSe value, 0,76 m (for the 24 hour timeslot) with an average value of approximately 0,69 m. Application of σ to the average predicted wave height yields an average uncertainty value of 0,42 m which is about 0,3 m less than the average RMSe. This implies a greater than 20 per cent uncertainty in the predicted wave height. Apart from inadequate input data for the wave forecast model, these discrepancies could also be attributed to the effect of the Agulhas Current on wave conditions along the south and south-east coast of South Africa.

The average RMSe at the Port Nolloth location was found to be 0,36 m while the average uncertainty value of 0,42 m was calculated. Thus, the forecasts for this location also appear to be reasonable as a correlation coefficient of 0,8 was obtained.

4.3 Wave Contours

Five case studies were selected to present specific predictions spatially together with the ERS-1 data. All the forecasts used were produced at 12:00 (T = 12:00).

An example of the predicted wave height contours of the UKMO and WAM forecasts as well as the ERS-1 tracks are presented in Figure 4. The wave height versus latitude plots are also given in these figures. The ERS-1 tracks were selected so that they would correspond with the time of the predicted wave heights.

It would be difficult to determine which model produced the best wave forecasts as only five cases were examined. However, these results give an indication of how well specific predictions compared spatially using the ERS-1 data.

5. DISCUSSION

The time-series comparisons determined for the UKMO and WAM wave forecasts, revealed that the WAM model produced a larger percentage of satisfactory forecasts than the UKMO model. However, the UKMO forecasts appear to have been more successful at the Durban location. As expected all cases the forecasts for the 48 hour forecast period were more reliable than for the 72 hour period.

It appears that during calm and also gradually varying conditions both models predict wave heights quite well. Wave height conditions that increased over a period of a day or more were predicted satisfactorily on a number of occasions. However, when the wave height increases rapidly (less than a day), the predictions tended to be poor. Under these storm conditions, WAM forecasts compared better with the observed wave heights than the UKMO forecasts. The UKMO forecasts also frequently under-predicted the wave heights during these events.

By examining the results of the timeslot-comparison, it was found that the RMSe's of the WAM forecasts are, on average, more than 20 per cent lower than the RMSe's of the UKMO forecasts. The correlation coefficients, on the other hand, are 33 per cent higher at the Möwe Bay and Port Nolloth locations and, 12 per cent higher at Slangkop. At the Durban location these coefficients were found to be approximately the same.

The five cases selected for plotting the wave height contours are not enough to unequivocally determine which model produced the best results. In order to determine this, more specific predictions (i.e., 24, 36, 48, 72 hours) of every forecast would have to be used.

Although it has been established that the forecasts of the WAM model compare most favourably with the observed data, the wave forecasts can still be improved. It should also be recognised that this study was performed in the summer season when mild to moderate wave conditions prevail for most of the time. During the winter season (June to August) extreme wave conditions prevail more frequently and are also more variable. These large fluctuations in wave height are coupled to the passage of intense low pressure systems which are more frequent during the winter months.

For both forecast values, the mathematical formulation used to determine the generation and propagation of wave conditions are state-of-the-art and are continuously being improved. However, the input data (the atmospheric forces) used to drive these models determines the reliability of a wave forecast to a large extent. In the southern hemisphere the input data are unfortunately sparse which results in

poor spatial data representation. Currently the input data consist mainly of data from coastal weather stations and some remotely sensed data sources. To improve the wave forecasts in the Southern Atlantic Ocean, it would be essential to improve the number and quality of input data sources. This could be done through the deployment of more offshore weather buoys. In addition the use of wave recording buoys off the coast of South Africa for verification purposes, would contribute to greater reliability of wave forecasts.

6. CONCLUSIONS

Considering the three comparative methods that were used to compare the UKMO and WAM forecasts with the observed data, obtained from wave recording buoys offshore of Möwe Bay, Port Nolloth, Slangkop and Durban as well as wave height data remotely sensed by the ERS-1 satellite, the following conclusions can be drawn:

The time-series comparison results showed that the WAM model produced a larger percentage of satisfactory wave forecasts than the UKMO model at the locations of Möwe Bay, Port Nolloth and Slangkop. On average, the WAM model produced over 35 per cent more satisfactory forecasts than the UKMO model.

By analysing the wave forecasts in terms of correlations coefficients and Root Mean Square errors (RMSes) it was found that the forecasts produced by the WAM model provided the best results.

The RMSes of the WAM forecasts are, on average, more than 20 per cent lower than the RMSes of the UKMO forecasts. The correlation coefficients are 33 per cent higher at the Möwe Bay and Port Nolloth locations and 12 per cent higher at Slangkop. At the Durban location these coefficients were found to be approximately the same.

Although it was not possible to determine which model produced the best results by comparing the predicted wave heights with remotely sensed wave heights along satellite tracks, it was found that this method may be useful in establishing the spatial reliability of the forecasts in terms of specific predictions (timeslots).

This comparative study was done during the months of November and December with mild to moderate wave conditions prevailing for most of the time. These results should therefore be considered to be more relevant for the summer season than for the winter season.

The differences between the results of the two models could amongst other things be attributed to the following factors:

- The UKMO is a second generation model whereby the non-linear transfer of wave energy is parameterised. The WAM model, which is a third generation model, solves the non-linear wave energy transfer function.

- In addition, different atmospheric input data sets are used to drive the two models, which would influence the output of these models.

It is concluded that the WAM model produces the most favourable results. However, these forecasts can still be improved by increasing the number of the input data sources (offshore weather stations) and also by evaluating the numerical modelling procedures of the wave forecast model.

7. RECOMMENDATIONS

Based on the conclusions the following recommendations can be made:

The WAM model should be implemented locally for providing the necessary wave forecasts for the South African region. (Note: the model has been installed at the head office of the SAWB; the model is presently running on a trial basis).

In order to establish the effectiveness of the WAM and UKMO forecasts during storm conditions, a similar comparison study should be conducted for the autumn and winter seasons (March to August).

The Agulhas Current is also a prominent feature along the south and south-east coast and influences the wave conditions in this region. This current-wave interaction should therefore also be investigated for incorporation in the wave forecast models in order to have reliable forecasts along both the south and south-east coast.

An essential component of the numerical modelling of the atmospheric forces and wave conditions are the data sources. As these are sparse in the southern hemisphere, especially in the Southern Atlantic Ocean, data coverage should be increased by, for example, the deployment of offshore weather buoys. The present network of wave recording buoys along the coast of South Africa (called WAVENET) and maintained by the CSIR, could be used for verification purposes in the wave forecasting procedures. These strategies should improve the reliability of the wave forecasts and also the general weather forecasts.

CHAPTER 28

A Comprehensive Wind, Wave and Current Measurement Program in the South China Sea

by Jagat N. Sharma,¹ S. Tryggestad,² and J. Bian³

Abstract

The South China Sea has been a prolific fishing ground and a busy shipping lane, and has recently become an important source of offshore oil and a center of rapidly growing economic activities. However, little systematic scientific study of the area has been carried out (Anonymous 1985 and Wyrski 1961). Recently, several Metocean (meteorological and oceanographic) studies were performed to support the offshore petroleum production in the area. This paper summarizes these and other studies, and then, describes a comprehensive Metocean measurement program (Sharma et. el. 1991). Many distinctive and unique features of the measurement program are presented and discussed. Published samples of wind, waves, and current data are used to illustrate the complexity of oceanographic conditions in the area. Economic benefits of the measurement program are estimated approximately and found to be many times the cost of the program. While many important design decisions can be made with the 18 months of data, many other decisions need to be made conservatively in the absence of a multi-year Metocean dataset. A comparison with the condition in the Gulf of Mexico reveals many similarities and some differences. Future data needs and their possible benefits are also discussed briefly.

Introduction

The South China Sea (Figure 1) is a semi-enclosed sea very similar to the Gulf of Mexico. It has been a prolific fishing ground and a busy shipping lane, and now, some of the fastest growing nations of the Asia-Pacific region surround it. As economic activity grows in the

area, the need for more and better meteorological and oceanographic will grow in this area. First, we briefly review various studies conducted in this area to support economic activities. Then, we summarize a comprehensive Metocean measurement program with which we were closely involved. Benefits of past studies are conservatively estimated and it is found that a similar future measurement program could be very cost effective. Future data

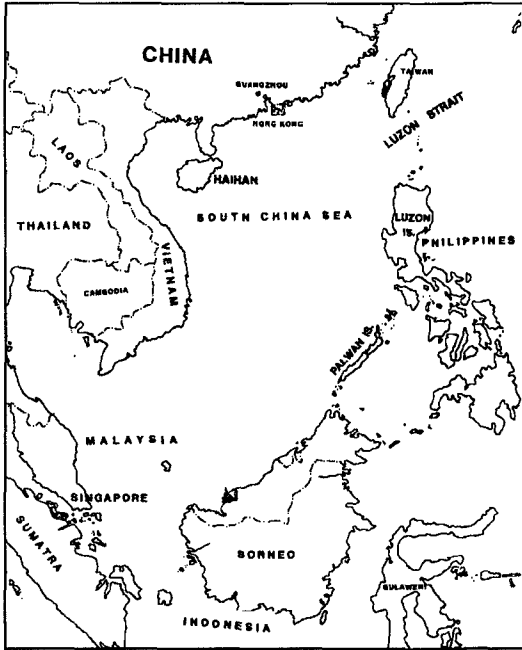

Figure 1. Location Map

needs are briefly discussed.

Finally, we present our conclusions and recommendations.

When China granted offshore leases to western companies in 1979, the only available Metocean information consisted of Wyrski 19961 and SSMO (Synoptic Ship Meteorological Observation) data which consists of visual observations from ships in the area. For few preliminary planning purposes, these data are adequate, but are inadequate for final design criteria preparation. Inadequacy of general understanding of the South China Sea Oceanography became very apparent when Glomar Java Sea sank near Hainan Island in a minimal typhoon.

Prior Measurements & Analysis in the South China Sea

In 1959-61, a hydrographic survey of the area was conducted and the results were published as a report by Wyrski (Wyrski 19961). In 1979-1982, Academia Sinica conducted several oceanographic surveys in the area. Western visiting scientists went on many of these cruises. A summary of the collected data has been published as a report in Chinese (Anonymous 1985). Several other oceanographic studies have modeled transport in and out of South China Seas. Results of these studies are useful in understanding the oceanography of the area. However, these studies did not include collection of wind, wave, and current data for model verification and calculation of operational and extreme design criteria.

Recently to meet some offshore industry needs, Oceanweather Inc. performed a proprietary hindcast study covering the entire basin using a third generation wave model. Wind, wave and depth averaged currents were hindcast in two hundred severest tropical storms during past 50 years. The same parameters were also hindcast for a continuous 10-year

period. Using the hindcast results, extreme and normal operating criteria can be prepared. For more details, please refer to Cardone (Cardone 1994). This study's strong points include basin-wide coverage, excellent use of historical meteorological data such as surface weather maps and tropical cyclone summary data. However, to verify the model results the study could use only limited wave measurements in shallow water in the southern part of the basin.

There is no high-quality measured wave data available in the public domain. Several high-quality long term data sets have been acquired recently in the northern part of the South China Sea. Unfortunately, these data are proprietary and unavailable except for limited data which appear in published papers (Yuan 1988, Sharma 1991). Some of the published results will be presented here to illustrate the complexities of South China Sea Oceanography.

Many other proprietary studies have been performed to support specific project needs. Several design criteria studies were performed by China Ocean Technology Company, Oceanweather Inc., and possibly others. To support the needs of specific projects, many operators measured specific features affecting their operations. Some of those data are of oceanographic interest but unavailable for research.

To support the construction and maintenance of their gas pipeline from Hainan Island to Hong Kong, Arco measured currents along their pipeline route. Currents in several typhoons were measured. During their drilling programs, Oxy and Amoco Orient vessels experienced very strong soliton currents. The measurement yielded some of the strongest soliton currents ever, and these measurements were subsequently useful in developing environmental design criteria.

To support their many offshore operations, Arco developed and implemented a typhoon emergency response plan. Corona et. al. (Corona 1996) presented the results of their implementation at the 1996 Offshore Technology Conference in Houston. In one year evaluation period, the study prevented 1,200 round trip helicopter flights (2,400 flight hours) transporting equivalent of 24,000 personnel. Besides saving the cost of flight time and vessel downtime, the emergency response plan greatly reduced the inherent transportation risks associated with flights in inclement weather. From the information provided in the paper, it is conservatively estimated that the total savings could easily exceed several tens of million dollars. A similar proprietary study was performed for the Lihua project. The results of the study are unavailable to public. An informal evaluation of the method indicated that savings in evacuation cost and downtime were several million dollars.

A better and simpler typhoon evacuation method has been developed recently (Sharma 1996). In this method, it is recognized that the long lead time needed for shutting down offshore operations presents special problems because the historical forecast errors for such long lead time are very high. Meteorological forecasts are used as received along with a few simple and easy measurements at site. Many oceanographic and meteorological features which consistently affect typhoon parameters are used in such a way that safety is not compromised. Using this method the essential operations could be continued by delaying total evacuation without risking even a single life. The method is implemented in a simple calculation method using PC applications such as

Excel, Lotus or Project. The calculation method is activated when a typhoon is about 800 miles away from the operating area. At this time, the safety engineer enters the number of helicopters available, their passenger capacities, round trip time and total number of personnel on the rig in order of their evacuation priority. From this information, time needed for various levels of evacuation including total evacuation is calculated. Meteorological forecasts without any modification are used in this method. From the forecast parameters, the arrival time of the edge of severe wind conditions unsuitable for helicopter operations is calculated. At all forecast time steps, the total evacuation time is maintained smaller than the quickest possible arrival time of the adverse edge of the typhoon. This could be achieved either by partial evacuation or by chartering more and/or bigger helicopters. Full evacuations are avoided most of the time because only a small fraction of all typhoons occurring within say 400 nautical miles of a site come close enough to affect operations. Using this method, operation managers could delay, or possibly avoid complete shut down without risking any life.

Many proprietary Metocean studies were performed to evaluate the possible exploitation of a difficult prospect named Lihua in 1000 feet water depth located at 150 miles Southeast of Hong Kong in the South China Sea. Very little results of these proprietary studies are available in journal papers or conference proceedings. The following description of a comprehensive meteorological and oceanographic measurement program are based on scant published results.

Lihua Measurement Program

In 1987-88, a consortium of Chinese Scientific Agencies and Oceanor of Norway deployed the following measuring instruments:

- two acoustic Doppler current profilers,
- four Aandera current meters,
- an ultrasonic current meter (UCM-30),
- Marex buoy for waves and wind,
- directional Wavec buoy,
- anemometers at four different elevations on a drilling rig,
- water temperature, oxygen content, and salinity,
- air pressure, tidal elevation.

Figure 2. Instrument Location

The instruments were spread out in a well thought out pattern to allow future 3-dimensional current studies (Figure 2). As presented on the figure 2, four different current meters are located at the corners of a trapezoid with each side equal to about one nautical mile. So, the upstream and downstream current meters registered a soliton pulse current about 15 to 20 minutes apart. Also, eddy currents can be clearly resolved with a suitable computer program.

Recognizing that the measurement program was in a frontier area, many unique and special steps were taken to insure success. Some of the **unique** and **distinctive** features of the measurement program were:

- global cooperative project organization,
- careful planning to overcome extremely unfavorable logistics,
- satellite search and rescue methods,
- redundant instruments for reliability,
- patrolling of instrument area to prevent theft, and
- quality control at every step.

As a result, the actual data recovery was substantially higher (about 95%) than the initial overall goal of 80%. Eighteen months of nearly continuous wind, wave, current, water temperature data were recorded. The measured data contains many features of special scientific and design interest. The following are some of the most important features:

- complex storm current profiles,
- interaction of typhoon and cyclonic eddy,
- interaction of typhoon and monsoon,
- waves higher than forecast from wind,
- intense current of a short duration (possible internal soliton signature), and
- relation between current and sea temperature.

To illustrate the above oceanographic features, sample data are presented and discussed.

Meteorological & Oceanographic Features

Wind, wave current and other meteorological parameters were continuously measured from August 1987 to February 1989. The instruments in the operating area were affected by 11 typhoons and 12 winter monsoon storms. The following paragraphs briefly describe some of the most important meteorological and oceanographic features:

Typhoons

Four typhoons registered significant wave heights over 7 meters (23 feet) and one over 9 meters (30 feet). Seven other distant passages of typhoons were recorded. Significant wave heights much greater than those predicted by a parametric model were measured in typhoons embedded in monsoon winds. Typhoon Nina passed over the instrument area while it was in its tropical storm stage. A maximum wind of 22 meters per second was measured by the two wind instruments mounted on the Marex buoy at a 6 meter elevation, but the measured waves were much higher than expected for a 22 meters per second typhoon.

Wind, waves and currents measured in Typhoons Betty and Cary are presented here (Figure 3) to demonstrate the quality and quantity of the collected data. Typhoon Cary followed Typhoon Betty within 6 days. Typhoon Betty entered the South China Sea in the evening of the same day the instruments were deployed. Even though the measuring instruments experienced only the outer periphery of the typhoon, the forceful presence of a dangerous typhoon is visible in the recorded data. Typhoon winds were from the east superimposed on southwest monsoon wind.

A diurnal cycle in the measured wind speeds can be seen on the plot. This cycle corresponds to a land breeze sea breeze effect at the site. This effect so far from land was unexpected.

Figure 3. Wind direction, wind speed and wave in Typhoons Betty and Cary.

The waves reflect the distant passage of Typhoons Betty and Cary. A maximum significant wave height of 3.5 meters was recorded in both typhoons.

While the wind and wave responses were similar in the two typhoons, the current responses were entirely different (Figure 4). The mean current during Typhoon Betty increased without any significant change in the diurnal current amplitude. In contrast, the mean current during Typhoon Cary increased only slightly, but the diurnal current amplitude increased significantly. The combined maximum current measured during the two typhoons are nearly equal.

If the sharp spike in the beginning of data had been measured by only one current meter, it could have been rejected as a spurious noise. In this case, the same spike was measured by all three current meters, and the spike could not be rejected. Similar spikes are seen

Figure 4. Currents measured by an ADCP and an Aandera current meter in Typhoons Betty and Cary.

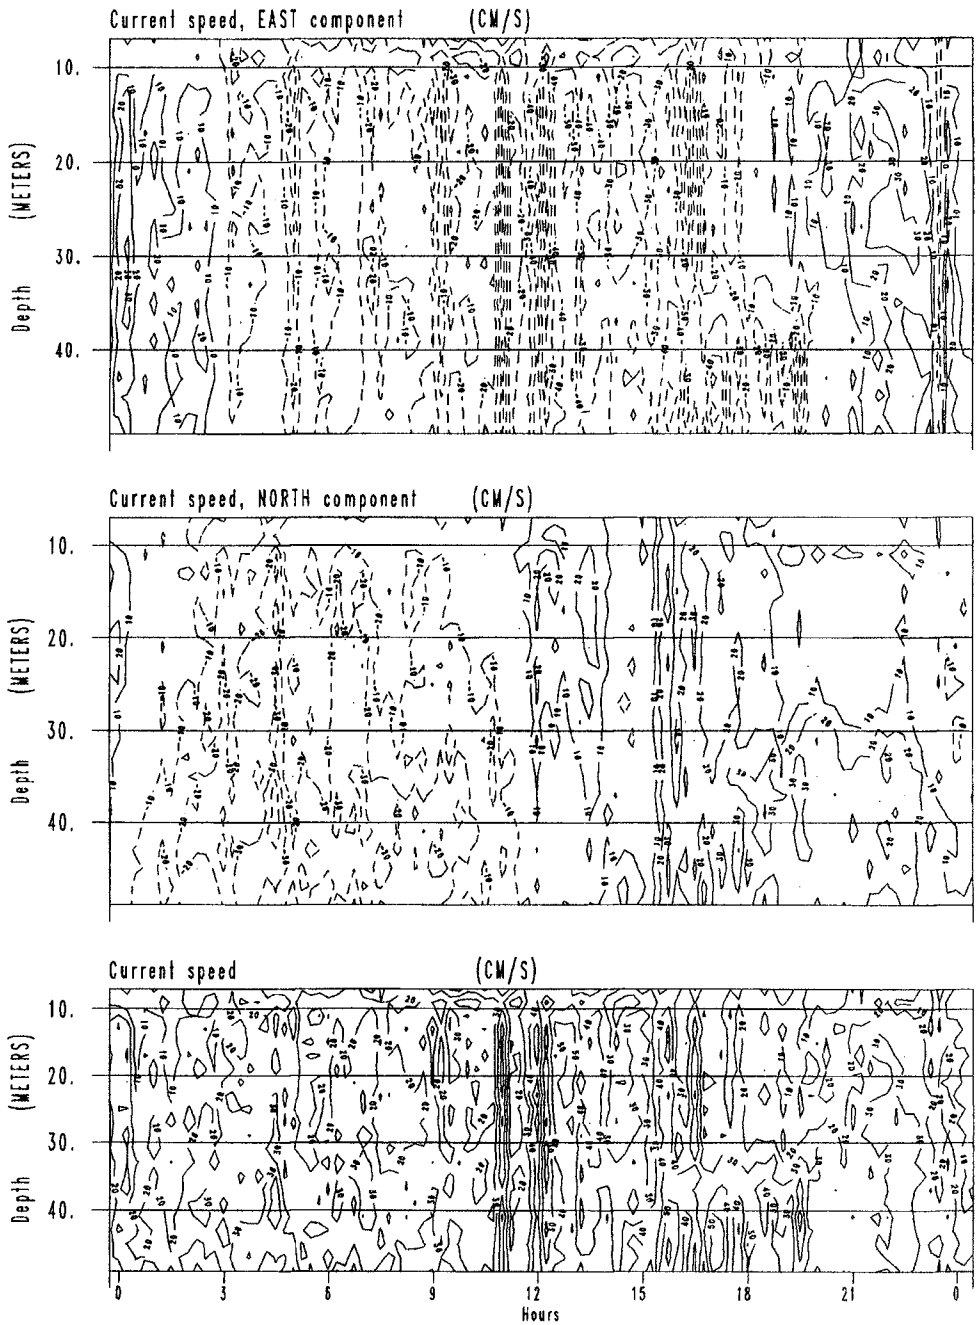

Figure 5. Contour plot of currents at all depth bins and time steps measured by an ADCP at -65 meter on August 14, 1987

when 1 to 2-minute average soliton data are converted to the same averaging period as used in this measurement program.

Acoustic Doppler Current Profiler Data

The data collected by the acoustic Doppler current profiler at -65 meter at two meter depth bins and all hours of August 14 are presented in Figure 5 as a contour plot. On this plot we see a strong current at about 1300 hours UTC. The currents are the combined effect of wind, tide and oceanic currents.

Figure 6 shows hourly current data recorded at every two-meter-depth with the acoustic Doppler current profiler at -65 meters on August 22, 1987 at 11 hours 43 minutes and 43 seconds UTC. Currents are nearly equal throughout the mixed layer depth. The current directions are also nearly constant from the sea surface to -55 meters. Currents are nearly constant between -20 and -55 meters depths. There is a sharp decrease in current at -15 meter, then a still sharper increase at -10 meters. The depth resolution in this case is 2 meters and the standard error in velocity measurement is 4 cm per sec. Data from three bins near the surface and close to the acoustic Doppler current profiler are suspect and excluded from our presentation.

The slab like measured currents are of special scientific and design interest. The design

Figure 6. A sample current profile in the upper mixed layer.

current near sea surface which should be associated with the design wind and wave could be very different depending on whether a shear or a slab current profile (Figure 7) is

Figure 7. Wind generated current profiles for design use.

acceptable. The cost of building offshore structures with large projected area near surface (such as a tension leg platform or a floating unit) could be up to 20% lower if a slab current profile is acceptable.

Tidal and Oceanic Current

Figure 8 presents an example of relation between sea water temperature and tidal and oceanic currents measured by the Aandera current meter at -50 meters from October 16 to October 20, 1987. The tidal currents are predominantly diurnal. Current speed and temperature appear to be correlated.

change in temperature from 24.C to 28.C over several tidal cycles suggests the ingress and egress of the Dongsha cold eddy over the instrument area (Figure 9). These and

Figure 8. Current and temperature measured by Aandera current meter at -50 meter.

other aspects of eddy and oceanic current effects need to be pursued by acquiring sea surface temperature images for the periods in question.

It should be noted that the current directions make a complete loop in each tidal cycle. In such currents, a floating tanker will weathervane one full circle during each tidal cycle.

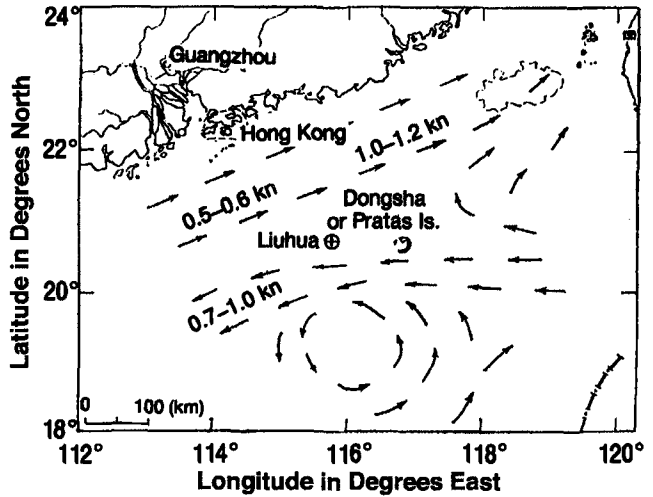

Figure 9. Dongsha Eddy Current in Summer

Strong Cold Front Passage

Wind, wave and current during the passage of a strong cold front are interesting because wind speed and direction change rapidly. With the passage of a strong cold front on the evening of September 25 immediately following our deployment, the wind velocity jumped from less than 2 meters per second to 12 meters per second within three hours. Also, the wind direction changed from north to south and then north again. During the passage of this cold front through Hong Kong, wind gusts up to 60 kilometer per hour were recorded by land based anemometers.

While the sudden jump in wind is very clearly seen in the wind record, the wave record shows a smaller jump from calm seas to about 3 meters significant. Interestingly enough, the effect on current is entirely unnoticeable. This is to be expected because during a sudden passage of a cold front, wind speeds and directions change so fast that the sea does not have enough time to respond.

Marine Fouling

Although marine fouling caused malfunctioning of the Aandera current meter at -50 m, photographs of marine growth constitute an important data base for marine fouling, which is an important parameter in design and operations. All other current meters and buoys functioned properly despite marine growth.

Every type of surface within about 100 meters of the sea surface were fouled mainly by two barnacles species (*pollicipes polymerus* and *lepas anatifera*). Near the surface, the fouling clusters were large and populated by bigger specimens (up to 2 inch). Both the cluster size and their density decreased with increasing depth. Macroscopic fouling was not observed below -100 meters. However, we cannot rule out long-term fouling of the structural elements below 100 meters, because the surfaces were not examined for short-term microscopic fouling.

Comparison with the Gulf of Mexico

A comparison of the meteorological and oceanographic conditions in the South China Sea and the Gulf of Mexico is instructive and has many practical uses. While tidal currents are very small in both the Gulf of Mexico and the South China Sea, severe tropical storms affect both basins. Maximum intensities of tropical storms in both operating areas are comparable, but the frequency of occurrence in the South China Sea is about 3 times that in the Gulf of Mexico.

The deep water Gulf of Mexico operations are occasionally shut down by strong oceanic currents caused by the Loop Current and its anti-cyclonic eddies. In the South China Sea, the background oceanic current is weak but appears to intensify under the influence of a typhoon during the Northeast Monsoon. Cyclonic wind field in a hurricane or typhoon has been known to interact with weak cyclonic eddies in both basins. The effect of this interaction on design and operation is poorly understood because no simultaneous measurement of good quality is available.

Before a hurricane approaches an operating area in the Gulf of Mexico, sky is usually clear with no wind, wave or current (in the absence of the Loop Current or its eddies). In the South China Sea, similar conditions exist before a typhoon approaches during the Southwest Monsoon (April-August). However during the Northeast Monsoon (September-March), strong wind, wave and current may be present even before a typhoon approaches. As a result, even a low intensity storm could produce very high waves with rapidly changing intensity and directions of wind, wave and current. Such events were recorded during the measurement program. Extreme design conditions could be governed by such conditions, and operating conditions could be more dangerous than the intensity of a typhoon may suggest.

Both basins have only few straits connecting them with open ocean. Even though most oceanic conditions, such as stratification, etc. are similar in the two basins, soliton induced strong currents have been noted only in the South China Sea.

While many comprehensive Metocean studies have been performed for the Gulf of Mexico, but very few similar studies have been performed for the South China Sea.

Applications & Benefits

The collected data has been applied to meet a variety of industry needs. Some of the most notable applications include:

- Wind and wave measurements were used in real time for operational planning and weather forecasting.
- Collected data were used extensively in developing both extreme and operational design criteria.
- Typhoon wave and current hindcast models were evaluated using the measured data. Monsoon effects on typhoon waves and currents are especially significant.

Possible future applications of data include:

- Complex measured currents could be studied to improve extreme and operational design criteria particularly using joint probability methods.

- Wave and current models could be evaluated using all data.
- Duration analysis of benign and inclement weather could be performed for operational planning.
- Real time wind, wave and current measurement integrated with a forecasting model could improve accuracy of forecasting in both NE Monsoon and typhoon resulting in lower cost of day-to-day operations, and enhanced safety of personnel & production platforms.
- Collected data could be used in future to develop better design criteria.

Only a very crude estimate of the benefits of the measurement program is possible. Even a rough conservative estimate shows that the value of benefits is many times the 2.2 million dollars spent on the measurement program.

First, drilling and testing operations during the measurement program benefited from the improved accuracy of forecasts, and many days of operating costs were saved at daily rates of up to \$500,000. Eighteen months of good quality data enabled safety evaluation of many unconventional but cheaper alternative production systems. Even assuming only 2% savings in the total cost of the final production system, the savings would be about 15.2 million dollars. Similar dollar amount savings are possible in the cost of a Tension Leg Platform if measured average slab current profiles are used in design.

Conclusions

Comprehensive Metocean data has been collected in a difficult area to support economic development. In comparison with other areas of similar interest, quantity of Metocean information available for the South China Sea is very small.

Some of the most important conclusions are presented below:

- A difficult measurement program in a remote area has been completed successfully to provide a valuable service to the industry.
- Extremely valuable deep water current data has been collected for operational planning purposes, especially for remotely controlled underwater operations.
- Pure tidal current ellipses will cause floating tankers to weather vane full circle in each tidal cycle in the absence of wind driven currents.
- Dongsha cold eddy appears to move in and out of the operating area during a tidal cycle. Wind velocity and direction also influence the location of the cold cyclonic eddy.
- Measured currents are much more complex than expected.
- The operational wind and wave climate is most severe during the winter monsoon.
- Typhoons imbedded in winter monsoons could be the worst weather conditions.
- A cost-effective measurement program is possible in a remote area.
- Site-specific data can improve the accuracy of monsoon and typhoon forecasts.
- Estimated benefits of a metocean measurement program are many times the cost of the measurement.

Recommendations

Countries surrounding the South China Sea have some of the fastest economic growth rates within the Asia-Pacific region. Here, coastal and marine economic activities are growing exponentially. However, very little comprehensive meteorological and oceanographic data are available to support these economic activities. The finished measurement program and

studies provide acceptable data for preliminary design criteria purposes, but, are insufficient to resolve many important design criteria issues, such as (i) joint occurrence probability of the northeast monsoon and a typhoon, (ii) joint probability of wind, wave, and current in a storm, and (iii) the role of complex currents in design criteria. Safe but economic design criteria are needed to design infrastructures for offshore oil production, a coastal plant or a harbor. Day-to-day operations could be interrupted by severe weather or typhoon. With good knowledge, one could plan operations to minimize downtime without compromising safety. Therefore, it is recommended that

- More environmental data should be collected preferably through a joint industry project.
- Ongoing site-specific Metocean measurement should be made part of economic activities in an offshore area.
- Measured data should be integrated with day-to-day weather forecasting and severe storm warning services.
- Collected data should be archived and made readily available for research and design criteria development.
- Extended current analysis of collected data could improve our understanding of the complex currents in the area resulting in safer and more cost-effective design and operating criteria.

Acknowledgments

We gratefully appreciate the financial and logistics support of Amoco Orient Petroleum Company and China National Offshore Nanhai East Oil Company during the measurement program.

CHAPTER 29

WAVE HEIGHT AND PERIOD DISTRIBUTIONS FROM LONG-TERM WAVE MEASUREMENT

Chung-Chu Teng¹ and Ian M. Palao²

Abstract

Both the univariate and joint distributions of the significant wave height (H_s) and the zero-crossing wave period (T_z) are studied using 16 years of hourly wave data measured from five National Data Buoy Center (NDBC) buoy stations. For the univariate distribution, the log-normal distribution fits both the H_s and the T_z well. The modified log-normal distribution proposed by Fang and Hogben (1982) does improve the fit at the high H_s end and at the peak for some stations. For H_s , the Weibull distribution, with parameters computed from the maximum likelihood (ML) method, fits the upper tail of the cumulative distribution; however, it underpredicts both the probability peak and the probability density at the high end. For the joint distribution, the marginal Weibull/conditional log-normal distribution best describes the measured data of the steeper sea states and has the best overall fit.

Introduction

The theoretical distribution and characteristics of individual wave heights and periods have been extensively studied and verified using measured data (see Tucker 1991). Unlike individual waves, distributions of H_s and T_z , which are important for ocean and coastal engineering, need to be determined empirically from real measurements. Thus, both the univariate and joint distributions of the two wave parameters have not been extensively studied in the past due to a lack of reliable, long-term wave measurements. However, the early studies conducted by Ochi (1978) and Fang and Hogben (1982) provide a very useful basis for studying distributions of H_s and T_z . Some recent studies (e.g., Ochi (1992); Mathisen and Bitner-Gregersen (1990); and Athanassoulis, et al. (1994)) present many ideas and useful results on this topic.

In this study, 16 years of hourly wave data measured at five NDBC buoy stations are used to study both the univariate and the joint distributions of H_s and T_z .

Measured Wave Data

Data used in the present study were obtained from five NDBC buoy stations, designated as stations 46001, 46002, 46003, 46005, and 46006. All five buoy stations, as shown in Figure 1, are located in the northeastern Pacific Ocean. Water depths (in meters) at these buoy stations are listed in parentheses below the station numbers in the figure. These buoy stations were chosen for this study mainly because they are located in very deep water, so that wave height and period are not affected by shallow water effects, and they have longer periods of available wave data. These buoy stations measure both meteorological and wave data and report hourly data in nearly real time through the Geostationary Operational Environmental Satellite (GOES).

Wave data are processed onboard the buoys by transforming the time-series data into wave frequency spectra. The processed wave data, together with meteorological data, are transmitted to shore via GOES. Then, the wave information received are further processed and analyzed (e.g., conducting transform function, noise correction, and data quality control). H_s and T_z are derived from the wave spectrum: $H_s = 4(m_0)^{1/2}$ and $T_z = 2\pi(m_0/m_2)^{1/2}$, where m_0 and m_2 are the zero-th and the second spectral moments, respectively.

Sixteen years (from 1980 through 1995) of hourly wave data measured at these buoy stations are used in this study. During these 16 years, periods of missing data were present in the wave records for all of the stations. These data gaps were caused by a number of different factors: sensor failure, payload failure, periodic loss of data during transmission, or the buoy not being on station due to refurbishment or mooring failure. Table 1 shows the monthly distribution of the available data points during the 16 years for all five stations. Data for these five stations cover 76% (46006) to 90% (46001) of the all possible hourly data. From the distribution, it is clear that the data gaps or missing data did not concentrate on any

particular month or season. In addition, the whole data set was carefully examined, and no data gap that could significantly affect long-term wave statistics was found. Thus, it can be assumed that the missing data or data gaps in this data set will not affect the long-term distributions of H_s and T_z .

Data Analysis

Univariate Distributions

For univariate (or marginal) distributions of H_s and T_z , two commonly used probability distribution functions are studied: the log-normal and the three-parameter Weibull distributions. Parameters in these two distributions are computed by three different methods: the least square (LS) method, the ML method, and the method of moments. More details of these methods are presented in Teng, et al. (1994) and Palao, et al. (1994).

(1) *Log-Normal Distribution*

$$p(x) = \frac{1}{\sqrt{2\pi\sigma x}} e^{-\frac{1}{2}\left(\frac{\ln(x)-\mu}{\sigma}\right)^2}$$

where μ and σ are parameters of the distribution.

The modified log-normal distribution, which includes a skew factor to make a better fit at high values (Fang and Hogben, 1982), is also examined in this study.

(2) *Three-Parameter Weibull Distribution*

$$p(x) = \frac{\beta(x-\gamma)^{\beta-1}}{\alpha^\beta} e^{-\left(\frac{x-\gamma}{\alpha}\right)^\beta}$$

where α , β , and γ are the shape, scale, and location parameters, respectively.

Joint Distributions

For joint distributions of H_s and T_z three frequently used distribution functions are examined: bivariate log-normal distribution, bivariate two-parameter Weibull distribution, and marginal three-parameter Weibull/conditional log-normal distribution. More details of these distributions can be found in Mathisen and Bitner-Gregersen (1990). In the following equations, x represents T_z and y represents H_s .

(1) *Bivariate Log-Normal Distribution*

$$p(x,y) = \frac{0.5}{\sqrt{1-\alpha_{xy}^2} \pi \sigma_x \sigma_y xy} e^{-\frac{0.5}{1-\alpha_{xy}^2} \left[\frac{(\ln(x)-\mu_x)^2}{\sigma_x^2} - \frac{2\alpha_{xy}(\ln(x)-\mu_x)(\ln(y)-\mu_y)}{\alpha_x \sigma_y} + \frac{(\ln(y)-\mu_y)^2}{\sigma_y^2} \right]}$$

where μ_x , μ_y , σ_x , σ_y , and α_{xy} are parameters of the distribution.

Computationally, μ_x and μ_y are the expected values of $\ln(x)$ and $\ln(y)$; σ_x and σ_y are the standard deviations of $\ln(x)$ and $\ln(y)$; and α_{xy} is the correlation coefficient between $\ln(x)$ and $\ln(y)$. The modified bivariate log-normal distribution, proposed by Fang and Hogben (1982), is also examined in this study for reference purposes. The modified distribution is identical to the bivariate log-normal distribution except for the addition of a multiplicative term describing the skewness of $\ln(y)$.

(2) *Bivariate Weibull Distribution*

$$p(x,y) = \left[\frac{\zeta y^{\zeta-1}}{\eta^\zeta} e^{-\left(\frac{y}{\eta}\right)^\zeta} \right] \left[\frac{\beta x^{\beta-1}}{\alpha^\beta} e^{-\left(\frac{x}{\alpha}\right)^\beta} \right]$$

where α , β , η , and ζ are parameters of the distribution.

This distribution uses two two-parameter Weibull distributions (i.e., one for H_s and one for T_z) as a joint model. The parameters are calculated using the LS method. The marginal distribution is used for T_z while the estimation of the distribution of H_s is conditional on T_z through the use of the η parameter.

(3) *Marginal Weibull/Conditional Log-Normal Distribution*

$$p(x,y) = \left[\frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{1}{2}\left(\frac{\ln(x)-\mu}{\sigma}\right)^2} \right] \left[\frac{\beta(y-\gamma)^{\beta-1}}{\pi\alpha^\beta} e^{-\left(\frac{y-\gamma}{\alpha}\right)^\beta} \right]$$

where α , β , γ , σ , and μ are parameters.

This distribution is calculated by using a three-parameter Weibull for H_s along with a log-normal for T_z . The parameters of this distribution are identical to the corresponding univariate distributions. The LS method is used to calculate the three Weibull parameters and the two log-normal parameters. Note the log-normal parameters are calculated for every 0.5-m wave height interval.

Results and Discussion

Figure 2 shows the comparisons between histograms of the measured H_s , and the univariate distributions for the five buoy stations. From visual judgment, the log-normal distribution, in general, fits the data better than the Weibull distribution. For the log-normal distribution, results obtained from the three different methods of parameter estimation are almost identical. The log-normal distribution slightly overpredicts the peak for the two northern stations (46001 and 46003) and slightly misses the peak location for two of the three southern stations (46005 and 46006). For the Weibull distribution, different parameter estimate methods produce different parameters and have different effects on the distribution shapes. The LS method always underpredicts the high wave range and overpredicts the location of the peak. The ML method provides much better prediction of the peak location and at high H_s , but significantly underpredicts the height of the peak and overpredicts at the lower range. The Weibull fits, based on the method of moments, are much poorer than the other two methods and are not presented in the figures.

Two goodness-of-fit statistics, the Kolmogorov-Smirnov statistic (K-S) and Chi-square statistic (χ^2), are used to evaluate the degree of fit between the data and the fitted distributions. Table 2 summarizes the values of these two statistics for the two distributions for each of the five buoy stations. Note the values of χ^2 are computed based on a wave height interval of 0.1 m. For the Weibull distribution, the goodness-of-fit values for the ML method, which are listed in the table, are always smaller (i.e., the fits are better) than those from the other two methods. Based on the two goodness-of-fit statistics, the log-normal distribution fits the data better than the Weibull distribution, regardless of the parameter estimate method used.

To further examine the fit of the univariate distributions of H_s , comparisons between the empirical cumulative distribution from the measured data and the theoretical cumulative distributions are made. Figure 3(a) shows an example of this comparison for station 46001. The log-normal distribution fits the data well, except for the upper tail (i.e., cumulative probability greater than 0.9) where it slightly underpredicts the empirical cumulative distribution. This trend was also reported by many previous studies (e.g., Ochi (1978); Fang and Hogben (1982)). However, among the five stations, stations 46001 and 46003 clearly show

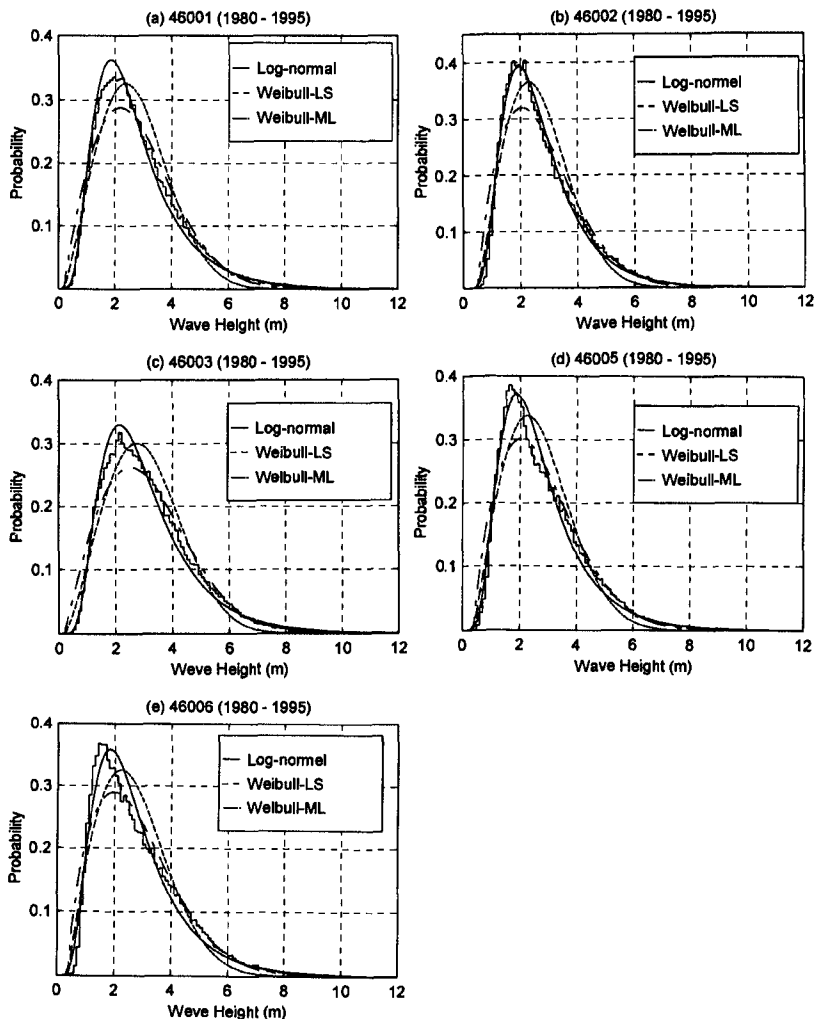

Figure 2. Comparisons of H_s between histograms and the univariate distributions for all five buoy stations

Table 2. Values of χ^2 and K-S for distributions of the zero-crossing wave period

	Log-Normal		Weibull	
	K-S	$\chi^2 (\times 10^{-6})$	K-S	$\chi^2 (\times 10^{-6})$
46001	0.01560	1.01749	0.03438	1.01889
46002	0.03862	0.91254	0.03086	0.91537
46003	0.01440	0.87029	0.03172	0.87135
46005	0.03021	0.92694	0.03337	0.92846
46006	0.02717	0.86185	0.02981	0.86325

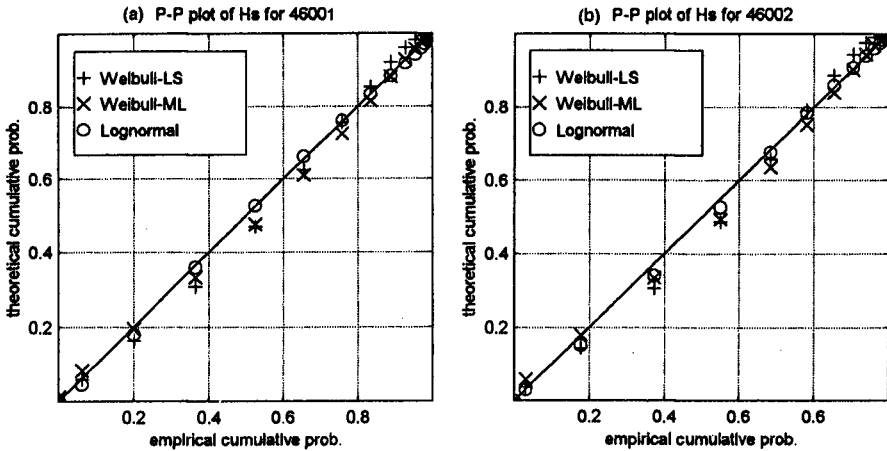

Figure 3. Comparisons of cumulative distribution for H_s between measured data and univariate distributions for (a) station 46001 and (b) station 46002

the underprediction. For other stations, there is very little or no underprediction from the log-normal distribution at the upper tail, as shown in Figure 3(b) for station 46002. For the Weibull distribution, the LS method overpredicts both the upper and lower tails for all five stations, while the ML method predicts well at the upper tail but underpredicts at the lower tail.

Figure 4 shows, for H_s at 46001, the histograms and univariate distributions including the Weibull, the log-normal, and the modified log-normal (Fang and Hogben (1982)) distributions. It is clear that the modified log-normal distribution significantly improves the fitting at high values and at the peak. The improvement is significant for stations 46001 and 46003. For other stations, there is very little or no improvement. Note the Weibull distribution, with parameters computed from the ML method, underpredicts the distribution at high values despite the better fit of the cumulative distribution at the high end. This trend is valid for all five stations.

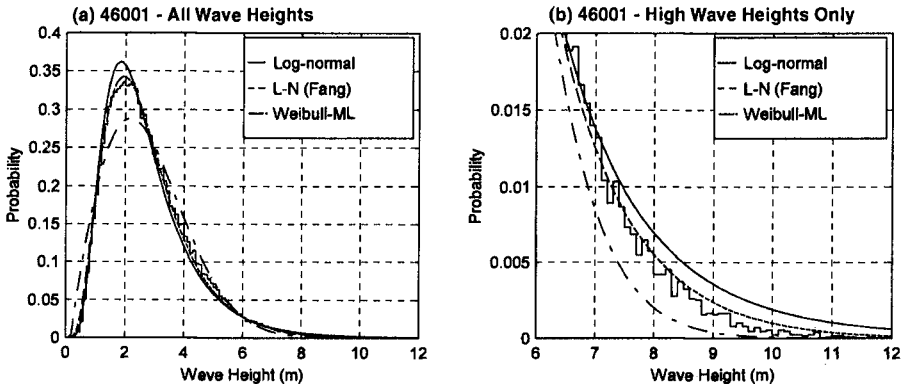

Figure 4. Comparisons of H_s between histograms and the univariate distributions for station 46001

For T_z , comparisons between the histograms and the univariate distributions are presented in Figure 5. Similar to H_s , the parameters of the log-normal distribution for T_z computed from the three methods of parameter estimation are almost identical. In addition, variations of these parameters from station to station are very small. The parameter μ varies from 1.88 to 1.96, and the parameter σ varies from 0.187 to 0.202. The log-normal distribution fits very well for the two northern stations (i.e., 46001 and 46003). For the three southern stations (i.e., 46002, 46005, and 46006), the histograms show broader peaks, and neither of the two distributions predicts the peak very well. Similar to their effects on H_s , the Weibull distribution based on the ML method predicts the upper range best and underpredicts the peak, while the LS method underpredicts the high range and does not predict the peak well. Again, the method of moments is much worse than the other two methods, and its results are not presented.

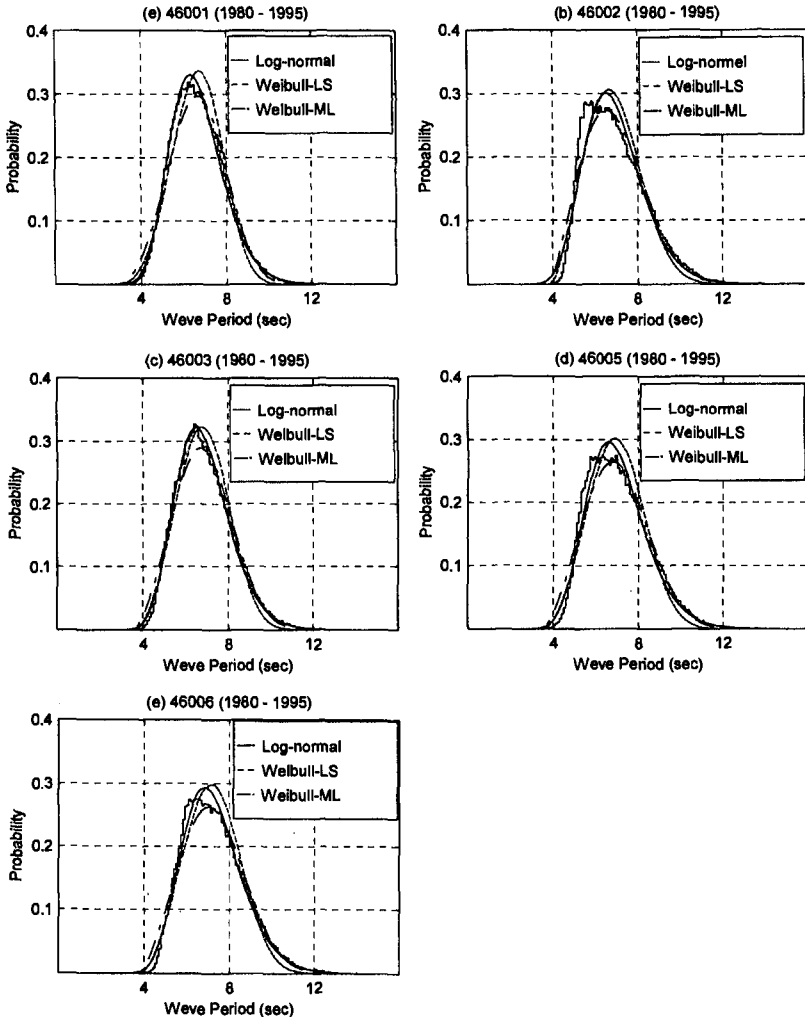

Figure 5. Comparisons of T_z between histograms and the univariate distributions for all five buoy stations

Table 3 presents values of K-S and χ^2 for T_z . Based on the two statistics, the log-normal distribution fits better than the Weibull distribution (using the ML method). Figure 6 presents comparisons between the empirical and fitted cumulative distributions of T_z for stations 46001 and 46002. For the log-normal distribution, unlike that for H_s , there is no underprediction at the upper tail of the cumulative distribution of T_z for all five stations. Performances of the Weibull distribution in modeling T_z using the LS and ML methods are similar to those for H_s .

The contour plots of the joint probability between H_s and T_z for station 46001 are presented in Figure 7. It is clear that both the bivariate log-normal and the bivariate Weibull distributions overpredict the joint probability for the steeper sea states, as indicated by the straight line. The marginal Weibull/conditional log-normal distribution fits this steeper sea range well. This trend was also shown by Mathisen and Bitner-Gregersen (1990) using wave data collected from the Norwegian Sea. The bivariate Weibull distribution also performs poorly at high wave periods. Except for steep seas, the bivariate log-normal distribution generally fits the data well. The modified bivariate log-normal distribution, proposed by Fang and Hogben (1982), was also studied. Its results are very similar to those from the original distribution and, thus, are not presented in this paper. Although the marginal Weibull/conditional log-normal distribution generally fits the data, it seems that it does not predict the very high probability location very well. The trends observed for station 46001 are also applicable to all other stations, but these results are not shown in this paper due to space limitations.

Table 3. Values of χ^2 and K-S for distributions of the significant wave height

	Log-Normal		Weibull	
	K-S	χ^2 ($\times 10^{-6}$)	K-S	χ^2 ($\times 10^{-6}$)
46001	0.02270	1.01465	0.04155	1.01859
46002	0.02113	0.91402	0.04693	0.91566
46003	0.02720	0.86907	0.03510	0.88058
46005	0.02652	0.92650	0.04303	0.92890
46006	0.03183	0.86031	0.04202	0.86336

Figure 6. Comparisons of cumulative distribution for T_z between measured data and univariate distributions for (a) station 46001 and (b) station 46002

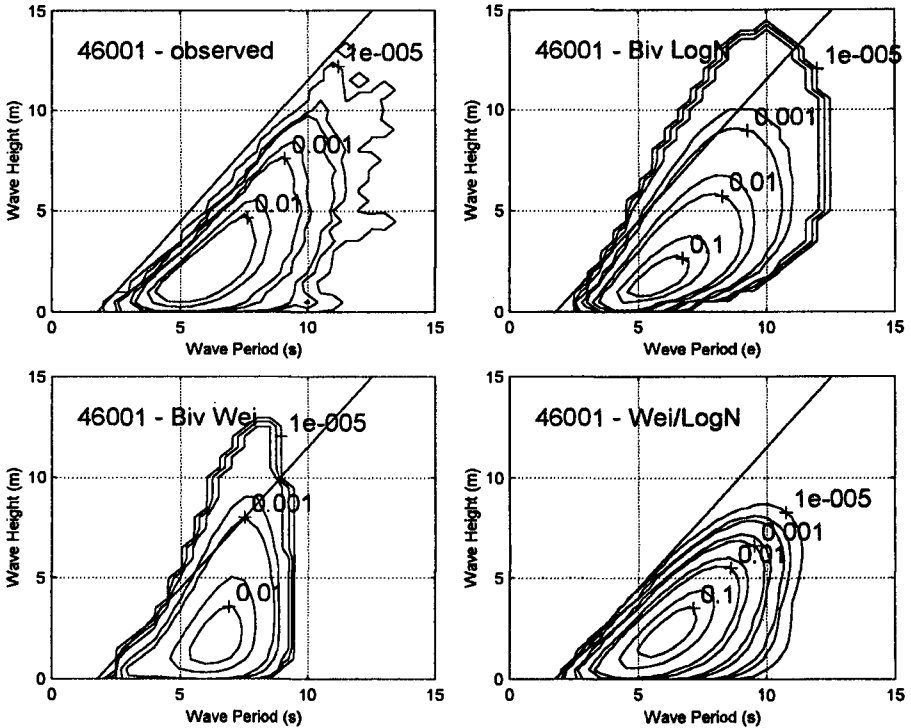

Figure 7. Contour plots of joint probability between H_s and T_z for (a) measured data, (b) bivariate log-normal distribution, (c) bivariate Weibull distribution, and (d) marginal Weibull and conditional log-normal distribution

The theoretical joint probability distributions are compared to the distribution of the observed data based on the correlation coefficients. For H_s , a correlation coefficient is computed for each 0.5-m wave height bin. For each wave height bin, the corresponding values of observed frequencies and frequencies calculated from the joint distributions across the 0.5-s T_z bins form a paired data set. A correlation analysis is then performed on the two paired data (i.e., observed frequencies versus calculated frequencies). The correlation coefficients for every 0.5-s T_z bin are computed similarly. Note the correlation coefficient at both the upper and lower ends may not be reliable due to limited data observations. Negative coefficient values show a polarity between the deviations of observed frequencies and the deviations of calculated frequencies. This shows a very poor fit between the measured data and the joint distribution. Figure 8 shows the correlation coefficients for all the H_s and T_z bins for all five stations. For H_s , it is clear that the marginal Weibull/conditional log-normal distribution fits better than other distributions. The bivariate Weibull distribution's performance is very poor and, therefore, unacceptable. All joint distributions have high correlation coefficients for the T_z fit. Note the bivariate Weibull distribution does not have correlation values for periods higher than 10 seconds because there are no calculated frequencies from which to compute the coefficients.

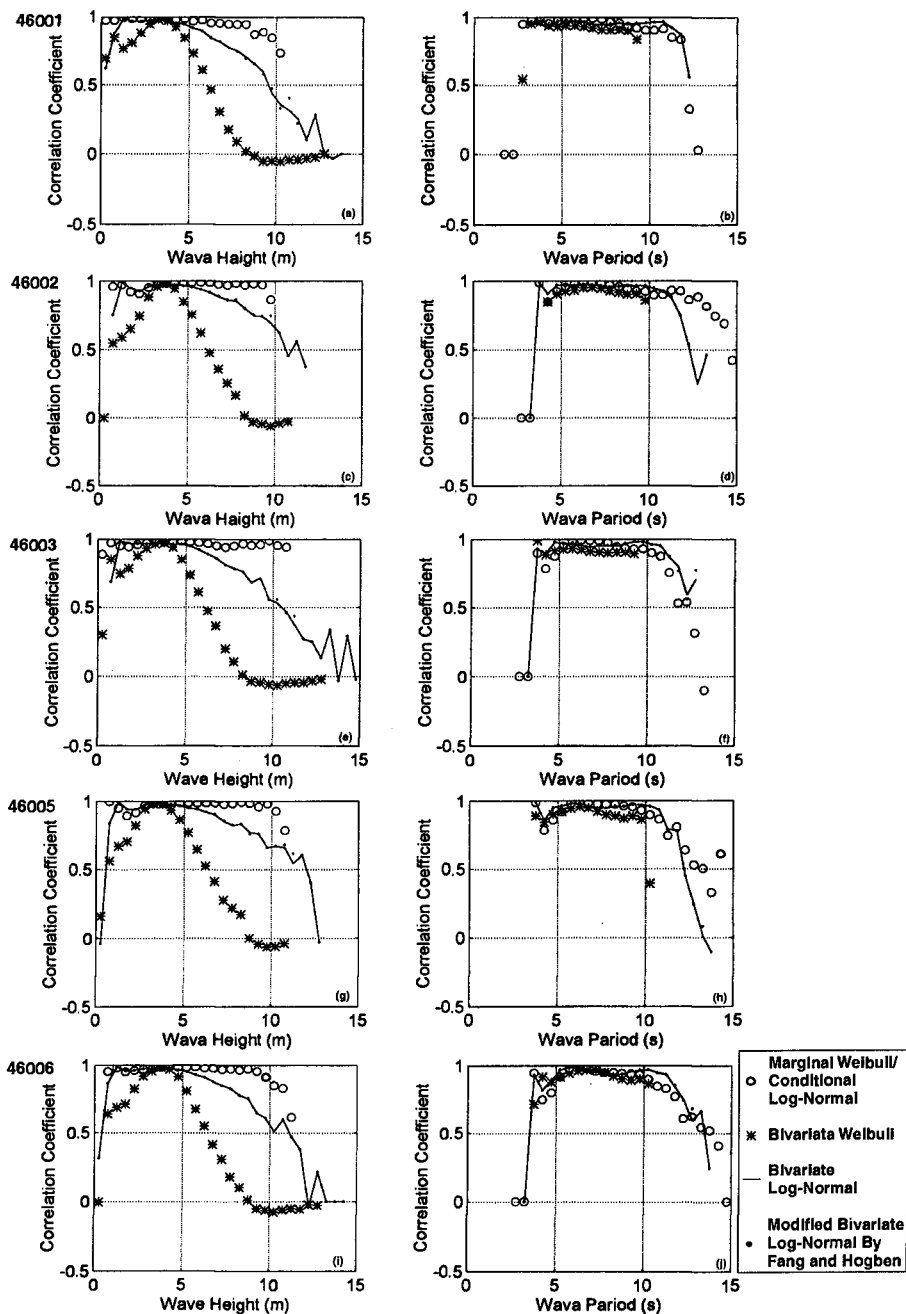

Figure 8. Coefficients of correlation between measured data and joint distributions for various H_s and T_z values for all five buoy stations

Conclusions

The results show that the log-normal distribution best fits both H_s and T_z for the five buoy stations. The modified log-normal distribution, proposed by Fang and Hogben (1982), significantly improves the fitting at the high H_s end and at the peak for some stations. For the three-parameter Weibull distribution, different methods of parameter estimation produce different parameters and distribution shapes. In general, the ML method is better than both the LS method and the method of moments. Although the Weibull distribution with parameters computed from the ML method fits the upper tail of the cumulative distribution for the H_s , it underpredicts both the probability peak and the probability density values at the high values.

Although the fit between various joint distributions and the measured data depends on the wave height and period range, the marginal Weibull/conditional log-normal distribution has the best overall fit based on the visual inspection and the correlation coefficients. Also, this joint distribution better estimates the data of the steeper sea states. Both the bivariate log-normal and the bivariate Weibull distributions overpredict the steeper sea states. The bivariate Weibull distribution also poorly fits the high wave period data.

CHAPTER 30

INTERFERENCE OF SMALL STRUCTURES IN THE VICINITY OF LARGE STRUCTURES

Subrata K. Chakrabarti, F. ASCE and Sumita Chakrabarti

Abstract

The purpose of this paper is to investigate the effect of large structures in the vicinity of small structures in the determination of wave forces on the small structures. The structures considered in this study are circular cylinders and analytical expressions are derived. It is shown that if the small cylinders are placed in close proximity of large cylinders (center distance/ caisson radius < 2.0), the wave forces on the small cylinder are largely influenced by the large cylinder.

INTRODUCTION

When large structures placed underwater encounter incoming waves, the waves alter in form in the vicinity of the structure. The problem is generally solved as a boundary value problem based on a linear velocity potential due to the incident wave. The diffraction effect of large coastal or offshore structures in waves is well-known. For an arbitrary shape of the structure the wave diffraction effect is solved numerically. For a fixed large caisson, this problem was solved by MacCamy and Fuchs (1955) in a closed form for Airy waves. This solution has been extended to the second-order wave theory [e.g., Molin (1979)]. For large cylinders in the vicinity of one another, the problem of multiple cylinder interaction is well-known [Chakrabarti(1978)]. In this case multiple diffraction from the neighboring cylinders is taken into account.

For structures which are placed near each other and are allowed to move independently, the problem of multiple radiation is taken into account in addition to multiple diffraction. Several research works addressed this problem in the diffraction regime, e.g., Ohkusu (1976).

The present study addresses the situation in which only one part of the structure is large enough to encounter diffraction effect. The other structure dimension is such that its effect on the waves is local and its presence has little influence on the large structure. Examples of such applications are composite structures, e.g., the Maurcen gravity platform in the North Sea and piles in the neighborhood of large caisson as shown in Fig. 1.

In this case, the small structure, such as, the pile, will experience a wave that is a combination of the incident wave and the scattered wave from the neighboring large structure. The size of the small structure is such that it falls in the Morison force regime in that both the inertia and drag effects are important.

¹Offshore Structure Analysis, Inc. 191 E. Weller Dr. North, Plainfield, IL 60544

²Biomedical Engineering Dept., Northwestern University, Evanston, IL 60201

Two different cases are considered in this study. In the first case, a pile is placed near a large caisson. Expressions of the forces on the pile are derived in the presence of the caisson based on the MacCamy-Fuchs theory. In the second case, the presence of large multiple cylinders on a small diameter member is investigated. Here, multiple scattering effect of waves on the small member is considered. An example of this situation may be found in the presence of multi-legged gravity offshore structure on risers.

Analytical solutions are derived for the total velocity potential at a point in the wave field which includes the wave scattering effect. The wave kinematics are derived based on this velocity potential. The forces on the small member are then expressed in terms of the wave kinematics. Numerical results are presented in all cases. Comparisons are made for the forces on the small structure with and without the presence of the large structure. In particular, the effect of spacing between the large and small structures is shown. The region where the influence of the large structure is significant in the design of the small structure is discussed.

LARGE VERTICAL CYLINDER

For a large vertical cylinder an analytical solution for the linear diffraction problem has been derived by McCamy and Fuchs (1954). In this case the expression for the incident wave is written in a convenient cylindrical polar coordinate (Fig. 1). The expression for the total potential at a point (r, θ) in the fluid field is obtained as

$$\Phi = \frac{H\omega}{2k} \frac{\cosh ks}{\sinh kd} \sum_{m=0}^{\infty} \delta_m i^{m+1} \left[J_m(kr) - \frac{J'(ka)}{H_m^{(1)'}(ka)} H_m^{(1)}(kr) \right] \cos m\theta \exp(-i\omega t) \quad (1)$$

in which H = wave height, ω = wave frequency, k = wave number, s = vertical distance from the ocean floor, d = water depth, a = caisson radius, and t = time. The quantities J_m and $H_m^{(1)}$ are the Bessel and Hankel functions of the first kind of order m respectively and prime denotes derivatives with respect to their arguments. Note that $H_m^{(1)} = J_m + iY_m$ where Y_m is the Bessel function of the second kind of order m . The value of δ_m is 1 for $m=0$ and 2 for $m>0$. The first term inside the bracket corresponds to the incident waves while the contribution of the scattered wave from the cylinder surface to the potential function is given by the second term within the bracket involving the Hankel function.

Note that while the above equation is written in complex form for mathematical convenience, only the real part of the expression matters. The horizontal water particle velocities are given in terms of Φ by

$$u_r = \frac{\partial \Phi}{\partial r} \quad (2)$$

and

$$u_\theta = \frac{1}{r} \frac{\partial \Phi}{\partial \theta} \quad (3)$$

Using the expression for Φ in Eqs. 2 and 3, we have

$$\bar{u}_r = \frac{\cosh ks}{\sinh kd} \sum_{m=0}^{\infty} \delta_m i^{m+1} \left[J_m'(kr) - \frac{J_m'(ka)}{H_m^{(1)}(ka)} H_m^{(1)'}(kr) \right] \cos m\theta \exp(-i\omega t) \quad (4)$$

and

$$\bar{u}_\theta = -\frac{1}{kr} \frac{\cosh ks}{\sinh kd} \sum_{m=0}^{\infty} m \delta_m i^{m+1} \left[J_m(kr) - \frac{J'(ka)}{H_m^{(1)'}(ka)} H_m^{(1)}(kr) \right] \sin m\theta \exp(-i\omega t) \quad (5)$$

where bar denotes nondimensional quantities and the velocities are normalized by dividing by the quantity $(H\omega/2)$. In Cartesian coordinate system the horizontal particle velocity and acceleration components at the pile center are

$$\begin{aligned} \bar{u}_x &= \bar{u}_r \cos\theta - \bar{u}_\theta \sin\theta \\ \bar{u}_z &= \bar{u}_r \sin\theta + \bar{u}_\theta \cos\theta \\ \bar{\dot{u}}_x &= -i\omega \bar{u}_x \\ \bar{\dot{u}}_z &= -i\omega \bar{u}_z \end{aligned} \quad (6)$$

where the coordinate x is the direction of waves and z normal to this direction. The derivation thus far has been carried out in the complex field. However, in order to apply the expressions for the kinematics in the Morison force, it is necessary to use the real parts of these quantities. The forces on a unit section of the pile in the neighborhood of the single cylinder are computed based on these kinematics using the Morison equation. The forces along and transverse to the wave direction respectively are

$$\bar{f}_x(\omega t) = -\pi C_M \frac{D}{H} \operatorname{Re}\{\bar{i}\bar{u}_x \exp(-i\omega t)\} + C_D \left| \operatorname{Re}\{\bar{u}_x \exp(-i\omega t)\} \right| \operatorname{Re}\{\bar{u}_x \exp(-i\omega t)\} \quad (7)$$

and

$$\bar{f}_z(\omega t) = -\pi C_M \frac{D}{H} \operatorname{Re}\{\bar{i}\bar{u}_z \exp(-i\omega t)\} + C_D \left| \operatorname{Re}\{\bar{u}_z \exp(-i\omega t)\} \right| \operatorname{Re}\{\bar{u}_z \exp(-i\omega t)\} \quad (8)$$

in which D = pile diameter, C_M = inertia coefficient and C_D = drag coefficient. The forces in the above expressions are nondimensionalized by the quantity $1/2 \rho D (H\omega/2)^2$.

While the Morison equation in general will not produce a transverse horizontal force on a pile, the diffraction effect of the wave from the caisson is expected to introduce a transverse force.

Note that these expressions do not state anything about the vortex induced lift force as the Morison equation fails to describe this phenomenon. The description of the transverse force in this case is complicated by the fact that the scattered wave introduces a flow field which has a direction different from that of the incident wave and depends on the location of the fluid field.

It is considered interesting to compare these forces with the forces on the same pile in the absence of the large caisson. The force on the pile in the x-direction (Morison force is absent in the z-direction) written in the same nondimensional form is expressed as

$$\bar{f}_{xa} = -\pi C_M \frac{D}{H} \bar{u} \sin \omega t + C_D \bar{u}^2 |\cos \omega t| \cos \omega t \quad (9)$$

where the nondimensional force has the same form as in Eq. 7 and

$$\bar{u} = \frac{gk}{\omega^2} \quad (10)$$

This last quantity approaches a value of one in deep water.

LARGE MULTIPLE CYLINDERS

Assume that the pile resides in the neighborhood of a multi-legged vertical structure whose legs represent large vertical cylinders. The pile experiences multiple diffraction from these cylinders. The effect of the waves on the pile, as before, is considered small in developing the theory. Considering the interaction of the waves with all large cylinders in the flow field, the total potential is described with reference to the coordinate system described at the center of the δ th cylinder as

$$\Phi^\delta = \frac{iH\omega}{2k} \frac{\cosh ks}{\sinh kd} \left\{ \begin{array}{l} \sum_{n=-\infty}^{\infty} -J_n(kr_\delta) \exp(in(\theta_\delta - \theta_\omega + \pi/2)) \\ + A_n^\delta H_n(kr_\delta) \exp(in\theta_\delta) \\ + (\sum_{\mu=1}^{\delta-1} + \sum_{\mu=\delta+1}^{\Delta}) \sum_{m=-\infty}^{\infty} A_n^\mu H_{n+m}(kr_{\delta\mu}) J_m(kr_\delta) \\ \exp(im(\theta_{\delta\mu} - \theta_\delta)) \exp(in\theta_{\mu\delta}) \end{array} \right\} \exp(-i\omega t) \quad (11)$$

in which Δ = total number of large cylinders, θ_ω = angle of incident wave with respect to the positive x-axis, r_δ , θ_δ = location of field point with respect to the center of δ th cylinder (see Fig. 2). For convenience, the center of the coordinate system is located at the center of the caisson δ . To numerically compute the potential function, the infinite sums in the above equation are

replaced by a finite sum from -N to N where N is the number of symmetric images provided of the caisson in question. The first term within the bracket is due to the incident wave, the second term arises from the scattering from the reference δ th cylinder and is similar to the MacCamy-Fuchs expression. The third series term is due to scattering from the balance of the cylinders in the neighborhood where the Bessel's addition theorem has been used to transfer the coordinate system to the reference cylinder.

The expression for Φ^δ satisfies Laplace's equation and all boundary conditions except the cylinder surface condition. As for the single cylinder, when this condition is applied, a matrix equation in the unknown coefficients A_n^δ is derived.

$$\left\{ \begin{aligned} & \sum_{\mu=1}^{\delta-1} \sum_{m=-N}^N A_m^\mu H_{n+m}(kr_{\delta\mu}) \exp(im\theta_{\mu\delta}) J'_n(ka_\delta) \exp(in\theta_{\delta\mu}) + A_{-n}^\delta H'_{-n}(ka_\delta) \\ & + \sum_{\mu=\delta+1}^{\Delta} \sum_{m=-N}^N A_m^\mu H_{n+m}(kr_{\delta\mu}) \exp(im\theta_{\mu\delta}) J'_n(ka_\delta) \exp(in\theta_{\delta\mu}) \\ & = J'_{-n}(ka_\delta) \exp(ikr_{0\delta} \cos(\theta_{0\delta} - \theta_\omega)) \exp(-in(-\theta_\omega + \pi/2)) \end{aligned} \right\}, n = -N, \dots, N \quad (12)$$

In the above, the higher the value of N, the better is the accuracy in Φ^δ . The order of the matrix is given by $(2N+1)\Delta$. The coefficients A_n^δ are computed by the matrix inversion.

Once the velocity potential at a field point, r_δ, θ_δ is known, the particle kinematics are computed as before from Eqs. 2 and 3 so that the forces on the pile may be obtained from the Morison equation. The spatial part of the radial and tangential velocities at the center of the pile (r_δ, θ_δ) is obtained from

$$\bar{u}_r^\delta = i \frac{\cosh ks}{\sinh kd} \left\{ \begin{aligned} & \sum_{n=-N}^N -J'_n(kr_\delta) \exp(in(\theta_\delta - \theta_\omega + \pi/2)) + A_n^\delta H'_n(kr_\delta) \exp(in\theta_\delta) + \\ & \left(\sum_{\mu=1}^{\delta-1} + \sum_{\mu=\delta+1}^{\Delta} \right) \sum_{m=-N}^N A_m^\mu H_{n+m}(kr_{\delta\mu}) J'_m(kr_\delta) \exp(im(\theta_{\delta\mu} - \theta_\delta)) \exp(in\theta_{\mu\delta}) \end{aligned} \right\} \quad (13)$$

and

$$\bar{u}_\theta^\delta = \frac{-\cosh ks}{kr \sinh kd} \left\{ \begin{aligned} & \sum_{n=-N}^N -n J_n(kr_\delta) \exp(in(\theta_\delta - \theta_\omega + \pi/2)) + n A_n^\delta H_n(kr_\delta) \exp(in\theta_\delta) + \\ & \left(\sum_{\mu=1}^{\delta-1} + \sum_{\mu=\delta+1}^{\Delta} \right) \sum_{m=-N}^N A_m^\mu (-m) H_{n+m}(kr_{\delta\mu}) J_m(kr_\delta) \exp(im(\theta_{\delta\mu} - \theta_\delta)) \exp(in\theta_{\mu\delta}) \end{aligned} \right\} \quad (14)$$

It can be shown that for a two cylinder case, the total number of images $N=7$ provides sufficient accuracy (up to 4 significant digits) for forces. For symmetric two caisson/ one pile configuration

at right angles to the flow, the last two terms in the radial velocity expression u_r^6 should provide equal values at the pile. This provides a check on the numerical computation. Thus the transverse force will be absent in this case as one would expect.

NUMERICAL RESULTS

In order to show the effect of a single large caisson on the forces on a pile, numerical values on the forces on the pile are computed with and without the presence of the caisson. For this comparison the values of the hydrodynamic coefficients are taken as $C_M=2.0$ and $C_D=1.0$. The water depth to the caisson radius is taken as 1.0 and the forces are computed at the still water surface. The pile diameter to the wave height ratio is considered to be 0.25. In deep water this corresponds to a Keulegan-Carpenter value of about 12. Three different diffraction parameter values ka are chosen: $ka=1.0, 2.0, 3.0$. The pile is placed at different distances from the center of the caisson at 0, 90, and 180 degree orientation. Note that 0 degree corresponds to the pile placed behind the caisson with respect to the wave direction, 180 degrees places it in front of the caisson while 90 degrees is transverse to the flow.

The results for ka values of 1.0, 2.0 and 3.0 are shown in Figs. 3-5. The x-axis corresponds to the nondimensional distance r/a where r is the distance between the centers of the caisson and the pile and a is the caisson radius. The y-axis represents nondimensional force amplitudes on the pile. The quantities FX and FZ show forces in the presence of the caisson while FXA is the force in its absence. For the 0 and 180 degree cases only the x forces (FX) are presented as one would expect. However, for the 90 degree case, there is a force component in the z direction (FZ) as well.

The 0 degree case shows the shielding effect. When the pile is very close to the caisson the x force on the pile is small compared to the single pile case. As the pile is moved away from the caisson in the 0 degree direction, the x force on the pile increases and approaches in value to the single pile forces. This increase is slow and the forces are close to each other at a distance of six radius away.

When the pile is in front of the caisson facing the wave, the force on the pile is affected by the oscillating nature of the wave as the pile is moved away. The effect of the caisson here is high and is felt by the pile for a long time. Interestingly, the diffracted wave being out of phase with the incident wave, the forces experienced by the pile as it is moved away, fluctuates in magnitude, sometimes re-inforcing and sometimes canceling the single pile forces. This oscillation frequency corresponds to the wave length of the incident (and diffracted) wave.

When the pile is transverse to the caisson with respect to the wave direction, the wave load on the pile is considerably higher than the pile alone case due to closeness of the caisson. As in the 180 degrees case, the load fluctuates about the pile-alone force as the caisson is moved along the 90 degree line. The load approaches the pile-alone force with increasing distance. In fact, at a distance of about five times the radius, the forces are almost identical. This orientation also experiences a transverse load whose magnitude is as much as 25 percent of the single pile load.

The transverse load is small in the close proximity of the caisson and grows steadily with distance reaching maximum quickly near a distance of two radii.

As the diffraction parameter is increased in value (equivalent to higher wave frequency), the oscillation frequencies at 90 and 180 deg. increase. The normalized forces, however, are higher at the lower ka values.

A second numerical example shown here is the load on a pile in the presence of two large caissons symmetrically placed around the pile (Fig. 6). In this case the pile is always assumed to be in the center while the distance of the caissons from the pile is varied symmetrically. The normalized x and z loads on the pile are plotted in Fig. 7 for a ka value of 2.0. The loads at still water surface as before are shown and the values of C_M and C_D are taken as 2.0 and 1.0 respectively. The other values are the same as before. In this case, the transverse force is zero due to the symmetric configuration since the forces produced by the caisson no. 1 will be equal and opposite to the forces generated due to the presence of caisson no. 2. On the other hand, the x -force is considerably higher than the single pile force due to the re-inforcement caused by the caisson pair. For example, close to the caissons (r/a near 1.0), the force on the pile is more than twice that of the single pile.

CONCLUDING REMARKS

Analytical expressions have been derived on forces on piles in the presence of caissons. The theory is derived for a pile near a single caisson as well as near multiple caissons. Numerical values are given for several examples, including pile near a single caisson, and pile in the center of a caisson pair. Results show that the force is influenced by the presence of the caisson for $r/a < 2.0$. A transverse force is generated for a single caisson case at 90 deg. due to diffraction of waves. Multiple caisson interaction with the pile is more pronounced. Many offshore and coastal structures include the geometry presented in the above examples, e.g., Maureen Gravity Platform, Risers on Tension Leg Platforms, etc. where this interaction may be important.

CHAPTER 31

WAVE DYNAMICS AT COASTAL STRUCTURES: DEVELOPMENT OF A NUMERICAL MODEL FOR FREE SURFACE FLOW

Zoheir A. Sabeur⁽¹⁾, N William H.Allsop⁽²⁾, Robert G.Beale⁽³⁾, John M.Dennis⁽⁴⁾

Abstract

The development of third generation wave models is needed for a detailed study of wave dynamics and impact at coastal structures. This would require the modelling of wave flows with high distortion of the free surface at confined boundaries. In our opinion, the Volume of fluid method, which uses concepts of local advection of fluid in free surface flow modelling, is the prime candidate for simulating realistic flows at sea defences and walls. In this paper, the numerical techniques for the simulation of waves with highly distorted water/air interfaces at a slope, using the volume of fluid method, are considered

Introduction

The volume of fluid method (VOF), originally developed by Hirt and Nichols [1], can be used for the study of transient waves within confined structures. The possibility for simulating the interaction (or interactions) of waves at structures with complex geometry leads to a more realistic modelling of wave impact at breakwaters and coastal defences. Furthermore, a stable numerical simulation of such wave dynamics can provide important information on impact pressures, jets and wave flows at specified locations of the coastal structure.

Thus, the numerical approach based on the VOF technique for the simulation of transient waves can lead to a good design for the construction of sea defences that sustain wave forces encountered during severe ocean, sea and atmospheric conditions.

In previous years, two dimensional depth integrated models have been widely used in the study of wave action at vertical walls and slopes [2]. However they are limited by the fact that the free surface is assumed to remain a single valued function of space in all flow cases. Vertical fluid accelerations which are large in magnitude and short in duration, during wave impact, cannot be modelled and the free surface is implicitly maintained as a simply connected function of space. These first generation type of models are well established in coastal engineering. They can provide solutions to problems involving wave propagation at structures with simple geometry and in flow cases where breaking and overturning waves do not take place. They are also important for the study of solitary waves and can be used in the development of the next generation wave models. [3], [4]

The speed and storage memory of modern computers have allowed scientists to develop the second and third generation wave models, and despite the task for a large amount of numerical operations, driven by new mathematical algorithms, the total CPU time used by such computers can be optimised and lead to an efficient study of wave dynamics at coastal structures.

Second generation wave models based on Boundary Integral Methods (BIM) which were developed by Peregrine *et al* , and others [5], raised important questions on the physics of impact pressures at vertical walls. Peregrine showed the existence of large magnitude vertical accelerations of a wave front at impact and the possible mechanisms by which air bubble entrapment could be governed. The existence of short timed (~ 1 msec) oscillatory impact pressure peaks at specific locations of the vertical wall suggests the existence of several types of wave interactions with the wall. Therefore, a detailed numerical investigation needs to be carried out.

As a result, the third generation wave models which describe the dynamics of waves before, at and after impact have been developed, and recent simulations of breaking and overturning waves at vertical walls and slopes have been completed.[6].

Mathematical formulation

The general equations for fluid motion under transient conditions are given by the Navier-Stokes equations (NS). They incorporate fluid mass and momentum conservation and take into account of the external forces that are applied on the fluid body.

In two dimensional cartesian coordinates, the NS equations are given by the following differential equations:

Conservation of mass:

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} = 0 \quad (1)$$

Conservation of momentum:

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial(\rho u^2)}{\partial x} + \frac{\partial(\rho uv)}{\partial y} = \rho F_x + \sum_{r=x,y} \frac{\partial \sigma_{xr}}{\partial r} \quad (2)$$

and

$$\frac{\partial(\rho v)}{\partial t} + \frac{\partial(\rho uv)}{\partial x} + \frac{\partial(\rho v^2)}{\partial y} = \rho F_y + \sum_{r=x,y} \frac{\partial \sigma_{yr}}{\partial r} \quad (3)$$

F_x and F_y represent the components of the resultant external force applied on the fluid in the x (horizontal) and y (vertical) directions respectively. σ is the stress tensor and ρ is the density of the fluid. u and v are the velocity field components in the x and y directions respectively. t is the time variable.

In the case of a Newtonian incompressible fluid the density ρ is constant in time and the stress tensor σ is assumed to vary linearly with the fluid deformation rate.

Thus:

$$\frac{1}{\rho} \begin{bmatrix} \sigma_{xx} & \sigma_{xy} \\ \sigma_{yx} & \sigma_{yy} \end{bmatrix} = \begin{bmatrix} -p & 0 \\ 0 & -p \end{bmatrix} + \gamma \begin{bmatrix} 2 \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \\ \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} & 2 \frac{\partial v}{\partial y} \end{bmatrix} \quad (4)$$

where p is the reduced pressure and γ is the kinematic viscosity. (All variables are used in (SI) units.). As a result, equations (1), (2) and (3) simplify and can be written in a compact vectorial form:

$$\operatorname{div}U = 0 \quad (5)$$

$$\text{and} \quad \frac{\partial U}{\partial t} + (U \cdot \operatorname{grad})U = F - \operatorname{grad}(p) + \gamma \nabla^2 U \quad (6)$$

U and F are the velocity and external force vector fields respectively.

Numerical Model

Sabeur *et al* developed a new VOF based model in recent years [7]; this model discretises the NS equations in both time and space by means of finite difference techniques. Equations (5) and (6) can be written as follows:

$$\operatorname{div}U^{n+1} = 0 \quad (7)$$

and

$$\frac{U^{n+1} - U^n}{\delta t} + \operatorname{grad}(p^{n+1}) = Q^n \quad (8)$$

δt is the time step and Q^n involves the finite difference advective terms and the external force F of the NS equations:

$$Q = -(U \cdot \operatorname{grad})U + \gamma \nabla^2 U + F \quad (9)$$

Various finite difference schemes can be implemented in the spatial discretisation of Q . As far as numerical stability and accuracy are concerned, each of the schemes have their advantages and drawbacks. The choice of the finite difference scheme greatly depends on the computing task required for the wave modelling case. ie, Number of wave propagation periods, wave length, boundary geometrical complexity.

When combined, equations (7) and (8) lead to the Poisson equation (PE) for the pressures:

$$\nabla^2 p^{n+1} = \operatorname{div}\left(\frac{U^n}{\delta t} + Q^n\right) \quad (10)$$

The volume of fluid method

The study of wave motion with a highly distorted free surface needs the implementation of the VOF method which tracks the fluid locally in space. For a specified rectangular grid and time step, fluid fluxes are computed at each cell face. The fractional amount of fluid per cell is then determined by the net flux of fluid advected in both vertical and horizontal directions.

The flux calculation leads to the update of the F function in time. That is the fractional volume of fluid at each cell centre point. Thus, a zero value of F in a cell means that it is empty while a unit value of F corresponds to a cell full of fluid. An intermediate value of F between zero and one normally represents a free surface cell, or indeed a trapped bubble. In strict numerical modelling terms, however, a true free surface cell is a cell that has at least one empty neighbouring cell. In figure 1 for example, the cell where $F= 0.99$ is not considered as a free surface cell because its four nearest neighbour cells are not empty. Therefore the PE is applied for such type of cell as if it was a full cell.

Figure 1. Illustration on the type of fluid and void cells considered by the VOF wave model.

In addition to the above, a numerical correction is performed on the F function values at the end of each computational cycle because, usually, a unit value of the F function (or, indeed a zero value) cannot be reached accurately by computational means. Instead, it is rounded to one (or zero) if it reaches a value of $1 \pm \epsilon$. (or $\pm \epsilon$). In practice, and for an efficient modelling of the fluid interface, ϵ should be no bigger than 0.00001.

Boundary conditions

In the VOF method, pressure and velocity equations must be specified.

Figure 2. A typical 2D VOF cell with six dynamic variables

Figure 2 shows the location of the six variables used in a staggered finite difference grid and computed for each time level n . In the case of a full cell located inside the flow (meaning, that the cell is totally surrounded by full cells), equations (8) and (10) are used to compute the velocities and pressures at time level $n+1$ respectively. Then, the F function value in the cell can be updated and the fluid advected in time. However, in the case of boundary cells, the computation of the pressures, the velocities and function F becomes tedious and time consuming.

Boundary cells can be classified as follows:

- Ordinary free surface cell
- Non-ordinary free surface cell
- Inflow cell
- Full cell at a vertical/horizontal/sloped rigid boundary

For each boundary cell, apart from the free surface cells, pseudo Poisson equations can be implemented by setting fluid mass conservation and virtual velocities inside local boundaries [8]. For example, rigid free-slip (or no slip) boundary conditions can be established for solid boundaries. The normal velocities to the boundaries and the gradient of the tangential velocities are set to zero. Parallel (or anti-parallel) and equal in magnitude virtual velocities are set for rigid free-slip (or no-slip) boundary conditions.

Free surface cells are provided with different pressure equations which involve the orientation and curvature of the interface, the nearest pressure inside the fluid, the local atmospheric pressure at the free surface and surface tension. The continuity of normal and tangential shear stresses is also enforced. A typical pressure equation at the free surface is given by:

$$-p + 2\gamma \frac{\partial U_n}{\partial r_n} = -p_{Air} \frac{\rho_{Air}}{\rho} + \frac{2\phi\psi}{\rho} \quad (11)$$

supplemented with a condition on stresses at the interface:

$$\gamma \left(\frac{\partial U_n}{\partial r_t} + \frac{\partial U_t}{\partial r_n} \right) = 0 \quad (12)$$

ϕ and ψ are the free surface tension and curvature respectively. p_{Air} and ρ_{Air} are the reduced pressure and density of air respectively. U_n and U_t are the normal and tangential velocities to the free surface. The reduced pressure at the interface, p , is interpolated (or extrapolated) from the nearest dynamic pressure inside the fluid and normal to the interface. It can be located from the orientation of the free surface. Hence, the nearest interpolation dynamic pressure can be found either below or above the fluid interface, or can be located to the left or to the right of the interface. The orientation and curvature of the interface are computed by the F function local gradients corresponding to nearest neighbouring cells to the free surface.

This approach for setting the boundary conditions at the free surface is used by most VOF methods, however the boundary conditions for cells which intercept the slope are not straightforward.

In the new VOF wave model, the conditions on the orientation of the interface, given by the local gradients of F , are slightly modified at air/water/slope boundary cells. Virtual values of F , inside the sloped structures, are given *a priori*. Then, a stable air/water/slope interface can be modelled.

Further numerical development of air/water/slope boundary conditions is needed. Applications of flows with the VOF method can be then extended to more complicated type of interface. For instance, in cases of floating and moving objects in fluids.

The simulation of progressive waves at sloped structures can be generated by a weakly reflective inflow boundary condition (WRIB). [6], [8]. Continuity of flow is enforced at the boundary and the free surface is assumed horizontal at all time. The velocity vector field U and water elevation η at the inflow boundary must satisfy the following conditions:

$$\frac{\partial U}{\partial t} - C \frac{\partial U}{\partial x} = \frac{\partial U_{in}}{\partial t} - C \frac{\partial U_{in}}{\partial x} \quad (13)$$

and

$$\frac{\partial \eta}{\partial t} - C \frac{\partial \eta}{\partial x} = \frac{\partial \eta_{in}}{\partial t} - C \frac{\partial \eta_{in}}{\partial x} \quad (14)$$

C is the wave celerity. U_{in} and η_{in} are the inflow velocity field and water elevation (above or below still water level) respectively. For example, they take the following sinusoidal forms:

$$U_{in}(x, y, t) = \frac{H\omega}{2 \sinh(kh)} [\cosh(ky) \sin(\omega t) + j \sinh(ky) \cos(\omega t + kx)] \quad (15)$$

and

$$\eta_{in}(x, t) = \frac{H}{2} \sin(kx - \omega t) \quad (16)$$

h is the still water level (SWL), ω the angular wave frequency, k the wave number and H the total wave amplitude. ($j = \sqrt{-1}$.)*

**(The use of imaginary complex j in equation (15) should not be confused with grid cell coordinate j .)*

Equations (13) and (14) are discretised forward in time and solved one time step earlier than the pressure and velocity equations. In this manner, the velocity field U and elevation η , can be provided for the computation of term Q , which appears in equation (8) at time level n . Water elevation η enables the computation of F at the inflow boundary free surface cell. At the free surface, F is given by:

$$F = \eta + h - \sum_{j=1}^{j=N} F_{ij} \delta y_{ij} \quad (17)$$

N values of F_{ij} are found strictly equal to unity in a water column, j , which is adjacent to the inflow boundary column. δy_{ij} is the height of cell ij .

The combination of PE, the pseudo Poisson equations at the boundaries, and the free surface pressure equations leads to a system of M equations with M unknowns. M is the number of grid cells occupied by the fluid where F is greater than zero. Once the pressure equations are computed at a specified time level, the new velocity field is calculated, the F function is updated and the fluid advanced accordingly. The updated values of F provide the new value of M .

In an early simulation of a dam-break flow by the VOF method, the Gauss-Seidel (GS) iterative scheme was used to solve the pressure equations. The GS algorithm requires a computational time that is proportional to M^2 . For M smaller than ~ 10000 , the algorithm converged after approximately 1200 iterations.

Numerical simulations, results and discussion

The speed of the pressure solver can be improved by adapting successive over-relaxation techniques (SOR) to the GS algorithm. However, as M gets larger with high resolution grids, or when diagonal dominance of the PE deteriorates, the SOR algorithm slows down and does not successfully converge. Powerful methods such as the Conjugate gradient (CG) or Lanczos (LZ), should be used to overcome this problem. The pressure field should be therefore represented in vectorial form and the structure of the corresponding Poisson matrix updated at each time step. Preliminary attempts to the matrix formulation, using parallel processors, [9] have been carried out and adapted to the VOF wave model. The simulation of a Dam-break flow showed similar results to the early calculations with the GS method.

The simulation of progressive waves at a slope, using the WRIB condition, has been completed. The stability of the VOF model over several wave periods and for two cases of slopes, in a 4m deep and 35m long rectangular tank, has been achieved. The computation of the pressure equations was performed on a uniform 150x80 rectangular grid and the minimum time set to 0.001 sec. In this early simulation, surface tension was not included and the pressure at the interface was set to zero. (void representation). The wave characteristics for each cases of slopes are given in the table below:

Wave parameters	T (sec)	H(m)	SWL(m)	Slope	Surf ξ
1st case	2.8	1.	1.5	1:3	0.3
2nd case	2.8	1.	1.5	1:4	0.2

Table 1. Wave characteristics used for model tests.

According to Battjes theory on breakers[10], the first and second wave test cases correspond to flows with spilling breakers. Spilling breakers occur with a surf similarity coefficient ξ smaller than 0.5, which is the case in our study. Large magnitude impact pressures are not encountered in such flows but distortions of the free surface with large velocity jets at air/water/slope boundaries do take place. In the first wave test case, shown in figure 3 for example, air entrapment at the slope region occurs at $t=11.65$ sec. Maximum velocity jets reaching approximately 5 m/s at the wave crest are calculated. The wave then spills along the slope, as shown in figure 4, and the front of the spill changes direction due to gravity. This change in the direction of motion causes the top of the wave to break and overturn, as shown in figure 5 at $t=13.60$ sec. Additional air bubbles are then trapped inside the fluid and lead to the formation of velocity jets that are parallel to the slope plane and persist in time. (Figure 6.) The kinetic energy of the wave flow region driven by the jets, decreases gradually in time and causes the collapse of part of the wave crest back onto the slope, as shown in figure 7. This feature of the model clearly illustrates the potential modelling of transient waves by the VOF technique. Similar observations to the above equally apply to the second wave test case. They are shown in figures 8-12.

Conclusion and recommendations

This work clearly demonstrates the potential of the VOF implementation to the NS equation for the study of wave dynamics within confined domains, i.e. coastal structures. The newly developed model is capable of simulating the full process of wave interaction with structures. Wave impact generated from collapsing and plunging breakers can be equally modelled and dynamic pressures and jets predicted at specified locations of the structure. The model also provides more understanding in wave dynamics at coastal structures which in turn helps to promote improved design methods.

In order to realise the full potential of VOF based wave models in coastal engineering, the following research and development is recommended:

- Implementation of the Conjugate gradient or Lanczos algorithms in the pressure solver.
- Development of boundary conditions at water/porous medium interfaces.
- Implementation of the compressible NS equations for air entrapment dynamics study.
- Extension of the theory to 3D for a better understanding of wave interactions.
- Calibration and validation of numerical data with laboratory results.
- Comparison of numerical predictions of wave dynamics with field data.

CHAPTER 32

Scale Effects in Oxygenation in the Breaker Zone of Coastal Structures

V.K. Tsoukala¹ and C.I. Moutzouris²

Abstract

The significance of oxygen transfer across the air-water interface with its associated impact on water quality and environmental pollution control in coastal zones has become a matter of concern for coastal engineers. In the present paper experimental data on oxygen transfer obtained in the large scale facility of Delft Hydraulics have been presented. The obtained oxygen transfer coefficients have been compared to existing models for gas transfer under breaking and non breaking waves. Scale effects are found to be an important factor which needs to be considered when laboratory results are translated to field conditions.

Introduction

Oxygen transfer across the air-water interface with its associated impact on water quality and environmental pollution control in coastal zones has become increasingly important for coastal engineers. Systematic studies of the oxygenation of water systems commenced with the emergence of water pollution problems associated with river systems (Streeter and Phelps, 1925). Years later these studies were augmented to incorporate lakes and oceans.

Understanding of the parameters influencing air-sea gas exchange has increased considerably in recent years, although little is known about the exact mechanisms that control the process. Recent research has also begun to investigate the penetration of other gases in water, including nitrogen oxide, N_2O , carbon dioxide, CO_2 , helium, He, and sulfur hexafluoride, SF_6 (Keeling, 1993, Woolf, 1991, Wanninkhof, 1992, Wanninkhof et al., 1995). However, available data for the evaluation of the different gas exchange models is still limited.

¹Research Associate, ²Professor

Laboratory of Harbour Works, Civil Engineering Department, National Technical University of Athens, 5 Iroon Polytechniou Str., Zografou, 157 73 Athens, Greece

Experimental results indicate that wave action increases the penetration of gases into the water (Jähne, 1985, 1987, Hosoi, 1977, Hasse and Liss, 1980). It is therefore considered that waves have a positive effect on the oxygenation of water bodies. Breaking waves enhance the aeration process by entraining air bubbles and increasing turbulent mixing. Field, laboratory and theoretical studies have been performed to study this phenomenon in detail. The presence of air bubbles increases the air-water interface area available for gas exchange. The formation of bubbles and increased turbulence that result from the action of breaking waves contribute to the increase of dissolved oxygen (DO) in water. Hosoi and Murakami (1986) assumed that oxygenation due to non-breaking waves in their experiments was negligible and that the whole water body is oxygenated through the wave breaking zone. Wallace and Wirick (1992) observed that breaking waves can increase the rate of aeration by up to 200 times due to the entrainment of bubbles.

The role of coastal structures in water oxygenation has recently come under investigation (Moutzouris and Daniil, 1994b, Hosoi et al., 1977), as wave breaking results in high oxygenation rates and therefore in improvement of water quality in the vicinity of coastal structures. For oceans the transfer coefficient is usually correlated to the wind velocity (Wanninkhof, 1992, Wanninkhof et al., 1993). It should be noted though that laboratory and field data give significantly different correlations possibly (Liss, 1983) due to scale effects.

A research program has been initiated at the Laboratory of Harbour Works (LHW), National Technical University of Athens, to investigate and model air penetration in the wave breaker zone of inclined coastal structures. Initial experimental results from a small wave flume at LHW (Daniil and Moutzouris, 1993) indicated that scale effects should be investigated for application to field conditions. In order to quantify these effects and to compare to earlier results, further experiments were conducted in a larger facility. Measurements were carried out in the large wave flume of Delft Hydraulics (DH), the Netherlands, financed by the European Community, as part of the Large Installations Program (LIP): "Training and Mobility of Researchers- Access to Large Scale Facilities".

This paper presents the preliminary results from this research program, which indicate that the scale of the phenomenon has a considerable influence on the transfer mechanisms. Oxygen transfer velocities determined from the large scale experimental result are compared in this paper to the models of Daniil and Gulliver (1991) for non-breaking waves and Daniil and Moutzouris (1994, 1995) for breaking waves, derived and verified from measurements in small scale facilities.

Experimental Procedure

Large scale oxygenation experiments under breaking waves were performed at the Wind Wave Flume of Delft Hydraulics (DH) as a part of the European Program: "Training and Mobility of Researchers - Access to Large -Scale Facilities".

The wave flume of Delft Hydraulics is "T" shaped with a total length of 100m and 8m width while the last 9 m are 25m wide. The outline of the flume is shown in Figure 1. The flume is equipped with a hydraulic dual piston wave maker for the generation of mechanical waves. Waves are generated by a computer-controlled wave board with adjustable rotation and translation. Waves with frequencies between 0.65-0.90 Hz and heights between 8.5-20.5 cm were produced.

A concrete structure with a uniform slope of 1:2.3 was placed at one end of the flume in order to model a sloping beach and initiate wave breaking. The structure was watertight and no water exchange between the front and the back of the sloping beach was possible. The water depth was 0.72m for all experiments.

Three capacitance wave gauges were used for recording the wave characteristics (Figure 1). The experimental procedure consisted of two distinct phases. During the first set of experiments, the water was deoxygenated using sodium sulfite (Na_2SO_3) and cobalt chloride (CoCl_2). About 8 kg of Na_2SO_3 and 0.55 Kg of $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ were required for every experiment and these were sufficient to deoxygenate an area of 12m length and 8m width.

In the second set of experiments the water was deoxygenated using the nitrogen stripping method. Long elastic tubes with small pores were connected to nitrogen cylinders equipped with regulating pressure valves. The elastic tubes were placed in a 12m long area of the flume which was isolated during the deoxygenation process from the rest of the flume by a movable divider. Approximately 60-70 m^3 of nitrogen were needed for each experiment. For the deoxygenation process approximately 10 hours were required.

The concentration of DO in the water body was monitored over time by a portable oxygen meter type OXI-96, at 21 sampling locations along the flume (see Figure 1). In order to verify the accuracy of readings obtained with the oxygen meter, water samples were also taken and analyzed using the azide modification of the Iodometric Winkler titration method for D.O. determination. The measurements of the dissolved oxygen concentration commenced immediately upon wave generation and continued until the DO value reached 80% of the estimated saturation level for the specific conditions of temperature and atmospheric pressure.

OUTLINE OF THE FLUME

DEOXYGENATED AREA

Figure 1. Schematic layout of the wave flume of the laboratory of Delft Hydraulics.

The transfer of oxygen between the air-water interface is a term of source or sink in the mass transfer equation. In the experiments performed the only source considered is oxygen transfer through the water surface. The oxygenation is characterized by the oxygenation coefficient K_2 (sec^{-1}) or the oxygen transfer coefficient (or oxygen transfer velocity) K_L (m/sec).

Data analysis

For all sampling locations the change in DO concentration under wave action was monitored and DO-time histories were obtained. A comparison of DO-time histories for experiments in the large and small scale facilities with waves of about the same period and height, illustrating that the transfer velocity is lower for the large scale facility is shown in Figure 2.

Figure 2. Comparison of DO-time histories at the wave breaking point for experiments in different scale facilities with approximately the same wave characteristics ($T=1.55$ sec $H=18.3$ cm).

The transfer coefficient K_L is determined from the one dimensional transport equation, using linear regression and the measured DO concentration time history from a location where the horizontal transport can be assumed negligible:

$$\ln (C_s - C) = - K_L (A/V)t + \ln (C_s - C_0) \quad (1)$$

where C is the concentration of DO (mg/l), C_0 is the initial concentration (mg/l), C_s is the saturation concentration (mg/l), K_L is the oxygen transfer coefficient (m/sec), A is the projected free surface area (m^2), and V is the aerated volume (m^3). It is assumed that the saturation concentration is steady and for the initial time $t=0$ the concentration is $C=C_0$.

Table 1. Experimental data from Delft Hydraulics wind wave flume for breaking and non-breaking waves.

In order to compare experimental data, it is necessary to transform the coefficients obtained to their values at 20^o C, using the equation given by Daniil and Gulliver (1988):

$$(K_{L,20}/K_L) = (Sc/Sc_{20})^{1/2} = (v/v_{20}) [293/(\theta+273)]^{1/2} (\rho/\rho_{20})^{1/2} \quad (2)$$

where $Sc = \nu/D$ is the Schmidt number, ν is the kinematic viscosity of water, D is the molecular diffusivity, θ is the water temperature in degrees Celsius, and ρ is the water density. The water density and the kinematic viscosity were determined by the relations given by Heggen (1983).

The transfer coefficients K_L at the wave breaking area and the transformed coefficients to 20 °C are presented in Table 1.

Comparison of results with existing gas transfer models

Various models have been proposed for the prediction of the oxygen transfer coefficient. The most commonly used is the surface renewal model, first developed by Dankwerts (1951). In this model the transfer coefficient is expressed as a function of the surface renewal rate:

$$K_L \propto \sqrt{Dr} \quad \text{or} \quad K_L Sc^{1/2} \propto \sqrt{v r} \quad (3)$$

where K_L is the oxygen transfer coefficient (LT^{-1}), and r is the average surface renewal rate (T^{-1}).

Figure 3. Comparison of large scale experiments to Daniil and Gulliver (1991) model for non-breaking waves.

Non Breaking waves

Based on this surface renewal model Daniil and Gulliver (1991) expressed the renewal rate as a function of a wave Reynolds number, and proposed the

following equation for the determination of the oxygen transfer coefficient, under non-breaking waves:

$$K_L = a H f S c^{-1/2} \quad (4)$$

The gas transfer coefficient is thus shown to be proportional to the vertical wave velocity at the water surface. Equation (4) provided the best comparison to the wave maker data and to data from other small scale flumes. Using data from the small scale facility of St. Antony Falls Hydraulic Laboratory the coefficient a was determined equal to 0.0159.

Experimental data from the large scale facility of Delft Hydraulic are compared to equation (4) in Figure 3. The experimental data are considerably lower than the predictive equation. Correlating experimental data from Delft Hydraulics, the constant of proportionality a for equation (4) is equal to 0.0089 which is approximately 0.60 of the predicted values of the model of Daniil and Gulliver (1991).

Breaking waves

For gas transfer under breaking waves, two models have been developed recently by Daniil and Moutzouris (1994, 1995). The constants were determined from experimental results in small scale facilities.

Figure 4. Comparison of large scale experiments to Daniil and Moutzouris, (1994) model for breaking waves.

Daniil and Moutzouris (1994), relate the transfer coefficient for breaking waves to the vertical wave velocity at the water surface with a qualitatively similar equation to Daniil and Gulliver (1991) equation as follows:

$$K_L Sc^{1/2} = a H f - b \quad (5)$$

where H is the wave height, f is the wave frequency, $a = 0.066$ and $b = 0.0028$ m/sec. Data from experiments in Delft Hydraulics are compared to equation (5) in Fig. 4. Fitting equation (5) to data from Delft Hydraulics yields $a = 0.019$ and $b = 0.0006$ m/sec.

Daniil and Moutzouris (1995) proposed the vorticity based model for gas transfer under breaking waves, where the renewal rate was expressed as a function of the wave vorticity at the water surface and the term L/d that express the influence of relative depth:

$$K_L Sc^{1/2} = a (L/d) (v\omega)^{1/2} + b \quad (6)$$

where L is the wave length, d is the water depth, v is the water viscosity, ω is the wave vorticity at the water surface. Daniil and Moutzouris (1995) give $a = 2.86$ and $b = -0.00246$ m/sec for breaking waves on a uniformly sloping beach based on a number of 9 experiments in the wave flume of LHW and mention that this model gives considerably better correlations, as compared to correlation with the vertical wave velocity and wave slope presented previously.

In Fig. 5 data from DH are compared to equation (6). Fitting equation (6) to data from DH give $a = 0.91$ and $b = -0.0004$ m/sec.

Although data for breaking waves from the large scale facility of DH are lower, approximately 30% of the corresponding coefficients obtained from small scale facilities for the same wave characteristics, the correlation of the data to the wave parameters of the existing models is good. This indicates that the existing models include the important wave parameters, but an attenuation coefficient expressing the effect of length scale should also be included.

Conclusions

Experimental data on oxygen transfer obtained in the large scale facility of Delft Hydraulics, as a part of the European program "Training and mobility of Researchers-Access to Large Scale Facilities", have been presented. The obtained

oxygen transfer coefficients have been compared to existing models for gas transfer under breaking and non breaking waves.

Figure 5. Comparison of large scale experiments to Daniil and Moutzouris model, (1995) for breaking waves.

In all cases the coefficients were considerably lower than the corresponding coefficients obtained from small scale facilities for the same wave characteristics. This could be possibly due to the minimized effect of solid boundaries in the large scale facility. Using the same wave parameters new constants were determined to the large scale experimental data with high correlation coefficients. For non breaking waves the coefficients obtained in the large scale facility were 60% of those obtained in the small wave facility for the same wave characteristics whereas for breaking waves the measured coefficients were 30% of those obtained in the small wave facility.

Finally it is concluded that the effect of scale is pronounced and should be taken into account when small scale laboratory results are translated to field conditions. The above comparisons and analysis indicate that the coefficients of the existing models should be expressed as a function of the length scale of the phenomenon.

Acknowledgments

The authors wish to thank Dr. E.I. Daniil for continuous assistance during the program.

CHAPTER 33

WAVE ACTIONS ON A VERTICAL CYLINDER IN MULTI-DIRECTIONAL RANDOM WAVES

Yu-xiu Yu*, Ning-chuan Zhang** and Qun Zhao***

Abstract

The wave actions on a vertical cylinder in multi-directional random waves are experimentally studied in this paper. The two-dimensional (2-D) wave method is extended to calculate the three-dimensional (3-D) wave forces. The variation of various hydrodynamic coefficients with KC number and wave directional spreading are investigated. The three-dimensional wave forces are compared with that of two-dimensional waves.

1. INTRODUCTION

The sea waves are three-dimensional (multi-directional) and irregular. So the effects of irregularity and directional spreading of waves should be included in the prediction method of the wave actions on cylinder. The wave actions on a slender rigid cylinder consist of in-line forces and lift forces (transverse forces) and both forces are nonlinear. Moreover, in multi-directional random waves, the in-line forces and the lift forces are mixed each other, it makes the problem more complex. At present the physical model test and the field observation are usually conducted to study it. But these study are rare owing to the complex of technique and the huge expense. Aage et al (1989), Chaplin et al (1993) and Hogedal et al (1994) studied the effects of spectral shape and the directional spreading on the 3-D wave action on a vertical cylinder, and no effect of spectral shape was found. Comparing with that of 2-D waves, for the 3-D waves, the in-line forces were smaller and the transverse forces were much larger. Moreover, the effect of directional spreading on the drag force is more than that on the inertial force and these effects were specially obvious at the place near and above the still water level. But they only gave a few data points of the ratio between the forces of 3-D waves and 2-D waves. Koterayama and Nakamura (1992) and Chaplin et al. (1993) measured the 3-D wave forces on a platform and in laboratory respectively. They measured the wave forces on cylinder and the orbital velocity of waves simultaneously and found that the 3-D wave forces could be simplified as a 2-D problem and calculated with Morison Equation.

In this paper, the effects of wave directional spreading and KC number on the wave forces and the hydrodynamic coefficients are emphasized. Moreover the 3-D wave forces are compared with 2-D one.

2. THEORETICAL CONSIDER AND ANALYSIS METHOD

2.1 Sea wave spectrum

The Sea wave is a complex 3-D random process. It is commonly described by the directional spectrum in frequency domain, which is generally expressed as the product of the frequency spectrum, $S(f)$ and the directional spreading function, $G(f, \theta)$, i. e.

$$\left. \begin{aligned} S(f, \theta) &= S(f) \cdot G(f, \theta) \\ \int_{-\pi}^{\pi} G(f, \theta) d\theta &= 1 \end{aligned} \right\} \quad (1)$$

There were many studies on the frequency spectrum and many formulas of spectrum have been proposed (Yu, 1992). The effects of the shape of frequency spectrum on wave force coefficients on cylinder in both 2-D and 3-D wave field can be negligible from Yu and Zhang (1989) and Hogedal (1994) respectively. Therefore, only the JONSWAP spectrum ($\gamma=3.3$) is used in test due to its popular application in the world. Concerning the directional spreading function there is not a generally recognized formular, and a simplified Mitsuyasu-type spreading,

$$\left. \begin{aligned} G(\theta) &= G_0(s) \left| \cos \frac{\theta}{2} \right|^{2s} \\ G_0(s) &= \left[\int_{\theta_{\min}}^{\theta_{\max}} \cos^{2s} \frac{\theta}{2} d\theta \right]^{-1} \end{aligned} \right\} \quad (2)$$

is used. In Eq. (2), the spreading parameter, s is independent on frequency. In this test, s is varied to change the directional spreading, and $s=\infty$ means an unidirectional irregular wave.

2.2 Effects of directional spreading on wave forces

The unidirectional wave forces on a cylinder consist of in-line forces and transverse forces. According to Morison Equation, the in-line forces consist of drag forces and inertial forces. The transverse forces are equal to lift forces (Yu and Miao, 1989). In the multi-directional irregular waves, the wave actions on a cylinder are rather complex. The waves may be coming from all directions and the in-line force induced by a component wave in a certain direction can be mixed with the lift force induced by the component wave in the perpendicular direction. In this paper, the multi-directional wave forces on a cylinder are still divided into the in-line forces, F_x , and the transverse forces, F_y , paralleled and perpendicular to the main wave direction respectively. There are two methods for calculating these forces:

(1) Extend the calculation method from 2-D wave forces to 3-D wave forces. The 3-D wave surface measured at the position of cylinder is treated as a unidirectional wave with the main wave direction. Then the in-line force can be calculated with Morison Equation, and the transverse force is calculated with lift force equation, but the effects of directional spreading on forces are included in the hydrodynamic coefficients. According to the field observation by Koterayama et al (1992) and the experimental study by Chaplin et al (1993), this approximate treatment was acceptable. Because the effects of directional spreading on drag force are different from that on inertial force and the ratio between drag force and inertial force is

dependent on KC number. So the applicability of this method will be further examined and the variation of hydrodynamic coefficients with the directional spreading parameter and KC number will be investigated in this paper.

KC number is usually defined as $KC = U_m \cdot T/D$, where T is the wave period; U_m the maximum horizontal orbital velocity, D the diameter of the cylinder. For irregular waves, the height and period of each wave in a wave train are varied. Here regardless of the directional spreading, the parameters of the significant wave and its maximum horizontal orbital velocity at the wave surface are chosen to define KC number, hereafter referred to as $(KC)_{\frac{1}{3}}$ or KC, and it is in agreement with the engineering practice.

(2) The multi-directional wave surface is decomposed into a set of wave components of definite amplitudes, frequencies, directions of propagation and initial phases. Using the decomposed wave components, more accurate prediction of wave kinematics can be made. Then the directional wave forces on a cylinder can be calculated with Morison Equation in vectorial form. In this way, the characteristics of the 3-D irregular wave forces can be better described. We will discuss it in the near future.

2.3 Forces calculation and force coefficients

(1) The total in-line wave forces acting on a whole cylinder can be calculated with Morison Equation and the drag coefficient, C_D and inertia coefficient, C_M can be determined by the method of least squares in time domain from test data (Yu and Zhang, 1989).

(2) There are some limitation for the application of Morison Equation to 3-D wave forces. So the single force coefficient method is also used to calculate the in-line forces, F_x , transverse forces F_y and their resultant forces, F_R .

$$\left. \begin{aligned} (F_x)_p &= \frac{1}{2} (C_{F_x})_p \rho D \int_0^d u_p^2 dz \\ (F_y)_p &= \frac{1}{2} (C_{F_y})_p \rho D \int_0^d u_p^2 dz \\ (F_R)_p &= \frac{1}{2} (C_{F_R})_p \rho D \int_0^d u_p^2 dz \end{aligned} \right\} \quad (3)$$

where C_{F_x} , C_{F_y} and C_{F_R} are the coefficients of in-line forces, transverse forces and resultant forces respectively. The subscript p is the index of the statistical characteristics. For example, when $p = \frac{1}{10}$, $(F_x)_{\frac{1}{10}}$, $(F_y)_{\frac{1}{10}}$ and $(F_R)_{\frac{1}{10}}$ are the average peak values of the highest one tenth in-line forces, transverse forces and resultant forces respectively. $U_{\frac{1}{10}}$ is the maximum horizontal orbital velocity of wave which height is $H_{\frac{1}{10}}$. The coefficients $(C_{F_x})_p$, $(C_{F_y})_p$ and $(C_{F_R})_p$ can be determined from measured wave forces with Eq. (3). With this method, only the characteristic value of the wave forces can be calculated.

2.4 Orbital velocity of waves

For calculating the wave forces on the cylinder, the orbital velocity and the acceleration should be known. It is difficult to measure the horizontal velocities along the water depth simultaneously, so they are usually calculated from wave surface with a suitable wave theory. For the multi-directional irregular waves there is not a generally recognized available wave theory. In the field observation ($d = 15m$, $H_{\frac{1}{3}}/$

$d \leq 0.19$) from Koterayama et al(1992) and the model test with multi-directional irregular waves ($d=2.0\text{m}$, $H_{\frac{1}{3}}/d \leq 0.15$) by Chaplin et al(1993), the wave surfaces and the orbital velocities were measured simultaneously. It is found that the measured horizontal orbital velocities in 3-D waves conform to that directly calculated from the wave surface with the 2-D linear wave theory. In our experimental study on the unidirectional wave action on pile array (Yu and Shi 1994, $d=1.0\text{m}$, $H_{\frac{1}{3}}/d \leq 0.34$), the linear wave theory and the Stokes wave theory of second order were used and compared each other. It was found that the results obtained with linear theory are better than another. Moreover, it is considered that the linear wave theory is suitable for the simulation of orbital velocity, acceleration and the wave forces on pile in irregular waves with linear summation method. So the linear wave theory is used in this test ($H_{\frac{1}{3}}/d \leq 0.297$).

3. EXPERIMENT

The experiments were conducted in the State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, China. The wave basin is 55m long, 34m wide and 1.3m deep. The multi-directional wavemaker consists of 30 independent segments of 0.8m wide. The wave absorbers were placed along the basin walls to prevent wave reflection from the walls.

DS-30 multi-point wave gages were used to measure the wave height. The top of the model cylinder was fixed onto a supporting frame, so the cylinder model worked as a cantilever beam under the wave action and the force meter was set between the cylinder and the support frame. The force meters were used to measure both the total in-line forces and the total transverse forces simultaneously. The sensitivity, linearity and stability of this meter are very good. The natural frequencies of the meter system in both directions in still water are 7.3~8.2Hz. A VAX-II computer was used for controlling wavemaker. Both the data acquisition and processing of wave surfaces and wave forces were conducted with a computer IBM-386.

The water depth was kept at 0.5m. The JONSWAP spectrum ($\gamma=3.3$) and the simplified Mitsuyasu type directional spreading, $E_q(2)$ were used to simulate the multi-directional waves with spreading indices from $s = \infty$, unidirectional wave, to $s=2\sim 5$ and the main wave direction is $\theta=0^\circ$. For each group of s , there were several wave heights and periods. Each of cylinder models with diameters of 2, 4 and 6cm was placed at the center line of basin and was 7m away from the wavemaker.

The single direction per frequency model (Yu et al, 1991) was used to generate the directional waves. The wave gage array consisted of four gages was used to measure the directional spectra. The wave surface measured with gage No. 5 was used to approximately represent that at the place of cylinder. The sampling of data was done at the interval of 0.05sec, and the data length was 204.8sec., 4096 points. The datum signals were lowpass filtered with a cut-off frequency of 4HZ.

There are several methods for evaluating directional spectrum, of which the Bayesian approach (Hashimoto et al. 1987) is better from our primary comparison (Liu and Yu, 1993) and therefore it is used in this paper.

4. RESULTS AND ANALYSES

4.1 Waves

The measured wave parameters are shown in Table 1. The surface variation of the multi-directional irregular waves is more complex than that of the unidirectional waves. The distributions of the instantaneous values of wave surface are close to normal distribution but there is a little trend of skewness in wave profiles, with an excess of high crest points and lack of low trough points. The distribution of wave height is close to Rayleigh distribution and is close to Gluhoviski distribution along with the relative water depth decreasing.

4.2 Characteristics of wave forces in time domain

Fig. 1 and Fig. 2 are the examples of the simultaneous histories of measured wave surface, total in-line wave forces, total transverse wave forces and total resultant wave forces. It is found that in the same condition of wave parameter and cylinder diameter, the in-line wave force decreases with s decreasing, but its frequency is basically the same as wave's. For the transverse forces, the effects of spreading parameter, s are more obvious. In Figs. 1 and 2, the KC numbers are not large. The transverse force of unidirectional wave, $s = \infty$, is pure lift force, whose value is small and frequency is higher. For the directional waves with $s = 15$, the transverse forces maybe consist of the components of in-line forces induced by oblique waves and the lift forces, and the former rapid increases with s decreasing. Its frequency is larger than wave's. The variation in resultant force is similar with that in in-line forces.

The experimental data and fitting curves of the variation of the ratios between transverse and in-line forces, resultant and in-line forces along with KC number show that even if the data points are scattered to some extent, but the variation law is clear and they are synthesized in Fig. 3. Along with s decreasing, the vortex shedding behind cylinder is changed by the gradually increased oblique waves, it makes lift forces decreasing and the oblique wave force increasing. Therefore, the transverse force changes from lift force dominating to component of in-line forces dominating. As $s = 15 \sim 25$, the value of transverse force can be up to more than half of in-line force, when $s = 2 \sim 5$, it can be up to 74% of in-line force. But the peak values of in-line forces and transverse forces are not of usual occurrence simultaneously, so the resultant forces increase slowly with s decreasing.

4.3 Wave force coefficients

The drag coefficient C_D and inertia coefficient C_M are varied with KC number and directional spreading parameter s as shown in Fig. 4. Both coefficients decrease with s decreasing.

The single force coefficients C_{F_x} , C_{F_y} and C_{F_r} can be determined with Eq. (3) from measured wave force data and they are also varied with KC and s , but their test datum points are less scattered. It can be noticed from Fig. 5 that the in-line forces and the resultant forces decrease and the transverse forces increase with s decreasing. Concerning the transverse forces, the lift forces induced by unidirectional waves ($s = \infty$) vary with KC along a wave type curve, but along with s decreasing it gradually becomes to a progressively decreasing curve similar to that of in-line forces.

4.4 3-D wave forces compare with 2-D wave forces

In Fig. 5, for a given KC number one can get a set of force coefficients from different curves of s , then divides each coefficient by that of $s = \infty$ to get the ratio

Table 1 Measured characteristic value of waves

	15-25	0.83	0.93	0.92	0.94
	2-5	0.80	0.83	0.80	0.83

4.5 Characteristics of wave forces in frequency domain

Fig. 6 shows two examples of wave spectrum and wave force spectrum. The spectral shapes of in-line force and resultant force basically conform to that of wave spectrum. But for unidirectional wave the transverse force spectrum is exactly the lift force spectrum and its peak frequently appears at the twice peak frequency of wave. When s is small, the transverse force spectrum have not a twice frequency peak but it is different in shape from wave spectrum.

5. EXAMINATION AND DISCUSSION

(1) For examining the feasibility of Morison Equation to calculate the in-line wave forces on cylinder, the values of C_D and C_M obtained from Fig. 4 are substituted into Morison Eq. to calculate the in-line wave force history with measured wave surface history. Then the calculated wave force history is compared with the measured one as Fig. 7 shows. For the unidirectional wave, two histories are conformable. Along with s decreasing the degree of conformability decreases to some extent, but two histories are basically conformable. It means that the in-line force of directional waves can be calculated with present method.

(2) Concerning the wave fore coefficients, there are rare data for directional waves. The experimental data obtained by Chaplin et al(1993) are very scattered. Koterayama et al gave the variation of C_D , C_M with KC from field observation, but the value of s is not clear. Their curve of C_D is basically within the range of curves in Fig. 4 and the curve of C_M is close to that of $s=15\sim 25$ in Fig. 4.

(3) Ratio between 3-D and 2-D wave forces

Some researchers studied the 3-D wave forces on cylinder mainly by experiments and gave some data concerning the ratio between 3-D and 2-D wave forces, which are collected in Table 3. These data are in comparison with present results. It turns out that the existing data are in the range of present results except the ratio of transverse forces, but in this paper, the variation of ratios with KC and s are given. About the transverse force, it is found from tests that when KC is small, the transverse forces induced by unidirectional wave are very small, but under the

Fig. 6 Measured wave spectrum and force spectra

actions of directional waves with small s , the transverse forces induced by oblique waves are large. Therefore, the ratio of transverse force can be up to about 5.0. It is reasonable.

6 CONCLUSIONS

1 The effects of directional spreading of waves on wave forces acting on a cylinder are obvious and the level of effect is dependent on $(KC)_{1/3}$ and s . Within

Note: (1) σ_θ is the standrad deviation of directional spreading function.
(2) * KC number is defined with peak frequency period , T_p and $H_{\frac{1}{3}}$.

the extent of this experiment, the in-line forces of multi-directional waves can decrease to 73—92% of that of unidirectional waves, and the transverse forces can increase to 200% or more.

2 Multi-directional wave forces exerting on a vertical cylinder can be predicated with the methods used for unidirectional wave except $s=2-5$, but the effects of directional spreading must be included in their force coefficients.

3 All wave force coefficients of C_D , C_M , C_{F_x} , C_{F_y} and C_{F_R} are varied with $(KC)_{1/3}$ and s . Among them, the scatters of the coefficients C_{F_x} , C_{F_y} and C_{F_R} are relatively small.

4 For unidirectional waves ($s=\infty$), the transverse force acting on cylinder is the pure lift force and its main frequency is frequently double or three times the wave frequency. Along with s dreasing the transverse component forces induced by the oblique waves increase. As the test results show, when $s=15-25$, the transverse component forces of oblique waves have been dominant.

CHAPTER 34

WIND/WAVE RELATION AND THE PRESSURE GRADIENT EFFECT

Spiros M. Gouloumis ¹

Abstract

The S.M.B. prediction model is used worldwide to hindcast sea wave characteristics using wind data. Even though wave parameters showed that qualitative similarities are present between ocean and small basin waves, major weather factors such as the wind speed and barometer pressure gradients in relation with the topography should be considered as calibration factors.

Introduction

The Laboratory of Harbour Works, National Technical University of Athens (N.T.U.A.), is conducting a Wave Measurement Project aiming at developing a wave prediction model adjusted to Greek Seas, especially in the Aegean Sea, well-known for its particular wind and wave conditions. Nowadays, the L.H.W. has installed the Wave Measurement, Transmission and Analysis network (in Greek: KYMATA) in the Aegean Sea and Cyprus using five Waverider buoys.

The Heraklio Wave Measurement Program was conducted in the South Aegean Sea for one year, using a Waverider buoy. In the present paper, the wind/wave interrelations and the S.M.B. prediction model are examined, taking into account the topography and the pressure systems affecting the East Mediterranean region.

The wind velocity gradient and the pressure jump are major factors in waves' development. The S.M.B. prediction model seems not always to be adequate in fully describing the development of the waves, in the Aegean Sea. A special model should be applied, distinguishing at least the most critical differences (North from South winds and storm from squall events).

Wave Measurements

The South Aegean Basin is about 130 km long from North to South and 300 km wide from West to East, while the whole Aegean basin, being a little narrower, is nearly 610 km long. Due to the orientation of the measurements' field and the dominant weather conditions in the Aegean Sea, the winds of interest are those blowing from the North during the winter season, when several storms occur. (See Fig. 1)

Fig. 1 Geomorphologic map of the Greek Archipelagos and the Aegean Sea region.

A Waverider buoy was moored about a mile off Heraklio shore North of Crete Island, at a water depth of about 22 m. Wave characteristics were recorded from of October 1, 1992 until September 22, 1993.

An accelerometer on board the buoy estimated the vertical acceleration. Water surface elevation time series of 20-min. duration was

recorded every second hour or continuously in cases where the wave was higher than a threshold defined height (2.5 m). Considering the quality of raw data, the measurements conducted are highly accurate.

A total of 5014 records were processed, examining the relationship between the wave characteristic parameters, as well as the wave energy density spectrum characteristics. The wave parameters investigated showed that qualitative similarities exist between ocean and small basin waves, and also that quantitative differences do exist (Gouloumis and Moutzouris, 1995).

Wind/Wave Interrelation

Significant wave heights were related to the corresponding wind speed blowing from the North and recorded onshore, considering several storm events of developing sea. The data plotted in Fig. 2 refer to rather high wind speeds, being proportional to the wave heights as it is widely accepted and supported from both theory and field measurements (Bretschneider, 1958; Pierson and Moshowitz, 1964; Hogben N., 1988). Further on, the spectral peak periods T_p of the waves vs. the corresponding wind speed seem to be in some agreement with the JONSWAP result (Fig. 3)

Fig. 2, 3 Significant wave heights and spectral peak periods vs. the wind speeds blowing three hours before the wave measurements

An interesting feature also is that the relation between the non-dimensional expressions of the characteristic wave heights H_s and the spectral peak periods T_p plotted in Fig. 4, is found to be almost identical to the result found if the deepwater fetch-limited equations for wave height and wave period in the Shore Protection Manual (SPM) (1984) are combined, and to the TMA equations for deep water (Hughes S., 1984), the only

difference being a coefficient of 0.01096 instead of 0.0105 and 1.0112 respectively. Thus, it can be supposed that waves have similar characteristic parameters both in the ocean and in the small Aegean basin examined.

Three wind records have been used from the Heraklio and Thira Island weather stations, corresponding to winds that were blowing simultaneously and 3 hours before the wave measurements. Thira is located at the North of the basin we examine. The Heraklio weather station seems to give the most appropriate wind data.

Fig. 4 The nondimensional expressions of the characteristic wave height H_s and the spectral peak period T_p .

An evaluation was carried out using the SMB method of predicting wave conditions from wind data, since "...the best equations to use in a simple wind/wave hindcast model are the SMB equations of SPM '77" (Parle P., Burrows R., 1989) and it is a widely used method in the design of most marine works. The SPM '77 simplified wave prediction equations using the SMB method are as follows:

$$gH_s/U^2 = 0.283 \tanh(0.0125 F^{0.42})$$

$$gT_z/U = 1.20 \tanh(0.077 (gF/U^2)^{0.25}), \text{ where } F = gX/U^2 \text{ is the fetch coefficient}$$

The data plotted refer only to the North wind records which is the dominant wind direction, in order that better correlation is achieved. In Fig. 5 the dimensionless wave height equation has been plotted vs. the fetch coefficient, where the effective fetch for the North direction is calculated to be 150.6 km.

The data plotted using the Thira wind records seem not to be suitable enough to describe weather conditions at Heraklio area, probably due to the location of the station (the island's airport on a plateau). Further more, it is not yet understood what is the effect of the numerous islands lying in the central Aegean Sea to the wind field and the wave generation conditions.

It should be noted that although a lot of data points are gathered near the values estimated by the SMB model, many other measurements are well out of the predicted values, scattered over a large area of Fig. 5.

Fig. 5 The dimensionless significant wave heights vs. the fetch coefficient.

The S.M.B. prediction model seems not always to be adequate in fully describing the development of the waves, in the Aegean Sea. A major reason could be that the wind field over the Aegean Sea is not uniform due to the topography forming a long, from North to South, rather narrow basin containing the Archipelagos Islands causing strong orographic effect.

The Pressure Jump Effect

In order to further investigate the situation, six representative storm events of developing sea were selected. The wind was always blowing from the 48 degrees north sector. In Fig. 6 the dimensionless wave heights have been plotted versus the fetch coefficient. The data clearly represent two different sea-states, one of which is characterized by sudden occurring high waves, corresponding to relatively low wind speeds.

Fig. 6 The six storm events forming two groups with different characteristics (Heraklio wind data recorded 3 hours before wave measurements)

Fig. 7 Significant wave heights' time series of six storm events.

The time series of measured significant wave heights (H_s) plotted in Fig. 7 show that three of the curves corresponding to the storm events of December 1st, 1992, January 31st and February 8th, 1993, are characterized by rapidly growing waves, being fully developed in just 3 to 6 hours, indicating the occurrence of squall storms and fast arising sea.

Examining the weather systems experienced at the time of the wave measurements, we can distinguish a certain combination of pressure systems over East Europe, similar for all three cases of fast arising sea not complying with the S.M.B. prediction model (Fig. 8 of the Appendix). Waves rise much faster during squall storms where intense winds, suddenly blowing, sweep over the Aegean Sea. Winds are triggered by the intense barometric gradient in South East Europe, caused by the combination of an East Europe High pressure field and the Low pressure systems passing over East Mediterranean, in the region of the island of Cyprus.

Medium velocity winds blowing over the Black Sea are canalized into the Aegean Sea through the mountain ranges of mainland Greece on the west and Asia Minor on the east, becoming very intense because of the Bernoulli phenomenon. Furthermore, simultaneously to the maximum wind gust, a major barometric pressure jump is noticed at all three episodes where wave development does not follow the S.M.B. prediction model, as it can be clearly seen in Fig. 9 of the Appendix.

In all other cases examined, where the measured wave heights were close to the predicted ones rarely exceeding them, the High pressure system lies at the west over central Europe and the pressure gradient is mild causing winds of normally arising speed (Fig. 10)

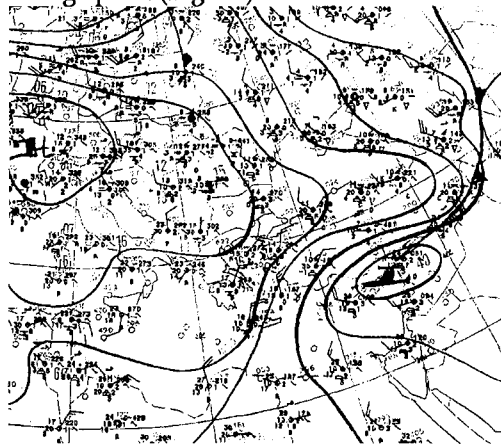

Fig. 10 Weather map dated on November 6th 1992, at 12:00 UTC. When the High pressure system lies at the west the pressure gradient is mild.

While the frontal systems pass over the measurements' region, the pressure jumps up to 9 milibars in total and on the order of 1 Mb per hour. In all three cases, the wave still rises following the pressure jump, even though the wind speed decreases. The relative isobar maps in Fig. 11 show clearly that a pressure front moves from north to south over the Aegean Sea, causing a forced wave which seems to reinforce the wind generated wave while interaction between them should be present, as well. Examining the barometric pressure records as well as the isobar maps of the events, we can estimate the speed of the pressure front propagation to be in the order of $U=51$ km per hour as the 610 km long Aegean basin was swept from north to south in about 12 hours. A resonant wave is therefore possible to be produced, since the face velocity at the specific depth of 22 m at the buoy location is $C=\sqrt{gh} = 52.2$ km/hour $\approx U$, indicating the possible presence of a squall line surge (Thieke R., Dean R., GARCIA A., 1994).

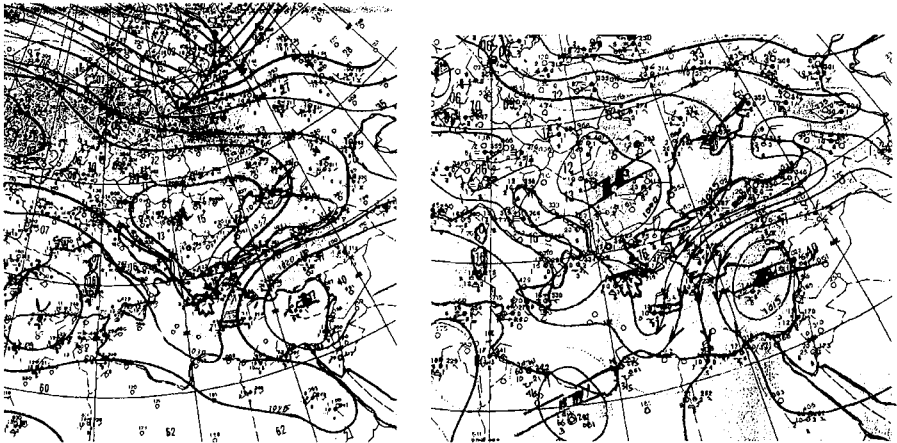

Fig. 11 Weather map dated on February 8th 1993, at 06:00 and 12:00 UTC. The High pressures propagate from north to south over the Aegean Sea.

Focusing on Fig. 6, it can be noted that during the three storm events where the wind is increasing in a normal way and there is no severe change in the barometric pressure, the wave development is generally over-estimated by the S.M.B. model. The dimensionless maximum wave heights appear close to the predicted values and they are all gathered together showing the maximum possible wave developed at this area under normal weather conditions.

On the other hand, considering the cases not complying with the SMB model, the dimensionless maximum wave height expressions show a tendency that unusually high significant waves can appear corresponding to relatively low wind speeds the fetch being constant, depend obviously on the pressure gradient propagation experienced. The corresponding characteristic wave periods of these cases are higher than the periods corresponding to the "normal" conditions, indicating long wave existence mentioned before (Fig. 12). Attention should also be paid to the characteristic periods of the maximum significant waves measured during the abnormal storms, being linear proportional to the wind speed.

Fig. 12 Characteristic wave periods versus wind speed transformed to period

The theory analyzed above in order to explain high waves measured corresponding to relatively low wind speeds at fetch limited conditions, is further supported by the storm episode of November 21, 1992. Even though it has the characteristics of the "abnormal" cases, it is well described by the S.M.B. model. Besides the fact that the wind speed rises very quickly and the pressure jump is intense (Fig. 13), the measured wave heights follow the S.M.B. model supporting even further the previous conclusion since the pressure front propagates from west to east as it seen in Fig. 14, not reinforcing the north wind generated waves as the buoy's location is sheltered from the west.

Fig. Wind speed, significant wave height and barometric time series of the storm episode dated November 21, 1992.

Fig. Weather maps of November 20th and 21st 1992, at 12:00 UTC. The Low pressure system travels from west to east not reinforcing the north wind generated waves.

Conclusions

Even though waves seem to have similar characteristic parameters both in the ocean and in the small Aegean basin examined, the S.M.B. prediction model is proved to be insufficient to fully predict wave climate in the Aegean Sea, where strong orographic effects and peculiar weather conditions are present.

It is necessary to consider all the meteorological factors involved to successfully predict wave heights under different weather conditions.

The wind velocity gradient and the pressure jump, when propagates to the same direction of the wind blowing, are major factors in describing the development of the waves. The possible effect of the Cyclades islands lying in the middle of the Aegean basin on the wave development and propagation has also to be assessed.

Large amount of measurements expected to derive from the Wave Measurement KYMATA network will hopefully give insight into the situation, now that a new perspective is applied.

The S.M.B. prediction model seems not always to be adequate in fully describing the development of the waves, in the Aegean Sea. A special model should be applied, distinguishing at least the most critical differences (North from South winds and storm from squall events).

Acknowledgments

Wind data and weather maps were obtained from the Greek National Meteorological Service. The contribution of the meteorologists Mrs. Petrou and Mr. Ziakopoulos to interpret the weather systems is highly appreciated.

Professors C. I. Moutzouris (N.T.U.A.) and M. S. Bruno (Stevens Institute of Technology) have substantially encourage the present work.

CHAPTER 35

NON-REFLECTED MULTI DIRECTIONAL WAVE MAKER THEORY AND EXPERIMENTS OF VERIFICATION

Kazunori ITO¹ , Hidehiro KATSUI², Masashi MOCHIZUKI³, Masahiko ISOBE⁴

ABSTRACT

In the hydraulic model test in a wave basin, reflected waves from models of structures and walls of the basin reflect again at the wave maker. The re-reflected waves disturb wave field in the basin and consequently reduce the accuracy of experiments. We developed a non-reflected multi directional wave maker theory. By taking into account both current and past water elevation data in front of the wave paddles, the theory makes the wave makers possible to absorb reflected multi directional waves. Numerical simulations and experiments show that this theory is superior to the conventional theory in its efficiency of the absorption.

1. INTRODUCTION

In general, multi directional wave experiments using wave makers placed in a line have the following problems: an experiment area with a uniform wave field is small, and reflected waves from a model and/or a wave basin cannot be absorbed efficiently. In order to create a larger experiment area, reflecting walls are installed at the end of multi directional wave makers placed in a line[1], or wave makers are set in the J-shape[2]. These methods are very effective to enlarge an experiment area. However, when a model is surrounded by wave makers and/or a reflecting wall, re-reflected waves from these wave makers and/or a reflecting wall exert a large effect on the model; thus, it becomes important to absorb reflected waves. The method proposed by Kawaguchi[3], which uses the data on water surface elevation at the wave paddle front, has been put to a practical use for absorbing uni- directional reflected waves. Hiraguchi et al.[4] carried out experiments by applying this method to multi-directional wave makers to absorb multi-directional waves. However, as only an orthogonal wave direction against a wave paddle is taken into account in Kawaguchi's method, the absorptivity decreases when the incidence angle of reflected waves is oblique. Ikeya et al.[5] proposed the method

for absorbing oblique waves using the data on water surface elevation at the front of two or more wave paddles. However, the absorptivity in this method also decreased due to the errors in computing reflected waves, as evanescent waves are not taken into account. Their theory does not have a wide application, because it stands on the assumption that a wave basin has side walls. Besides, as the above two methods take only a representative frequency into account, the absorptivity decreases when a wave has dominant frequency dispersion.

This paper aims to establish a non-reflected wave maker theory for multi-directional waves in consideration of directional dispersion, frequency dispersion and evanescent waves[6], and to report the results of the basic experiments on oblique regular waves to verify the theory[7].

2. FORMULATION OF NON-REFLECTED WAVE MAKER THEORY

Fig. 1 shows the coordinates used in the analysis: x- and y-axes in the horizontal direction, and z-axis in the vertical upward direction.

Wave paddles are set along the x-axis. Here, let us take a piston-type wave maker by way of example to develop the theory.

Fig.1 Definition of coordinate

2.1. WAVE MAKER THEORY

The fluid treated here is inviscid and unconsolidated. When a small amplitude wave theory can be applied to the wave and the amplitude of a wave paddle is small enough, the problems of wave making with the constant water depth are governed by the following equations:

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \tag{1}$$

$$\frac{\partial \Phi}{\partial t} + g\eta = 0 \tag{2}$$

: z = 0

$$\frac{\partial \eta}{\partial t} - \frac{\partial \Phi}{\partial z} = 0 \tag{3}$$

: z = 0

$$\frac{\partial \Phi}{\partial n} = \frac{\partial X}{\partial t} \tag{4}$$

: y = 0

$$\frac{\partial \Phi}{\partial z} = 0 \tag{5}$$

: z = -h

where, $\Phi(x,y,z,t)$: velocity potential, $\eta(x,y,t)$: water surface elevation, g : gravity acceleration, h : water depth, n : normal direction, X : displacement of a wave paddle.

Now, the theory is developed for regular waves. By separating a variable Φ , Eq.(6) can be obtained from Eq.(1) and (5).

$$\Phi(x,y,z,t) = \sum_{n=0}^{\infty} \phi_n(x,y) \frac{\cosh[k_n(z+h)]}{\cosh k_n h} e^{-i\omega t} \tag{6}$$

When $n=0$, angular frequency ω and a wave number kn in Eq.(6) satisfy the

dispersion relation Eq.(7) of a progressive wave component; when $n=1$ to ∞ , they satisfy the dispersion relation Eq.(8) of an evanescent wave component. Here, k_n is an imaginary number when $n=1$ to ∞ , and \hat{k}_n is the imaginary part of k_n .

$$\omega^2 = gk_n \tanh k_n h \tag{7}$$

$$\omega^2 = -g\hat{k}_n \tan \hat{k}_n h \tag{8}$$

Next, use Eq.(4) as follows:

$$\left. \frac{\partial \Phi}{\partial n} \right|_{y=0} = \frac{\partial \Phi}{\partial y} = U(x,y)F(z)e^{-i\omega t} \tag{9}$$

where, $U(x,y)$: amplitude of wave paddle velocity $F(z)$: function of wave paddle motion ($F(z)$ of a piston-type wave maker = 1)

By substituting Eq.(6) into Eq.(9) and integrating in the vertical direction using orthogonality, Eq.(10) can be obtained as follows:

$$U = \frac{D_n}{G_n} \frac{\partial \phi_n}{\partial y} \tag{10}$$

In the case of a piston-type wave maker, D_n and G_n can be obtained as follows, respectively.

$$D_n = \frac{\tanh k_n h}{2k_n} \left[1 + \frac{2k_n h}{\sinh 2k_n h} \right] : n = 0 \quad , \quad = \frac{\tan \hat{k}_n h}{2\hat{k}_n} \left[1 + \frac{2\hat{k}_n h}{\sin 2\hat{k}_n h} \right] : n = 1, 2, 3, \dots \tag{11}$$

$$G_n = \frac{\tanh k_n h}{k_n} : n = 0 \quad = \frac{\tan \hat{k}_n h}{\hat{k}_n} : n = 1, 2, 3, \dots \tag{12}$$

If water surface elevation η_p of a progressive wave component is given as Eq.(13), U which is necessary for making a progressive wave can be determined as Eq.(14) from Eq.(10) with $y=0$.

$$\eta_p = a e^{i\{k_0(x \cos \theta + y \sin \theta) - \omega t\}} \tag{13}$$

$$U(x,0) = \frac{D_0}{G_0} \frac{g a k_0}{\omega} \sin \theta e^{i\{k_0(x \cos \theta)\}} \tag{14}$$

where, the subscript 0 represents a progressive wave, and a represents a complex amplitude of component waves.

ϕ_n of an evanescent wave is the solution of Eq.(15) and the boundary condition $\lim_{y \rightarrow \infty} \phi_n = 0$; then, from the relation in Eq.(10), Eq.(16) can be obtained.

$$\frac{\partial^2 \phi_n}{\partial x^2} + \frac{\partial^2 \phi_n}{\partial y^2} - \hat{k}_n^2 \phi_n = 0 \tag{15}$$

$$\phi_n = -\frac{D_n G_n}{D_n G_0} \frac{g a k_0 \sin \theta}{\omega \sqrt{\hat{k}_n^2 + k_0^2 \cos^2 \theta}} e^{i k_0 x \cos \theta - y \sqrt{\hat{k}_n^2 + k_0^2 \cos^2 \theta}} \tag{16}$$

Therefore, when making a regular wave, the water surface elevation η_e of an

evanescent wave component at the wave paddle front ($y=0$) can be described as follows:

$$\eta_e(x, 0, t) = -\frac{D_0 G_n}{D_n G_0} \frac{ik_0 \sin \theta}{\sqrt{\hat{k}_n^2 + k_0^2 \cos^2 \theta}} e^{ik_0 x \cos \theta - i\omega t} \quad (17)$$

Thus, the water surface elevation at the wave paddle front can be obtained by adding the water surface elevation of a progressive wave component and that of an evanescent wave component as in Eq.(18):

$$\eta(x, 0, t) = \left[1 - \frac{D_0 G_n}{D_n G_0} \frac{ik_0 \sin \theta}{\sqrt{\hat{k}_n^2 + k_0^2 \cos^2 \theta}} \right] a e^{ik_0 x \cos \theta - i\omega t} \quad (18)$$

Multi-directional waves can be described as superposition of component waves. Therefore, the wave paddle velocity $A^{(i)}(x, y=0, t)$ and the water surface elevation at the wave paddle front $\eta^{(i)}$ are obtained in Eq.(19) and (20), respectively.

$$\left. \frac{\partial \Phi}{\partial n} \right|_{y=0} = A^{(i)} = \sum_{j=1}^{\infty} \frac{D_{j0}}{G_{j0}} \frac{g a_j k_{j0}}{\omega_j} \sin \theta_j e^{i\{k_{j0}(x \cos \theta_j) - \omega_j t\}} \quad (19)$$

$$\eta^{(i)}(x, 0, t) = \sum_{j=1}^{\infty} \left[1 - \sum_{n=1}^{\infty} \frac{G_{jn} D_{j0}}{G_{j0} D_{jn}} \frac{ik_{j0} \sin \theta_j}{\sqrt{\hat{k}_{jn}^2 + k_{j0}^2 \cos^2 \theta_j}} \right] \times a_j e^{i(k_{j0} x \cos \theta_j - \omega_j t)} \quad (20)$$

Both the actual wave paddle velocity and water surface elevation are real variables, thereby becoming the real parts in Eq.(19) and (20). Hereafter, a symbol $\tilde{\sim}$ in this paper stands for a real variable.

2.2. ABSORPTION THEORY

The conventional non-reflected wave maker theory[3],[5], where the water surface elevation measured at the wave paddle front is converted into a wave making signal, is based on a so-called feedback control. This method has a great advantage in the aspect of practical control. This paper develops a new non-reflected wave maker theory using the data on water surface elevation at the wave paddle front.

In the case of non-reflected wave making, the water surface elevation at the wave paddle front ($\tilde{\eta}^{(m)}$) is the sum of the water surface elevation of a progressive wave which is a target wave ($\tilde{\eta}_p^{(i)}$), the water surface elevation of an evanescent wave which is created due to wave making ($\tilde{\eta}_e^{(i)}$), the water surface elevation of a progressive wave component of a reflected wave ($\tilde{\eta}_p^{(r)}$), and the water surface elevation of an evanescent wave which is created due to the motion of wave paddle to absorb a reflected wave ($\tilde{\eta}_e^{(r)}$); that is, ($\tilde{\eta}^{(m)} = \tilde{\eta}_p^{(i)} + \tilde{\eta}_e^{(i)} + \tilde{\eta}_p^{(r)} + \tilde{\eta}_e^{(r)}$). As $\tilde{\eta}^{(i)}$ ($= \tilde{\eta}_p^{(i)} + \tilde{\eta}_e^{(i)}$) can be calculated by Eq.(20), a reflected wave $\tilde{\eta}^{(r)}$ ($= \tilde{\eta}_p^{(r)} + \tilde{\eta}_e^{(r)}$) can be obtained as $\tilde{\eta}^{(r)} = \tilde{\eta}^{(m)} - (\tilde{\eta}_p^{(i)} + \tilde{\eta}_e^{(i)})$, where no re-reflection occurs from the wave paddle since reflected waves are absorbed.

The relation between the water surface elevation $\tilde{\eta}^{(r)}$ at the wave paddle

front which includes an evanescent wave and the wave paddle velocity $\tilde{A}^{(r)}$ is defined by transfer function $H_{pe}(\omega, \theta)$ as $\tilde{A}^{(r)}(x, 0, t) = H_{pe}(\omega, \theta) \tilde{\eta}^{(r)}(x, 0, t)$ in the case of a regular wave. The concrete form of $H_{pe}(\omega, \theta)$ is described in the following equation, which uses the real parts in Eq.(19).

$$H_{pe}(\omega, \theta) = \frac{D_0}{G_0} \frac{gk_0}{\omega} \sin \theta \times \left\{ 1 + \left(\sum_{n=1}^{\infty} \frac{D_n G_n}{D_n G_0} \frac{k_0 \sin \theta}{\sqrt{\hat{k}_n^2 + k_0^2 \cos^2 \theta}} \right)^2 \right\}^{-\frac{1}{2}} \quad (21)$$

Assuming that a reflected wave $\tilde{\eta}^{(r)}$ is in a narrow band spectrum of frequency and wave direction, Eq.(22) and (23) can be obtained as follows:

$$\tilde{\eta}^{(r)}(x, y, t) = \sum_{m=1}^{\infty} \tilde{a}_m \cos \varphi_m \quad (22)$$

$$\varphi_m = (\bar{k} + \Delta k_m) \left[x \cos(\bar{\theta} + \Delta \theta_m) - y \sin(\bar{\theta} + \Delta \theta_m) \right] - (\bar{\omega} + \Delta \omega_m) t + \varepsilon_m \quad (23)$$

where, ε_m is a phase number.

When $H_{pe}(\omega, \theta)$ can be expanded around a representative frequency $\bar{\omega}$ and a representative wave direction $\bar{\theta}$ using Taylor expansion in consideration of the first order quantity, the motion velocity of a wave paddle which absorbs reflected waves can be obtained in Eq.(24).

$$\tilde{A}^{(r)}(x, 0, t) = \bar{H}_{pe} \sum_{m=1}^{\infty} \tilde{a}_m \cos \varphi_m + \frac{\partial \bar{H}_{pe}}{\partial \omega} \times \sum_{m=1}^{\infty} \Delta \omega_m \tilde{a}_m \cos \varphi_m + \frac{\partial \bar{H}_{pe}}{\partial \theta} \sum_{m=1}^{\infty} \Delta \theta_m \tilde{a}_m \cos \varphi_m \quad (24)$$

Then, by obtaining a series of the second and third terms in the right side of Eq.(24) using simultaneous equations of $\tilde{\eta}^{(r)}$, $\partial^2 \tilde{\eta}^{(r)} / \partial t^2$ and $\partial^2 \tilde{\eta}^{(r)} / \partial x \partial t$ in consideration of the first order quantity, the motion velocity of a wave paddle can be expressed as follows:

$$\begin{aligned} \tilde{A}^{(r)} = & \bar{H}_{pe} \tilde{\eta}^{(r)} + \frac{\partial H_{pe}}{\partial \omega} \left\{ \frac{1}{2\bar{\omega}} \left(-\bar{\omega}^2 \tilde{\eta}^{(r)} - \frac{\partial^2 \tilde{\eta}^{(r)}}{\partial t^2} \right) \right\} \\ & + \frac{\partial H_{pe}}{\partial \theta} \left\{ \frac{1}{2} \left(1 - \frac{\bar{c}}{\bar{c}_g} \right) \cot \bar{\theta} \tilde{\eta}^{(r)} - \frac{1}{2\bar{\omega}^2} \left(1 + \frac{\bar{c}}{\bar{c}_g} \right) \right. \\ & \left. \times \cot \bar{\theta} \frac{\partial^2 \tilde{\eta}^{(r)}}{\partial t^2} - \frac{1}{\bar{k} \bar{\omega} \sin \bar{\theta}} \frac{\partial^2 \tilde{\eta}^{(r)}}{\partial x \partial t} \right\} \end{aligned} \quad (25)$$

where, \bar{k} : wave number of a progressive wave against $\bar{\omega}$
 \bar{c} : phase velocity of a progressive wave against $\bar{\omega}$
 \bar{c}_g : group velocity of a progressive wave against $\bar{\omega}$
 \bar{H}_{pe} : transfer function regarding a representative value

The second term in the right side of Eq.(25) is a correction term for frequency dispersion, and the third term is a correction term for directional dispersion.

From the above equations, the wave paddle velocity $\tilde{A}^{(r)}$ for absorbing can be calculated from a reflected wave; then, by subtracting $\tilde{A}^{(r)}$ from the wave paddle velocity $\tilde{A}^{(i)}$ for making a target wave, a wave paddle can be controlled. Thus, non-reflected wave making becomes possible.

3. DISCUSSION ON THE THEORY THROUGH NUMERICAL CALCULATION

3.1. DISCUSSION ON AN EVANESCENT WAVE

An evanescent wave occurs due to the difference between the wave paddle motion and a vertical distribution of horizontal water particle velocity of the target wave. The amplitude of an evanescent wave becomes largest at the wave paddle front, and decreases in accordance with the distance from a wave paddle.

Fig. 2 shows the ratio of progressive wave amplitude and evanescent wave amplitude, when a regular wave is created using a piston-type wave maker. From the figure, it is clear that when a piston-type wave maker creates a deep-sea wave with the large ratio of wavelength and water depth kh , an evanescent wave is more likely to occur; while, as the wave direction is tilted, it occurs less frequently.

Therefore, in the control method where a reflected wave is detected by using the water surface elevation at the wave paddle front, an evanescent wave must not be neglected. By taking into account of this wave, the absorption of a reflected wave is expected to be improved.

Fig.2 The ratio of progressive wave amplitude and evanescent wave amplitude

3.2. DISCUSSION ON NON-REFLECTED CONTROL

In a practical use of a reflected wave absorption control, a reflected wave is detected by a wave gauge installed on the wave paddle front as in conventional methods. Therefore, the differential of the theoretical equation(25) is necessarily approximated with finite- differential. Besides, it is not easy to give a representative wave direction in advance. For some structural models, a representative wave direction of a reflected wave is particularly difficult to predict. In the case of a floating model, wave direction of a reflected wave reaching a wave paddle varies from hour to hour according to the motion of the model. Here, a practical calculation method is adopted; as for a representative frequency, a representative value of the wave to be created is given in advance, and a representative wave direction is approximated using Eq.(26) and (27).

$$\theta(t) = \cos^{-1} \left[-\bar{c} \frac{\partial \tilde{\eta}^{(r)} / \partial x}{\partial \tilde{\eta}^{(r)} / \partial t} \right] \tag{26}$$

$$\bar{\theta}(t) = \frac{1}{N} \left[(N-1) \bar{\theta}(t - \Delta t) + \theta(t) \right] \tag{27}$$

where, $\theta(t)$: wave direction at the time t
 $\bar{\theta}(t)$: a representative wave direction

N is the value obtained by dividing the elapsed time of absorption control of reflected waves by the intervals of sampling of water surface elevation (Δt), that is, the number of times of sampling. $\partial/\partial x$ is the mean finite-differential of the second order, which is calculated from the data on water surface elevation at the front of two or more wave paddles. When $\partial/\partial t$ is defined as the unilateral finite-differential of the second order and $\partial^2/\partial t^2$ is as the unilateral finite-differential of the first order, they can be calculated from the data on water surface elevation measured in the past using a water gauge. As shown above, the characteristic of absorption control in this theory is the use

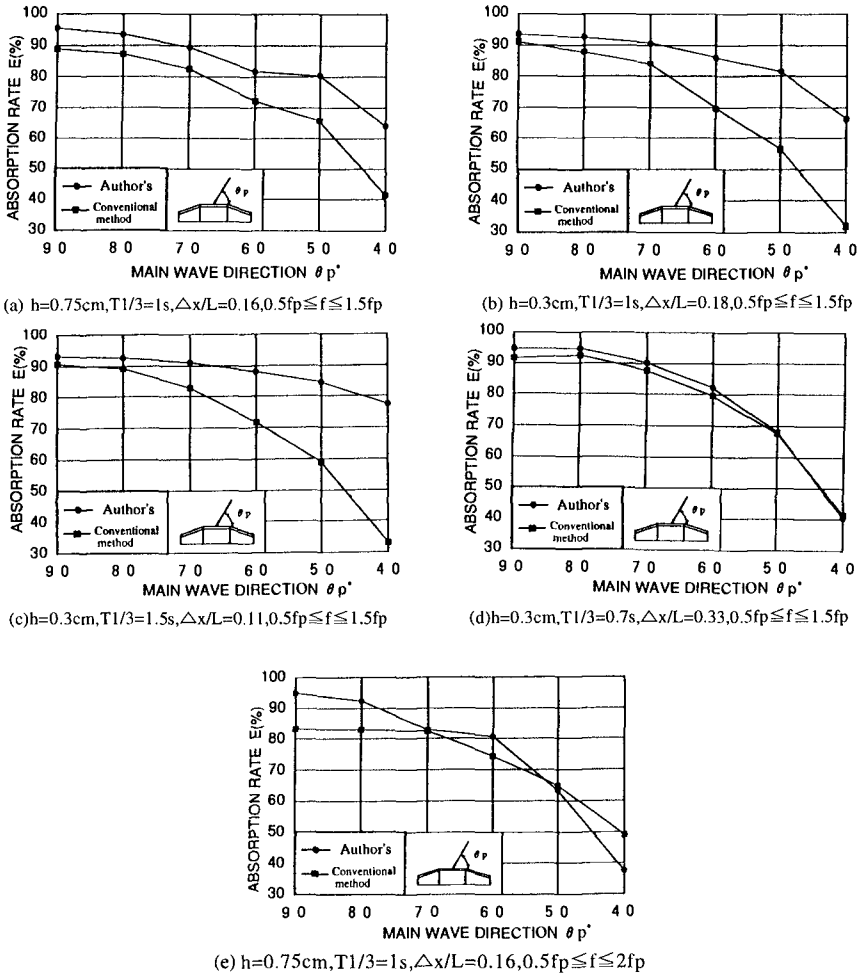

Fig.3 The comparison of the absorption rate between Author's method and Conventional method

of data on water surface elevation at the wave paddle front and the past data. As a result of numerical calculation without approximating the derivation in Eq.(25), this theory was proved valid regardless of a wave direction or water depth. Next, by approximating the derivation in Eq.(25), numerical calculation was conducted. The conditions of a reflected wave include Bretschneider-Mitsuyasu spectrum, Mitsuyasu-type directional function ($S_{max}=10$), significant wave height 3cm, significant wave period 0.7s, 1.0s, 1.5s, and the water depth 0.3m, 0.75m. Wave direction against the peak wave direction is in the range of $\pm 30^\circ$. The frequency range is 0.5 to 1.5 times and 0.5 to 2.0 times as large as the peak frequency f_p . The intervals of wave gauges (Δx) is 0.25m, and Δt is given as 0.01s. Using these, it is quantitatively examined using the absorption rate E which is defined by Eq.(28).

$$E = \left[1 - \frac{\sqrt{\left(\int_0^T (\tilde{A}_r(x,0,t) - \tilde{A}_n(x,0,t))^2 dt \right)}}{\left(\int_0^T \tilde{A}_r(x,0,t)^2 dt \right)} \right] \times 100 \% \tag{28}$$

where, $\tilde{A}_r(x,0,t)$: the wave paddle velocity in Eq.(19)

$\tilde{A}_n(x,0,t)$: the wave paddle velocity in Eq.(25)

For comparison, the results of conventional method are also shown: in the conventional method, there are no second and third terms in the right side of Eq.(25); $\sin \theta$ in the right side of transfer function equation(21) is 1; and the total series is 0.

Fig.3 shows the comparison of the absorption rate when the peak frequency of a reflected wave, water depth and the frequency range are varied. From (a) and (b), it is clear that when the peak frequency is 1s, this theory is superior to the conventional method in terms of absorptivity, regardless of the water depth. When frequency becomes 1.5s as in (c), the ratio of the wave gauge space and the wavelength ($\Delta x/L$) becomes smaller and the approximation becomes more accurate, thereby improving the absorptivity. On the other hand, in (d) where frequency is 0.7s and the water depth is 0.3m, the accuracy of approximation decreases, showing no significant difference from the conventional method. Therefore, when the frequency range of reflected waves is about 0.5 to 1.5 times as large as f_p , this theory is significant on condition that $\Delta x/L$ is 0.33 or smaller. In (e) where the frequency range is larger (0.5 to 2.0 times as large as f_p), this theory exceeds the conventional method on condition that the wave direction is around 90° ; however, as the wave direction is tilted, there becomes no difference from the conventional method. This is caused by the limit in assuming a narrow band spectrum and the error in approximation.

Fig.4 The C-shape multi directional wave makers

4. EXPERIMENTS ON REFLECTED WAVE ABSORPTION

4.1. EXPERIMENTAL EQUIPMENT AND METHOD

(1) EXPERIMENTAL EQUIPMENT

A multi-directional wave maker is a multiplex piston-type wave maker, consisting of 52 wave makers. Two capacitance-type wave gauges were installed with a space of 25cm on a 50cm-wide wave paddle: one at the front of a driving shaft, the other in the middle of two driving shafts. As shown in Fig.4, multi-directional wave makers were arranged in the C-shape within a wave basin (35×24m). The number of wave makers on each side was 15, 22, and 15, respectively. The L-shape installation is also possible: 30 wave makers on the long side and 22 on the short side of the wave basin. Cut-off walls called guide walls were installed at each corner of the C-shape. The neutral point of each wave paddle can be shifted arbitrarily within the range of $\pm 40\text{cm}$ stroke. The power of each driving shaft can also be adjusted arbitrarily.

(2) EXPERIMENTAL METHOD

The experiment was carried out by making waves from WAVE MAKER 1 and 2 shown in Fig.5, with the WAVE MAKER 3 serving as absorption control as in Eq.(25). Following the method proposed by Toida et al.[8], the power of five driving shafts installed at the ends of the wave makers 1 and 2 (C, F) was controlled to be 100% to 0%, in order to decrease the effect of diffraction waves from the ends. In addition, in order to decrease the effect of diffraction waves from the corner, the method of shifting the neutral point of wave paddles[7] was adopted. In absorption control in Eq.(25), both ends were controlled for the purpose of decreasing diffraction waves.

The water surface elevation at the front of WAVE MAKER 3 was measured at the lattice points (24×15) with a 30cm-space, as described by hatching in Fig.5.

4.2. DISCUSSION ON AN EVANESCENT WAVE

Regular waves were made in the vertical direction from the wave makers 2 in Fig.5, then both the water surface elevation at the wave paddle front and an evanescent wave were measured. The measurement conditions were: frequency changing from 0.7s to 1.0s and 1.5s, water depth from 50cm to 60cm, 70cm and 80cm, and wave height from 0.5cm to 0.8cm.

Fig.6 shows the relation of the ratio of wavelength and water depth kh and the amplitude

Fig.5 Measurement area and definition of wave direction

Fig.6 shows the relation of the ratio of wavelength and water depth kh and the amplitude

The water surface elevation at the front of WAVE MAKER 3 was measured at the lattice points (24×15) with a 30cm-space, as described by hatching in Fig.5.

4.2. DISCUSSION ON AN EVANESCENT WAVE

Fig.6 The comparison between theoretical evanescent wave and experimental one

absorption control was conducted using Eq.(25), the wave height distribution showed uniformity. However, around A, at the end of the wave makers, showed a tendency to form a standing wave field.

Fig.8 shows the similar results, when frequency was given as 1.5s. The absorptivity by Eq.(25) was high.

(Regular wave: $T=1s, H=5cm, \theta=45^\circ$) Fig.9 shows the results when the wave direction was 60° . Though the pattern of isolines was slightly different, there was no significant difference in the region where a standing wave field was formed and in the isoline

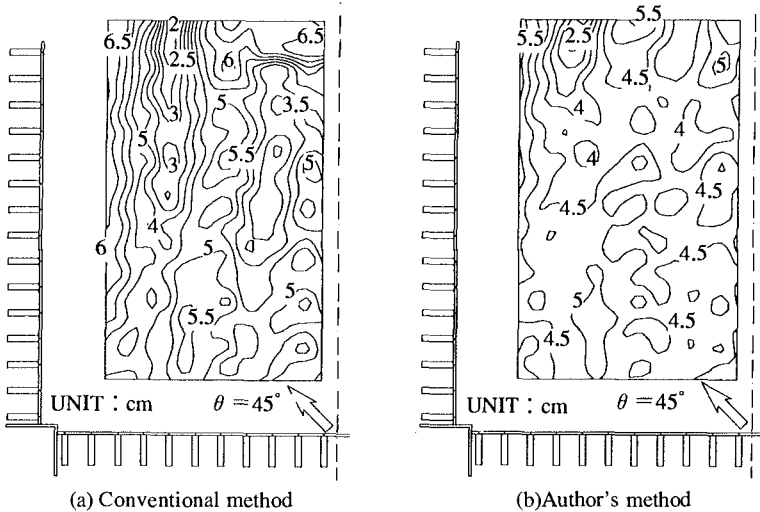

Fig.8 The contour of the wave heights
Regular wave: $T=1.5s, H=5cm, \theta=45^\circ$)

Fig.7 The contour of the wave heights
Regular wave: $T=1.5s, H=5cm, \theta=60^\circ$)

values. Thus, it is judged that both absorption controls had the same degree of absorptivity.

4.4 CAPABILITY OF NON-REFLECTED WAVE MAKER THEORY FOR MULTI DIRECTIONAL WAVES

The experiments were carried out to investigate capability of absorption for multi directional waves. WAVE MAKER1 and WAVE MAKER 2 generated multi directional waves and WAVE MAKER 3 absorbed waves propagating toward WAVE MAKER 3. WAVE MAKER 3 was driven by using author's method or conventional method for the sake of comparison. Furthermore WAVE MAKER 3 was controlled as the reflecting wall. The water elevations were measured by STAR ARRAY that was located in front of WAVE MAKER 3 (Fig.5). Directional spectrum were calculated by using Expanded Maximum Entropy Principle Method(EMEP). Since EMEP can not estimate the phase interaction of incident and reflected waves, STAR ARRAY was set over one wave length (2.7 m) distant away from WAVE MAKER 3.

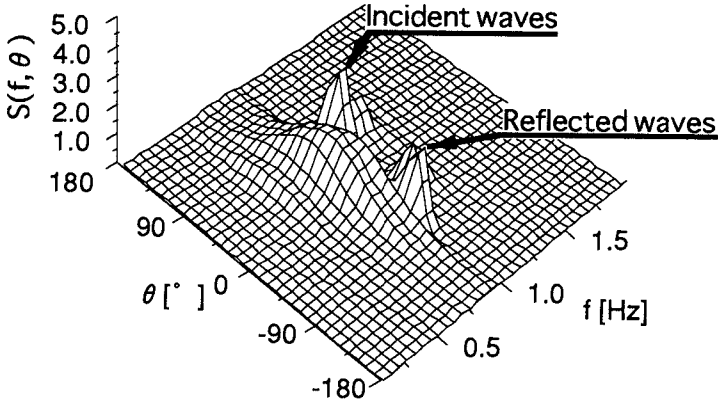

In the experiments, the wave generated by WAVE MAKER1 and 2 had Bretschneider-Mitsuyasu spectrum, Mitsuyasu type directional function ; $S_{max}=10,70$, $H_{1/3}=5\text{cm}$, $T_{1/3}=1\text{s}$ and $\theta_p=45^\circ$. S_{max} is spreading parameter, $H_{1/3}$ significant wave height, $T_{1/3}$ significant wave period, θ_p is principal wave direction.

Fig.10 shows the directional spectrum in the case of $S_{max}=70$. In the case of WAVE MAKER 3 being the reflecting wall (Fig.10 (a)), three peak frequency appear at around 0° , -45° and 45° . The wave direction of incident component waves appears at about 45° . Reflected component waves corresponding to the incident component waves propagate to the direction of -45° . The component wave of which frequency is about 0.9Hz can be understood as the component waves that propagate crosswise between WAVE MAKER 1 and 2. On the other hand, the reflected component waves less than 1.3Hz can not be seen in the case of author's method (Fig.10 (b)). This figure indicates that the author's method can absorb multi directional waves effectively. And the directional spectrum analysis showed the similar results for $S_{max}=10$ and $S_{max}=70$.

But, the results of directional spectrum analysis did not indicate the remarkable difference between author's method and conventional one.

The conventional method can effectively absorb the wave trains which propagate toward the wave paddles only at a right angle. But this can not absorb the wave trains coming obliquely to the wave paddles. Thus reflected waves should remain in the basin. Now we try to explain the reason why the directional spectrum could not show the remarkable difference between the author's method and the conventional one. In the calculation of directional spectrum, cross-spectrum must have presumption error and smoothing operation is indispensable for cross-spectrum analysis. Consequently, it is judged that the influence of the reflected waves vanished in the process of the calculation.

Fig.11 shows significant wave heights($h_1 \sim h_4$) at STAR ARRAY. Legends(●, ○, ■) indicate the difference of the control method of WAVE MAKER 3; ● for standstill as a wall, ○ for control by the author's method, ■ for control by the conventional one. As shown in figure($S_{max}=70$), each significant wave height does not show the large difference between the author's method and the conventional one and distribution of $H_{1/3}$ is uniform. But, for $S_{max}=10$, the significant wave heights of the conventional method is not specially uniform. This attributes to the disturbance caused by the reflected waves from WAVE MAKER 3. Therefore, we may conclude that as an angle between wave direction and wave paddle is large, the conventional method can not absorb oblique wave groups with such wave direction.

5. CONCLUSION

This paper established a non-reflected wave maker theory for multi-directional waves considering evanescent waves as well, using the data on water surface elevation at the front of two or more wave paddles and the past data. From the results of numerical calculation and experiments, this theory was proved to have higher absorptivity than the conventional method.

Acknowledgments

The authors also wish to thank Professor Masaru Mizuguchi at Chuo University for his helpful suggestions. The authors would like to express his gratitude to Mr. Takamitsu Noguchi, Mr. Masaki Anzai, and Mr. Hiroyuki Kishi of Taisei Service, Inc. for their cooperation.

CHAPTER 36

Fifty Years of Wave Growth Curves¹

Paul C. Liu²

Abstract

It has been over fifty years since the public release of the well-known monograph of Navy H.O. 601, prepared by Sverdrup and Munk (1947) during World War II. In celebrating 50th anniversary of the International Coastal Engineering Conference that was started in 1948, it is of interest to revisit the wave growth curves developed in H.O. 601 and compare them with a recent study on wave growth curves (Donelan et al. 1992). It is clear that while significant progress has been made over the last 50 years, Sverdrup and Munk's original idea still prevails in light of modern developments.

Introduction

The mid years of the decade of 1990s observe many 50th anniversaries of events that relate to the end of World War II. The end of the war marks the start of two important events that are of interest to coastal and ocean engineers: the public release of the well-known monograph of the Navy H.O. 601 by Sverdrup and Munk (1947) and the beginning of the International Coastal Engineering Conference. These two events practically ushered in the modern era of wind wave studies, and on this Silver Conference of ICCE it is interesting to pay a return visit to Sverdrup and Munk's wave growth curves given in H.O. 601 and to compare them with the

¹GLERL Contribution No. 1034

²NOAA Great Lakes Environmental Research Laboratory, Ann Arbor, MI 48105-1593. Email: liu@glер1.noaa.gov

recent study of wave growth curves given by Donelan et al. (1992). This paper summarizes the essentials of the development of the two growth curves 50 years apart to show the differences in general approaches and the significance of the conceptual basis of H.O. 601 that prevails over time and still appears refreshing in light of modern achievements.

The Wave Growth Curves According to Sverdrup and Munk

When Sverdrup and Munk set out to develop techniques for wave forecasting in the early 1940's in support of U.S. amphibious operations during World War II, the state of knowledge at the time was based mainly on empirical relationships. Notable results such as that maximum wave heights are proportional to the square root of the fetch and that wave height is proportional to the wind speed or the square of the wind speed, all dependent on dimensional constants.

Sverdrup and Munk started the initial efforts to realistically model the wind waves by examining the growth of waves on the basis of energy considerations. They formulated the fetch equation as

$$\frac{c}{2} \frac{dE}{dx} + \frac{E}{2} \frac{dc}{dx} = R_t + R_v$$

where E is the mean energy per unit surface area, c is the wave phase speed, and R_t and R_v are the energy transferred to the waves at the sea surface due to the tangential stress and normal pressure of wind, respectively.

By formulating the physical considerations of R_t and R_v , incorporating measured information available at the time, and normalizing significant wave height, H , wave phase speed, c , and fetch, x , with wind speed, U , and gravitation acceleration, g , they were able to derive analytical expressions for dimensionless wave height, gH/U^2 , and dimensionless wave speed, c/U , (the wave age,) as functions of dimensionless fetch, gx/U^2 .

In essence they focused on the two basic parameters, the wave age $\beta = c/U$ and the wave steepness $\delta = H/L$, L is the wave length, where empirical functional relationships between the two can be deduced from the above fetch equation. They then derived three separate expressions for gx/U^2 in terms of β and δ over three divided ranges of β . Wave height relations were then obtained in the dimensionless form from linear theory as

$$\frac{gH}{U^2} = 2\pi\delta\beta^2 = f\left(\frac{gx}{U^2}\right).$$

Following these developments, the final analytical expressions given in H.O. 601 also included no less than 17 empirical constants. These growth curves are plotted in Figure 1 as thin solid lines along with the historical data originally used.

The developments of Sverdrup and Munk clearly set the stage for modern wind wave prediction and study. Their innovative introduction of the concept of *significant waves* based on statistical considerations is still the most basic and effective parameter used in characterizing wave field parameters. One might conclude that is also part of Sverdrup and Munk's innovations. However, the use of dimensionless parameters was actually suggested to Sverdrup and Munk by Morrough P. O'Brien based on intuitive understanding of fluid mechanics and knowledge of similitude and model laws² (Wiegel and Saville, 1996.) The practice of correlating dimensionless parameters gH/U^2 and c/U with respect to gx/U^2 is still widely used today as part of the basic analysis of wind and wave measurement.

²The author is indebted to Prof. Wiegel for pointing out this important historical fact to him.

Figure 1. H.O. 601 growth curves and data as compared with later and more recent developments. The original H.O. 601 curves are shown as thin solid lines. The results of JONSWAP, Mitsuyasu, and others are summarized in dashed lines as given in Hasselmann (1982). The results of Donelan et al. (1992) are shown as the thick solid curves. Nondimensional significant wave height, H_s^* , and wave period, T_s^* , are plotted as functions of nondimensional fetch, X^* .

An Ode to H.O. 601

Sverdrup and Munk prepared the H.O. 601 that established the physical foundations for wind wave predictions and subsequent wave studies. Bretschneider (1952) made further analysis with additional data and developed practical curves that became the widely used SMB (Sverdrup-Munk-Bretschneider) method of wave forecasting. With the advance of spectrum analysis in the 1950's and increasing use of computers in the 1960's, along with new instrumentation and measurement techniques, new approaches have subsequently evolved. But the basic principles implemented in H.O. 601 have been continuously practiced, some maybe unwittingly, by most of the later wind wave analysis and model developments.

Hasselmann (1984) in an article that pays tribute to Walter Munk's 65th birthday, entitled "An Ode to H.O. 601," presented a comparison of the H.O. 601 growth curves with modern data of JONSWAP program (Hasselmann et al., 1973) and Mitsuyasu (1969) as shown in Figure 1. He commended the legacy of H.O. 601 and concluded that "The progress in measurement techniques has clearly been commensurate with the progress in wave modeling." More recent modeling developments (Komen et al., 1994) appear to substantiate this effect.

The Wave Growth Curves of Donelan et al.

The work of Donelan et al. (1992) provides an interesting account of the current state of the art of the wave growth curve studies. They explored the fetch-limited wind wave growths, using the wind and wave measurements from a linear array of five towers located along the prevailing wind direction on the eastern shore of Lake St. Clair, and found the differential growth of spectral wave energy between the towers, $\Delta E / \Delta x$, to be a linear function of local wave age, U / c_p , where U is the wind speed, and c_p the phase speed of the waves at the spectral peak as:

$$\frac{c_p^2}{2gE} \frac{\Delta E}{\Delta x} = 0.78 \times 10^{-4} \left(\frac{U}{c_p} - 0.83 \right).$$

Note that the right-hand side vanishes at $U/c_p = 0.83$, which is the well-established condition for a fully development wave field (Pierson and Moskowitz 1964.) Now combining the differential equation with that of the well-known empirical relation between nondimensional energy, $\varepsilon = g^2 E / U^4$, and wave age substantiated by most of the measurements made from many parts of the world:

$$\varepsilon = 0.0023 \left(\frac{U}{c_p} \right)^{-3.2},$$

readily yields the following fetch relations:

$$X^* = 4.0946 \times 10^4 \ln \left[\frac{1}{1 - 5.5414 \varepsilon^{\frac{1}{3.2}}} \right] - 2.2690 \times 10^5 \left[1 + 2.7707 \varepsilon^{\frac{1}{3.2}} \right] \varepsilon^{\frac{1}{3.2}},$$

and

$$X^* = 4.0946 \times 10^4 \ln \left[\frac{\frac{U}{c_p}}{\frac{U}{c_p} - 0.8302} \right] - 3.3992 \times 10^5 \left[\frac{U}{c_p} + 0.4151 \right] \left[\frac{c_p}{U} \right]^2.$$

where X^* is the nondimensional fetch gx/U^2 . The corresponding results of these two equations are also plotted as the thick solid lines in Figure 1 in which $H_s^* = 4g\sqrt{\varepsilon}/U^2$ and $T_s^* = c_p/U$ are used to facilitate the comparison with original H.O. 601 curves. An examination of Figure 1 indicates that the results of Donelan et al. (1992) are lower than the H.O. 601 curves, but reach the fully developed stage much later.

In general, however, while data measurement and analytic modeling have made significant progress over the past 50 years, the ingenuity of Sverdrup and Munk's original development with very limited available data not only helped the Allied forces during the North Africa operations that led to WW II victory, but also remained reasonably close to the modern and latest measurements.

Concluding Remarks

For the most part, the wave growth curve developments of Sverdrup and Munk and that of Donelan et al. (1992) are basically similar. Both are basically started on available measured results followed by analytical derivations. With limited data Sverdrup and Munk's development required 17 constants for the operation. Donelan et al., however, with much more and better established data and analysis relied on four empirical constants. The current state of the art of wind wave modeling as given in the comprehensive book by Komen (1994) cautioned that "Despite the progress, we still are not able to make wave predictions that always fall within the error bands of the observations." It appears that after 50 years development and progress on wave modeling and wind wave studies, while wave modeling techniques have made significant progress for practical applications, there is ample room of further progress and enhancement remain to be explored.

CHAPTER 37

DEVELOPMENT OF A THIRD GENERATION SHALLOW-WATER WAVE MODEL WITH UNSTRUCTURED SPATIAL MESHING

Michel BENOIT ¹, Frédéric MARCOS ¹, Françoise BECQ ²

Abstract

A numerical third-generation wave model dedicated both to deep water and near-shore applications is presented and applied to several test-cases to highlight its capabilities. Among its main features, this model uses a finite-elements technique for the discretization of the modelled area, which makes it suitable to represent complex bottom topographies and irregular shorelines. Furthermore, the piece-wise ray method used for wave propagation allows to use rather large time-steps, which in turn allows to keep the computational time at a very moderate level. The implementation of shallow-water physics in the model is also described, in particular with respect to depth-induced breaking. Several applications of the model are presented and compared to field or laboratory data for their validation. Finally, the main research and development items are mentioned and discussed.

1. INTRODUCTION

Although originally developed for deep water applications and meteorological purpose (e.g. WAMDI Group, 1988), spectral “phase-averaged” wave models are presently being extended towards the near-shore and coastal domains. This extension implies first to improve the physics of the numerical models so that they become able to reproduce shallow-water effects. Several efforts have already been attempted in this way by developing numerical formulations for bottom friction, depth-induced breaking and non-linear interactions between triplets of waves (the so-called “triad-interactions”) (e.g. Ris *et al.*, 1994 ; Van Vledder *et al.*, 1994).

A second point to consider is the ability of the model to deal with the complex bottom topography of coastal and near-shore areas. Compared to oceanic applications, these shallow-water domains usually need a finer spatial discretization to properly represent bathymetric gradients and irregular shorelines. This requires a number of properties from the numerics of the wave model (discretization techniques, integration schemes) which are usually not encountered in present third-generation wave models. For instance, if one wishes to apply the WAM model to local areas, the size of the finite-difference spatial grid has to be decreased over the whole domain, which highly increases the number of computational points and

¹ Research Engineer — Maritime Group

² PhD Student — Maritime Group

EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 CHATOU, FRANCE

often leads to use nested grids. Furthermore, the explicit scheme for wave propagation in WAM will then imply a strong decrease of the time-step in order to ensure that the Courant Number remains lower than 1. This, in turn, will cause a significant increase of the computational time, so that the computation will likely become unrealistic at an operational stage.

This paper deals with the development of a third generation spectral wave code applicable to deep water oceans, but also dedicated to shallow-water domains. This model, named TOMAWAC (which stands for "TELEMAC-based Operational Model Addressing Wave Action Computation"), is included in the TELEMAC modelling package developed by LNH, which contains numerous finite elements modules covering a wide range of maritime hydrodynamics applications.

The TOMAWAC model is presented in Section 2. Special attention to the implementation and validation of depth-induced breaking is paid in Section 3. Section 4 presents the application of the model on a test-case of waves propagating on a current whirl. In Section 5, the model is applied to the simulation of an actual storm in the North-eastern part of the Atlantic Ocean and in the Channel. Finally, present and future research items are presented and discussed in Section 6.

2. PRESENTATION OF TOMAWAC WAVE MODEL

2.1 Main modelling equations of TOMAWAC

TOMAWAC solves the wave action conservation equation (or wave action balance equation) in spherical or Cartesian co-ordinates for infinite or finite water depth. The wave action density N is defined as the ratio of directional variance density F to relative (or intrinsic) angular frequency σ : $N = F / \sigma$.

The directional variance density $F(f, \theta)$ corresponds to the "classical" directional spectrum of waves and models the way the wave energy (or variance) spreads over frequency f and direction θ .

In the presence of a current field \vec{U} , the action density is conserved (Bretherton and Garret, 1968). This leads to the following equation for the variance density $F(x, y, f_r, \theta, t)$, expressed in TOMAWAC as a function of time t , spatial Cartesian co-ordinates x and y , direction of propagation θ and relative frequency f_r :

$$\frac{\partial(B.\tilde{F})}{\partial t} + C_x \frac{\partial(B.\tilde{F})}{\partial x} + C_y \frac{\partial(B.\tilde{F})}{\partial y} + C_\theta \frac{\partial(B.\tilde{F})}{\partial \theta} + C_{f_r} \frac{\partial(B.\tilde{F})}{\partial f_r} = B.Q \quad (1)$$

$$\text{with : } F(f, \theta) = \frac{C_g}{C_g + \vec{U} \cdot \vec{k} / k} \tilde{F}(f_r, \theta)$$

The absolute angular frequency $\omega = 2\pi.f$ (as observed in a fixed frame of reference) is related to the relative angular frequency $\sigma = 2\pi.f_r$ (as observed in a frame moving with the speed \vec{U}) by the Doppler equation: $\omega = \sigma + \vec{k} \cdot \vec{U}$, where \vec{k} is the wave-number vector, as given by the dispersion relation for linear waves as a function of water depth d : $\sigma^2 = g k \tanh(k.d)$

The transfer rates in space, direction and relative frequency are computed according to the linear wave theory :

$$\begin{aligned} C_x &= C_g \cdot \sin \theta + U_x & C_\theta &= -\frac{1}{k} \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial \vec{n}} - \frac{\vec{k}}{k} \cdot \frac{\partial \vec{U}}{\partial \vec{n}} \\ C_y &= C_g \cdot \cos \theta + U_y & C_{f_r} &= \frac{1}{2\pi} \left(\frac{\partial \sigma}{\partial d} \left(\frac{\partial d}{\partial t} + \vec{U} \cdot \text{grad } d \right) - C_g \vec{k} \cdot \frac{\partial \vec{U}}{\partial \vec{s}} \right) \end{aligned}$$

\vec{n} is the direction perpendicular to wave propagation direction and \vec{s} corresponds to the direction of propagation (given by θ). The coefficient B results from the fact that the conservation equation must be basically written for the action density expressed as a function of wave number : $B = C.C_g / (2\pi \sigma^2)$.

$C = \sigma / k$ and $C_g = \partial \sigma / \partial k$ are the phase and group speeds respectively.

The TOMAWAC model is unsteady (variable wind forcing conditions usually given by the wind-speed 10 m above the sea surface), but the current field U is assumed to be steady in version 1.2 of the code, as well as the water depth.

2.2 Modelisation of source and sink terms in TOMAWAC

In the Q term at the right-hand side of the balance equation (1), TOMAWAC 1.2 operationally includes the following physical processes : generation by wind (Q_{in}), dissipation by white-capping (Q_{wc}), bottom friction (Q_{bf}) and depth-induced breaking (Q_{br}), non-linear interactions between quadruplets of frequencies (Q_{nl4}). For each of these processes, several state-of-the-art formulations, calibrated against data from experimental campaigns in the field, are available in TOMAWAC and summarized in Table 1. The presentation of all the formulations is clearly out of the scope of this paper and can be found in the mentioned references. However, a more detailed presentation of depth-induced breaking is given in Section 3. In addition to these processes, a term modelling the non-linear transfers between triads of waves in shallow water (Eldeberky and Battjes, 1995) is presently under development and will be soon operational for use.

2.3 Numerical aspects of TOMAWAC

2.3.1 Spatial and spectral discretizations

Finite elements spatial discretization

Spectral wave models usually use finite differences grids for spatial meshing. This may however become a limitation for nearshore applications, where complex bathymetry and irregular shoreline often require a refined resolution. As already mentioned in the introduction, the first solution to this problem is to use nested grids, but this implies an heavy management of input/output files, complicates programming and significantly increases the computational effort.

The finite elements technique used in TOMAWAC (and in all the models of the TELEMAC system as well) overcomes this problem quite elegantly because the user can determine locally the size of the mesh and then optimize the number of nodes according to the accuracy expected in the various parts of the computational domain. The maritime area to be modelled is then discretized in a number of triangular elements whose size may be varied according to the desired resolution. This unique feature allows for instance to have on a same grid large oceanic areas (with mesh size in the order of several hundreds of kilometres) and nearshore areas (with mesh size in the order of one kilometre or less). Examples of spatial grids used by TOMAWAC are given in the following sections of this paper dealing with applications and validation test-cases.

Directional-spectral discretization

The range $[0 ; 2\pi]$ of wave directions is discretized in a number of equally spaced directions. This number of directions usually lies between 12 ($\Delta\theta = 30^\circ$) and 72 ($\Delta\theta = 5^\circ$). The discretized frequencies follow a logarithmic distribution ($f_{i+1} = (1+\epsilon).f_i$). The number of frequencies usually lies between 15 and 30. This results in a directional-spectral grid for the directional wave spectrum which is regular over directions and logarithmic over frequencies.

2.3.2 Numerical schemes

The wave action balance equation is solved in TOMAWAC by a fractional step method, including :

- a convection step (left-hand side of the balance equation (1)) :

$$\frac{\partial(B \cdot \tilde{F})}{\partial t} + \vec{V} \cdot \overrightarrow{\text{grad}}(B \cdot \tilde{F}) = 0 \quad \text{with : } \vec{V} = (C_x; C_y; C_\theta; C_{fr})$$

- and a source terms integration step (right-hand side of the equation (1)) :

$$\frac{\partial(B \cdot \tilde{F})}{\partial t} = B \cdot Q \quad \text{which reduces to : } \frac{\partial \tilde{F}}{\partial t} = Q \quad \text{as B is independent of time.}$$

Propagation step :

The convection step is treated by a piece-wise ray method or method of characteristics. Due to the fact that the convective field is stationary, the characteristics curve have to be computed only once, at the beginning of computation. The results are stored in computer memory. At each time step, the convection step is thus reduced to an interpolation, which allows to save a good amount of computing time.

Source terms step

The source terms integration is carried out through a weighted implicit scheme :

$$\frac{\tilde{F}^{n+1} - \tilde{F}^*}{\Delta t_s} = \alpha \cdot Q^* + (1-\alpha) \cdot Q^{n+1}$$

where \tilde{F}^* is the value of the variance spectrum after the propagation step and Q^* represent the value of source-terms based on \tilde{F}^* .

Choosing $\alpha = 0$ ($\alpha = 1$) makes the scheme fully implicit (explicit). In one selects $\alpha = 0.5$, this scheme reduces to the semi-implicit scheme used in the WAM model (WAMDI Group, 1988).

2.3.3 Vectorization

TOMAWAC is fully vectorized and may be run either on super-computers or on workstations, depending on the size of the computational domain.

3. IMPLEMENTATION OF DEPTH-INDUCED BREAKING IN TOMAWAC

The modelling in TOMAWAC of energy dissipation due to depth-induced breaking is achieved by solving two successive problems : (i) estimation of the total energy dissipation due to breaking for the whole directional wave spectrum and (ii) distribution of this total dissipation over both frequencies and directions.

(i) Total dissipation of wave energy due to breaking:

The transformation of statistical parameters of an incident random wave train across the surf zone can be basically treated by two classes of models both based on the wave energy balance. The “probabilistic models” are based on a wave-by-wave approach (e.g. Dally, 1992) and offer a detailed description of the transformation of wave height distribution. This type of models was however not selected in TOMAWAC because of their important computational cost. The second class of models, the so-called “parametric models”, assumes that the wave height distribution $p(H)$ and the breaking probability conform to distributions whose shapes are *a priori* known all along the bathymetric profile. By combining these distributions with a dissipation rate per breaking wave, the total dissipation term \bar{D} is obtained as a function of local wave and bathymetric parameters. As mentioned in Table 1, three such parametric models together with a model based on turbulence considerations for monochromatic waves have been implemented in TOMAWAC :

- Battjes and Janssen (1978) model (BJ78) : The authors assume that the local depth limits the wave heights in the distribution to a maximum height H_m which is a function of water depth and incident conditions (Miche criterion). So the wave height distribution follows a Rayleigh distribution clipped at $H=H_m$. All the waves having a wave height of H_m are assumed to break. The dissipation rate per unit area for a breaking wave is evaluated by using the analogy with an hydraulic jump. As the breaking wave height H_m is assumed to be in the order of water depth, the combination with the fraction of breaking waves Q_b leads, after algebraic manipulations, to the formulation for the breaking dissipation rate:

$$\bar{D} = \frac{\alpha}{4} f_p \rho g H_m^2 Q_b \quad \text{with } \alpha = 1$$

H_m is given by : $H_m = \frac{0.88}{k} \tanh\left(\gamma \frac{k \cdot d}{0.88}\right)$ with $0.5 < \gamma < 0.8$

Note that in shallow-water the above criterion reduces to : $H_m = \gamma \cdot d$.

Figure 1 : Schematic diagram of parametric surf-breaking models.

- Thornton and Guza (1983) model (TG83) : Based on field observations, the authors assume a Rayleigh distribution for the wave heights even in the surf zone, but propose two different formulations for the breaking probability. The first one assumes that all waves may break with the same probability, so the repartition of breaking waves, $p_{b1}(H)=W_1(H) \cdot p(H)$ is directly proportional to the Rayleigh distribution (figure 1.b). As, in general however, the largest waves of the

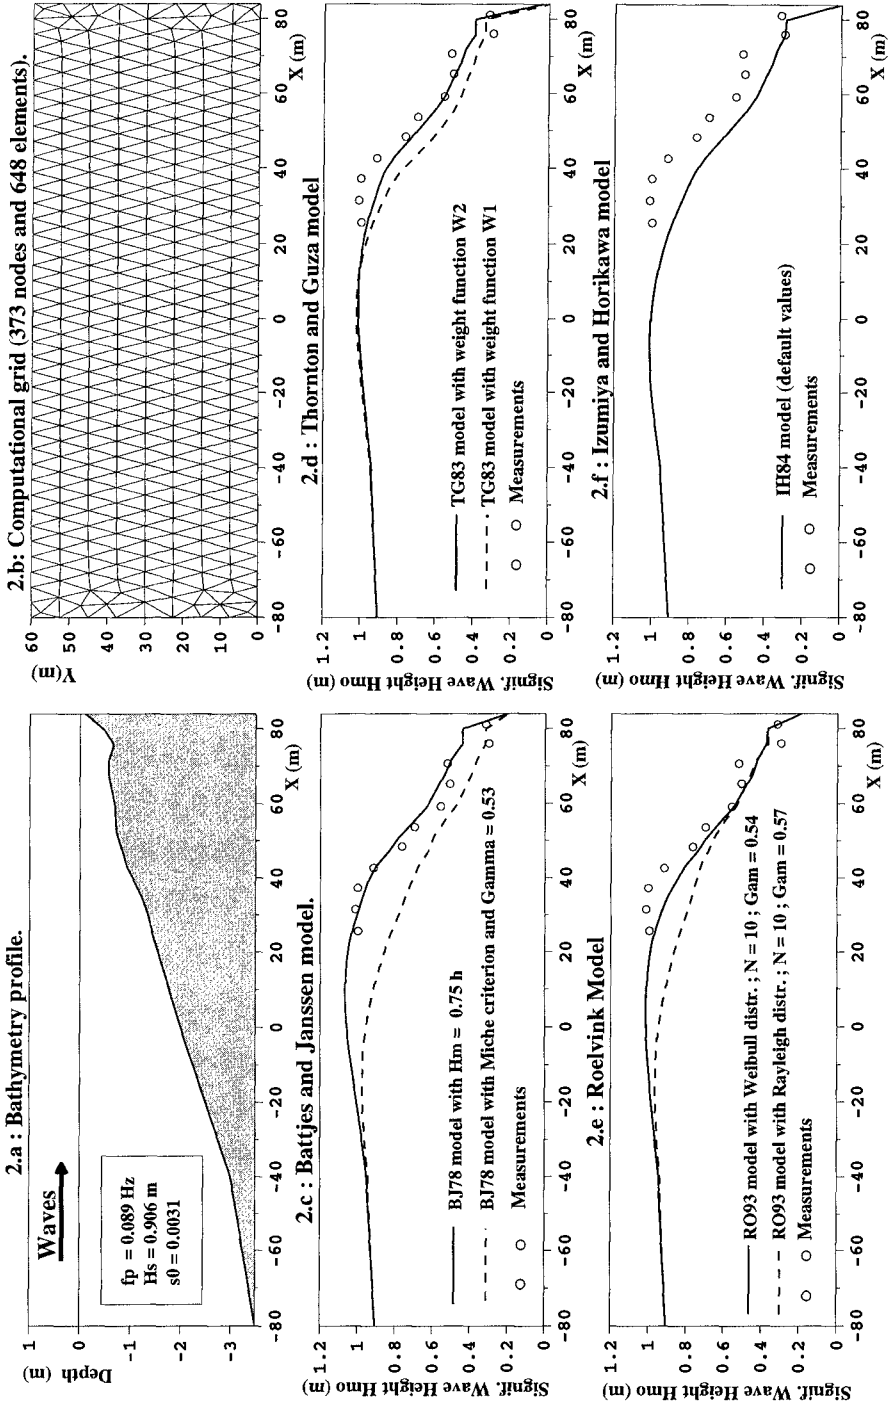

Figure 2 : Application of TOMAWAC wave model to case DUCK 41510 - Validation of surf-breaking models

distribution are more likely to break, another formulation W_2 (leading to $pb_2(H)$) is formulated. The average dissipation rates are obtained by combining $p_b(H)$ with a dissipation rate per breaking wave (based on bore theory) :

$$\bar{D}_1 = \frac{3\sqrt{\pi}}{16} B^3 \rho g f_p \frac{H_{rms}^7}{H_m^4 h} \quad \text{and} \quad \bar{D}_2 = \frac{3\sqrt{\pi}}{16} B^3 \rho g f_p \frac{H_{rms}^5}{H_m h} \left[1 - \left(1 + \left(\frac{H_{rms}}{H_m} \right)^2 \right)^{-5/2} \right]$$

• Roelvink (1993) model : The originality of this model lies in the use of two different functions for the distribution of wave heights, namely a Rayleigh and a Weibull distributions. The breaking probability is close to the second formulation of the TG83 model where the H_{rms} dependence is suppressed. The average dissipation terms \bar{D} then read (m and A depend on local wave parameters) :

$$\bar{D}_{Weibull} = \frac{\alpha}{2} \rho g f_p m A H_{rms} \int_0^{\infty} \left(\frac{H}{H_{rms}} \right)^{2m+1} \exp \left[-A \left(\frac{H}{H_{rms}} \right)^{2m} \right] \left[1 - \exp \left(- \left(\frac{H}{\gamma h} \right)^n \right) \right] dH$$

$$\bar{D}_{Rayleigh} = \frac{\alpha}{2} \rho g f_p H_{rms} \int_0^{\infty} \left(\frac{H}{H_{rms}} \right)^3 \exp \left(- \left(\frac{H}{H_{rms}} \right)^2 \right) \left[1 - \exp \left(- \left(\frac{H}{\gamma h} \right)^n \right) \right] dH$$

• Izumiya and Horikawa (1984) model (IH84) : this model is based on the Reynolds equations and was developed for monochromatic waves propagating over a bathymetry profile. The breaking dissipation term is expressed as a function of wave energy E :

$$D = -\beta_0 \left(\frac{Cg}{C} \frac{E}{\rho g h^2} - M_{*s}^2 \right)^{1/2} \frac{E^{3/2}}{\rho^{1/2} d^{3/2}} \left(\frac{2Cg}{C} - 1 \right)^{1/2}$$

where M_{*s}^2 is a stable wave criterion (about $0.9 \cdot 10^{-2}$) and $\beta_0 = 1.8$.

(ii) Distribution of total dissipation over both frequencies and directions :

No directional dependence has been demonstrated until now, so the discussion will be restricted to the frequency dependence. Vincent *et al.* (1994) have analyzed laboratory data for the evolution of single-peaked spectra along a monotonic bathymetry profile. The normalised energy loss was found to be quite independent of frequency allowing the assumption that the spectral distribution of energy dissipation is directly proportional to the energy density, so that :

$$Q_{br}(f, \theta) = -\bar{D}(m_0, f_p, d) \frac{F(f, \theta)}{m_0} \quad \text{with} \quad m_0 = \int_0^{\infty} \int_0^{2\pi} F(f, \theta) df d\theta$$

Experiments from Beji and Battjes (1993) for waves propagating over a bar also indicate the same trend, leading to the above state-of-the-art method currently used in other wave models (Ris *et al.*, 1994 ; Van Vledder *et al.*, 1994).

On the other hand, Mase and Kirby (1992) observed in their laboratory experiments a frequency dependence of the breaking dissipation. They proposed to add a quadratic dependence on frequency, so that :

$$Q_{br}(f, \theta) = -(a_0 + f^2 a_1) \cdot F(f, \theta) \quad \text{with} \quad \bar{D}(m_0, f_p, d) = \int_0^{\infty} \int_0^{2\pi} (a_0 + f^2 a_1) \cdot F(f, \theta) df d\theta$$

As, from the observations, a linear dependence on frequency could not be excluded, both the quadratic and linear dependences have been implemented in TOMAWAC (in addition to the above classical approach neglecting any frequency dependence). The inclusion of the frequency dependence for the breaking sink term does not significantly modify the evolution of the significant wave height along the

profile. As expected however, the mean frequency is found to decrease when a quadratic dependence of frequency is activated. Indeed the higher frequencies of the spectrum are more concerned by breaking dissipation, shifting the spectral shape towards the lower frequencies. However, such a behaviour can not be validated solely, but must be analysed in conjunction with (in particular) triad interactions, which play a central role in the energy flux between the spectral components in shallow water.

(iii) Example of validation of depth-induced breaking in TOMAWAC model :

A field experiment was conducted on September 4-6, 1985, at the Field Research Facility of the U.S. Army Coastal Engineering Research Center (CERC) in Duck, North California (Ebersole and Hughes, 1987). The case presented below was recorded on September 4, 15:10 hrs (41510). The wave conditions imposed at the seaward boundary for the application of TOMAWAC are summarized on figure 2.a. The numerical simulations were carried out for the bathymetry profile shown on figure 2.a with a computational grid of approximately constant mesh (figure 2.b). The surf-breaking dissipative term was assumed to be frequency independent.

The TOMAWAC results (figures 2-c to 2-f) show that all breaking models are able to correctly reproduce the significant wave height variations along the bathymetry profile. BJ78 model was used in a first run with a value of γ determined from the Battjes and Stive (1984) formulation ($\gamma=0.53$) and with the Miche criterion for the computation of H_m (Figure 2.c). This results in an overestimation of the dissipation. In fact, Battjes and Stive formulation is not efficient for low values of steepness s_0 . This test-case requires to increase γ up to 0.75, which gives quite good results. The use of the weighting function W_2 in TG83 model gives better results on this experiment than W_1 (figure 2.d), even if it does not well reproduce the wave height enhancement observed before breaking. RO93 model gives too much dissipation with the Rayleigh distribution (figure 2.e), but the use of the Weibull distribution improves the results. The IH84 model is also too much dissipative (figure 2.f), but partly reproduces the wave height enhancement before breaking.

4. WAVES PROPAGATING OVER A CURRENT WHIRL

This computation has to show the capability of TOMAWAC to represent wave-current interactions on a realistic (although schematic) case of a current eddy. This case was proposed by Mathiesen (1987) as fairly representative of the whirls sometimes occurring in the nearshore zone.

4.1 Description of the test case

The spatial domain is a square of 80 km (figure 3). We consider an idealised circular whirl, centered on the origin :

- The tangential current velocity increases linearly from zero at the center of the whirl : $u(r) = u_1 \frac{r}{r_1}$ for $r \leq r_1 < r_0$

- Further away from the whirl center, the current follows a gaussian profile :

$$u(r) = u_{\max} \exp \left[- \left(\frac{r - r_0}{b r_0} \right)^2 \right] \text{ for } r > r_1$$

For this run, $u_{\max} = 1$ m/s, $r_0 = 10$ km and $b = 0.3$, which leads to $r_1 = 9.5277$ km.

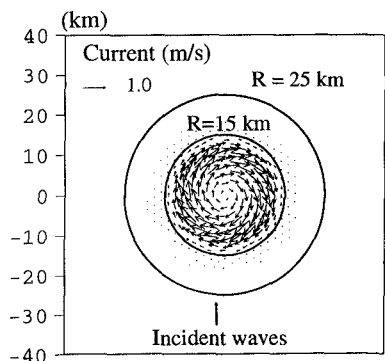

Figure 3 : Definition sketch and current field for the whirl test-case.

Mathiesen (1987) developed a semi-analytical model for this refraction problem using a ray tracing technique. This technique can be carried out upward or backward. Mathiesen used the backward ray method to determine the point (x,y,f,θ) where the energy originates to reach the point of interest. Such computations were performed for different wave frequencies and directions in order to build a complete wave spectrum. Therefore, his results can be compared with those of TOMAWAC.

The input offshore directional wave spectrum, chosen by Mathiesen (1987), is written in the form : $F(f,\theta) = S(f).D(f,\theta)$ where $S(f)$ is the frequency spectrum and $D(f,\theta)$ is the directional spreading function. The frequency spectrum is a classical JONSWAP spectrum with a peak frequency f_p equal to 0.1 Hz. $D(f,\theta)$ is based a Gaussian-shaped directional distribution :

$$D(f,\theta) = \frac{1}{\sqrt{2\pi}\sigma_0} \exp\left(-\frac{(\theta - \theta_m)^2}{2\sigma_0^2}\right)$$

θ_m is the mean incident wave direction (here $\theta_m = 0$) and σ_0 is the circular standard deviation given by the following expression :

$$\sigma_0 = \sigma_{0p} \left(\frac{f}{f_p}\right)^{-2.03} \quad \text{if } f < f_p$$

$$\sigma_0 = \sigma_{0p} \left(\frac{f}{f_p}\right)^{1.04} \quad \text{if } f \geq f_p$$

where $\sigma_{0p} = \sigma_0(f_p) = 25^\circ$

The water depth is supposed to be constant at 200 m. The computation is achieved with Cartesian co-ordinates, without any source term ($Q=0$). The mesh used consists of 1876 points and 3590 elements of about 2 km on one side.

4.2 Results and discussion

Several computations were performed with TOMAWAC, using different time-steps and different directional resolutions. Only the results obtained with a time-step of 1200 s and a directional resolution of 7.5° will be presented below. The 25 discretized frequencies range from 0.04 Hz to 0.4 Hz (geometrical factor 1.1). The computed normalised significant wave height is given on figure 4. We can clearly see two zones where wave heights are enhanced separated by a zone where they are decreased. The greatest increase in wave height is obtained when waves propagate against the current while the greatest decrease is observed when they go the same way. The variations of significant wave height remain in the range $\pm 30\%$.

Figure 4 : Map of normalised significant wave height

Figure 5 : Computed directional wave spectra at various locations

Figure 5 shows the wave spectra computed at various locations. We can see the presence of crossing seas, with several directional peaks in the spectrum, especially at points n°1 and 3. The directional distribution of wave energy is very inhomogeneous on this test-case. On figure 6, the directional spectra at $f = 0.1$ Hz are plotted for the eight points presented in figure 4. Mathiesen (1987) gives similar results with his model whose directional discretization (2.5°) was finer than ours. The TOMAWAC results compare very satisfactorily with the semi-analytical solution. The model thus appears to be able to reproduce the main features of the directional spectra, although they have a quite complex shape at several locations.

Figure 6 : Directional spectra at $f = \text{fp} = 0.1$ Hz - Comparison with Mathiesen (1987) model

5. SIMULATION OF THE STORM OF JANUARY 25, 1990 IN THE CHANNEL

Of all the storms to hit the Atlantic coast of France during the winter of 1989-1990, the one on January 25, 1990 was one of the most violent, with winds of force 9 to 11 (on the Beaufort scale) over French Brittany. On this particular day, the strongest gust of wind recorded at the Hague signal station was measured at 46 m/s (166 km/h). The winds blew continuously from the West, which was particularly conducive to the formation of strong waves to the West of Cotentin, and on that day, the buoys located at Ouessant registered wave heights of over 16 metres !

The period chosen for computer simulation with TOMAWAC runs from January 16 to 30, 1990, with a time-step of 5 minutes. The computational mesh consists of 6 205 nodes and 11 444 triangular elements (figure 7). The broadest meshes cover approximately 40 km on the grid boundaries, whereas the most refined ones cover less than 5 km in the English Channel. The directional wave energy spectrum has been discretized into 25 frequencies and 12 directions. The windfields (two horizontal components of the 10 m wind-speed) were provided every 6 hours from the French meteorological model results. Boundary conditions were provided by a previous simulation performed on a coarser grid covering the Northern part of the Atlantic Ocean. All source terms, including surf-breaking, were activated for this computation. The simulation was carried out without taking tidal effects into account. It required less than two hours of computing time on a Cray C98 computer for modelling an actual duration of 14 days.

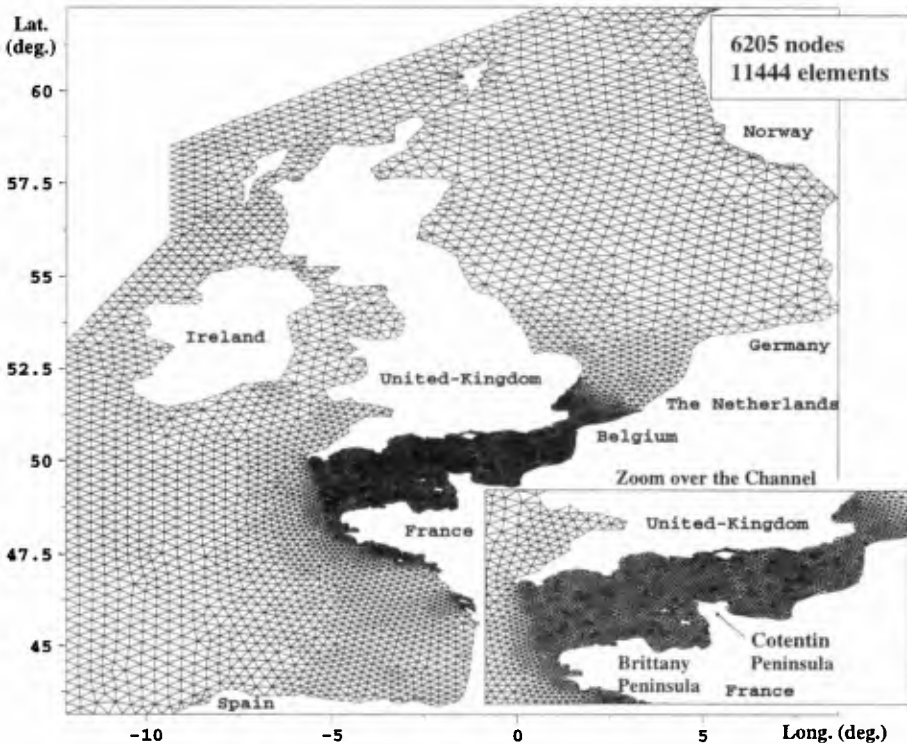

Figure 7 : Grid used for the simulation of the storm of January 25, 1990.

Figure 8 shows a chart of significant wave heights computed at the paroxysm of the storm, along with the energy spectra at the same moment at various points in the Channel. We can see that the storm's maximum intensity occurs close to the West Brittany. The further we move into the Channel, the smaller the wave heights, even though heights still manage to reach 5.5 m to the West of Cotentin (Flamanville). To validate the simulation, computational results are compared with the buoy measurements at Ouessant and Flamanville on figure 9. On both places, numerical results compare quite satisfactorily to buoy data. Furthermore, it appears from figure 8 that wave breaking significantly contributes to decrease the wave heights along the coasts of the French Brittany Peninsula.

The TOMAWAC model thus gave a good overall account of itself as far as reproducing the height of the waves was concerned, even though it slightly underestimated the January 25, 1990 peak at Ouessant. The mean periods are also fairly well reproduced, despite being generally rather overestimated by the code.

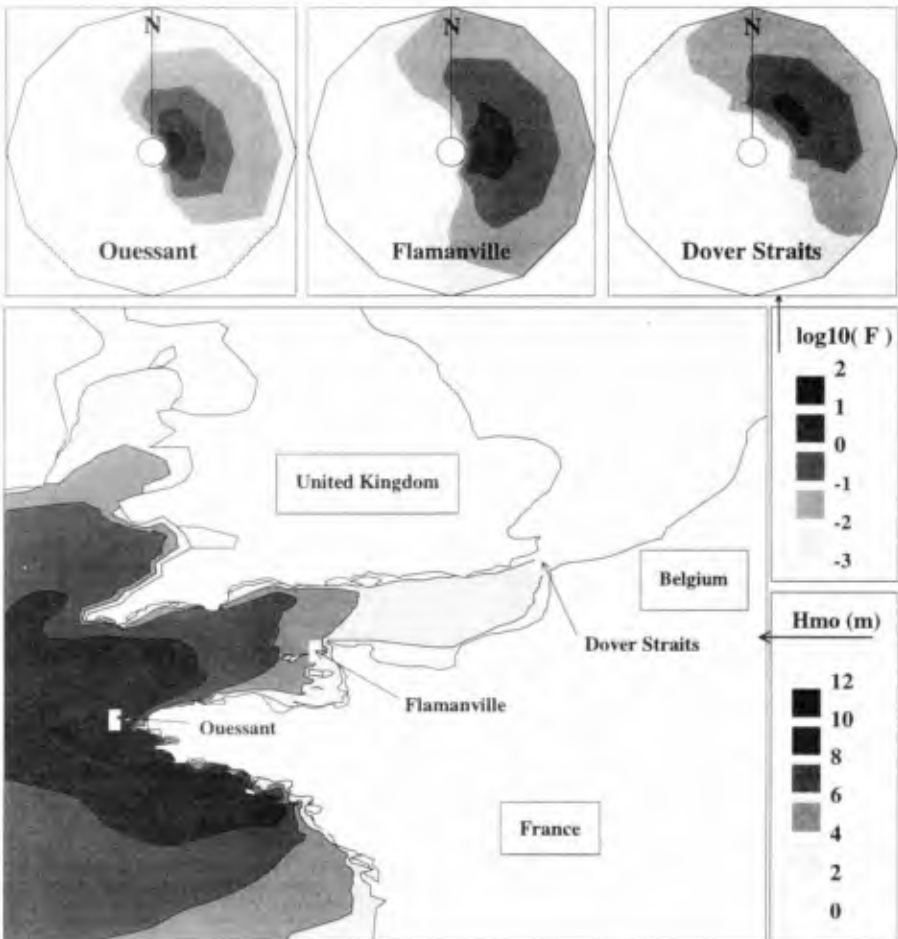

Figure 8 : Results of TOMAWAC at the peak of the storm of January 25, 1990. (Upper plots : directional spectra ; Lower plot : map of significant wave height)

Figure 9 : Comparison of TOMAWAC results with buoy data at two locations.

6. CONCLUSIONS — FUTURE WORK

The applications presented in the previous sections show some of the capabilities of the TOMAWAC wave model, in particular for the simulation of storm waves for both offshore and nearshore areas. These cases are however only samples from the numerous test-cases performed during the validation step of the model. As a part of the TELEMAC modelling system, TOMAWAC indeed follows the Insurance Quality Procedure of EDF-LNH, with precise development rules and a complete documentation.

The inclusion of shallow-water effects such as bottom friction and depth-induced breaking has allowed to further extend the range of validity of the model towards the nearshore zone. In addition, the numerical background for spatial discretization (unstructured “finite elements” grid) and propagation scheme (piecewise ray method) make the model very attractive for the modelling of shelf seas and shallow-water domains.

Present development efforts are dedicated to the extension of the TOMAWAC model towards the very shallow water depth, in particular by considering the non-linear interactions between triads of waves. The possibility to deal with unsteady currents and water levels is also a field of present research, in order to study the interactions between waves, storm-surges and tides.

7. ACKNOWLEDGEMENTS

This study is a joint research program between EDF-Laboratoire National d'Hydraulique and the French Ministry of the Sea (Service Technique de la Navigation Maritime et des Transmissions de l'Équipement — STNMTE).

CHAPTER 38

New Optimization Method for Paddle Motion of Multi-Directional Wavemaker

Akira Matsumoto ¹ and Minoru Hanzawa ²

Abstract

Uniformity of monochromatic oblique waves in a wave basin is investigated. A new method, using non-linear least square formulation, to determine individual wave paddle motions of multi-directional wavemaker to improve uniformity, is proposed. The possibilities and limitations of the method are discussed. Trial computations and comparisons with experiments demonstrate the validity and usefulness of the method.

Introduction

It is of prime importance to reproduce the desired oblique planar wave train in a wave basin. If an accurate and simple method were available for this purpose, directional random waves could also be reproduced through superposition of various oblique waves for constituent elements. Up to now, however, monochromatic oblique waves generated by a multi-directional wavemaker using the conventional snake principle (Biesel, 1954) have shown considerable spatial variations in wave height and wave propagating direction due to the finite length of the entire wavemaker and the finite width of each paddle (Takayama, 1982).

To reduce these spatial variations, Dalrymple (1989) presented a theory which utilizes reflection from the sidewall. Although his method is widely employed, if a reflective structure is to be tested using it, significant re-reflection will occur from the sidewall and the resultant wave field will become contaminated. In this context, a method which does not use sidewall reflection is quite promising. This kind of approach was first proposed by Ishida and Watanabe

¹Researcher, Applied Hydraulics Laboratory, TETRA Co., Ltd., 2-7 Higashi Nakanuki, Tsuchiura, Ibaraki, 300, Japan.

²Senior Researcher, Ditto.

(1984) for a discrete-type multi-directional wavemaker under the condition of normal incidence. They showed that such spatial variations can be suppressed by controlling the amplitude of some of the wave paddles at both ends of the wavemaker without using the sidewall reflection. Mizuguchi (1993,1994) established a theory for continuous-type multi-directional wavemaker and proposed a general method to produce a uniform wave field for waves of oblique incidence. Toita *et al.* (1994) validated his method experimentally. The method employs linear decrease of paddle amplitude at both ends of the wavemaker while the conventional method uses a constant paddle amplitude. Although this method is very successful, the total length of the wave board to be controlled must be equal to one wavelength for the best result. The method is thought to be somewhat empirical. It cannot specify the target area in the basin, and the experimental work does not refer to uniformity of the wave propagating direction. Hanzawa *et al.* (1994) applied an electromagnetic wave theory for the generation of oblique waves. The applicability of this was investigated numerically using the boundary element method presented by Isaacson (1989). They suggested that the Dolph-Chebyshev distribution (Dolph, 1946), which was originally derived to determine the current distribution feeding to broadside antenna array and is optimum to minimize the beam width when a side lobe level is specified, showed possibility to improve the uniformity of an oblique water wave field.

In this paper, a new optimization method is proposed to determine each wave paddle motion to improve the uniformity of the monochromatic oblique wave field without using sidewall reflection. First, the amplitude of each wave paddle is determined using a non-linear least square method instead of the intuitive linear decrease proposed by Mizuguchi. Second, the wave heights and water particle motions are computed to investigate the generated wave fields. Finally, the method is validated by comparing computed and experimental wave fields. In comparison to Mizuguchi's method, the proposed method improves the uniformities of both the wave propagating direction and wave height, and the method can specify the location of the target area in the basin arbitrarily.

Formulation of the Problem

A wavemaker of continuous piston type is assumed to be installed in constant depth in a very wide wave basin with negligible sidewall reflection. In the following linear wave analysis, $2N$ is the total number of driving rods, a_i is the amplitude of the i -th rod, M is the total number of reference points distributed within the reference area, and A_j is the wave amplitude at the j -th reference point. Within the reference area, the uniformity of the wave field is improved. In this study, the magnitude of a_i is determined as the optimum value while the phase difference between adjacent paddles is simply decided in accordance with the conventional snake principle. Fig.1 gives a schematic view of the formulation.

The Hankel function gives a unit solution of the Helmholtz equation, expressing waves spreading from a point source over a horizontal bottom. Lin-

earity of the equation permits an arbitrary superposition of such unit solutions for multiple sources distributed along the wave paddles. A particular solution is obtained by determining the alignment of the point sources so that the resultant oblique wave field has a uniform wave height distribution within a given area in the basin. Fig.2 shows the coordinate system and waves emitting from a point source on the wave board.

Figure 1: Schematic view of the formulation.

Figure 2: Coordinate system.

Neglecting the evanescent mode waves, the water surface profile at the j -th reference point (x_j, y_j) can be written as follows (Mizuguchi, 1993).

$$\eta_j = \alpha \sqrt{E_s^2 + E_c^2} \cos \left\{ \arctan \left(\frac{E_s}{E_c} \right) - \sigma t \right\} \quad (1)$$

The wave amplitude at the j -th reference point normalized by the representative amplitude of the driving rod, b_0 , is thus expressed as

$$A_j = \frac{\alpha}{b_0} \sqrt{E_s^2 + E_c^2} \quad (2)$$

where

$$\alpha = \frac{2 \sinh^2 kd}{\sinh 2kd + 2kd} \quad (3)$$

and

$$E_s = \sum_{i=-N}^{N-1} a_i \cos \beta \{ N_{ij} \cos (ikw \sin \beta) - J_{ij} \sin (ikw \sin \beta) \} \quad (4)$$

$$E_c = \sum_{i=-N}^{N-1} a_i \cos \beta \{ N_{ij} \sin (ikw \sin \beta) + J_{ij} \cos (ikw \sin \beta) \} \quad (5)$$

$$N_{ij} = \int_{-kw}^{kw} \left(1 - \frac{|q|}{kw} \right) N_0 \left(\sqrt{\left(k \left(x_j - iw - \frac{w}{2} \right) - q \right)^2 + (ky_j)^2} \right) dq \quad (6)$$

$$J_{ij} = \int_{-kw}^{kw} \left(1 - \frac{|q|}{kw} \right) J_0 \left(\sqrt{\left(k \left(x_j - iw - \frac{w}{2} \right) - q \right)^2 + (ky_j)^2} \right) dq \quad (7)$$

in which, t is the time, σ is the angular frequency, k is the wave number, d is the water depth, β is the wave propagating direction measured counterclockwise from the y -axis indicated in Fig.2, w is the width of a wave paddle, and N_0 and J_0 denote the Bessel and Neumann functions of zeroth-order. In Eq.(6) and (7), when $i=-N$ or $i=N-1$, the integration is performed in the range of $[0, kw]$ or $[-kw, 0]$ respectively.

Denoting the target wave amplitude normalized by the representative amplitude of the driving rod, b_0 , by A_c , the total residual squared is given by

$$r^2 = \sum_{j=1}^M [A_c - A_j]^2 \quad (8)$$

The problem can then be regarded as a non-linear least square problem. The optimum amplitude of each rod is obtained by finding the values of a_i which

minimize r^2 . In this study, as expressed in Eq.(9), A_c is taken to be 1/2 of the wave generating efficiency of a two dimensional piston type wavemaker.

$$A_c = \frac{2(\cosh 2kd - 1)}{\sinh 2kd + 2kd} \quad (9)$$

Marquardt's method is suitably employed to solve Eq.(8) because of its stability in computation. Since this type of approach allows arbitrary collocation of reference points, it makes experiments more flexible.

Optimum Distribution of Driving Rod Amplitude

The general description of the least square problem is to find a set of N unknown parameters

$$(x_1, x_2, \dots, x_N) \quad (10)$$

which minimizes the value of

$$r^2(\mathbf{x}) = \sum_{j=1}^M f_j^2(\mathbf{x}) \quad (11)$$

where $f_j(x_1, x_2, \dots, x_N)$ ($j = 1, \dots, M$) are arbitrary functions of \mathbf{x} .

When $r^2(\mathbf{x})$ depends nonlinearly on a set of N unknown parameters x_i , ($i = 1, \dots, N$), the minimization must proceed iteratively. From the given initial trial values for the parameters, the calculation proceeds in a way that improves the trial solution. Such a procedure is then repeated until $r^2(\mathbf{x})$ reaches an equilibrium (Press *et al.*, 1992).

Table 1 and Fig.3 summarize the conditions and the setup for computation and experiments in this study. The wave basin was 50m long, 40m wide, 1.5m high. Wave absorbers placed along the side wall and the onshore slope were used to prevent waves from reflecting from the wall. The number of driving rods was 28 (the number of wave paddles was 27) and the width of a wave paddle was 0.9m.

Table 1: Experimental conditions.

Case	Water depth (m)	Wave period (s)	Wave direction (°)	Reference area
1	0.6	1.8	0.0	A
2	0.6	1.8	22.5	B
3	0.6	1.8	22.5	A

The reference area of the uniform wave field is the rectangular region of $x=-4$ to 4m, $y=4$ to 12m (Area A) and $x=-9$ to -1m, $y=4$ to 12m (Area B).

Within this area, 81 reference points are collocated at every 1m grid point. A uniform distribution of the driving rod amplitude is used for the initial values and the iteration count of the minimization procedure is one. Computation to calculate the wave amplitude at the j -th reference point in Eq.(8) is made in the manner presented by Mizuguchi under the assumption of small amplitude wave theory.

Figure 3: Wave basin.

Fig.4 gives the computed distributions of the rod amplitude for Case 1 and Case 2. This figure shows that the present method yields the distribution of the rod amplitude with high peaks at both ends of the wavemaker. The conventional method uses constant rod amplitude, while Mizuguchi proposed a linear decrease at both ends. These peaks, representing singularities at both ends, produce an improved uniformity of the wave field in the reference area. Such a non-uniform distribution of the point source intensities was correctly suggested by Nishimura *et al.* (1994) for the continuation condition at the artificial boundary of a wave field calculation.

The relationship between the iteration count of the minimization procedure and the values of residual squared for Case 1 is illustrated in Fig.5. This figure shows that only one time of iteration can reduce the value of residual squared up to approximately 1/100 of the original value. A preliminary investigation demonstrates that the uniformity of the wave field can be well improved by the distribution of the rod amplitude obtained by only one time of iteration. It is worth noting that not only the uniformity of the wave field in the reference area, but also that in its peripheral region can be widely improved to coincide

with its target value because of the continuity of the fluid, and the fact that too much iteration count narrows the area of such a peripheral region. As this study stresses the development of the new method and the examination of properties of generated wave fields, hereafter the number of iteration counts will be fixed to one.

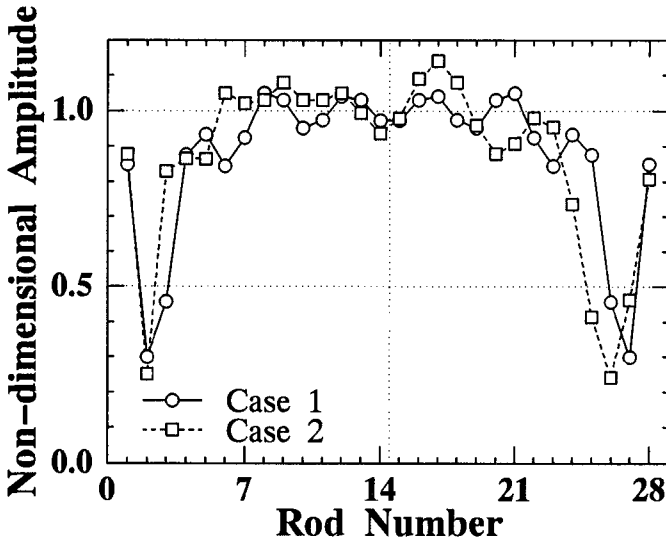

Figure 4: Computed distribution of the driving rod amplitude.

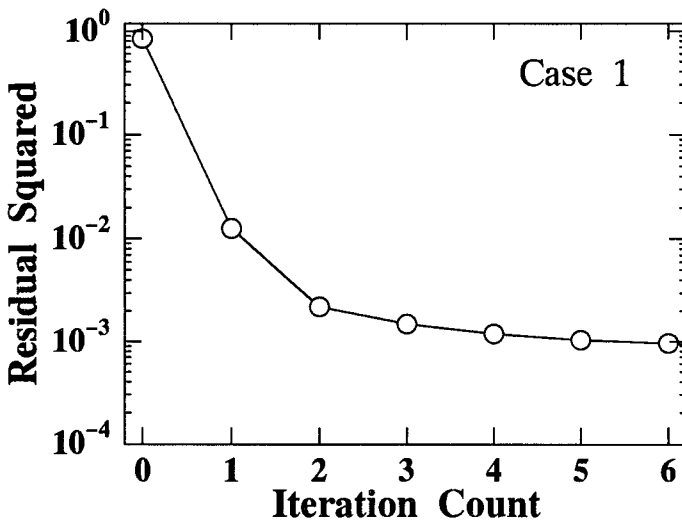

Figure 5: Changes of the residual squared.

Properties of Generated Waves

A series of computations on wave height, wave propagating direction and flatness of the hodograph of two component horizontal composed velocities were conducted to investigate the properties of oblique waves generated by the proposed method. Computations were carried out at every 50cm grid point over the area indicated in Fig.3

Fig.6 shows definitions of the wave propagating direction and the flatness of the hodograph. Because of the phase difference between one velocity component and the other, the path of the water particle does not follow a straight line but it forms an ellipse (Takayama, 1982). The wave direction is defined by the direction of longer radius. It should be noted that this definition gives a mean value of the wave direction because the wave direction at a fixed location varies from time to time. The flatness of the hodograph χ , is defined by using a longer and shorter radius as follows:

$$\chi = r_2/r_1 \quad (12)$$

where, r_1 is the longer radius and r_2 is the shorter one. The flatness of the hodograph indicates the magnitude of fluctuation of the wave propagating direction and is equal to zero if the wave field has complete uniformity.

Figure 6: Trajectory of a water particle.

Fig.7 shows the computed distributions of the normalized wave height, the deviation of the wave propagating direction, and the flatness of the hodograph for Case 2. These results were obtained by the conventional method, Mizuguchi's method, and the proposed method. The normalized wave height was defined as the ratio of generated wave height to twice the amplitude of the driving rod. The target value is 0.97 according to the water depth and wave period used. The dark areas indicate that the normalized wave height is between 0.9 and 1.1, deviations of the wave propagating direction is between -2.5° and 2.5° , and the flatness of the hodograph is less than 0.05 respectively.

The wave fields computed by the conventional method display wavy features of considerable variations around 30% in the normalized wave height and the wave propagating direction differs by nearly 10° from the target values over a large area. Furthermore, the flatness of the hodograph shows the maximum value to be over 0.15. These wavy features are considered to be largely related to the phenomenon that the wave energy of the oblique uni-directional random waves have directional spreading and the multi-directional random waves show a spatial variation of the directional spectrum.

As shown in the figure, the proposed method reduced these wavy features to produce a wave field in which the error in the normalized wave height was less than 10%, the error in the wave propagating direction less than 2.5° , and the error in flatness of the hodograph less than 0.05. It is interesting to note that although the design procedure for paddle amplitude was, as was described above, derived from the viewpoint of wave height, not only the uniformity of the wave height but also the uniformities of both the wave propagating direction and flatness of the hodograph were significantly improved simultaneously. This may be explained by using the transfer function between the time series of the water particle velocities and the water surface elevation. The uniformity of the wave field for Case 1 produced by the proposed method is also improved with favorable results. See Matsumoto *et al.* (1995) for the reference.

Mizuguchi's method also reduced the wavy features. However, it produced some spots of unacceptable errors. These may be ascribed to the fact that his method modifies only a few wave paddles at both the generator ends empirically while the proposed method controls all the paddle amplitudes as an optimum distribution.

The normalized wave height computed by the proposed method for Case 3 is indicated in Fig.8. In this case, the wave ray from the center of the whole wave paddle did not go through the center of the reference area. The figure demonstrates that, even in such a case, the uniformity of the wave field can be improved by the proposed method. This supports the idea that the proposed method has a high possibility to reproduce a desired directional random wave field, which does not show any spatial variation of directional spectrum, by the superposition of oblique waves.

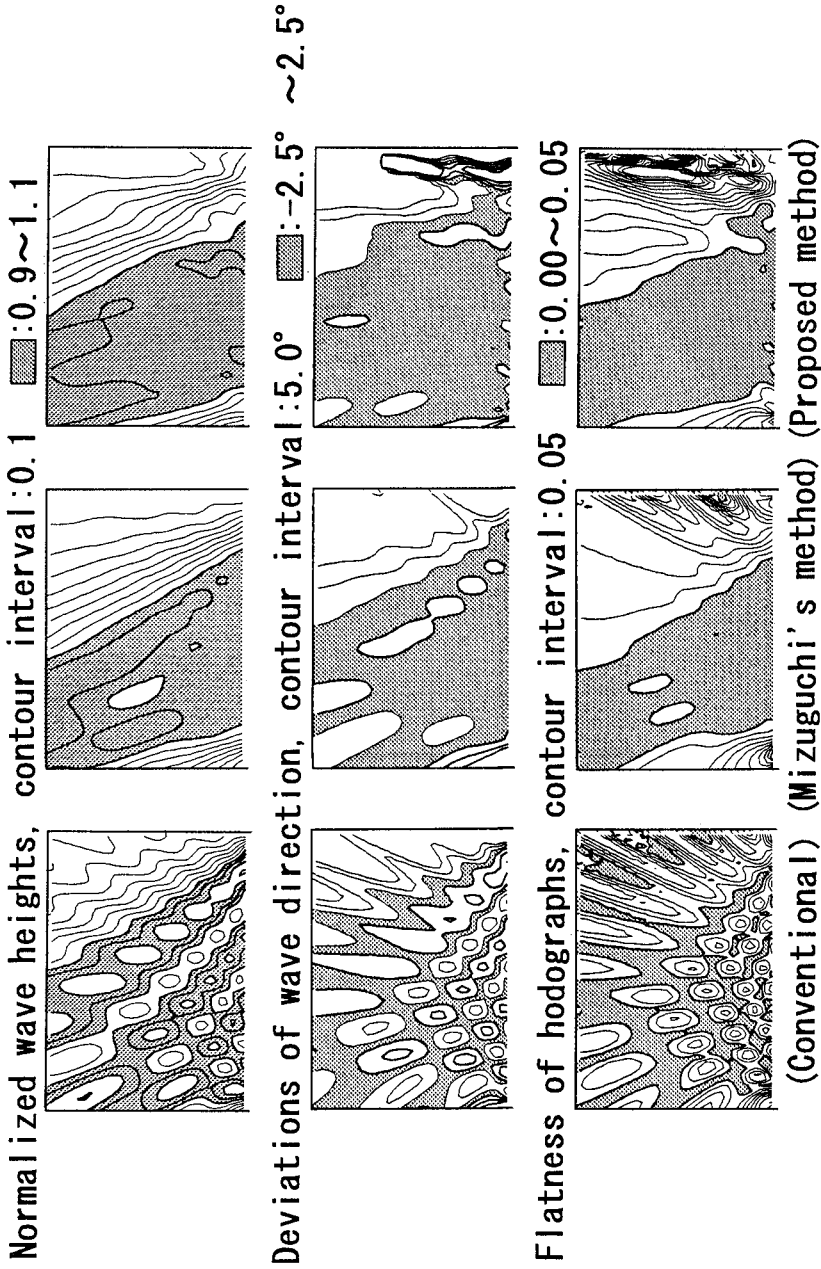

Figure 7: Computed wave fields (Case2).

contour interval:0.1  :0.9~1.1

Figure 8: Computed normalized wave height (Case3).

Comparison with Experiments

Experiments were carried out to provide the wave height distribution and the water particle velocity to examine the performance of the proposed method. Equipment and experimental conditions are summarized in Fig.3 and Table 1. The representative amplitude of the driving rod was 3.7cm. Both the water surface elevation and two component horizontal water particle velocities were measured using capacitance type wave gauges and electromagnetic velocimeters along the measurement line ($y=7.0\text{m}$) as indicated in Fig.3. In the analysis, time series of the water surface elevation and water particle velocity before reaching the reflected waves from the sidewall were used.

Figs.9 and 10 compare the measured and computed distributions of the relative wave heights normalized with the target wave height for Case 1 and Case 2. In these figures, the loss of wave generating efficiency due to leakage of energy through the spacing between the wave board and the bottom of the wave basin, which was measured in the preliminary experiment, are taken into account. The agreement is good for both the proposed and conventional methods. A comparison of the measured and computed wave heights for Case 3 was also conducted. The measured wave heights agree well with those computed. This confirms the validity of the proposed method and the linear analysis of the wave field.

Figs.11 and 12 present the measured and computed hodographs of normalized horizontal velocities for Case 2 obtained at the location $x=2.25\text{m}$, $y=7.00\text{m}$, $z=-0.15\text{m}$. The diagonal dotted line shows the specified wave direction. The measured values follow computed ones quite well for both the conventional and proposed method. The water particle motions are also found to be reproduced well. Fig.12 indicates that the wave propagating direction coincides with its target direction. Moreover, the orbital curve becomes thinner, i.e., the magnitude of fluctuation of the wave direction decreases. These results confirm the validity of the proposed method from the viewpoint of the uniformity of wave direction.

Figure 12: Hodographs of composed velocities (Case 2, Proposed method).

Concluding Remarks

Throughout this study, it was clarified that the method as presented actually improves the uniformity of both wave height and wave propagating direction. Since the method can specify the target area in the basin arbitrarily, it should prove very useful for applying to multi-directional random wave fields. As the method is formulated by using an inverse problem, it is applicable independent of the type of wavemaker and boundary conditions in the wave basin.

Acknowledgment

CHAPTER 39

GENERATION OF SECOND-ORDER LONG WAVES BY A WAVE GROUP IN A LABORATORY FLUME AND ITS CONTROL

M. Mizuguchi and H. Toita

ABSTRACT

Generation of second-order long waves at a wave maker by non-periodic wave group is analyzed in time series by Mizuguchi(1995). The analysis, which include a way to control the long wave generation, is briefly described. Then confirmation by using a single wave packet is successfully undertaken both in numerical simulation by Boussinesq equation and in laboratory experiment.

1. INTRODUCTION

Long period waves (infra-gravity waves) are of typical time scale a few minutes. Recent studies on field waves in the nearshore zone reveals that these long waves are quite significant and cannot be neglected even for engineering purposes.

Reproduction of a field phenomenon in laboratory experiments is a way to understand it if tried or a proof of understanding if successfully done. Here we deal with a method of correct reproduction of the long waves coexisting with grouping short-period waves. Ottesen Hansen et al.(1980) presented a theoretical analysis of the bound second-order long waves in the frequency space. The long waves are calculated as the second-order difference waves of the two primary waves with slightly different frequencies in Stokes-type nonlinear analysis. They also give discussions both on the production of spurious free long waves at a wave maker and on a method to suppress them. Kostense(1984) successfully applied the method to bichromatic waves. However this approach in frequency space cannot be applied to non-periodic wave

Dept. Civil Eng., Chuo Univ., Kasuga 1-13-27, Bunkyo-ku,
Tokyo JAPAN

groups such as the initial growth stage of the wave generation and a single wave packet.

On the other hand, Longuet-Higgins and Stewart(1962) show a way to describe these long waves by applying linear long wave equation with a forcing term given by second-order quantity (radiation stress) of the short period waves. Mizuguchi(1995) follows their approach to study the behavior of the second-order long waves produced at the wave maker when grouping waves are generated in a laboratory flume. He also shows a way to control them in time domain. Here we report their experimental confirmation both numerically and physically.

2. TIME SERIES ANALYSIS OF SECOND-ORDER LONG WAVE GENERATION

Radiation stress approach employed by Mizuguchi(1995) is briefly described below. He assumes one dimensional case with a constant depth h . Then basic conservation equations are

$$\text{mass:} \quad \eta_t + (hu)_x = 0 \quad (1)$$

$$\text{momentum:} \quad u_t + g\eta_x = -(S_{xx}/\rho)_x/h \quad (2)$$

where η and u are surface elevation and onshore velocity for long waves. S_{xx} is a radiation stress component. Here the long waves are assumed to be of small amplitude. Eliminating u in Eqs.(1) and (2), we have the linear long wave equation with a forcing term.

$$\eta_{ct} - g(h\eta_x)_x = (S_{xx}/\rho)_{xx} \quad (3)$$

For a wave group, which propagates in a steady form on a constant depth, Longuet-Higgins and Stewart(1962) shows Eq.(3) has the following particular solution (the bound long waves) η_* ,

$$\eta_* = -S_{xx}(x - c_g t)/\rho(c^2 - c_g^2) \quad \text{where } c^2 = gh. \quad (4)$$

For the long waves under short wave groups in a laboratory flume, the general solution for $x > 0$ (wave maker at $x=0$) is written as

$$\eta(x, t) = f(x - ct) + \eta_*(x - c_g t) \quad (5)$$

where $f(x - ct)$ is a general solution of Eq.(3), which propagates in the positive direction. Uniqueness exclude other general solution, which propagates in the negative direction. Functional form of f should be determined by either initial conditions or boundary conditions. In

other words the general solution $f(x-ct)$ is needed to satisfy conditions which reflect a real situation.

When generating either grouping waves or irregular waves, we normally neglect the existence of the second-order long waves. Then this natural boundary condition at the wave maker is written as

$$u=0 \quad \text{at } x=0. \quad (6)$$

Surface elevation η of Eq.(5) gives the following horizontal velocity u ,

$$u(x,t)=(c/h)f(x-ct)+(c_g/h)\eta_*(x-c_g t) \quad (7)$$

For a boundary condition where $u(0,t)$ is specified, Eq.(7) yields

$$f=-n\eta_*(h/c)u|_{x=0} \quad (8)$$

where $n=c_g/c$. For the natural boundary condition described by Eq.(6), we have the following solution

$$\eta(x,t)=\eta_*(x-c_g t)-n\eta_*[n(x-ct)]. \quad (9)$$

In addition to the bounded long waves $\eta_*(x-c_g t)$, free long waves, whose magnitude is $-n$ times of the bound one, are generated and propagate with the phase speed \sqrt{gh} .

To control the free long waves, in particular, to suppress the free long waves, one put $f=0$ in Eq.(8) so that the following extra board motion is added to the motion for the group of primary waves.

$$u|_{x=0}=(c_g/h)\eta_* \quad (10)$$

To introduce arbitrary free long waves $f(x-ct)$ at the wave maker, one should further add

$$u|_{x=0}=(c/h)f. \quad (11)$$

Generation of free long waves for an initial value problem is also discussed in Mizuguchi(1995).

3. NUMERICAL AND EXPERIMENTAL CONFIRMATION

Numerical as well as physical experiments are conducted to confirm the theoretical analysis.

For numerical simulation, Boussinesq equation is employed. Boussinesq equation can describe weakly nonlinear and weakly dispersive waves and is known to be able to simulate well the water waves in shallow water up to the second-order phenomena. We follow the normal procedure in the numerical coding, that is, the staggered

mesh in space and the leap-frog method in the time stepping. One advantage of the numerical simulation is that the boundary condition at the wave maker is exactly specified by the horizontal velocity as is done in the analysis.

Laboratory experiment is conducted in a flume of 40m long, 30 cm wide with a piston-type wave maker. The displacement of the wave maker board is calculated by numerically integrating the corresponding velocity at $x=0$. The displacement of the wave maker board is assumed to be negligibly small.

A group of waves are generated by introducing the velocity

$$u_p = A(t) \cos(2\pi t/T) \quad (12)$$

at $x=0$, where u_p is the vertically uniform horizontal velocity. $A(t)$ is a slowly-varying amplitude function and is given by

$$A(t) = (a_{\max}/2) [1 - \cos(2\pi t/T_g)] \quad 0 < t < T_g \text{ otherwise } A=0. \quad (13)$$

Here T the period of the primary waves, T_g the duration of the wave group, and a_{\max} is the maximum amplitude of primary waves. In the experiments, T , T_g and a_{\max} are chosen to be 1.0 s, 8.0 s and 0.5 cm respectively. The small value of the amplitude a_{\max} assures the small amplitude assumption for the primary waves and also justify the way to convert the velocity to the motion of a wave maker. Water depth is 10 cm so that Boussinesq equation is applicable.

First we generate the group of waves in a traditional way, or without any consideration on second-order phenomena. Figure 1 shows comparison of the surface profiles among measured, simulated and of analysis. Overall agreement is very good. The amplitudes measured in the physical experiment show a little decay while propagating. Linear modulation of the wave group, which is not long enough, might be responsible for the decay, although frictional loss may not be negligible. Figure 2 shows long waves obtained by low-pass filtering the data in Fig. 1. All three envelopes agree very well, revealing the separation process of the free long wave, generated at the wave maker, from the bound long wave. Near the wave maker they almost cancel each other to give zero velocity at the wave maker. Some distance from the wave maker the free long wave, which is a positive hump in this case, starts to emerge as it leads the bound long waves with faster phase velocity. The free and bound long waves may be completely separated after travelling long distance, though nonlinear effects may come in to play non-negligible role there.

Next we generate a group of waves with the extra velocity of Eq.(10) or the corresponding paddle motion, which is shown in Fig. 3. Figure 4 shows comparison of the three envelope profiles. As is in Fig. 1, they show good agreement. The measured maximum amplitude in the laboratory experiment is a little smaller than 0.5 cm even very near the wave maker. This may be caused by some mechanical loss and/or the displacement of the paddle to account for Eq.(10). It is noted that there is little difference between the data plotted in Fig. 1 and in Fig. 4.

Fig. 5 shows long waves obtained from the data in Fig. 3. Again three profiles are in good agreement, though they are quite different from those in Fig. 2. The analytical result in Fig. 5 is the Longuet-Higgins and Stewart solution (hereafter abbreviated LHS solution) or Eq.(4). This shows that one can realize the LHS solution by introducing the velocity of bound waves

Fig. 1 Surface profiles of normally generated grouping waves

Thick solid lines : laboratory experiment

Thin lines : numerical simulation (Boussinesq equation)

Broken lines : theory (a permanent wave group)

to the wave making. The long waves measured in the physical experiment decrease their magnitude while propagating, as the amplitude of the primary waves also decrease their amplitude. The long waves in Boussinesq model also show a slightly larger difference from the analytical one than those in Fig. 2. The difference may result from the fact that modulation of the wave group is more significant when the free long waves are suppressed. The total magnitude of long waves is larger than that with the free waves and resultant modulation stronger.

It is worthwhile to be stated here that the LHS solution is correct as a solution of the problem and can be realized in an ideal situation. However free long waves, generated at the wave making process as shown in Fig. 2 and/or free long waves generated while wave groups shoals on a sloping bottom as discussed in Nagase and Mizuguchi(1996), contribute to canceling the LHS bound waves which tend to be infinitely large in the very shallow water.

Fig. 2 Long waves obtained by low-pass filtering the data in Fig. 1. Vertical scale is ten-times larger than that in Fig. 1.

Fig. 3 Displacement of the wave paddle

 Broken line ... free long waves suppressed

Fig. 4 Surface profiles of grouping waves with no free long waves

4. CONCLUSIONS

From the results stated above, we can conclude

1) A time-domain analysis to understand the generation of second-order long waves in a laboratory flume is presented.

2) Analytical results are successfully confirmed both numerically and experimentally, showing a way to control the generation of second-order long waves for non-periodic wave group.

3) Even in very shallow water bounded long waves is described by the solution of Longuet-Higgins and Stewart(1962). However the observed long waves may not be so large as predicted by the LHS solution as accompanying free long waves nearly cancels it in reality.

CHAPTER 40

Kinematic Predictions in Large Shallow Water Waves.

Susan Smith¹ & Christopher Swan².

Abstract.

The present paper concerns the description of extreme waves in shallow water, and in particular contrasts the success of two recently developed wave theories (Sobey, 1992 and Baldock and Swan, 1994) to model the maximum water particle velocities arising beneath a highly nonlinear and transient (or unsteady) wave event. To achieve these comparisons exact numerical calculations were undertaken using the time-stepping procedure outlined by Dold and Peregrine (1984). Comparisons between this numerical “data” and the kinematics models confirm the importance of both the non-linearity and the unsteadiness, and further suggest that the nature of the wave-wave interactions has important implications for the accuracy of the kinematics predictions. In particular, the local Fourier series solution (Sobey, 1992) is shown to be unable to model the global wave frequency-difference terms, and therefore tends to over-predict the fluid velocities beneath the still water level. In contrast, the double Fourier series solution (Baldock and Swan, 1994) explicitly incorporates both the nonlinearity and the unsteadiness of the wave, and typically provides a good description of the flow field beneath the still water level. However, this solution is limited in terms of the total number of Fourier components included, and consequently the largest velocities arising close to the water surface are typically under-predicted in the largest wave events. Nevertheless, both kinematics models provide a significant improvement over the existing design solutions.

Introduction.

Within both coastal and offshore engineering the identification of an appropriate wave climate represents a fundamental input into the design process. If,

¹Research student & ²lecturer, Department of Civil Engineering, Imperial College, London, SW7 2BU. United Kingdom.

as is usually the case, design calculations are required to assess the applied fluid loading, the stability and transport of bed material, or the potential for over topping, a second and equally important aspect of the design involves the prediction of the water particle kinematics. In respect of this latter point current design procedures are either based upon a non-linear steady wave theory, or an unsteady linear theory. In the first of these cases the wave model incorporates the non-linearity of the wave motion, but neglects the unsteadiness or the transient nature of the sea state. Indeed, within this category the most commonly applied model is based upon a fifth-order Stokes' solution (Fenton, 1985). In this case a large wave is characterised by a representative wave height (H) and a wave period (T), and it is assumed that the wave forms part of a regular wave train which propagates without change of form. Alternatively, a higher-order stream function solution (Dean, 1965) may also be applied in which the wave profile is either specified in terms of H and T , or the series solution is matched to a measured surface profile, $\eta(t)$, using some form of constrained minimisation. However, in both applications of the stream function solution the wave is assumed to propagate without change of form, and thus the dispersive properties are neglected.

In contrast, a linear random wave theory recognises the fact that a realistic sea state comprises a large number of wave components, many of which may be described as free waves and thus travel at a phase velocity (c) which is only dependent upon the wave period (T) and the water depth (d). Solutions of this type fall into the second category (noted above) in that they partially incorporate the unsteadiness of the sea state, but are restricted in the sense that they neglect the nonlinearity. Indeed, in solutions of this type all terms of order a^2k^2 and above (where a is the wave amplitude and k is the wave number) are neglected. As a result, such solutions make no attempt to model the nonlinear wave harmonics which include both the higher-order Stokes' terms and the nonlinear wave-wave interactions arising between two or more frequency components (Longuet-Higgins and Stewart, 1960).

Unfortunately, it is now widely recognised that the largest waves within a sea state are both nonlinear and unsteady. As such, they do not arise as part of a regular wave train, but occur as individual events within a random, or irregular, sea state. If one considers a typical broad-banded spectrum in deep water, frequency dispersion provides a plausible explanation for the evolution of the largest wave events. In this case the extreme events are produced by constructive interference when a large number of wave crests arise at one point in space and time. Indeed, recent field measurements undertaken at the Tern Platform (Rozario et al, 1993) have confirmed the validity of this argument, and have demonstrated that the most probable shape of the largest wave is closely related to the auto correlation function of the underlying wave spectra (Tromans et al, 1991).

However in intermediate and shallow water depths the evolution of the largest waves is perhaps more complicated. For example, although frequency

dispersion provides an effective method of focusing wave energy in all but the shallowest water depths ($kd < 0.4$), large waves may also be related to changes in the local bathymetry (Peregrine, 1983); the interaction with uniform and depth-varying currents (Swan, 1990, 1992); or the occurrence of side-band instabilities (Benjamin and Feir, 1969). Although these effects are entirely separate, they will each produce extreme events which are both highly non-linear and unsteady. As a result, it is clear that the present design solutions do not model the fundamental characteristics of the largest wave events. Indeed, previous work presented by Baldock and Swan (1994) and Baldock, Swan and Taylor (1996) has considered large deep water waves, and has demonstrated that the underlying kinematics can only be predicted if both the nonlinearity and the unsteadiness is taken into account. However, the relative importance of these effects in shallow water remains unclear. For example, recent experimental observations (Baldock and Swan, 1996) have shown that the transfer of energy to the nonlinear harmonics is strongly dependent upon the water depth. However, these results are primarily concerned with intermediate water depths, and only contrast the measured data with one fully nonlinear unsteady wave model. The present paper will address this point, and will consider the extent to which recently developed wave theories are able to model extreme shallow water waves. In particular, exact numerical calculations based on the time-stepping procedure outlined by Dold and Peregrine (1984) will be used to contrast the kinematic models presented by Sobey (1992) and Baldock and Swan (1994).

Kinematics Models.

In recent years the possible inadequacy of the existing design solutions has been recognised, and in particular two alternative wave models have been proposed. In both cases these models are based upon a time-history of the water surface elevation measured at one spatial location, $\eta(t)$, and are thus appropriate to design calculations. In particular, they represent a significant improvement over the existing design solutions in that they attempt to incorporate both the nonlinearity and the unsteadiness of the wave motion. The first model, proposed by Sobey (1992) is based upon a local Fourier series approximation originally outlined by Fenton (1992). Within this solution the time-history of the water surface elevation, $\eta(t)$, is subdivided into a large number of local windows within which the surface profile is assumed to be locally steady. This does not imply that the entire wave form propagates without change of form, merely that a small section of the wave profile is locally steady during the time interval that it passes the measuring point. If (x, z) represent the usual Cartesian co-ordinates in which $z=0$ corresponds to the still water level, and $z=-d$ represents the bottom boundary, a velocity potential ϕ may be defined within each window such that:

$$\phi(x, z, y) = C_E x + \sum_{j=1}^J A_j \frac{\cosh(jk(d+z))}{\sinh(jkd)} \sin(jkx - j\omega t) \quad (1)$$

where C_E is the co-flowing Eulerian current, ω is the fundamental wave frequency (or $2\pi/T$, where T is the corresponding wave period) and k is the fundamental wave number (or $2\pi/\lambda$, where λ is the wave length). The constant coefficients A_j (for $j = 1$ to J) thus represent the amplitudes of the individual harmonics which are determined by minimising the errors in the free surface boundary conditions. Within this solution the input parameters correspond to the upper limit of the series expansion (or the truncation order J), the local window length (τ), and the time interval between adjacent data describing the surface profile (Δt). Although the minimisation procedure is somewhat involved, and the outcome strongly dependent upon the input parameters, the scheme is computationally efficient, and suitable for use on a standard personal computer.

In contrast, the wave solution proposed by Baldock and Swan (1994) explicitly includes both time and space dependence. This solution is based upon a double Fourier series solution first proposed by Lambrakos (1981), and adopts a velocity potential defined by:

$$\phi(x, z, t) = \sum_{m=1}^M \sum_{n=1}^N \cosh k(z+d) [A_{nm} \cos(k_n x - \omega_m t) + B_{nm} \sin(k_n x - \omega_m t)] \quad (2)$$

In this case the proposed solution incorporates a total of M wave numbers each with M frequency components (where typically $N = M$), such that a total of $2NM$ wave harmonics are included within the overall solution. If T_1 defines some large fundamental period, over which the solution is assumed periodic, the fundamental wave frequency is defined by $\omega_1 = 2\pi/T_1$, and the corresponding wave number (k_1) is calculated using the linear dispersion equation. Having identified these values the solution matrix (k_n, ω_m) is assembled from wave numbers and frequency components which are integer multiples of the fundamental:

$$k_n = nk_1, \quad \omega_m = m\omega_1 \quad (3)$$

The final solution is again based upon a time-history of the water surface elevation measured at one spatial location (i.e. $\xi(t)$ at $x = 0$). In effect the unknown coefficients A_{nm} and B_{nm} , together with the unknown surface profiles at all other spatial locations (i.e. $\eta(t)$ at $x \neq 0$), are determined by a minimisation of the error in the nonlinear free surface boundary conditions arising at all points in space and time. Provided the fundamental period is sufficiently large relative to the dominant (or peak) wave period, an appropriate mix of free waves and bound waves are generated. As a result, the final wave solution deforms in both space and time, and has to date been shown to provide a good description of the wave-induced water particle kinematics arising in deep water (Baldock and Swan, 1994).

To assess the effectiveness of these solutions in intermediate and shallow water depths, we have sought to compare the predicted water particle velocities with

exact numerical calculations based upon the time-stepping procedure outlined by Dold and Peregrine (1984). Previous studies (Johannessen and Swan, 1996) have shown that these and other time-stepping procedures (notably Longuet-Higgins and Cokelet (1976), Fenton and Rienecker (1980) and Craig and Sulem (1993)) are in near-perfect agreement with laboratory data, and thus provide an excellent benchmark with which to test potential design solutions. At this stage it should be noted that these time-stepping solutions, although exact, are not appropriate for typical design calculations since they are based upon initial conditions which require a spatial representation of both the water surface elevation and the velocity potential at the water surface (i.e. $\eta(x)$ and $\phi(x)$ at $z=\eta$). This information is seldom available in a laboratory study, and never available from field data.

Test Conditions.

To assess the effectiveness of the wave solutions three test cases were considered in which an extreme wave group was produced in a water depth of $d=0.7\text{m}$, 0.3m , and 0.15m respectively. In each case the underlying frequency spectrum was broad-banded (at a laboratory scale), and consists of a total of 29 frequency components which were each of equal amplitude and equally spaced within the period range $0.6 \leq T \leq 1.4\text{s}$. Expressed in terms of an energy spectrum within the frequency domain this distribution of wave components has a peak frequency at approximately 0.71Hz , and decays according to ω^{-4} . In each of the three test cases the initial conditions used to commence the time-stepping procedure were such that the wave energy was fully dispersed within the spatial domain. On this basis a linear wave theory was used to provide both the surface elevation $\eta(x)$ and the magnitude of the velocity potential at the surface ($\phi(x)$ at $z=\eta(x)$). However, the relative phasing of the wave components was such that after a large number of time-steps (typically larger than 100) frequency dispersion produced a focusing of wave energy such that a large highly nonlinear wave event was generated at one point in space and time. The numerically predicted horizontal velocities, $u(z)$, arising beneath this large wave event were chosen as an appropriate yard-stick with which to judge the success of the kinematics models discussed previously.

Discussion of Results.

Figures 1a-1c concern the broad-banded spectrum ($0.6\text{s} \geq T \geq 1.4\text{s}$) in the three different water depths ($d = 0.7\text{m}$, 0.3m , and 0.15m respectively), and describes the time-history of the water surface elevation, $\eta(t)$, predicted at the spatial location at which the maximum crest elevation arises. In each of these cases the exact numerical calculations (following Dold and Peregrine, 1984) are compared to both a linear wave solution and a second-order approximation based upon the sum of the interactions identified by the Longuet-Higgins and Stewart (1960). These latter two

models are based upon the twenty nine free waves which were initially implemented within the time-stepping procedure, and are thus very different to either a linear random wave theory or a hybrid second-order solution (Stansberg, 1993) based upon a Fourier analysis of the measured water surface elevation. To facilitate comparisons of this type the time base on the horizontal axis has been shifted such that (for each wave solution) the maximum crest elevation arises at $t=0$. Comparisons of this type, and in particular the difference between the exact numerical calculations and the linearly predicted results, demonstrate the importance of the nonlinear wave-wave interactions. For example, in deep water conditions ($d=0.7\text{m}$) figure 1a suggests that a linear solution underestimates the maximum crest elevation by approximately 25%; while the inclusion of the second-order terms only accounts for approximately 30% of the total nonlinear effects. These results are consistent with deep water data presented by Baldock and Swan (1994).

However, comparisons with figures 1b and 1c clearly suggest that the nature of the nonlinear contribution differs significantly with the water depth. For example, in figure 1b (corresponding to a water depth of 0.3m) the nonlinear increase in the maximum crest elevation is reduced to approximately 20%; while the second-order interactions account for approximately 50% of this increase. Furthermore, if one considers the shallow water depth ($d=0.15\text{m}$ in figure 1c) there is almost no nonlinear increase in the maximum crest elevation when compared to a linear theory based upon the component free waves. However, the maximum crest elevation (relative to linear theory) does not alone provide an appropriate measure of the nonlinearity of a wave form. Indeed, if one considers the steepness of the wave profiles outlined in figures 1a-1c, there is almost no change depending on the water depth.

An explanation for this effect lies in the nature of the nonlinear wave-wave interactions and, as will be indicated below, these also have implications for the ability of the nonlinear wave models to accurately predict the water particle kinematics. If one considers the second-order solution originally outlined by Longuet-Higgins and Stewart (1960), the nonlinear wave-wave interactions may be subdivided into two categories. Firstly, there are the so-called frequency-sum terms which correspond to a transfer of energy into the short wave or high frequency components. These may be interpreted as representing local nonlinear wave-wave interactions, and are responsible for increases in the local energy density as well as the increase in the maximum crest elevation. In contrast, the second category of interactions are represented by the so-called frequency-difference terms. These correspond to a transfer of energy into the long wave, or low frequency, wave components. These interactions may be interpreted as representing the global changes which are, in particular, responsible for the set-down beneath the wave group.

Before considering the relative magnitude of these varying nonlinear wave-wave interactions, we will first contrast the ability of the nonlinear kinematics models discussed previously (namely Sobey, 1992 and Baldock and Swan, 1994) to

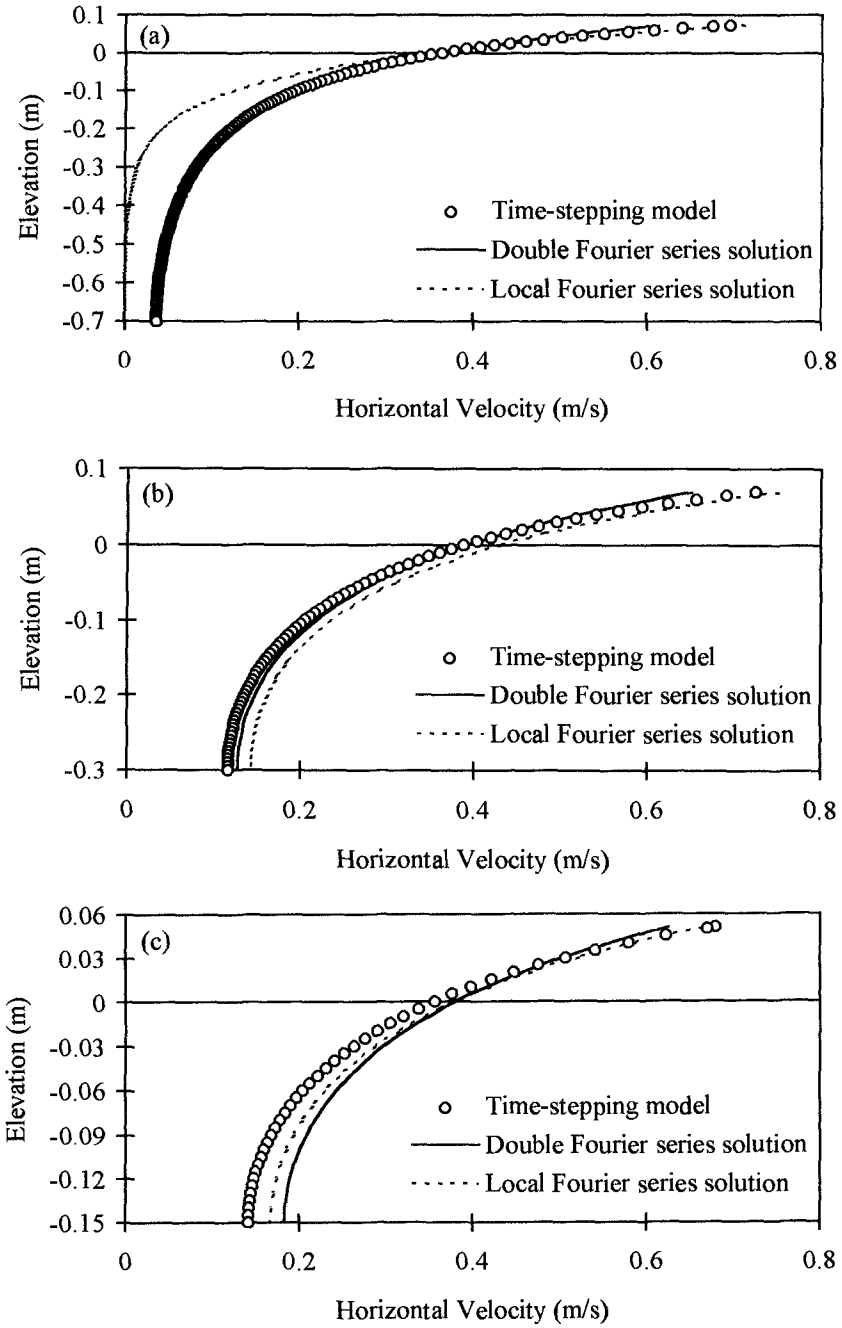

Figures 1a-1c. Time-histories of the water surface elevation, $\eta(t)$.
 (a) Deep water: $d=0.7\text{m}$ (b) intermediate water: $d=0.3\text{m}$ (c) shallow water: $d=0.15\text{m}$.

reproduce the exact numerical calculations provided by Dold and Peregrine (1984). Figures 2a-2c again relate to the broad-banded spectrum in three different water depths, and describe the depth variation in the maximum horizontal velocity, $u(z)$, arising beneath the largest wave crest (i.e. $t=0$ in figures 1a-1c). Since the kinematics models are both based upon a least squares fit to the predicted nonlinear surface profile, it may be assumed that in all cases the surface profile, $\eta(t)$, is well represented by these models. Indeed, if this were not the case the underlying kinematics could not be confidently predicted. However, despite near-perfect agreement with the surface profile, the predicted kinematics show considerable variation. For example, in the deep water case ($d=0.7\text{m}$ on figure 2a) the double Fourier series solution (Baldock and Swan, 1994) provides a very good description of the nonlinear kinematics up to the still water level, but slightly underestimates the maximum velocities within the vicinity of the water surface. In contrast, the local Fourier series solution (Sobey, 1992) provides an excellent description of the kinematics within the wave crest, but wildly underestimates the horizontal velocities beneath the still water level.

The reasons for these discrepancies are clear. Firstly, the double Fourier series solution is based upon a fifteenth order approximation (or $N=M=15$ in equation 2), and thus incorporate a total of 225 harmonics. However, since the peak of the input spectrum arises at $N=M=3$, the accuracy of the solution is approximately equivalent to a fifth-order Stokes' solution. Since the wave events under consideration are extremely steep (within 5% of their breaking limit), it is not at all surprising that this level of approximation underestimates the near-surface crest kinematics. Unfortunately, the nature of this solution is such that small increases in the order of the approximation (i.e. $N=M=18$) provides little by way of increased accuracy, but has a large effect upon the computational requirements. Indeed, significant increases in the order of the approximation become practically unrealistic. In contrast, the local Fourier series solution is only fitted to a small section of the wave profile in any one window, and in the vicinity of the largest crest the curvature of the surface profile is such that the solution locates a large proportion of the wave energy in the high frequency range. As a result, it obtains a good description of the surface profile and the near-surface kinematics, but the predicted velocities decay too rapidly with depth (as is consistent with high frequency wave components), and the solution thus underestimates the kinematics at all points beneath the still water level.

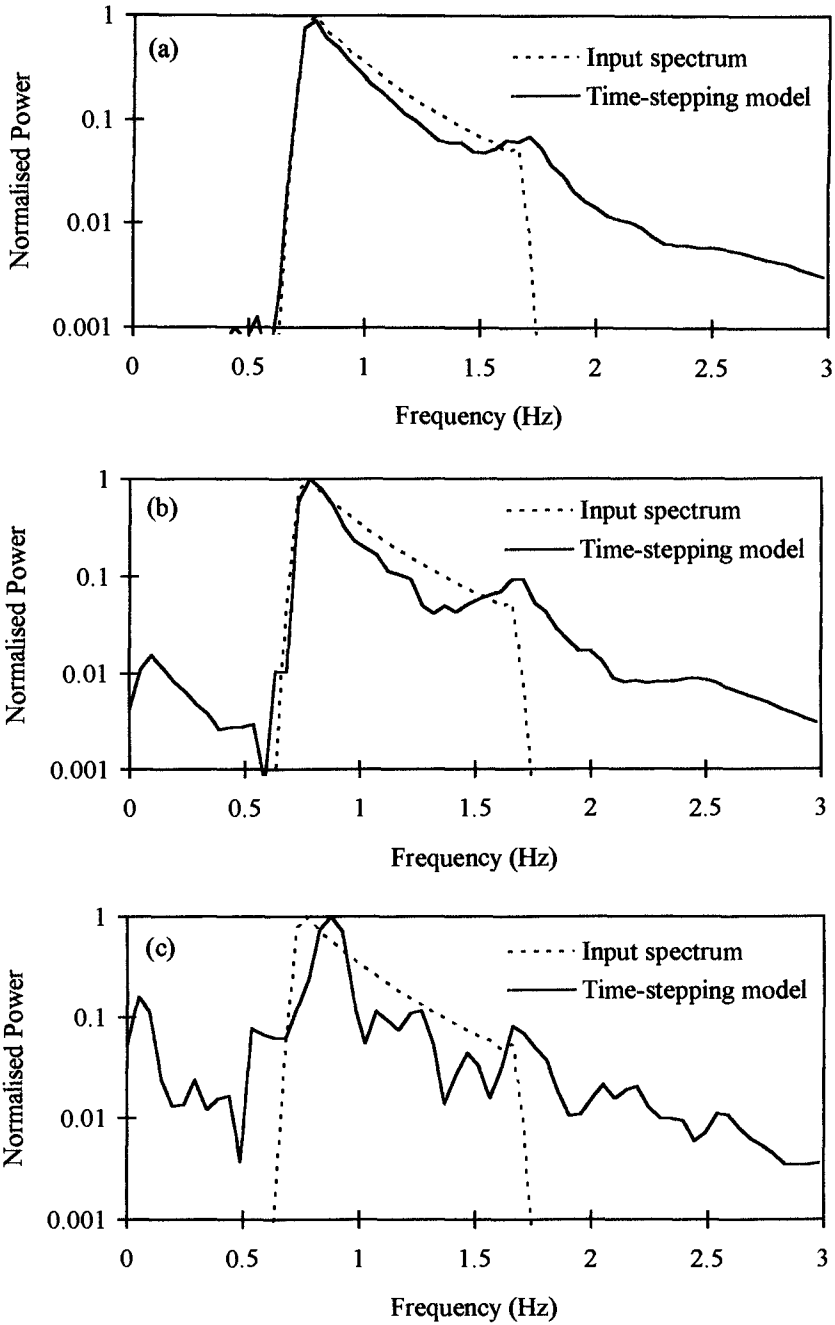

A similar pattern of results is also presented in figures 2b and 2c corresponding to water depths of $d=0.3\text{m}$ and 0.15m respectively. In each of these cases (and indeed many other cases which have also been investigated) the local Fourier series solution provides a good description of the maximum horizontal velocities arising close to the water surface. However, with increasing depth beneath the surface, the description becomes poor. In contrast, the double Fourier series solution provides reasonable agreement over most of the water column, but consistently under-predicts the largest velocities arising close to the water surface.

Figures 2a-2c. Horizontal velocities beneath the wave crest, $u(z)$.
(a) Deep water: $d=0.7\text{m}$ (b) intermediate water: $d=0.3\text{m}$ (c) shallow water: $d=0.15\text{m}$.

To explain the varying success of these solutions, and in particular its dependence on the water depth, the normalised power spectra derived from a Fourier transform of the numerically predicted water surface elevations are presented on figures 3a-3c. In the deep water case (figure 3a) it is clear that the dominant nonlinear interactions generate high frequency or frequency-sum terms which in turn produce a large increase in the local energy density in the vicinity of the large wave crest. This is consistent with the experimental study presented by Baldock, Swan and Taylor (1996), and explains the large local increase in the maximum water surface elevation. However, as the water depth reduces it becomes apparent that there is a larger transfer of energy into the low frequency, or frequency-difference, terms. These results are consistent with the analysis of measured wave records presented by Mansard et al (1988), and with recent laboratory data presented by Baldock and Swan (1996). The relative importance of the total nonlinearity within the numerically calculated wave profiles is further considered in figure 4a. Within this figure each water depth has been considered separately, and the total transfer of energy out of the input range (ie. $0.6 \leq T \leq 1.4$ or $4.5 \leq \omega \leq 10.5$) has been determined from the wave spectra given in figures 3a-3c. At first sight these results are perhaps unexpected since it suggests that the shallow water case ($d=0.15\text{m}$) represents the most nonlinear wave form, at least defined in terms of energy transfers, despite the fact that the maximum crest elevation in this case shows no significant increase above the linearly predicted value (figure 1c). However, the reasons for this are clarified in figure 4b where the relative importance of the local and global nonlinearity is addressed. In this case the transfer of energy into the high and low frequencies are expressed as a percentage of the total energy transferred out of the input range for each water depth. These results clearly suggest that in deep water the local nonlinearity is dominant; while a reduction in the water depth leads to an increase in the importance of the frequency-difference terms, and a reduction in the importance of the frequency-sum terms. As a result, in the shallow water case ($d=0.15\text{m}$) the transfer of energy into the frequency-difference terms (or global interactions) is larger than the transfer of energy into the frequency-sum terms (or local interactions).

This variation in the nature of the nonlinearity explains the success (or otherwise) of the kinematics models. For example, the double Fourier series solution is based upon a best fit to a measured (or in this case predicted) time-history of the water surface elevation which includes several complete wave forms. As such, it is able to resolve both the local and the global nonlinearity, and is only restricted in the sense that the total number of harmonics is small when compared to the peak of the wave spectrum. As a result, this solution will give satisfactory results provided the transfer of energy to either the high frequencies or the low frequencies is not too large. For example, if the local nonlinearity is very strong the double Fourier series solution will typically underestimate the maximum horizontal velocity arising close to the water surface (figure 2a); while if the global nonlinearity is excessive, this solution will typically underestimate the set-down beneath the wave group, and will therefore tend to overestimate the horizontal velocities arising close to the bottom boundary (figure 2c). In contrast, the local Fourier series solution is fitted to a small section of

Figures 3a-3c. Normalised power spectra based on predicted $\eta(t)$.

the water surface profile within an individual window. As a result, it can successfully model the high frequency, or local nonlinearity, since this will determine the local curvature of the surface profile. However, given the input in any one window, it is unable to resolve the global nonlinearity, since the window length is significantly shorter than the length-scale appropriate to the set-down beneath the wave group. As a result, in those cases where the global nonlinearity is important, one would typically expect the local Fourier series solution to overestimate the velocities beneath the still water level (figures 2b and 2c).

Concluding Remarks.

The present paper has considered the description of highly nonlinear and unsteady (or transient) wave events, and has demonstrated that the nature of the nonlinear wave-wave interactions is strongly dependent upon the water depth. In particular, in deep water the exact numerical calculations indicate that the local nonlinear wave-wave interactions, corresponding to the frequency-sum terms, are dominant. However, as the water depth reduces the global nonlinearity, represented by the frequency-difference terms, become progressively more important. This result has important implications for the prediction of the underlying kinematics. For example, a double Fourier series solution (Baldock and Swan, 1994) is limited in respect of the total number of Fourier components which can practically be included; while the local Fourier series solution is unable to model the global non-linearity and thus becomes less effective in shallow water. However, despite these reservations, it should be stressed that these models will typically provide an improved description of the water particle kinematics when compared to the existing design solutions which either ignore the unsteadiness of the wave form, or the nonlinearity. In particular, the double Fourier series solution can accurately incorporate both the increased crest-trough asymmetry due to the local nonlinearity, and the set-down beneath the wave group due to the global nonlinearity, provided the extreme wave event is not too close to its breaking limit.

ABSTRACT

The results of a field experiment aimed at investigating the evolution of fetch limited waves in water of finite depth are presented. In particular, non-dimensional growth curves, the parametric form of the one dimensional spectrum and the directional spreading of the spectrum are investigated.

INTRODUCTION

Commencing with the cornerstone JONSWAP experiment (Hasselmann et al., 1973), the investigation of the evolution of deep water wind generated ocean waves has been a common theme. Although this case represents a very idealized situation, the resulting evolution provides valuable insight into the complex physics of wind wave evolution. In addition, the resulting non-dimensional growth curves and parametric spectral forms have proved a valuable aid to preliminary engineering design and for use in the validation of comprehensive spectral models.

The limitation of such studies to deep water is restrictive, particularly when it is considered that a significant percentage of coastal engineering works are in areas where finite water depth will influence the resulting wave field. Despite the obvious requirement, there exists no comprehensive counterpart to JONSWAP (Hasselmann et al., 1973) in finite depth water.

This paper presents the results of such an experiment. The evolution of the wave spectrum has been measured at a number of points along a shallow lake. The relatively simple geometry and bathymetry of the lake and the absence of contaminating swell results in a near ideal test basin in which to investigate fetch limited growth in finite depth water.

²Fugro-Inpark, P.O. Box 3000, 2260 DA Leidschendam, The Netherlands

The paper investigates three basic areas of finite depth fetch limited evolution: the development of non-dimensional energy and non-dimensional peak frequency with fetch, the one dimensional spectral form and directional spreading.

DESCRIPTION OF EXPERIMENT

The site chosen for the present experiment was Lake George (see Figure 1). The lake is approximately 20 km long by 10 km wide and has a relatively uniform bathymetry with an approximate water depth of 2 m. A series of 8 measurement stations were established along the long North-South axis of the lake as shown in Figure 1. With the exception of Station 6, the sites consisted of minimum blockage space frame towers, designed to provide minimum contamination to either wind or wave measurements made from the towers. The central site, Station 6, consisted of a large platform with temporary accommodation for the research team. Each of the sites was instrumented with a surface piercing Zwarts poles. In addition, cup anemometers at a reference height of 10 m were located at Stations 2, 4, 6, 7 and 8. Air temperature and relative humidity and water temperature were also measured at Stations 2, 6 and 8. A spatial array consisting of 7 Zwarts poles was established adjacent to the platform at Station 6 to provide high resolution measurements of the directional wave spectrum.

NON-DIMENSIONAL GROWTH CURVES

It is convenient to represent the data in terms of the non-dimensional variables: non-dimensional energy, $\epsilon = g^2 E / U_{10}^4$, non-dimensional frequency, $\nu = f_p U_{10} / g$, non-dimensional fetch $\chi = gx / U_{10}^2$ and non-dimensional depth $\delta = gd / U_{10}^2$ where g is gravitational acceleration, E is the total wave energy or variance of the wave record, f_p is the frequency of the spectral peak, d is the water depth, x is the fetch and U_{10} is wind velocity.

Figures 2 and 3 show scatter plots of ϵ (Figure 2) and ν (Figure 3) verses χ . The data have been partitioned into discrete intervals of δ . Figures 2 and 3 show data in the range $\delta = 0.2 - 0.3$. A preliminary investigation of the north/south data indicated that the data which conformed to deep water conditions was consistent with previous deep water growth law formulations. In particular, ϵ was well modeled by the JONSWAP relationship (Hasselmann et al., 1973), $\epsilon = 1.6 \times 10^{-7} \chi$ and ν by the Kahma and Calkoen (1992) form, $\nu = 2.18 \chi^{-0.27}$.

Noting these deep water asymptotic limits to the data, a nonlinear least squares analysis of the data yielded the model

Figure 1: Map of the Lake George experimental site. The measurement locations are labelled S1 to S8. Data were transmitted to the Base Station on the western shore of the lake where it was logged under computer control. The contour interval is 0.5 m, with the maximum contour value 2 m.

$$\varepsilon = 3.64 \times 10^{-3} \left\{ \tanh A_1 \tanh \left[\frac{B_1}{\tanh A_1} \right] \right\}^{1.74} \quad (1)$$

where

$$A_1 = 0.493\delta^{0.75} \quad (2)$$

$$B_1 = 3.13 \times 10^{-3} \chi^{0.57} \quad (3)$$

and

$$\nu = 0.133 \left\{ \tanh A_2 \tanh \left[\frac{B_2}{\tanh A_2} \right] \right\}^{-0.37} \quad (4)$$

where

$$A_2 = 0.331\delta^{1.01} \quad (5)$$

$$B_2 = 5.215 \times 10^{-4} \chi^{0.73} \quad (6)$$

Equations (1) and (4) are shown in Figures 2 and 3 respectively. As these figures contains data for a finite range of δ (ie. $\delta = 0.2 - 0.3$), two curves are shown, one for each of the extremes of δ for that figure. Generally, the proposed

Figure 2: A scatter plot of non-dimensional energy, ϵ against non-dimensional fetch, χ . Only data with values of non-dimensional depth, δ between 0.2 and 0.3 are shown. The north/south data are shown as the large dots and the lower quality east/west data as the small dots. Equation (1) is shown for the two extremes of δ (ie. 0.2 and 0.3) by the two dashed lines. The deep water asymptotic form of Equation (1) is shown as the solid line.

relationships [(1) and (4)] approximate the data well. As with all previous field measurements of this type there is some data scatter.

At short non-dimensional fetch the waves are in deep water and approach the deep water asymptotic limits which are consistent with the numerous previous deep water data sets. As the non-dimensional fetch increases, the effects of the finite water depth become more pronounced and the data progressively deviate from the deep water limit. At relatively large values of non-dimensional fetch, further spectral development ceases as shown by the “plateau” regions of the curves in Figures 2 and 3. Rather than there being a single universal growth curve, there are a family of curves, one for each value of non-dimensional depth.

Lake George is approximately twice as long as it is wide and whether this aspect ratio limits the wave development along the north/south fetch must be addressed. To investigate this point, cases for which the wind direction was approximately perpendicular to the long east and west boundaries of the lake were extracted from the full data set. As there are no measurements of wind speed

Figure 3: A scatter plot of non-dimensional peak frequency, ν against non-dimensional fetch, χ . Only data with values of non-dimensional depth, δ between 0.2 and 0.3 are shown. The north/south data are shown as the large dots and the lower quality east/west data as the small dots. Equation (4) is shown for the two extremes of δ (ie. 0.2 and 0.3) by the two dashed lines. The deep water asymptotic form of Equation (4) is shown as the solid line.

along the fetch for these cases, only data from Station 6, where the wind was always measured have been considered. As these east/west events are common, we can be very selective with the data, retaining only those cases for which the wind direction is within $\pm 10^\circ$ of normal to the respective shore lines. This east/west data set is also shown in Figures 2 and 3. Since there is no detailed information to determine the development of the wind field with fetch for these cases and since there is moderately elevated land to the east and west of the lake (compared with north/south which is quite flat) the east/west data set is considered to be of inferior quality to the north/south data set. Nevertheless, the east/west data set is consistent with the north/south data, confirming that the lake geometry has no significant influence on the results. It should be noted that there is only a relatively small range of values of χ for each selected range of δ for the east/west data, since all data is obtained from only a single dimensional fetch of approximately 5 km. Also, since the east/west data is believed to be of lesser quality than the north/south data, it was not used in the nonlinear least squares curve fit used to develop (1) and (4).

SPECTRAL EVOLUTION

Bouws et al. (1985) proposed the TMA spectral form for the representation of wind generated waves in water of finite depth

$$E(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \exp \left[\frac{-5}{4} \left(\frac{f}{f_p} \right)^{-4} \right] \cdot \gamma \exp \left[\frac{-(f-f_p)^2}{2\sigma^2 f_p^2} \right] \cdot \Phi \quad (7)$$

and

$$\Phi = \left\{ \frac{[k(f, d)]^{-3} \frac{\partial k(f, d)}{\partial f}}{[k(f, \infty)]^{-3} \frac{\partial k(f, \infty)}{\partial f}} \right\} \quad (8)$$

Based on the wavenumber scaling arguments implicit in the TMA spectral form, Bouws et al. (1985, 1987) speculated that the spectral parameters should be functions of the non-dimensional wavenumber, $\kappa = U_{10}^2 k_p / g$, where k_p is the wavenumber of the spectral peak. To investigate this dependence with the present data set, the spectral parameters of α , γ and σ are presented as functions of κ in Figures 4, 5 and 6, respectively. As with previous studies of spectral evolution, there is significant scatter in the data.

Figure 4: Values of the parameter α as a function of non-dimensional wavenumber, κ . The solid line is a least squares fit to the data [Equation (9)]. The TMA result is shown by the dashed line and the JONSWAP form, transformed from frequency to wavenumber space, by the dash-dot line.

Figure 5: Values of the peak enhancement parameter, γ as a function of non-dimensional wavenumber, κ . The horizontal line represents the data mean.

Within the data scatter, a relationship between α and κ is clear, with α an increasing function of κ (see Figure 4). A least squares fit to the data yields the power law relationship

$$\alpha = 0.0091\kappa^{0.24} \quad (9)$$

Equation (9) is shown on Figure 4, together with the TMA result, $\alpha_{TMA} = 0.0078\kappa^{0.49}$. Both (9) and the TMA form are consistent with the data. In deep water the general TMA form reverts to that of JONSWAP. The deep water JONSWAP result scales α in terms of the non-dimensional frequency, ν , $\alpha_{JONSWAP} = 0.033\nu^{0.67}$. Assuming a deep water linear dispersion relationship, this result can be converted to wavenumber space, $\alpha_{JONSWAP} = 0.01\kappa^{0.33}$. This JONSWAP result is also shown in Figure 4 and is broadly consistent with the finite depth formulations.

All results are comparable and confirm that the trend towards decreasing values of α with increasing maturity of the waves, already observed in deep water, also holds in finite depth situations.

In contrast to the observable trend in α with κ , no similar result is apparent for either γ or σ . This result is consistent with both TMA (Bouws et al., 1985, 1987) and JONSWAP (Hasselmann et al., 1973). There is, however, significant sampling variability associated with these parameters. The mean values of the

Figure 6: Values of the spectral parameter, σ as a function of non-dimensional wavenumber, κ . The horizontal line represents the data mean.

data set yield $\gamma_{mean} = 2.70$ and $\sigma_{mean} = 0.12$.

DIRECTIONAL SPREADING

Two common models have been proposed to represent the directional spreading of wind waves: $\cos^{2s} \theta/2$ and $\text{sech}^2 \beta \theta$. A number of different techniques have been reported for the fitting of such analytical forms to the data. Mitsuyasu et al. (1975) and Hasselmann et al. (1980) analyzed their buoy data using the Fourier Expansion Method (Longuet-Higgins et al., 1963; Young, 1994) and determined the value of s from the first 2 components of the Fourier expansion. Donelan et al. (1985) compared this approach with one in which the directional form was matched to the half-power points of the measured spreading function. It was argued that matching the half-power points was more meaningful since interest is concentrated on the energetic region of the directional distribution. This technique appeared to reduce the scatter in the data.

In addition to these techniques, application of a nonlinear least squares fit [Levenberg-Marquardt method, Press et al. (1986)] was also investigated with the present data. This least squares approach, was adopted here, together with a Maximum Likelihood Method analysis of the data from the directional array.

Both formulations of the spreading function yield qualitatively similar results,

indicating the spectrum is narrowest at the spectral peak frequency and broadens at frequencies both larger and smaller than the peak value. The $\cos^{2s} \theta/2$ formulation exhibited marginally less scatter than the $\text{sech}^2 \beta \theta$ form and was adopted for further analysis.

A least squares analysis of the directional data yields the following form for the present finite depth data

$$s = \begin{cases} 11 \left(\frac{f}{f_p}\right)^{2.7} & f < f_p \\ 11 \left(\frac{f}{f_p}\right)^{-2.4} & f \geq f_p \end{cases} \quad (10)$$

Equation (10) has been constrained to yield narrowest spreading at $f/f_p = 1$. The scatter in the data is such that the actual point of narrowest spreading cannot be determined with great accuracy. It is clearly, however, in the vicinity of the spectral peak frequency.

Equation (10) is shown in Figure 7 together with the deep water results of Mitsuyasu et al. (1975), Hasselmann et al. (1980) and Donelan et al. (1985). As the results of Mitsuyasu et al. (1975) and Hasselmann et al. (1980) are both wave age dependent, mean values typical of their respective data sets have been used to construct Figure 7 (Mitsuyasu et al., 1975 - $U_{10}/C_p = 1.1$; Hasselmann et al., 1980 - $U_{10}/C_p = 1.4$). As Donelan et al. (1985) provide no functional form expressed in terms of s , the result in Figure 7 was obtained from digitizing the result given in their Figure 30.

The present results are marginally narrower (higher s) than those of both Mitsuyasu et al. (1975) and Hasselmann et al. (1980), they are however significantly broader than the high resolution results of Donelan et al. (1985). As shown by Donelan et al. (1985), the results of both Mitsuyasu et al. (1975) and Hasselmann et al. (1980) are excessively broad due to the instrumentation and analysis technique utilized. The present result [Equation (10)] should have comparable resolving power to the result of Donelan et al. (1985). The inference is that finite depth wind wave spectra are broader than their deep water counterparts. Due to the relatively narrow range of $k_p d$ spanned by the present data set a more emphatic statement cannot be made. At present it is necessary to rely on these two independent data sets (Donelan et al., 1985 - deep water; Lake George - finite depth). There is always some possibility that, in addition to water depth, there are other unknown influences responsible for the different spreading.

CONCLUSIONS

The data set presented in this paper represents the first comprehensive field study of the evolution of fetch limited waves in water of finite depth. The data set is sufficiently comprehensive to fully define non-dimensional growth curves for both energy and peak frequency. In contrast to deep water results, a single growth relationship does not exist for each quantity. Rather, a family of curves result,

Figure 7: The dependence of the directional exponent s for the present finite depth data as a function of f/f_p [Equation (10)] (thick solid line). Also shown for comparative purposes are previous deep water data sets: Mitsuyasu et al. (1975) - 'dash dot line'; Hasselmann et al. (1980) - 'dashed line'; Donelan et al. (1985) - 'open circles'.

depending on the non-dimensional depth.

The one-dimensional spectrum has been shown to conform to the TMA form. The spectral parameter α is shown to be a function of the non-dimensional peak wavenumber, κ .

The directional spreading is qualitatively similar to deep water results. The spectra are narrowest at the spectral peak frequency and broaden at frequencies both above and below the peak. Compared with deep water results, finite depth spectra appear to exhibit broader spreading. This is possibly due to the different nonlinear coupling which will exist in finite depth cases.

The present data set is significantly more comprehensive than previous finite depth studies. The results of these previous studies are, however, consistent with the present results. This occurs, despite the fact that a wide range of bed materials exist for the various data sets. As a result, it can be speculated that bed material has little influence on spectral evolution under fetch limited conditions. This is markedly different to other finite depth cases, such as swell attenuation, where the rate of decay is very sensitive to the bed material.

CHAPTER 42

Measurement of Breaking Waves Using Particle Image Velocimetry

Kuang-An Chang ¹ and Philip L.-F. Liu ²

1. Introduction

The water wave breaking problem has been studied for many years. The most popular experimental methods for studying this problem include the flow visualization method and the Laser Doppler Velocimetry (LDV). However, the first method lacks quantitative description and the second method, in general, needs hundreds of measurements to form a flow field. Instantaneous quantitative flow field information is nearly impossible, if these two methods are used. In recent years, the Particle Image Velocimetry (PIV) has been proven to be a powerful tool for two-dimensional instantaneous velocity measurement. Tens to hundreds of velocity measurements using the LDV can be done in only one single measurement using the PIV.

The LDV is the most common tool for non-intrusive velocity measurements. By using the LDV and the phase average method, Mizuguchi (1986) and Okayasu et al. (1986) measured hundreds of points under a plunging breaker on sloping beaches. The flow fields of the mean and turbulence velocity were formed and the vorticity was calculated. In addition, Nadaoka et al. (1989) studied turbulent structures in surf zone using either the phase-averaged method or the moving-averaged method and demonstrated the differences between these two methods. In their work, the strain rate and its principal axes, Reynolds stress and momentum transport were obtained. More recently, a series of papers published by Ting and Kirby (1994, 1995, 1996) attempted to describe the turbulence structure under plunging and spilling breaking waves. In their works, turbulence transport under trough level was studied based on the turbulent kinetic energy equation. All the work mentioned above are based on either the phase or the moving average in turbulence measurements. In other words, experimental studies of wave breaking contain, in general, instantaneous and/or phase-averaged velocity information. As far as the authors know, the ensemble-averaged velocity field is rare for the unsteady problems such as breaking waves. However, the wave period in the

¹Graduate Student, ²Professor, School of Civil and Environmental Engineering, Cornell University, Ithaca, NY 14853

surf zone is not quite constant even for the monochromatically generated waves. The effect of the questionable “phase average” is not yet known.

Beside the LDV technique, the PIV has been used to measure velocity field in recent years. A good review of the PIV technique can be found in Adrian (1991). However, the PIV is still a quite new tool in water-wave related studies. A detailed description of the PIV used in a coastal engineering laboratory is given by Greated et al. (1992). By using PIV, Quinn (1995) studied near-breaking and broken waves on different slopes and compared the results with those of Boussinesq models. Skyner (1996) studied near-breaking plunging waves and compared PIV results with a boundary element model. The instantaneous flow field and the evolution of a quasi-steady breaking wave generated by a submerged airfoil was studied by Lin and Rockwell (1994, 1995). Hornung et al. (1995) measured velocity field and calculated vorticity under a hydraulic jump and used the results to confirm a control-volume prediction. Perlin et al. (1996) studied a plunging breaker in deep water and found the largest particle velocity is about 30% greater than the phase speed. In all the work mentioned above either the instantaneous flow field information or the quasi-steady breaker such as hydraulic jump was reported. No turbulence properties have been obtained.

In this study, deep-water spilling breaking waves are investigated by applying the PIV technique. By repeating the initial and boundary conditions carefully, the mean velocity and turbulence intensity are obtained from ensemble average.

2. Experimental Set-up

Figure 1: Experimental Set-up

The experiments were conducted in a 30m long, 0.6m wide and 0.9m deep wave tank. Waves are generated by a piston-type wavemaker controlled by a Pentium PC. Monochromatic waves were generated by moving the wave board periodically as fol-

lows: $\xi(t) = -A \cos(2\pi ft)$ in which $A = 7.0$ cm and $f = 1.0$ Hz. The error of the wave board motion is less than 0.5% of the stroke if the same motion is repeated. The PC also sent out pulses to trigger a camera so that the time interval between starting wavemaker and triggering camera can be well controlled. The breaking point, defined as the front face of wave becomes vertical, is about 1/3 of the wavelength away from the wave board at $x = 38$ cm with $x = 0$ representing the center of wave board trajectory. The wavelength, calculated from linear theory, is 1.2m. A wave gauge placed close to breaking point at $x = 35$ cm showed that the wave height is 14.5cm. The water depth was kept at 20cm. A light sheet about 1mm in thickness at the center of tank was created by frequency-doubled dual Nd:YAG lasers with a -12.7mm cylindrical lens combined with a 2000mm spherical lens. The lasers have a 200mJ/pulse maximum output energy and 10ns pulse duration in 532nm wavelength. A high resolution digital CCD camera (1316×1034 pixels) connected to a Pentium PC with a frame grabber in it was used to perform the so-called "on line" PIV. The camera equipped with a 60mm focus lens set at f/4.0 was located 2.7m in front of the light sheet. The field of view (FOV) is 40cm which is 1/3 of the wavelength and the resolution is 0.3mm/pixel. The time interval between two laser pulses was 2ms with error less than 1 μ s. In order to resolve the directional ambiguity, a rotating mirror was used (Adrian 1986). The lasers were located on top of the tank. The light sheet was redirected by a mirror to the test section. A black tape was stuck on the bottom of tank to reduce the reflection. The seeding particles were conifer pollen which has mean diameter 54 μ m and their specific weight are close to that of water. The conifer pollen has been proven to be good seeding particles for large scale PIV experiments (Greated et al. 1992). Velocity fields of three areas were measured. The first area is centered at $x = 40$ cm where the wave starts to break. The second and the third area are centered at $x = 70$ cm and $x = 97$ cm, respectively, which are about 1/4 and 1/2 wavelength behind the breaking point. Only the results from the first and third measuring areas are shown here. The ensemble-averaged velocity was obtained by repeating 24 runs at the third measuring area for studying the turbulence generated by broken waves. See figure 1 for the sketch of experimental set-up.

After the image was captured, it was then analyzed by first applying the threshold to remove the noise and then performing the auto-correlation (Lourenco and Krothapalli 1994). The interrogation area for velocity calculation was 64×64 pixels. The timing was calibrated to have an uncertainty less than 1ms. Following the same procedure as the experiments were done, the error in velocity measurement is 1 cm/s which was obtained from the standard deviation of the stationary flow.

3. Results and Discussion

It is known that the particle velocity exceeds phase speed when a wave starts to break. This can be seen from figure 2 and 3. Figure 2 shows the velocity field under the second crest (first one doesn't break) just before breaking. The maximum velocity is 1.08 m/s which is 90% of the phase speed. Figure 3 shows the same wave crest just passing its breaking point. It has maximum velocity 1.52 m/s which is 25% greater than phase speed. Therefore it is expected that the particle velocity will be at least 25% higher than the phase speed during breaking.

Figure 2: The first breaking wave reaching the breaking point at $t = 1.39$ sec with FOV from $x = 21$ to 61 cm and $z = -17.4$ to 14.4 cm (the first measuring area).

Figure 3: The first breaking wave passing the breaking point at $t = 1.50$ sec with the same FOV as figure 2.

Once the wave breaks, it generates lots of air bubbles near the surface which make the measurement very difficult. Due to this reason, we only show velocity field at one particular moment—broken wave crest just passes the third measuring area. At this moment the area has the strongest turbulence and the measurements are not affected by air bubbles. In order to obtain turbulence intensity, 24 measurements with same boundary and initial conditions were taken. Figure 4(a) shows the instantaneous

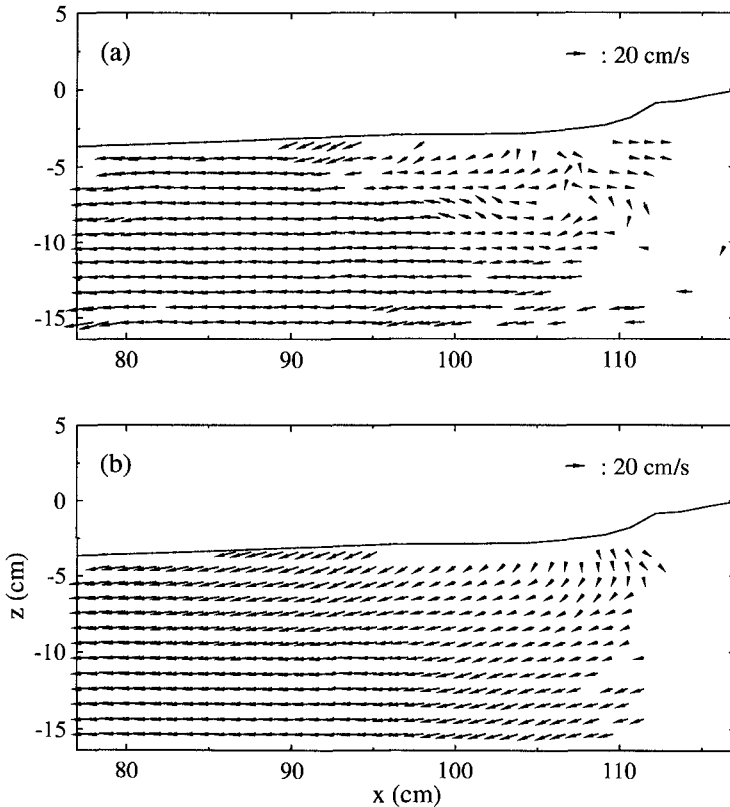

Figure 4: (a) Instantaneous velocity field (b) ensemble-averaged mean velocity field at $t = 3.39$ sec with FOV from $x = 77$ to 117 cm and $z = -16.4$ to 15.4 cm (the third measuring area).

velocity field of one of the 24 measurements at the third measuring area centered at $x = 97$ cm which is about $1/2$ wavelength behind the breaking point. Figure 4(b) shows the ensemble-averaged mean velocity from all 24 measurements. From the figure one

can see that some velocity data are missing near the right side. This is due to the residue air bubbles from the just-passed breaking waves. The linear kriging method (see Agterberg 1970) was used to interpolate and extrapolate the missing data. The

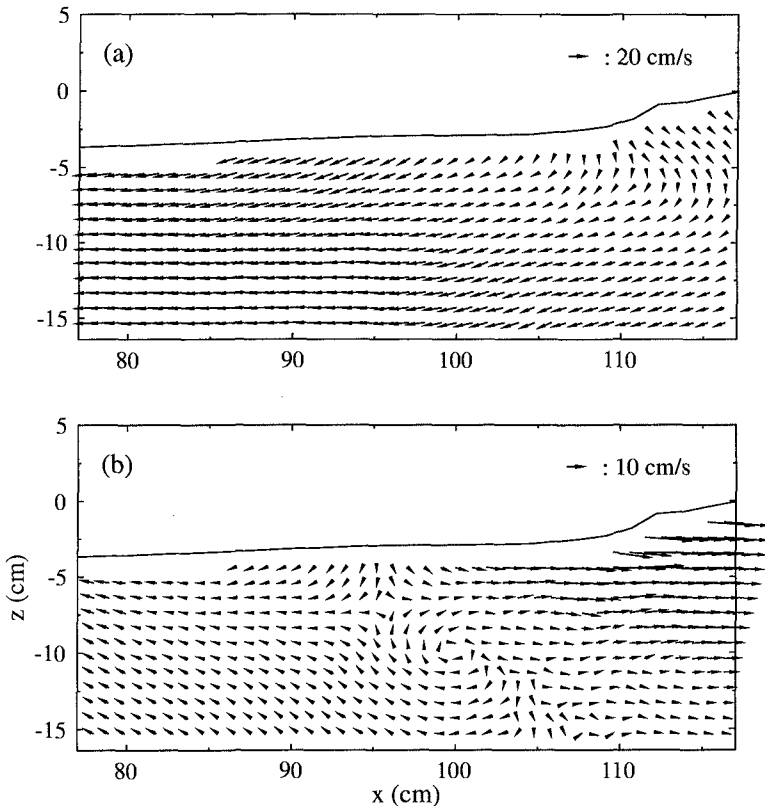

Figure 5: Linear kriging interpolated mean velocity field of figure 4(b) at (a) fixed frame (b) moving with $(-0.2, -0.05)\text{m/s}$.

interpolated velocity field is shown in figure 5(a). Figure 5(b) shows the same velocity field but from a moving frame $(-0.2, -0.05)\text{m/s}$. A clockwise vortex near the center of figure 5(b) can be clearly seen. This vortex is also shown in the later vorticity plot. Figure 6 shows the mean velocity contour in the horizontal and vertical directions. The vorticity of mean flow calculated by applying central finite difference is plotted in figure 7. One can find that the vorticity is negative in most of the area with the order of magnitude in a couple sec^{-1} . Figure 8 shows the turbulence intensity

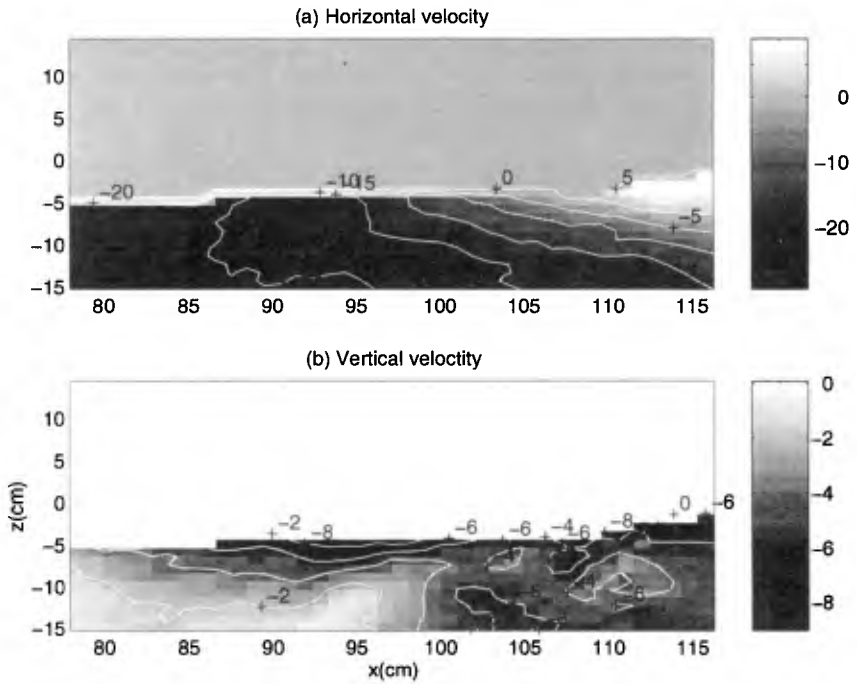

Figure 6: (a) Horizontal (b) vertical velocity (cm/s) of mean flow in the third measuring area.

Figure 7: Vorticity (1/s) of mean flow in the third measuring area.

calculated from the ensemble average. Since the ensemble average is based on large number of samples, the ensemble-averaged turbulence intensity from different number of measurements were compared. It is found, from the contour plot, that the result from 15 measurements or more is close to that from 24 measurements. This may not mean 15 measurements are enough in performing ensemble average, but simply mean that the result from 15 measurements is quite close to that from 24 measurements and 15 measurements may be the minimum requirement. In other words, since it is difficult to obtain many measurements for calculating ensemble average in such kind of unsteady flow, at least 15 or more measurements may be necessary for performing the ensemble average. From figure 8 one can see the distribution of the turbulence

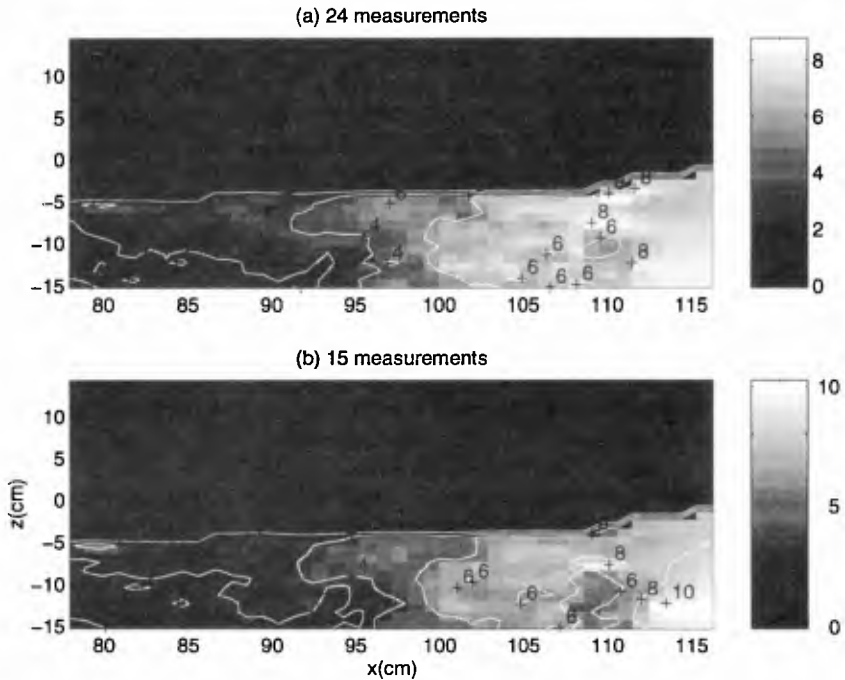

Figure 8: Turbulence intensity (cm/s) calculated from (a) 24 measurements (b) 15 measurements in the third measuring area.

intensity is quite uniform in the vertical direction. The maximum turbulence intensity in figure 8 is 10 cm/s. However, the maximum local mean velocity is only about 30 cm/s. This means that the turbulence intensity is almost the same order of magnitude as the local mean velocity, especially in the region close to the crest.

4. Conclusion

The PIV technique is proved to be a powerful tool in flow velocity measurement. The velocity field of non-breaking and near-breaking waves can be obtained without much difficulty. The maximum particle velocity of the deep-water spilling breaker is close to its phase speed at the breaking point and at least 25% greater than its phase speed during breaking. For broken waves, the mean velocity and turbulence intensity can be obtained from the ensemble average by repeating the same initial and boundary conditions. The turbulence intensity is about the same order of magnitude as the local mean velocity in the region the broken crest just passing through it. However, for the region which has highly concentrated air bubbles, more effort is needed in the future.

CHAPTER 43

Computation of the near-bottom kinematics of shoaling waves

Luc Hamm¹

Abstract

Two practical formulations from Isobe and Horikawa (1982) and Swart and Crowley (1988) are tested against laboratory measurements: seven cases with monochromatic waves and two cases with random waves. It appears that the Isobe and Horikawa formulation can be used with confidence over a large range of wave conditions except in the surf zone when monochromatic waves are considered. The covocoidal theory from Swart and Crowley provides a more comprehensive description of wave properties but abnormal results have been noticed in a few cases. The use of one representative wave height and period in random waves may lead to an underestimation of velocity moments with low steepness waves.

1. Introduction

Shoaling waves (i.e. waves normally transforming over a sloping bottom) exhibit a more or less pronounced vertical asymmetry of the free surface elevation and orbital velocity when approaching the breaking point. Classical wave theories developed by assuming a flat bottom are able to predict the horizontal asymmetry of the waves in deep and intermediate water depths but not such a vertical asymmetry (Soulsby et al, 1993).

In this paper, we shall focus mainly on the prediction of near-bottom (i.e. outside the bottom boundary layer) kinematics of shoaling waves which is of special interest for the computation of sediment transport on the shereface and in the nearshore zone.

¹ Chief Engineer, Sogreah Ingénierie, BP 172, F-38042 Grenoble Cedex 9 - France

Firstly, the main results obtained from published experimental investigations in laboratory will be reviewed. Secondly, two existing practical formulations able to predict the near-bottom orbital velocities of shoaling waves will be briefly described. Their ability and accuracy will be then assessed against laboratory measurements in the third part of this paper.

2. A review of laboratory experiments

a) Monochromatic waves

A summary of the published laboratory studies reviewed for this paper is presented in table 1. Historically, many studies have focused on the prediction of the horizontal velocity under the crest which is one of the most important quantities used for design purposes (Dean and Perlin, 1986; Kirkgöz, 1986). The main result of interest is that **near the bottom**, the linear theory gives the best overall adjustment for flat and sloping beds up to the breaking point and within the surf-zone. It should be pointing out that this very flattering comparison cannot be extrapolated to the overall velocity profile (Hattori, 1986). In particular, the observed skewness of velocities (Nadaoka and Kondoh, 1982) cannot be predicted.

Table 1 Measurements of near bottom orbital velocities in laboratory (regular waves)

Authors	beach slope	n° of tests	type of measurements	measur. in surfzone
Iwagaki & Sakai (1970)	flat	22	profiles at crest and time series near bottom	No
Tsuchiya & Yamaguchi (1972)	1/100	3	at crest and trough above mid-depth	No
Stive (1984)	1/40	2	profiles at crest and trough	Yes
Flick et al. (1981)	1/35	2	time series near bottom	Yes
Isobe & Horikawa (1982)	1/10 & 1/20	21	time series near bottom	Yes
Nadaoka & Kondoh (1982)	1/20	12	near-bottom mean velocity and velocity skewness	Yes
Hattori (1986)	1/20	15	profiles at crest and trough	No
Sato et al. (1988)	1/20	3	time series near bottom (+ random waves)	Yes
Kirkgöz (1986)	1/4.45 to 1/12	17	profiles at crest	No

This skewness is peaking at the breaking point and tends to decrease significantly in the surfzone except for steep waves. It is a relevant indicator of the development of asymmetries observed in shoaling waves which are of two kinds.

The horizontal asymmetry includes an increase of the velocity speed under the crest (u_c) which could become twice the velocity speed under the trough (u_t). This increase is accompanied by a shortening of the crest duration T_c (i.e. the duration of time when the velocity is in the direction of the wave propagation).

This is explained by the development of higher harmonics which are locked to the primary (sinusoidal) wave. The ratio u_c/u_t was found to be maximum at the breaking point and then to decrease significantly in the surf zone (Stive, 1984).

The vertical asymmetry includes a steepening of the velocity (temporal) profile between a trough and the following crest producing a higher acceleration than between the crest and the following trough. This is explained by the development of phase differences between the harmonics and the primary wave (Flick et al., 1981) induced by the slope of the bottom and producing a sawtooth shape.

b) Random waves

When randomness of waves is considered, the situation becomes complicated by presence of bounded and free low frequency waves. In intermediate depths, bounded second-order wave velocities can be computed from second-order random theories (Dean and Perlin, 1986).

In the nearshore zone, partially standing long-waves are often present. Guza and Thornton (1985) have analysed velocities measured at Torrey Pines beach including the surfzone. They have shown that low frequency velocity variance increases monotonically as depth decreases. Cross-shore high frequency velocity moments appear to be near gaussian offshore, reach a maximum deviation from gaussian near the mean breaker location and trend back to gaussian as the shoreline is approached. Such an evolution cannot be predicted by a monochromatic or a linear gaussian model.

Roelvink and Stive (1989) carried out detailed near-bottom velocity measurements in a laboratory flume and also found that high frequency velocity moments were very significant in the nearshore region. They used a non-linear wave theory to successfully predict these moments.

3. Practical formulations tested

Existing formulations have been reviewed by Soulsby et al. (1993). Two of them have been chosen for the validation tests presented hereafter.

a) Isobe and Horikawa

Isobe and Horikawa (1982) proposed two series of empirical corrections of the linear velocity profile. As a first step, an estimation of the ratio $u_c/(u_c + u_t)$ is obtained for their equations (13) to (23). From these expressions, u_t could be predicted assuming that u_c is accurately computed with the linear theory.

Similarly, the ratio T_c/T could be computed. Two sinusoidal profiles could then be adjusted to simulate the velocity profile under the crest and under the trough.

In a second step, the vertical asymmetry is accounted for by introducing two time lags in the above profile with the equations (24) to (28). To apply these expressions, one should correct the following typing errors:

- 1) The right side of equation (23) should read $0.5 - 0.018(T\sqrt{g}/d)$.
- 2) In the second right side of equation (28), π is outside the brackets.

Please also note that in equation (28), the origin of time is at $0.5(T - T_c)$ following figure 9 of Isobe and Horikawa.

b) The covocoïdal theory

In order to provide a simple and accurate tool for engineering purposes, Swart and Loubster(1978) have presented a numerical method and a parametrized solution of the problem valid at any water depth for a flat bottom. They called it the vocoïdal theory (vocoïdal stands for **V**ariable **O**rders **C**osinus **O**idal function). It is based on basic assumptions concerning the form of the free-surface elevation, the orbital velocity and the celerity which are expressed as:

$$\eta(t) = H(\cos^{2P}(\pi \frac{t}{T}) - \eta_{*t}) \quad (1)$$

$$\frac{u(z,t)}{C} = k\eta \frac{\cosh(M(X)kz)}{\sinh(M(X)k(h+\eta))} \quad (2)$$

$$\frac{C^2}{gh} = \frac{1}{kh} \tanh(Nkh) \quad (3)$$

t is time, H and T are the wave height and period, $X = t/T$, P is the wave profile parameter, η_{*t} is the non-dimensional wave trough, k is the wave number, C the celerity, z the vertical coordinate, $M(X)$ is the orbital velocity function and N is the wave celerity parameter. Equations (1) and (3) have been originally proposed by Van Hijum (1972) and equation (2) by Mejlhede(1975). A numerical method to solve this simplified problem has been established by Swart(1978).

Then, a parametrized form of this solution has been derived empirically from numerous computations in order to provide analytical equations very easy to use. The comprehensive derivation and validation of the method could be found in Swart (1978) and Swart and Loubster(1979).

This theory was then extended by Swart and Crowley(1988) to the case of a sloping bottom by modifying equations (1) and (2) in order to introduce a parametrized form of the vertical asymmetry. This new theory has been called the Covocoidal theory. The same numerical approach has been used and an analytical parametrized form of the solution was also given. This parametrization has then been slightly modified by Swart and Crowley(1989). This is this parametrized solution which has been tested here.

c) An unsuccessful test

Finally, it should be noted that Hattori and Katsurakawa (1990) followed the idea of Flick and al (1981) by proposing empirical formulae of phase lags. Such a method could be easily used with numerical wave models based on Fourier developments. Unfortunately, we have not been able to recompute the results presented in their paper (i.e. figure 5 of their paper from their equation (5)).

4. Validation tests

The two formulations have been tested against several laboratory data with monochromatic and random waves.

a) Monochromatic wave tests

As a first test, two velocity time-series of near-breaking shoaling waves measured by Isobe and Horikawa (1982) on a fixed slope of 1 in 20 have been used. The first one has been obtained with a deep-water steep wave ($H/L_0 = 0.059$) and the second with a low-steepness wave ($H_0/L_0 = 0.0067$). The measured and computed velocity profiles are shown on figure 1. For both cases the agreement is excellent with Isobe and Harikawa's formulation and reasonable with the covocoïdal theory. It is worth to note that in the first case, the ratio H/h is 0.88 far over the limiting value on a flat bottom. It means that very accurate high order Fourier wave theories cannot provide any result here.

A second test made use of the measurements of the skewness of the velocity from Nadaoka and Kondoh (1982) along a 1 in 20 slope. Two typical cases including as previously high and low steepness waves have been simulated. Figure 2 presents the results obtained. In order to perform the computations of the velocity, the wave height transformation has been computed with a finite amplitude wave model including the surfzone.

Outside the surfzone negative abnormal values are obtained with the covocoïdal theory in the first case. Furthermore, the skewness is peaking too much offshore in the second case. On the other hand, the Isobe and Horikawa formulation is providing smoother results in reasonable agreement with the measurements. In the surfzone, no formulation is able to predict the decrease of the skewness.

Because the covocoïdal theory provides a comprehensive wave description, further tests considering the free surface elevation profile have also been performed. Measurements of wave crests and troughs on a 1 in 12 slope reported by Bowen et al (1968) have been simulated. The results are shown in figure 3. The agreement is quite good in the outer shoaling region. Further inshore the wave crest elevation is rather overestimated and the trough underestimated. This deviation from the measurements increases in the surfzone.

Finally, a last test concerning the shape factor (B_o defined as the ratio of the standard deviation of the surface elevation over the wave height) has been carried out using the data from Stive (1984). A good prediction of this factor is essential in surfzone models in order to accurately compute the radiation stresses and the set-up. Figure 4-up indicates that before the breakpoint, the use of the covocoïdal theory can improve the computation of B_o compared to a classical second-order cnoidal theory. This is no more the case in the surfzone. Results are even worse in the case of a low-steepness wave (figure 4-down).

b) Random wave tests

Results obtained with monochromatic waves show that both approaches can be used before the breaking point but not in the surfzone. If we now consider random waves which generate wider surfzones, it implies that a probabilistic approach considering the joint distribution of wave heights and periods to compute the velocity distribution will not work properly in the nearshore. This is the reason why an alternative approach to estimate the velocity moments in random waves is considered here. It consists of applying the two formulations with a representative wave height and period. Flume data at prototype scale collected in the Delta flume in the Netherlands (Arcilla et al., 1994) have been used to test that approach. Figure 5 presents the computation of the second order and the third order velocity moments (high frequency part only) obtained by using the root-mean-square wave height and the peak period of the waves. In the first case (test 2A) the bottom slope is monotonic but in the second (test 1C) a bar has developed which explains the presence of two peaks. Furthermore, the low steepness of the waves in the second case makes it a more difficult case to simulate: a significant underestimation of the third order velocity moment is clearly visible in figure 5-down.

5. Conclusions

The validation tests of the two formulations indicate that the Isobe and Horikawa (1982) formulation can be used with confidence in a large range of wave conditions except inside the surfzone when monochromatic waves are considered. The covocoïdal theory provides a more comprehensive description of the waves properties but abnormal results have been noticed in a few cases. This is probably due to the limitations of the parametrization which is rather complex and should be carefully checked at both limits: « deep »-water and breaking point. The accuracy of the prediction is generally reasonable. More tests with random waves are needed to confirm the choice of the root-mean-square wave height as the most suitable input.

Acknowledgements

CHAPTER 44

FORMULATION AND VALIDATION OF VERTICALLY 2-D SHALLOW-WATER WAVE MODEL

Bradley D. Johnson¹, Nobuhisa Kobayashi², and Daniel T. Cox³

Abstract

A numerical model is developed to predict the time-dependent, two-dimensional velocity field under normally incident breaking waves on beaches and coastal structures. Use is made of the depth-integrated continuity and horizontal momentum equations, where the momentum equation includes the momentum flux correction due to the vertical variation of the horizontal velocity. The third equation for the momentum flux correction is derived from the depth-integrated wave energy equation together with a cubic horizontal velocity profile. The three equations are solved using the MacCormack finite difference method. The quasi two-dimensional model is compared with two laboratory data sets and is found to predict the vertical variation of the horizontal velocity measured below the trough reasonably well. However, the energy dissipation in the model is primarily numerical for breaking waves on gentle slopes despite the explicitly modeled energy dissipation due to wave breaking.

Introduction

The quantitative prediction of detailed sediment transport on beaches and armor stability on coastal structures requires a numerical model that can predict the time-dependent, vertically two-dimensional velocity field of breaking waves on slopes with sufficient accuracy and reasonable computation time.

Available time-dependent, one-dimensional and other numerical models for breaking and nonbreaking waves on inclined structures and beaches (e.g., Kobayashi and Wurjanto 1989) are relatively simple and robust. Generally, these models predict the free surface elevation fairly accurately, within about 20% errors. The comparisons of a one-dimensional model with the experiment for regular waves spilling on a rough, impermeable 1:35 slope conducted by Cox *et al.* (1995) indicated that the horizontal velocity measured below the wave trough level was represented by the computed depth-averaged velocity reasonably well. The temporal variation of the bottom shear stress was predicted poorly because errors in the computed horizontal velocity were magnified in the computed bottom shear stress and because the bottom friction factor was not really constant. These limited comparisons suggest that a vertically

¹Ph.D. Student, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716.

³Assistant Professor, Department of Civil Engineering, Texas A&M University, College Station, TX 77843-3136.

two-dimensional model will be required to predict the detailed vertical variations of the fluid velocities and shear stress which are essential for predicting cross-shore sediment transport on beaches and hydrodynamic forces acting on armor units on coastal structures.

A simplified two-dimensional model called VBREAK has been developed assuming a cubic horizontal velocity profile outside of the wave boundary layer. The vertically two-dimensional problem is then reduced to a depth-integrated one-dimensional problem in which three time-dependent, one-dimensional differential equations can be solved numerically for the water depth h , depth-averaged horizontal velocity U , and near-bottom horizontal velocity u_b . The simplified two-dimensional model is computationally as efficient as the previous one-dimensional models. As a result, the new model can be applied easily and routinely using workstations. This paper summarizes the numerical model VBREAK described in detail by Kobayashi and Johnson (1995) and the comparisons of the model to available data presented in Johnson *et al.* (1996).

Mathematical Formulation

The approximate governing equations adopted in the numerical model named VBREAK are derived from the two-dimensional continuity and Reynolds equations

$$\frac{\partial u'_j}{\partial x'_j} = 0 \quad (1)$$

$$\frac{\partial u'_i}{\partial t'} + u'_j \frac{\partial u'_i}{\partial x'_j} = -\frac{1}{\rho} \frac{\partial p'}{\partial x'_i} - g\delta_{i2} + \frac{1}{\rho} \frac{\partial \tau'_{ij}}{\partial x'_j} \quad (2)$$

in which the prime indicates the physical variables and the summation convention is used with respect to repeated indexes. The symbols used in (1) and (2) are depicted in Fig. 1 where t' = time; x'_1 = horizontal coordinate taken to be positive landward; x'_2 = vertical coordinate taken to be positive upward with $x'_2 = 0$ at the still water level (SWL); u'_1 = horizontal velocity; u'_2 = vertical velocity; ρ = fluid density which is assumed constant; p' = pressure; g = gravitational acceleration; δ_{i2} = Kronecker delta; and τ'_{ij} = sum of turbulent and viscous stresses. Assuming that the viscous stresses are negligible, τ'_{ij} may be expressed as (e.g., Rodi 1980)

$$\tau'_{ij} = \rho \left[\nu'_t \left(\frac{\partial u'_i}{\partial x'_j} + \frac{\partial u'_j}{\partial x'_i} \right) - \frac{2}{3} k' \delta_{ij} \right] \quad (3)$$

in which ν'_t = turbulent eddy viscosity; and k' = turbulent kinetic energy per unit mass.

To simplify (1) and (2) with (3) in shallow water, the dimensional variables may be normalized as

$$t = \frac{t'}{T'} ; \quad x_1 = \frac{x'_1}{T' \sqrt{gH'}} ; \quad x_2 = \frac{x'_2}{H'} ; \quad p = \frac{p'}{\rho g H'} \quad (4)$$

$$u_1 = \frac{u'_1}{\sqrt{gH'}} ; \quad u_2 = \frac{u'_2}{H'/T'} ; \quad \nu_t = \frac{\nu'_t}{H'^2/T'} ; \quad k = \frac{k'}{\sqrt{gH'} H'/T'} \quad (5)$$

$$\sigma = T' \sqrt{\frac{g}{H'}} ; \quad \eta = \frac{\eta'}{H'} ; \quad z_b = \frac{z'_b}{H'} ; \quad h = \frac{h'}{H'} \quad (6)$$

Figure 1: Definition sketch
 terms of the order of σ^{-2} are neglected in the normalized equations corresponding to (1) and (2).

The conventional notations of $x = x_1$, $z = x_2$, $u = u_1$ and $w = u_2$ are used in the following. The simplified depth-integrated continuity and horizontal momentum equations under the assumption of $\sigma^2 \gg 1$ are expressed as

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} = 0 \quad (7)$$

$$\frac{\partial q}{\partial t} + \frac{\partial}{\partial x} \left(qU + m + \frac{1}{2}h^2 \right) = -\theta h - \tau_b \quad (8)$$

with

$$m = \int_{z_b}^{\eta} (u - U)^2 dz \quad (9)$$

where h = water depth given by $h = (\eta - z_b)$; q = volume flux per unit width; U = depth-averaged horizontal velocity defined as $U = q/h$; θ = normalized bottom slope defined as $\theta = dz_b/dx$; τ_b = bottom shear stress; and m = momentum flux correction due to the vertical variation of the horizontal velocity u . The vertical momentum equation yields essentially hydrostatic pressure for shallow water.

To include energy dissipation due to wave breaking in Boussinesq equations, Zelt (1991) and Schäffer *et al.* (1992) added a term corresponding to the term for the momentum flux correction m in (8). Zelt (1991) expressed this additional term in the form of horizontal momentum diffusion with an artificial viscosity. The artificial viscosity was calibrated for breaking solitary waves where the diffusion term was activated using a semi-empirical criterion for solitary wave breaking. On the other hand, Schäffer *et al.* (1992) expressed the additional momentum flux using a simple approach based on a surface roller that represented a passive bulk of water riding on the front of a breaking wave. An empirical geometric method was used to determine the shape and location of the surface rollers during the computation. Unlike the present model, these models do not predict the vertical variations of the fluid velocities.

The equation for the momentum flux correction m is derived from the depth-integrated instantaneous wave energy equation (Kobayashi and Wurjanto 1992)

$$\frac{\partial E}{\partial t} + \frac{\partial}{\partial x} (E_F) = -D \quad (10)$$

in which T' and H' are the reference wave period and height used for the normalization. The parameter σ defined in (6) is the ratio between the horizontal and vertical length scales and is assumed to be much larger than unity.

The normalized variables in (4) and (5) are assumed to be on the order of unity in shallow water. The normalization of ν'_i and k' in (5) is based on the turbulence measurements in a wave flume by Cox *et al.* (1994) which have indicated that ν'_i and k are on the order of unity or less inside and immediately outside the surf zone, respectively. The

The specific energy E defined as the sum of kinetic and potential energy per unit horizontal area is given by

$$E = \frac{1}{2} (qU + m + \eta^2) \quad \text{for } z_b < 0 \quad (11)$$

$$E = \frac{1}{2} (qU + m + \eta^2 - z_b^2) \quad \text{for } z_b > 0 \quad (12)$$

in which the potential energy is taken to be relative to the potential energy in the absence of wave action with SWL at $z = 0$. The energy flux E_F per unit width is expressed as

$$E_F = \eta q + \frac{1}{2} (qU^2 + 3mU + m_3) \quad (13)$$

with

$$m_3 = \int_{z_b}^{\eta} (u - U)^3 dz \quad (14)$$

in which m_3 = kinetic energy flux correction due to the third moment of the velocity deviation $(u - U)$ over the depth. The energy dissipation rate D per unit horizontal area in (10) is given by

$$D = \int_{z_b}^{\eta} \tau \frac{\partial u}{\partial z} dz \quad (15)$$

where use is made of the no slip condition $u = 0$ at $z = z_b$.

The energy dissipation rate D may be expressed as the sum of dissipation due to bottom friction, D_f , and dissipation due to wave breaking outside of the wave boundary layer, D_B . The wave boundary layer is not analyzed explicitly in this numerical model. The energy dissipation rate D_f inside the wave boundary layer may be estimated by (Jonsson and Carlsen 1976)

$$D_f = \tau_b u_b; \quad \tau_b = f_w |u_b| u_b; \quad f_w = \frac{1}{2} \sigma f'_w \quad (16)$$

where u_b = near-bottom horizontal velocity immediately outside the wave boundary layer and f'_w = friction factor (Jonsson 1966). Assuming that the thickness of the wave boundary layer is much smaller than the water depth, D_B may be estimated as

$$D_B = \int_{z_b}^{\eta} \nu_t \left(\frac{\partial u}{\partial z} \right)^2 dz \quad \text{outside boundary layer} \quad (17)$$

Rearranging the instantaneous wave energy equation (10), the equation for the momentum flux correction m is derived

$$\frac{\partial m}{\partial t} + \frac{\partial}{\partial x} (3mU + m_3) = 2U \frac{\partial m}{\partial x} - 2(\tau_b \tilde{u}_b + D_B) \quad (18)$$

in which $\tilde{u}_b = u_b - U$ = near-bottom horizontal velocity correction due to the vertical variation of the horizontal velocity u outside the wave boundary layer.

In order to express m , m_3 , and D_B in terms of \tilde{u}_b , the horizontal velocity u outside the wave boundary layer is assumed to be expressible in the form

$$u(t, x, z) = U(t, x) + \tilde{u}_b(t, x) F(\zeta) \quad (19)$$

with

$$\zeta = [z - z_b(x)]/h(t, x) \quad \text{for } 0 \leq \zeta \leq 1 \tag{20}$$

in which F = normalized function expressing the vertical variation of the velocity deviation ($u - U$) from $\zeta = 0$ immediately outside the wave boundary layer to $\zeta = 1$ at the free surface. Substitution of (19) into the normalized continuity equation corresponding to (1) yields the vertical velocity $w(t, x, z)$ where $w = 0$ at $z = z_b$. The dimensional turbulent eddy viscosity ν'_t outside the wave boundary layer is assumed to be given by

$$\nu'_t = (C_\ell h')^2 \left| \frac{\partial u'}{\partial z'} \right| \tag{21}$$

in which C_ℓ = mixing length parameter. The turbulence measurements inside the surf zone by Cox *et al.* (1994) have indicated that (21) is a reasonable first approximation outside the wave boundary layer and that C_ℓ is on the order of 0.1 ($C_\ell = 0.1$ is used herein). The corresponding normalized turbulent eddy viscosity ν_t defined in (5) is expressed as

$$\nu_t = C_\ell^2 \sigma h^2 \left| \frac{\partial u}{\partial z} \right| \tag{22}$$

Substitution of (19) with (22) into (9), (14), and (17) yields

$$m = C_2 h \tilde{u}_b^2 \quad ; \quad C_2 = \int_0^1 F^2 d\zeta \tag{23}$$

$$m_3 = C_3 h \tilde{u}_b^3 \quad ; \quad C_3 = \int_0^1 F^3 d\zeta \tag{24}$$

$$D_B = C_B C_\ell^2 \sigma |\tilde{u}_b|^3 \quad ; \quad C_B = \int_0^1 \left| \frac{dF}{d\zeta} \right|^3 d\zeta \tag{25}$$

Madsen and Svendsen (1983) and Svendsen and Madsen (1984) assumed a cubic velocity profile for their analyses of a hydraulic jump and a turbulent bore on a beach. Accordingly, the function F in (23) – (25) outside the wave boundary layer is assumed to be cubic and expressed as

$$F = 1 - (3 + 0.75a)\zeta^2 + a\zeta^3 \quad \text{for } 0 \leq \zeta \leq 1 \tag{26}$$

in which a = cubic velocity profile parameter. The shear stress τ should drop to zero at the free surface. To satisfy $\frac{\partial u}{\partial z} = 0$ at the free surface, $a = 4$. The assumed form (26) results in $\tau = 0$ at $\zeta = 0$ immediately outside the wave boundary layer in contradiction with the turbulence measurements inside the surf zone by Cox *et al.* (1994). The cubic profile assumed by Svendsen and Madsen (1984) suggests that the parameter a is approximately 3 and the range of $a = 3-4$ is considered in the following. Substitution of (26) into (23) – (25) yields C_2 , C_3 , and C_B as a function of a .

Fig. 2 shows the cubic velocity profile function F given by (26) as a function of ζ for $a = 3.0, 3.5,$ and 4.0 . The abscissa in Fig. 2 is the value of $-F$ because \tilde{u}_b is expected to be negative under the wave crest. Fig. 2 hence depicts the normalized vertical variation of the horizontal velocity deviation ($u - U$) under the wave crest. The assumed cubic profile is not sensitive to the parameter a in the range of $a = 3-4$ except in the vicinity of the free surface where no velocity data is available inside the surf zone. Fig. 3 shows the parameters C_2 , C_3 and C_B as a function of the cubic

Figure 2: Cubic velocity profile function $-F$ as a function of ζ

Figure 3: C_2 , C_3 , and C_B vs. a

profile parameter a . These parameters vary little for $a = 3-4$. Fig. 3 indicates that $C_2 \simeq 0.5$, $C_3 \simeq -0.03$ and $C_B \simeq 13$. The computed results are also found to be insensitive to a and in this paper $a = 3$ for most comparisons with data.

To obtain \tilde{u}_b for the computed h and m , it is assumed that

$$\tilde{u}_b = -\left(\frac{m}{C_2 h}\right)^{1/2} \quad \text{for } U \geq 0 \tag{27}$$

$$\tilde{u}_b = \left(\frac{m}{C_2 h}\right)^{1/2} \quad \text{for } U < 0 \tag{28}$$

which ensures that $|u_b| \leq |U|$ with $u_b = (U + \tilde{u}_b)$.

To examine the degree of numerical dissipation hidden in the computed results, the instantaneous energy equation (10) is averaged over time. The time averaged energy balance is

$$\frac{d}{dx} (\overline{E_F}) = -\overline{D_f} - \overline{D_B} - \overline{D_n} \tag{29}$$

Where the overbar denotes time averaging and E_F , D_f , and D_B are given by (13), (16), and (25) respectively. The time-averaged numerical dissipation rate $\overline{D_n}$ is added in (29) so that $\overline{D_n}$ can be estimated for the computed $\overline{E_F}$, $\overline{D_f}$, and $\overline{D_B}$.

Numerical Method

To solve (7), (8) and (18) for h , q , and m , these equations are combined in the following vector form:

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} + \mathbf{G} = 0 \tag{30}$$

with

$$\mathbf{U} = \begin{bmatrix} h \\ q \\ m \end{bmatrix} ; \quad \mathbf{F} = \begin{bmatrix} q \\ F_2 \\ F_3 \end{bmatrix} ; \quad \mathbf{G} = \begin{bmatrix} 0 \\ G_2 \\ G_3 \end{bmatrix} \tag{31}$$

and

$$F_2 = qU + m + \frac{1}{2}h^2 \quad ; \quad G_2 = \theta h + \tau_b \quad (32)$$

$$F_3 = 3mU + m_3 \quad ; \quad G_3 = 2 \left(\tau_b \tilde{u}_b + D_B - U \frac{\partial m}{\partial x} \right) \quad (33)$$

Eq. (30) is solved numerically using the MacCormack method (MacCormack 1969) which is a simplified variation of the two-step Lax-Wendroff method (e.g., Anderson *et al.* 1984) and has been applied successfully for the computation of unsteady open channel flows with hydraulic jumps (e.g., Chaudhry 1993). The use of the Lax-Wendroff method for (30) would be very difficult because this method requires the Jacobian of \mathbf{F} with respect to \mathbf{U} .

The values of \mathbf{U}_j at the node j with $j = 1, 2, \dots, s$ and at the present time t are known in the following, where $s =$ the most landward node. Computation is initiated at time $t = 0$ with no wave action in the computational domain, thus $h = q = m = 0$. The unknown values of \mathbf{U}_j^* at the node j and at the next time level $t^* = (t + \Delta t)$ are denoted by the superscript asterisk. The predictor, corrector and final steps of the MacCormack method are expressed as

$$\dot{\mathbf{U}}_j = \mathbf{U}_j - \frac{\Delta t}{\Delta x} (\mathbf{F}_{j+1} - \mathbf{F}_j) - \Delta t \mathbf{G}_j \quad \text{for } j = 1, 2, \dots, s-1 \quad (34)$$

$$\ddot{\mathbf{U}}_j = \dot{\mathbf{U}}_j - \frac{\Delta t}{\Delta x} (\dot{\mathbf{F}}_j - \dot{\mathbf{F}}_{j-1}) - \Delta t \dot{\mathbf{G}}_j \quad \text{for } j = 2, 3, \dots, s-1 \quad (35)$$

$$\mathbf{U}_j^* = \frac{1}{2} (\mathbf{U}_j + \ddot{\mathbf{U}}_j) \quad \text{for } j = 2, 3, \dots, s-1 \quad (36)$$

The variable time step Δt is calculated by the following approximate expression

$$\Delta t = \frac{C_n \Delta x}{\max(|U_j| + \sqrt{h_j})} \quad \text{for } j = 1, 2, \dots, s \quad (37)$$

in which C_n is the Courant number and the denominator in (37) is the maximum value of $(|U_j| + \sqrt{h_j})$ at all the wet nodes.

Use of the MacCormack method results in numerical high-frequency oscillations which tend to appear at the rear of a breaking wave, especially on a gentle slope. For open-channel flows, Chaudhry (1993) summarized a procedure to smooth these high-frequency oscillations. To apply this procedure for breaking waves on slopes excluding the boundary points, the computed water depth h_j^* at the node j and at the next time level t^* is used to calculate the parameter ν_j at the node j defined as

$$\nu_j = \frac{|h_{j+1}^* - 2h_j^* + h_{j-1}^*|}{|h_{j+1}^*| + 2|h_j^*| + |h_{j-1}^*|} \quad \text{for } j = 2, 3, \dots, (s^* - 1) \quad (38)$$

The parameter $\epsilon_{j+0.5}$ at the midpoint of the nodes j and $(j+1)$ is given by

$$\epsilon_{j+0.5} = \kappa \left(\frac{h_j^* + h_{j+1}^*}{2} \right)^{0.5} \max(\nu_j, \nu_{j+1}) \quad \text{for } j = 2, 3, \dots, (s^* - 2) \quad (39)$$

in which κ = numerical damping coefficient for regulating the amount of damping of the high-frequency oscillations. The computed water depth h_j^* is modified as

$$h_j^* = h_j^* + \epsilon_{j+0.5} (h_{j+1}^* - h_j^*) - \epsilon_{j-0.5} (h_j^* - h_{j-1}^*) \quad \text{for } j = 3, 4, \dots, (s^* - 2) \quad (40)$$

Likewise, U_j^* and m_j^* are smoothed using (40) with h_j^* being replaced by U_j^* and m_j^* , respectively, where $\epsilon_{j+0.5}$ is the same. The smoothed h_j^* and U_j^* are used to calculate $q_j^* = h_j^* U_j^*$. Chaudhry (1993) suggested expressions of ν_j at the boundary points for open-channel flows. However, the addition of these expressions in (39) and (40) is found to produce spurious fluid motions even in the absence of waves on slopes. As a result, the smoothing at the end points is not recommended for breaking waves on slopes. For breaking waves on gentle beach slopes, $\kappa = 1$ has been used to damp the high-frequency oscillations. For waves surging on steep slopes of coastal structures, $\kappa = 0.1$ appears to be sufficient. However, the smoothing procedure based on (38) tends to cause more damping near the shoreline where the water depth h is very small. To remedy this uneven damping, the factor $[(h_j^* + h_{j+1}^*)/2]^{0.5}$ is included in (39) to reduce the damping near the shoreline.

The landward boundary is located at the moving shoreline on the slope where the water depth is essentially zero and the landward boundary algorithm is a minor extension of the previous one-dimensional algorithm. The seaward boundary conditions on h and q utilizes the method of characteristics in basically the same way as the previous models (e.g., Kobayashi and Wurjanto 1989) with the inclusion of the momentum flux correction, m . However, the value of m at the seaward boundary needs to be found using (18). The value of m at $x = 0$ might be taken as $m = 0$ at $x = 0$ if the seaward boundary is located outside the surf zone. This is because the vertical variation of the horizontal velocity assumed in (18) is caused by wave breaking in this numerical model for shallow water waves. However, the boundary condition of $m = 0$ at $x = 0$ will yield $m = 0$ for $t > 0$ and $x > 0$ because $m = 0$ is a trivial solution of (18). It is hence required to introduce $m \geq 0$ at $x = 0$ so that $m \geq 0$ for $t > 0$ and $x > 0$. One option is to rewrite (18) in terms of \tilde{u}_b as

$$\frac{\partial \tilde{u}_b}{\partial t} + \frac{\partial}{\partial x} (U \tilde{u}_b) = -\frac{C_3 \tilde{u}_b}{2C_2} \left(\frac{\tilde{u}_b}{h} \frac{\partial h}{\partial x} + 3 \frac{\partial \tilde{u}_b}{\partial x} \right) - \frac{\tau_b + C_{B\ell} |\tilde{u}_b| \tilde{u}_b}{C_2 h} \quad (41)$$

where $C_{B\ell} = C_B C_\ell^2 \sigma$. Note that $\tilde{u}_b = 0$ is not a trivial solution of (41). The value of $m = C_2 h \tilde{u}_b^2$ at $x = 0$ may then be obtained using the value of \tilde{u}_b at $x = 0$ computed using (41) which is approximated by an explicit first-order finite difference.

Comparison of Previous 1-D and Present Models

To demonstrate the effectiveness of the MacCormack method, the present model VBREAK is reduced to a one-dimensional model and compared with the previous one-dimensional model IBREAK of Kobayashi and Wurjanto (1989). The quasi one-dimensional model uses an explicit first order finite difference of (41) to obtain the value of $(\tilde{u}_b)_1^*$ and thus m_1^* , the momentum correction factor at the next time level at the seaward boundary. However, when the value of m_1^* is set to zero at all times, the computed values of m_j^* at any node are zero for all times everywhere inside the computational domain. Thus the computed horizontal velocity has no vertical variation through the specification of zero vertical variation at the seaward boundary.

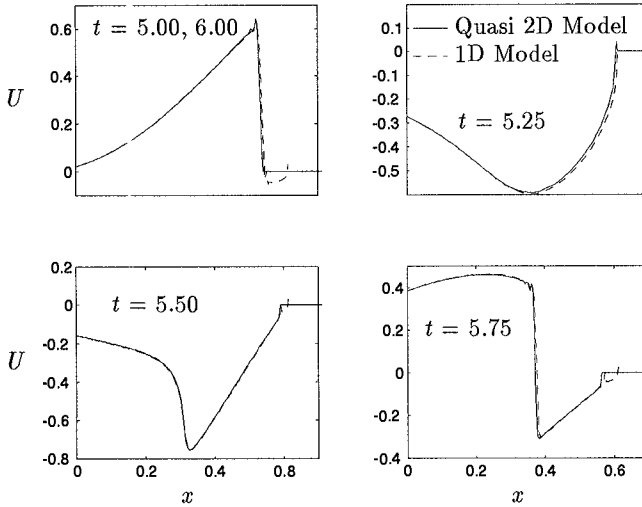

Figure 4: Cross-shore variations of computed depth-averaged velocity U

The only difference, then, between VBREAK and IBREAK is the different numerical methods employed to solve the same governing equations where IBREAK is based on the dissipative Lax-Wendroff method. Use is made of the 1:2.5 riprap revetment test conducted by Ahrens (1975) for the comparison. The computed free surface elevations turn out to be essentially identical while the computed depth-averaged velocities U display minor differences near the shoreline as shown in Fig. 4. The cross-shore variation of the depth-averaged velocity is depicted at 5 times throughout the final wave period. The computed velocities for each model are identical at $t = 5$ and 6 due to wave periodicity in Fig. 4.

Comparison with Data of Stive (1980)

The model is compared with the comprehensive measurements of test 1 presented by Stive (1980) and Stive and Wind (1982). Because the numerical model predicts the vertical variations of the horizontal velocity, the comparison of the measured and computed velocities can be made without any ambiguity. In Stive's test 1, the incident regular waves with period $T' = 1.79$ s broke as spilling breakers on the 1:40 concrete beach. The seaward boundary for the computation is taken to be at the location of still water depth $d'_i = 0.2375$ m, where the near-breaking wave profile was shown to be similar to the cnoidal wave profile as explained by Kobayashi *et al.* (1989). The measured wave height at the seaward boundary was $H' = 0.172$ m. The friction factor of 0.05 is used as in the previous computation by Kobayashi *et al.* (1989). A Courant number of 0.3 is adopted for the stable computation.

The measured and computed temporal variations of the free surface are compared at $x = 0, 1.29, 2.15,$ and 3.01 in Fig. 5. The variation of the free surface from the mean water level $\bar{\eta}$ for the last wave from $t = 29.0$ to $t = 30.0$ is shown in each panel. The crest of the computed wave form has been matched by hand with the measured crest;

Figure 5: Measured and computed wave profiles.

• Data - - - Computed u — Computed U

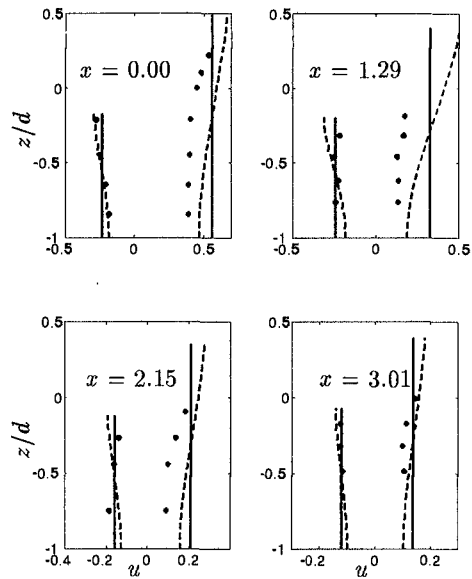

Figure 6: Measured and computed maximum and minimum normalized horizontal velocities

therefore, Fig. 5 should indicate only the comparison of the predicted and measured wave shapes. The first panel shows that the specified incident cnoidal wave at $x = 0$ agrees well with the measured profile. The high frequency oscillations following the wave crest are apparent in Fig. 5.

The maximum and minimum horizontal velocities at $x = 0, 1.29, 2.15,$ and 3.01 are depicted in Fig. 6. In each panel the dashed line represents the computed horizontal velocity u and the solid line is the computed depth averaged velocity U . The vertical axis is the ratio of z/d where z is the vertical coordinate and d is the water depth below SWL. The maximum and minimum values in Fig. 6 are obtained at each elevation z without regard to the vertical phase differences. Panel one indicates that although the specified and measured free surface elevations match at the seaward boundary well, the maximum horizontal velocity is considerably overpredicted. Likewise, at locations $x = 1.29, 2.15,$ and 3.01 the maximum velocity is overpredicted. The greatest computed variation of the velocity over the depth occurs after breaking, at $x = 1.29$. This, however, does not correspond well to the velocity measured below the trough level that displays virtually no variation with depth at $x = 1.29$.

Comparison with Data of Cox *et al.* (1995)

Comparison is also made with the data collected by Cox *et al.* (1995) that included detailed velocity profiles inside the surf zone. The experiment was performed in a wave flume with a 1:35 beach constructed of Plexiglas with a layer of sand glued to the surface to increase the bottom roughness. At each measuring line, water velocity measurements were taken at approximately twenty elevations. The free surface and

Figure 7: Measured and computed free surface

Figure 8: Normalized phase-averaged horizontal velocity u at three elevations at L4

velocities were measured for the duration of the last 50 waves out of 300 at each line. The numerical model is run with 300 waves of 2.2 s period in order to be consistent with the experimental procedure. The phase averaging is based on the last 50 waves in the same way as the measured data.

The friction factor $f'_w = 0.05$ is used. A Courant number of 0.4 maintained numerical stability in the following comparison. The seaward boundary is located landward of the break point, at measuring line L3 as defined by Cox *et al.* (1995). The height of the incident regular waves at L3 was $H' = 12.71$ cm and the corresponding still water depth was 17.71 cm.

Fig. 7 depicts the free surface at $x = 0.0, 0.49, 0.98,$ and 1.47 in the surf zone at L3, L4, L5, and L6 where L denotes the measuring line. The free surface prediction is quite good despite a lagging phase error seen most prominently at $x = 1.47$.

Fig. 8 shows the predicted and measured phase-averaged horizontal velocities at three elevations at L4 as a typical example. The first panel shows the velocities near the wave trough level. The solid line represents the measured values excluding dropouts in the data near the free surface. The second panel is a comparison at approximately mid-depth. The near bottom (1.1 cm above the bottom) velocities are plotted in the last panel. The unrealistic kink seen in panels one and three are due to the adopted relations (27) and (28) where the abrupt change in the velocity correction \tilde{u}_b is assumed to occur with the sign change in the depth averaged velocity, U .

The measured and computed horizontal and vertical velocity profiles are compared at six equally-spaced phases over one wave period for L5 in Fig. 9. The first panel depicts the computed and measured horizontal velocity as a function of the normalized

Figure 9: Vertical variations of horizontal and vertical velocities at six phases at L5

vertical distance $(z - z_b)$ above the bottom. The computed and measured free surfaces are shown as a black dot and as a horizontal line, respectively. The second panel depicts the comparison of the measured and computed vertical velocities at the same six phases. The discrepancy between the measured and computed vertical variations are caused, in part, by the aforementioned phase mismatch. As a whole, the agreement is reasonable in spite of the assumed simple vertical velocity profile (26). This is probably because the comparison is limited to below the wave trough level.

The normalized energy quantities involved in (29) are shown in Fig. 10. The numerical dissipation rate \overline{D}_n dominates over the dissipation rate due to bottom friction, \overline{D}_f , and the dissipation rate due to wave breaking, \overline{D}_B . This clearly indicates the shortcoming of the assumed velocity profile (26) which may be reasonable below the trough level but can not account for the much larger dissipation occurring above the trough level. Velocity data above the trough would be required to improve (26).

Conclusions

A numerical model is developed to predict the cross-shore and temporal variations of the free surface elevation η , the depth-averaged horizontal velocity U , and the near-bottom horizontal velocity correction \tilde{u}_b associated with the momentum flux correction m due to the vertical variation of the horizontal velocity u under the action of normally incident breaking waves. The three governing equations required for the three unknown variables are the depth-integrated continuity and horizontal momentum equations together with the new equation for the momentum flux correction m derived from the depth-integrated wave energy equation.

The normalized vertical profile of the horizontal velocity u outside the thin wave boundary layer is assumed to be cubic on the basis of limited available data. The turbulent shear stress outside the wave boundary layer is assumed to be expressed using the turbulent eddy viscosity whose mixing length is proportional to the instantaneous water depth. Although two additional empirical parameters are introduced in rela-

Figure 10: Computed cross-shore variation of normalized energy flux, bottom dissipation, breaking dissipation, and numerical dissipation.

tion to these assumptions, the computed vertical profiles of the horizontal velocity are found to be fairly insensitive to these empirical parameters in their ranges expected from limited available data.

The numerical model is reduced to a one-dimensional model and compared to the previous one-dimensional model. With appropriate simplification of the seaward boundary condition, the momentum flux correction equals zero identically throughout the computation domain for all times. The results are essentially the same for both models. This comparison demonstrates the efficiency and accuracy of the MacCormack method in the solution of the finite-amplitude shallow-water equations. The model is compared with the laboratory data presented by Stive (1980) and Stive and Wind (1982). The free surface elevations are predicted fairly accurately, while the maximum horizontal velocities are consistently overpredicted. The model is compared with the detailed fluid velocity measurements of Cox *et al.* (1995). Again, the free surface elevations are predicted fairly well. The horizontal velocity prediction is satisfactory apart from some phase mismatch and the unrealistic discontinuity in the velocity accompanying the sign change in U . As a whole, the agreement is reasonable considering the assumed simple vertical velocity profile. However, the model does not offer significant advantages over the previous one-dimensional models.

CHAPTER 45

Particle Velocity Distribution in Surface Waves

Geir Moe¹ and Øivind A. Arntsen²

Abstract

In offshore and ocean engineering it is often of interest to be able to model particle velocities in the so-called splash zone, in which during a wave cycle, a given point is sometimes submerged, sometimes in air. (Emergence effects.) This paper applies the so-called Gerstner wave theory, extends it to narrow banded irregular waves, and presents it in an Eulerian description to second order in wave amplitude, so that the results may be compared with measurements made at fixed positions in the fluid. Mean horizontal velocities have been determined, and shown to compare excellently to laboratory measurements, both for regular and irregular waves. At this point in time, it can not be said whether the fit will be equally good in real ocean waves.

Introduction

The design of structures in an ocean environment is often governed by wave loading, requiring the determination of water particle kinematics. However, real ocean waves are irregular and nonlinear, and no universally accepted theory is available for predictions of such flows, especially not in the splash zone. This is unfortunate, since rather large contributions to the total loading may originate in the splash zone. The most important statistical properties of particle kinematics at fully submerged points for mildly nonlinear, irregular waves have been successfully determined by Longuet-Higgins (1963). The term "particle kinematics" is here used to denote particle velocities as well as accelerations. When emergence effects in the splash zone are to be included, most of the available models are of an approximate, "engineering" type, such as Wheeler stretching or similar, e.g. the models associated with the names of Chakrabarti, Gudmestad or

¹ Professor, Department of Structural Eng., Norwegian University of Science and Technology, N-7034 Trondheim, Norway.

² Associated Professor, Department of Structural Eng., Norwegian University of Science and Technology, N-7034 Trondheim, Norway.

Heideman, see e.g. Skjelbreia et al. (1991) for full references. A different type of approach was introduced by Tung (1975). He used Airy wave theory, but modified the results by checking whether a splash zone point at a given instant was submerged, or in air, by comparing the vertical coordinate to the instantaneous location of the wave profile, again predicted by Airy theory. Technically this was done by multiplication with a step function, constructed such that the flow velocity became zero when the considered point was in air. Cieslikiewicz & Gudmestad (1993) used a similar approach in conjunction with the previously mentioned higher order wave approach of Longuet-Higgins. However, their results compared only moderately well to Laser Doppler measurements of particle velocities made by Skjelbreia et al. (1989).

In the present paper an alternative theory will be explored, which gives quite good predictions of the mean of the measured horizontal particle velocity. Good agreement were found for several cases tested, in irregular as well as regular waves. The idea underlying this model is quite simple: it is assumed that the particle paths are circles which are traversed at constant velocity. This assumption leads to a deep water wave theory commonly denoted as the Gerstner wave, which will be presented in the next section. A word of caution may be appropriate at this point: The comparison is made between a Gerstner wave and experimental results from a closed wave tank in which waves were generated into quiescent water. The measurements cover only the initial phases after the wave generator had been turned on, the flow field will change if the wave generator is left on for a long time, see Mei (1972). Real ocean waves may have different characteristics from this, since there the waves have been generated in a different manner, viz. over vast areas and during long times, and by different mechanisms of generation. Even so, it is suggested that studies of waves under carefully controlled conditions in test basins may shed considerable light on the general wave kinematics problem.

Basic Equations

The derivation of Airy wave theory is well known and will not be repeated here. It is normally developed in an Eulerian frame of reference, the key point being that the boundary condition at the free surface is applied at the still water level, and that quadratic velocity terms are dropped from the surface boundary condition. Its justification rests on a number of assumptions, notably that the wave amplitude is vanishingly small compared to the wavelength. However in engineering practice linear theory is routinely applied to situations where the amplitude typically is 0.01 to 0.05 of the wavelength, and experience indicates that acceptable accuracy will usually be obtained for most of the physical quantities involved, provided the observation point stays submerged at all times. One major advantage to the Airy theory is that it is linear, and that therefore the principle of superposition applies. The Gerstner wave is also linear, (Kinsman, 1965). It satisfies continuity and the surface conditions exactly, but the flow is rotational. The Gerstner wave will now be described in the usual coordinate system with the x -axis in the direction of wave propagation and z vertically upwards, and the origin at the still water level.

Assuming deep water waves of wave period $T = 2\pi/\omega$ and wave length $\lambda = 2\pi/k$, the location of the particle $x(x_0, z_0, t)$, $z(x_0, z_0, t)$ at time t is given by:

$$x = x_0 - ae^{kz_0} \cos(\omega t - kx_0), \tag{1}$$

$$z = z_0 + ae^{kz_0} \sin(\omega t - kx_0). \tag{2}$$

This is in fact a Lagrangian description of particle motions. It easily seen that for fixed values of x_0, z_0 , and varying t , the coordinates (x, z) describe a circle about the point (x_0, z_0) , whose radius is a at the surface (i.e. at $z_0 = 0$), and decays exponentially with the distance below the surface. The shape of the free surface $\eta(x,t)$ follows by setting $z_0 = 0$:

$$\eta(x,t) = a \sin(\omega t - kx_0(x,t)) \tag{3}$$

When t is kept constant, the equation defines the surface profile, as a function of x . This represents a trochoid³ as depicted in Fig. 1 for fixed time $t = 0$.

Figure 1. Free surface variation of a Gerstner wave.
 Data as for wave case R15b. (Skjelbreia et al., 1989)
 $H = 0.13$ m, $T = 1.5$ s, $\lambda = 3.5$ m, $d = 1.3$ m.

The phase velocity $c = \lambda/T$ is as for the Airy wave, and a close inspection of the free surface condition would reveal that it will be satisfied exactly, provided the deep water dispersion relation is satisfied, see e.g. Kinsman (1965) or Lamb (1932):

$$c = \omega / k \tag{3B}$$

$$k = \omega^2 / g \tag{3C}$$

It is now necessary to convert to a description in terms of fixed coordinates (x, z) , in order to describe the particle velocities at a given point, i.e. an Eulerian description is required. Without loss of generality one may consider the point $(x = 0, z)$.

³ trochoid: the curve generated by a point somewhere on the radius line (centre distance a) of a circle (radius $r = \lambda/2\pi$) as the circle circumference rolls on a fixed straight line.

This is convenient because then (kx_0) represents a small parameter, of order (ka) , so that a low order Taylor expansion may be used for functions of (kx_0) . In the final expressions the equations will be expanded to second order in (ka) . From (1) with $x = 0$ initially to first order one has

$$x_0^{(1)} = ae^{kz} \cos(\omega t) , \tag{4}$$

$$\zeta^{(1)} = z - z_0 = ae^{kz} \sin \omega t . \tag{5}$$

The second order expression for x_0 may be found by substitution of the above first order approx. into (1),

$$\begin{aligned} x_0 &= a \exp(kz - k\zeta^{(1)}) \cos(\omega t - kx_0^{(1)}) \\ &= ae^{kz} (1 - k\zeta^{(1)}) (\cos \omega t + kx_0^{(1)} \sin \omega t) \\ &= ae^{kz} \cos \omega t . \end{aligned} \tag{6}$$

Similarly for z one has

$$\begin{aligned} \zeta &= z - z_0 \\ &= ae^{kz} (1 - k\zeta^{(1)}) (\sin \omega t - kx_0^{(1)} \cos \omega t) \\ &= ae^{kz} \sin \omega t - ka^2 e^{2kz} . \end{aligned} \tag{7}$$

Thus for a point at the surface $z_0 = 0$, and $z(0,0, t)$ represents the surface elevation $\eta(0, t)$ as shown in Fig. 2. At a crest $z = a$ and $\sin \omega t = 1$ and from (7) follows that $\zeta = a$, while at a trough $\zeta = -a$, both accurate to second order in a . Zero crossing occurs at $\sin \omega t = ka$, i.e. at $\omega t = ka$ or $\omega t = \pi - ka$. Thus the crests are sharper and the troughs more rounded than for a pure sine wave. This was to be expected, since the formulae represents the trochoid.

Figure 2. The surface variation of the trochoid correct to second order in ka .
Data as in Fig. 1.

In the same manner one may find the horizontal and vertical velocity components at $(x = 0, z)$ as

$$u = a\omega e^{kz_0} \sin(\omega t - kx_0) = a\omega e^{kz} \sin \omega t - a^2 k\omega e^{2kz}, \quad (8)$$

$$w = a\omega e^{kz} \cos \omega t. \quad (9)$$

Mean particle velocity, regular waves

The above are expressions for regular deep water (Gerstner) waves of amplitude a and period $T = 2\pi/\omega$ and wave length $\lambda = 2\pi/k$. The particles moves in closed circles, hence the mean velocity when following a particle is zero. (Laplacian description). For a stationary observer (Eulerian description) the picture is different, however, and that is the relevant viewpoint when comparing to measurements taken at a fixed point. From (9) is seen that the vertical mean velocity is zero,

$$\bar{w} = 0. \quad (10)$$

For points that are always submerged, the mean horizontal velocity can similarly be determined from (8)

$$\bar{u} = -a^2 \omega k e^{2kz}. \quad (11)$$

For points in the splash zone, $-a < z < a$, emergence effects must be considered. The considered point will be in air for $z_0 > 0$ or, using $z_0 = z - \zeta$ and (7), the point will be in water, provided

$$z_0 = z + ka^2(1 + 2kz) - a(1 + kz)\sin \omega t < 0. \quad (12)$$

Solving and retaining terms to second order in amplitude a in the numerator and denominator, (and remembering that in the splash zone z is of order a .) one obtains

$$\Rightarrow \sin \omega t \geq \sin \theta_0 = \frac{z + ka^2}{a(1 + ka)}. \quad (13)$$

Thus the limiting phase angle is $(\omega t)_0 = \theta_0$ (cf. Fig. 2), and the mean value of horizontal particle velocity in the splash zone becomes

$$\begin{aligned} \overline{u(0, z)} &= \frac{1}{\pi} \int_{\theta_0}^{\pi/2} u(0, z, t(\theta)) d\theta \\ &= \frac{a\omega}{\pi} [e^{kz} \cos \theta_0 - ake^{2kz} (\frac{\pi}{2} - \theta_0)]. \end{aligned} \quad (14)$$

The considered contribution represents the value of the integral in the phase angle range $(-\pi/2 < \theta < \pi/2)$, which in view of symmetry yields the average over a full cycle. The result is shown in Fig. 3, which also includes the experimental points from a project conducted at SINTEF NHL, Trondheim, under the supervision of Dr. Skjelbreia (Skjelbreia et al., 1989). The experimental data points have been read off from a figure presented in Cieslikiewicz & Gudmestad (1992).

Figure 3. $E[u]$ vs depth. Regular wave case.

Irregular waves

Typically the variance spectrum, $S_{\eta}(\omega)$, of the sea surface is known. Let us for simplicity assume that the particle kinematics represent ergodic and narrow band processes, and further that h , u and w are Gaussian, so that their peaks are Rayleigh distributed. The choice of a frequency, that can be considered to be the most representative for the narrow process $u(x, z, t)$, is not straight forward. In the splash zone one might think that the zero crossing frequency of u (which is ω_{42}) would be the best choice, however the surface shape is dictated by the zero crossing frequency of η (ω_{20}), and this would also govern the frequency of the horizontal particle velocity. The shape of the variance spectrum of the horizontal particle velocity will change with depth, since the wave components of higher frequencies attenuate more rapidly with depth, than those of the lower frequencies. The frequency of the depth averaged horizontal particle velocity turns out to be ω_{20} which therefore is chosen as the representative frequency for the narrow band process used herein.

$$\omega_{20} = (M_2 / M_0)^{1/2}, \quad (15)$$

$$\omega_{42} = (M_4 / M_2)^{1/2}, \quad (16)$$

$$M_j = \int_0^{\infty} \omega^j S_{\eta}(\omega) d\omega. \quad (17)$$

The expected value of u in an irregular seastate depends on the wave amplitude, which is a slowly varying envelope for η , and is as such Rayleigh distributed with parameter σ_{η} , viz.

$$f_A(a) = \frac{a}{\sigma_{\eta}^2} \exp\left(-\frac{a^2}{2\sigma_{\eta}^2}\right); a \geq 0, \quad (18)$$

in which $f_A(a)$ is the probability density of a . Then the expectation of u is given by

$$E[u] = \int_0^{\infty} f_A(a) E[ua] da. \quad (19)$$

Equation (19) states that for a given amplitude, the result depends on the expectations of u , summed over all amplitudes, and weighting according to their frequency of occurrence. The ergodicity theorem implies that the calculation of (19) may be done as a time average. Since the wave spectrum is narrow-banded, the components in (19) represent almost harmonic waves occurring sequentially rather than superposition of components that occur simultaneously. Hence the decision whether the point is in air can be made on a wave by wave basis for each value of the amplitude. Then the expectations in (11) and (14) represent $E[ua]$ for points that are submerged or in the splash zone respectively. For a given depth, z , the decision whether the point is submerged or not depends on the amplitude a . Hence (19) must be split in two integrals, one for $(-z) > a$ which can be evaluated analytically, and another in which the lower integration limit must first be determined according to (13), and the integral in (19) then must be evaluated numerically. The results are shown in Fig. 4 together with points representing the results of the measurements made by Skjelbreia and his team. The experimental values have been read off from a figure, this time the figure is taken from Cieslikiewicz & Gudmestad (1993). It is seen that the fit between experiments and theory is very good.

Discussion

The Gerstner theory used herein shows results that correspond very well to the Skjelbreia experiments. In contrast, application of linear (Airy) wave theory resulted in considerable discrepancies between experiments and theory. In the results presented in the two papers by Cieslikiewicz and Gudmestad, the discrepancy relative to maximum of the mean velocity as calculated from the measurements, amounted to about 25% through much of the splash zone and up to 40% in the zone of total submergence. This was the case both for the regular and the irregular wave case. The regular wave case R15b was also modeled using an eighteen Fourier component method (ACES107). As

recommended in the guide the integrated Stokes flow in a wave flume should be equal to zero and set accordingly in the Fourier-series model. The results are presented in Fig. 3. We see that this model fit the observations much less than the Gerstner approach.

It must be emphasized very strongly that the case considered herein is laboratory measurements, and hence different from real ocean waves in many ways. The Airy wave can be made equal to the Gerstner wave, provided a so-called Stokes drift is added. Stokes drift is a steady current that decays exponentially with depth, and is in fact equal and opposite to the current determined herein for the totally submerged case, as given by (11). Integrated over the whole depth this yields a total flow of water in the direction of wave propagation and per unit width of the wave crest, equal to ωa^2 . Under the conditions at which the experiments were conducted, such a flux can not take place, since it violates continuity both at the wavemaker and at the wave front. This can hardly be remedied by superposition of another irrotational flow. Therefore it may not be too surprising that the Gerstner wave is in better agreement with measurements, even though it has the unusual character of being rotational. Another rotational solution to this problem has been presented by Kyoizuka (1995). One possibility is that the required rotation is generated from shear along the boundaries of the fluid region. It is not known how well the two theories discussed herein will compare to measurements in real ocean waves.

Figure 4. $E[u]$ vs depth. Irregular wave case.

Conclusions

- The Gerstner wave has been presented in an Eulerian description, to second order in the wave amplitude.
- Mean particle velocities have been computed for the regular and irregular case.
- The results have been compared to laboratory measurements, exhibiting an excellent fit, see Fig. 3 and Fig. 4.
- No statements can at this time be made on how the predictions from the present theory would compare to measurements in the ocean.

CHAPTER 46

A comparison of analysis methods for wave pressure data

Murray Townsend¹ and John D. Fenton²

ABSTRACT

A comparison of a range of wave pressure analysis methods has been conducted using both numerical data generated by a Fourier steady wave method and experimental data gathered in a wave flume. The results show that the local methods (local sinusoid approximations and local polynomial approximations) are more accurate than the traditional global linear spectral method. A new local polynomial approximation method shows improvement compared to similar methods developed previously.

INTRODUCTION

Pressure transducers have been used for many years by coastal engineers for measuring the wave climate at a site of interest. These instruments are well suited to this purpose, being unobtrusive and robust. Problems do occur, however, when the surface elevation is inferred from the pressure data. The problem is fundamentally a poorly posed one, the subsurface pressure data being an attenuated representation of the flow conditions. In addition, the nonlinearity of waves in the coastal zone means that the traditional linear analysis methods may be inaccurate for such an application. The aim of the present study is to evaluate existing analysis techniques and if possible to improve the accuracy and robustness of those that are more suitable. Both numerical and experimental data was used in the analysis.

The methods examined include one global method and several local methods. The global method is the linear spectral method, described at length by Bishop and

¹Research Student, Australian Maritime Engineering Cooperative Research Centre (AMECRC), Department of Mechanical Engineering, Monash University, Clayton, Victoria, 3168, Australia.

²ARC Senior Research Fellow, Department of Mechanical Engineering, Monash University, Clayton, Victoria, 3168, Australia.

Donelan (1987). The local methods are the first order Local Sinusoidal Approximation (LSA) method, the empirical LSA method (Nielsen, 1989), the fully nonlinear Local Polynomial Approximation (full LPA) method (Fenton, 1986) and the simple LPA method (Fenton and Christian, 1989). A new method, using LPA, is presented and tested - the nonlinearly optimised LPA (NOLPA). There is a new local Fourier approximation method (Barker and Sobey, 1996) based upon the surface method of Sobey (1991), which is being published in these proceedings.

ANALYSIS METHODS

Linear spectral method

The most common analysis technique used in this area is the linear spectral method, which has been presented and comprehensively discussed by Bishop and Donelan (1987). Briefly, the spectrum of the water surface elevation, $S_s(\omega)$ is related to the spectrum of the dynamic pressure at the pressure transducer, $S_p(\omega)$ by:

$$S_s(\omega) = \left[\frac{N(\omega)}{K_p(\omega)} \right]^2 S_p(\omega), \quad (1)$$

where ω is the angular frequency of each Fourier component, $N(\omega)$ is an empirical correction factor and $K_p(\omega)$ is the pressure response factor defined as:

$$K_p(\omega) = \frac{\cosh k(\omega)y_p}{\cosh k(\omega)D}, \quad (2)$$

where D is the mean water level (MWL) and y_p is the height of the pressure transducer from the sea bed.

The authors have, for the purpose of this paper set $N(\omega)$ to 1 for all ω . Bishop and Donelan consider the presence of $N(\omega)$ as an attempt to compensate for poor measurements, instruments and/or analysis methods. As the authors are using 'exact' nonlinear waves and pressure traces to conduct these tests none of the above need be considered and only potential inadequacies in the linear spectral method will be highlighted.

It was necessary to determine a maximum ω above which the pressure response factor was not applied, as doing so would cause the method to 'blow-up' when $K_p(\omega)$ became small. To determine this limit, the ratio of the spectral amplitude to $K_p(\omega)$ was determined at each ω . When this ratio began to increase at frequencies above the spectral peak the method had started to 'blow-up'.

Local sinusoidal approximation methods

The first of the computer-based local methods to emerge were the two developed simultaneously by Nielsen (1989). Both are known as LSA methods in which a sine curve is passed through three points from the pressure data which are adjacent or with a small number of intermediate points between them. This sine curve is used to determine the 'local' frequency. The water surface elevation at the instant in time of the central point can then be calculated by one of two methods. One method applies a transfer function derived from stretched linear theory (the first order LSA), the other applies a semi-empirical transfer function.

First order local sinusoidal approximation

This transfer function is expressed:

$$\hat{\eta}_n = \frac{p_n}{\rho g} \frac{\cosh k_n \left(D + \frac{p_n}{\rho g} \right)}{\cosh k_n z}, \quad (3)$$

where $\hat{\eta}_n$ is the water surface elevation corresponding to the n th central pressure reading, p_n is the n th central pressure reading, k_n is the n th wave number derived from the local frequency calculated from the three pressure readings and ρ is the water density.

The local frequency is determined by:

$$\hat{\omega}_n^2 = \frac{-p_{n-M} + 2p_n - p_{n+M}}{p_n (M\delta)^2}, \quad (4)$$

which is an estimate corrected by:

$$\omega_n^2 = \hat{\omega}_n^2 \left[1 + \frac{1}{12} (\hat{\omega}\delta)^2 \right]. \quad (5)$$

Empirical local sinusoidal approximation

Nielsen derived this transfer function from Dean (1974):

$$\hat{\eta}_n = \frac{p_n}{\rho g} \left[A \left(\frac{y_p}{D} \right) \frac{-p_{n-M} + 2p_n - p_{n+M}}{p_n g (M\delta)^2} \left(D + \frac{p_n}{\rho g} - y_p \right) \right] \quad (6)$$

where M is a positive integer the value of which can be estimated by $M \approx \sqrt{D/g}/\delta$ and is a multiplier which smoothes noisy data by selecting more widely spaced points instead of adjacent ones in the frequency calculation, δ is the sampling period of the data, and $A(y_p/D) = 0.67 + 0.34 y_p/D$ and accounts for the height of the pressure transducer above the sea bed.

Both the above are extremely simple to apply with little computational effort required. In this study M was set to 1 when used with numerically generated data as no noise was present in the input and the authors felt that this gave a better indication of the method's robustness. With real data M was calculated by the above equation.

Local polynomial approximations

The other two local methods are LPA techniques and were developed by Fenton (1986) and Fenton and Christian (1989). Both utilise the principle of low-degree polynomial approximation, partly based on least-squares approximation methods and partly on solving locally the full nonlinear equations of motion.

Fully nonlinear local polynomial approximation

The approach followed for the full LPA (Fenton, 1986) was to approximate the complex velocity potential as follows:

$$w(x, y, t) = \phi(x - ct, y) + i\psi(x - ct, y) \\ = c_e(z - ct) + \sum_{j=0}^J \frac{a_j}{j+1} (z - ct)^{j+1}, \quad (7)$$

where $z = x + iy$, c_e is the Eulerian current and the surface elevation is given by

$$\eta(x, t) = \sum_{j=0}^J b_j (x - ct)^j. \quad (8)$$

From equation (7) ϕ satisfies Laplace's equation identically throughout the flow and the bottom boundary condition ($v(x, 0, t) = 0$) is satisfied if the coefficients a_j and b_j are real.

To satisfy the necessary boundary conditions on the free surface the steady kinematic equation is invoked such that:

$$\psi(x - ct, \eta(x - ct)) = -Q, \quad (9)$$

where Q is a constant, and the steady Bernoulli equation:

$$R = \frac{1}{2} \left| \frac{dw}{d(z-ct)} \right|_s^2 + \eta, \quad (10)$$

where R is the Bernoulli constant and s denotes the surface $y=\eta$.

Bernoulli's equation is also written about the position $(0, y_p)$, the position of the pressure transducer, expressed as a Taylor series in $x-ct$:

$$p(0, y_p, t) = R - \frac{1}{2} \left| \frac{dw}{d(z-ct)} \right|_{y_p}^2 - y_p = \sum_{j=0}^J p_j (-ct)^j. \quad (11)$$

The p_j are calculated using a least squares fit across K data points where K is an odd integer greater than or equal to $J + 3$ with $(K - 1)/2$ data points each side of the point of interest. For the above method $K = 21$ was found to give good results for both smooth and noisy data and is the value used in these tests. $J = 4$ was found to be the optimum degree of approximation.

By manipulation of equations (7), (8), (9), (10) and (11) and isolating powers of $(x-ct)$, a system of nonlinear equations in terms of the unknown a_j and b_j is obtained. The solution of these equations is performed for each point in the pressure series using direct iteration to achieve convergence. The surface elevation data obtained was then passed through a simple 3-point smoothing routine. Space does not permit explanation of the details regarding the solution of these equations for the a_j and b_j coefficients.

Simple local polynomial approximation

The simple LPA (Fenton and Christian, 1989) is somewhat simpler in that a point value is used to describe each value of η at $t = 0$ as opposed to the polynomial expansion across the window in the former method. The resulting solution is much simplified with the extraction of a system of quite manageable nonlinear equations. Unfortunately, there are only 6 equations in that set with a total of seven unknowns. It was necessary to introduce more equations to be able to find a solution. The first assumption required is that the wave speed c is given by long wave theory:

$$c = \sqrt{g\eta}, \quad (12)$$

and the second is that the main fluid velocity component a_0 is given by:

$$a_0 = -c. \quad (13)$$

For the results that follow the value of K was set to 17.

Nonlinearly optimised local polynomial approximation

This method (NOLPA) was developed using some of the ideas mentioned in the two sections above. The same basic idea of approximating the velocity potential by a low degree polynomial over a small window of data remains, but the method of solving this nonlinear problem is quite different.

The velocity potential ϕ is represented by equation (7) and substituted into Bernoulli's equation at the pressure transducer

$$\frac{P}{\rho}(x, y_p, t) = R - \frac{1}{2}(u_p^2 + v_p^2) - gy_p, \quad (14)$$

where u_p and v_p are the horizontal and vertical velocities ($\partial\phi/\partial x$ and $\partial\phi/\partial y$ respectively) at the pressure transducer ($y=y_p$). Neglecting the kinematic boundary condition, this equation can be solved across K pressure points (K is an odd integer greater than or equal to $J+3$) using a nonlinear least squares solver such as the Levenberg-Marquardt method (Grace, 1994). The actual function to be optimised by this method is written

$$F = \sum_{k=1}^K \left[R - \frac{1}{2}u_{pk}^2 - \frac{1}{2}v_{pk}^2 - gy_p - \frac{P_k}{\rho} \right]^2. \quad (15)$$

The initial estimates of the unknowns R/gD , c/\sqrt{gd} , $a_0 - a_J$ were set to the still water values $\{1.5, 1, -1, 0, 0, 0, 0\}$ and the time vector t_k (embedded in the velocity equations) was scaled such that the temporal length of the window was between -1 and +1. This, along with the appropriate rescaling if the system on equations approximates orthogonality in the velocity potential (Fenton, 1994), a property not held by the polynomial chosen.

Once this solution has been obtained, the location of the surface can be calculated. Bernoulli's equation at the unknown surface η

$$F_{\eta} = R - \frac{1}{2}u_{\eta}^2 - \frac{1}{2}v_{\eta}^2 - g\eta, \quad (16)$$

is a nonlinear equation in one unknown and can be solved at any time within -1 and +1. In the results that follow the surface estimates shown were calculated in the middle of the window ($t = 0$).

When dealing with experimental data each window was smoothed using an equally weighted moving average filter which was made larger or smaller depending upon the quality of the pressure data used. $K = 11$ was used for numerically generated smooth data while $K = 17$ was used for real data. As with the other LPA method it was found to be unnecessary to use a degree of approximation greater than $J = 4$.

It was sometimes required, when analysing extreme waves, such as in Figure 4, that the length of the window be made a smaller proportion of the wavelength than was normally used to allow convergence of the least squares routine. To give an adequate number of data points in the smaller window, the number of points actually used in the solution was increased by cubic spline interpolation, adding data points in between the originally sampled data, in a similar manner to Sobey (1991) with his surface based local Fourier method.

Methodology

The methods described above were tested with data from a Fourier method for generating steady waves (Fenton, 1988) and with experimental data obtained in a wave flume. The input from the Fourier method was generated for three different wavelengths, $\lambda/D=6.31, 10$ and 19.95 all with 64 data points per wavelength plus 5 extra points at each end of the data. The waves shown are extreme with a height/depth ratio (H/D) of 0.6. The gathering of the experimental data is described below.

Experimental Procedure

Experiments were performed in the large wave flume in the Department of Mechanical Engineering at Monash University. The facility is 52m long, 2.5 m wide with two working sections of 4m and 2.5m connected by a ramp. The shallower working section was modified for a working depth of 1.5m with a false floor. It is capable of generating both regular and irregular waves using a feedback system to obtain the desired sea state. There is a wave absorbing beach at the far end which allows less than 10% reflection across the range of working frequencies.

Four pressure transducers were set into a false wall in the flume at y_p/D ratios from 0 to 0.5. Two more transducers were mounted further 'downstream' at y_p/D of 0 and 0.5 to obtain phase data if required. The surface elevation above the first column of transducers was measured using a capacitance wave probe.

Results

Numerically generated data

Figure 1 shows results for a short wave with $\lambda/D = 6.31$, $H/D = 0.6$ with the pressure measured on the bed ($y_p/D = 0$). It seems that LPA methods should not be used for waves shorter than this, the full LPA and the NOLPA underestimating the crest. The traditional linear spectral method and the simple LPA do not perform at all well. Considering the considerably attenuated signal that occurs with such a short wave it is significant that the two LSA methods are almost identical and predict the wave height well although the wave shape is poor. Note the failure of the LSA methods on the wave "shoulder".

Figure 2 shows a longer wave with $\lambda/D = 10$ and all other properties the same as the previous figure. At this wavelength/depth ratio, the level attenuation of the pressure signal is much less and the quality of the output from all methods is higher. Only the simple LPA underestimates the crest while the full LPA and the NOLPA perform extremely well. The LSA methods perform in a similar manner to the previous figure and the linear spectral method does not describe the trough of the wave very well.

Figure 1: $\lambda/D = 6.31$, $H/D = 0.6$, $y_p/D = 0$

Figure 2: $\lambda/D = 10.0$, $H/D = 0.6$, $y_p/D = 0$

The wave in Figure 3 is identical to that in the previous figure, the difference being that the pressure was sampled higher in the water column, at $y_p/D = 0.5$. The most noticeable improvement is the result from the linear spectral method, the higher measurement position detecting the higher frequency components required to describe the trough of the wave. The performance of the simple LPA is much improved, while all other methods are similar in their performance to Figure 2.

Figure 3: $\lambda/D = 10.0$, $H/D = 0.6$, $y_p/D = 0.5$

Figure 4 is a longer wave again, with $\lambda/D = 19.95$ but with the pressure, once again measured at the bottom. Once again the linear spectral method cannot describe both the sharp crest of the wave and the long flat trough, as the high frequency components attenuate completely before reaching the sea bed. The LSA methods predict both the profile and the height well, with a slight overprediction of the crest, as does the NOLPA. The simple LPA underpredicts the crest, as could be expected, while the full LPA performs very well.

Figure 4: $\lambda/D = 19.95$, $H/D = 0.6$, $y_p/D = 0$

Experimental data

The irregular wave results shown in this section were generated from a JONSWAP spectrum with the properties: peak frequency, $f_0 = 0.4$ Hz, $D = 1.55$ m, Stokes current, $c_s = 0$, and a sampling rate of 20 Hz. The exception is Figure 7 where there is an Eulerian current, $c_e = 0.134$ m/s in the direction of wave propagation. This peak frequency corresponds to a λ/D ratio of approximately 6 in this water depth, a condition where the LPA methods are not expected to perform at their best. Unfortunately the flume is not capable of generating irregular waves with a lower peak frequency.

The full LPA method is not shown in these results. This method was shown to be extremely sensitive to noisy data in an earlier, numerical comparison (Townsend and Fenton, 1995), where convergence appeared to be case dependent with regard to the number of data points per window.

The almost identical performance of the two LSA methods was shown in the previous section and due to the more cluttered appearance of the experimental results, the first order LSA has not been included. The empirical LSA has also proved to be more robust when dealing with noisy data.

Figure 5: $y_p/D = 0$, $c_s = 0$

Figure 5 shows a zero Stokes current condition with the pressure measured at the floor of the flume. The effect of the noise in the pressure signal is evident, with the linear spectral method providing the smoothest output due to its inherent low pass filtering. The empirical LSA performs well, with the exception of the expected occasional failure, while the simple LPA and the NOLPA perform almost identically, which is well considering the shortness of the waves.

The wave trace shown in Figure 6 is the same as in Figure 5 except that the pressure data was measured almost halfway up the water column ($y_p/D = 0.484$). All methods exhibited an improvement with this data, with the signal to noise ratio being more favourable.

Figure 7 shows a wave train with a superimposed Eulerian current of 0.134 m/s. In this case the first order LSA differs from the empirical LSA in that, like the linear spectral method, it can be modified to account for the current. The linear spectral method and the first order LSA were modified by including the current in the wave number calculation. The LPA methods already had the current included in the expression for ϕ (equation 7). Surprisingly the differences between the first order LSA and the empirical LSA are quite small. The current level is the highest that can be generated in the wave flume but it seems that it is not high enough to have a

significant effect on the wave properties. All other methods performed in a manner similar to the other irregular wave traces

Figure 6: $y_p/D = 0.484$, $c_s = 0$

Figure 7: $y_p/D = 0$, $c_e = 0.134$ m/s

Figure 8 shows a moderately long regular wave with wave period, $T = 4.1$ s and zero Stokes current. This gives a λ/D ratio of approximately 12 in the wave flume. All methods perform well with this moderately long and high wave, although it can be seen that the empirical LSA is affected by the noise in the pressure signal.

Figure 8: regular wave, $T = 4.1\text{s}$, $y_p/D = 0$, $c_s = 0$, $\lambda/D \approx 12$

Conclusions

A comprehensive comparison of a variety of global and local wave analysis methods has been conducted. The aim was to compare the accuracy of these methods for determining wave surface elevation data from sub-surface pressure readings. Overall the local methods are more effective in dealing with highly nonlinear steady waves than is the global linear spectral method. Unsurprisingly, all methods provided better results with pressure readings taken higher up in the water column.

The linear spectral method performed better for moderate waves but behaved poorly when the waves were steep and y_p/D was small. Both the LSA methods behaved similarly, generally predicting wave heights well. These methods were affected by noise although a post analysis smoothing routine would result in fairly smooth curves. Of the two, the empirical LSA is the simpler to apply, without sacrificing any accuracy compared to the first order method. However a disadvantage of the LSA methods is the failure just above the trough or the 'shoulder' of the wave.

The simple LPA method does not perform as well as the LSA methods when predicting wave heights from pressure readings at low y_p/D values but generally describe the wave profile with greater accuracy and is reasonably accurate when y_p/D is high. It is able to deal with noise in a satisfactory manner, better in fact than the full LPA method. In addition to this, the simple LPA is much easier to derive and program than the full LPA. The fragility of the full LPA method is unfortunate as its accuracy is higher than all other methods if no noise is present.

Many of these shortcomings have been addressed by the nonlinearly optimised local polynomial approximation. Accuracy is comparable to the full LPA, it is simple to develop the theory and it is possible to deal with noise in a relatively simple manner. As with all the LPA methods, it performs better when dealing with longer waves, due to the polynomial form of the velocity potential. As a rational nonlinear method these results are promising and there is potential for further development to determine the full wave kinematics.

CHAPTER 47

A Nonlinear Model for Wave Propagation

Ting-Kuei Tsay¹ Philip L.-F. Liu² Nan-Jing Wu³

Abstract

Employing the Hamiltonian theory, the canonical equations of water waves is used to derive a nonlinear model. In this paper, a unified nonlinear model for water wave propagation is presented. This model can be simplified to the mild-slope equation in the linear case. It is consistent with Stokes wave theory when water depth is deep and reduces to an equation of Boussinesq's type in shallow waters. Results of numerical computations of nonlinear water waves propagating over a submerged bar and a rectangular step are also presented in one-dimensional case. Nonlinear behaviors of water waves are captured, but further works are needed.

Introduction

A unified mathematical model for wave propagation from deep sea into the coastal waters has been long in pursuit. In early seventies, the mild-slope equation was first derived independently by Berkhoff (1972) and Smith & Sprinks (1975). The mild-slope equation reduces to the Helmholtz equation in deep waters and constant water depth. It reduces to shallow water wave equation when water depth becomes shallow. Because of depth integration, the mild-slope equation has simplified the three-dimensional problem into a two-dimensional one on the horizontal plane. Although the original equation is derived for monochromatic waves, it has been used for the entire spectrum of wave frequency. Based on the mild-slope equation, several numerical models have been developed to describe the combined wave refraction and diffraction successfully (Bettess and Zienkiewicz, 1977; Tsay and Liu, 1983).

In order to take other physical mechanisms, such as absorbing boundary, energy dissipation and fast-varying water depth, etc, into accounts, a variety of model equations has been employed to develop numerical mod-

els for computation of wave scattering (Chen, 1986; Kirby, 1986; Tsay et al., 1989). However, all of the model equations are limited to linear waves. The nonlinear effects can not be ignored for waves of finite amplitude or when linear waves propagate into the shallow water regions. For weakly nonlinear waves over varying topography, mathematical models have been proposed either using Stokes' approach or employing Boussinesq equations (Liu & Tsay, 1984; Witting, 1984; Liu, et al., 1985; Nwogu, 1993; Liu, 1993). These models are limited to different water depth regimes. A unified model to describe wave transformation when it propagates from deep sea into coastal shallow water is strongly desired (Witting, 1984; Nwogu, 1993; Liu, 1993).

The governing equations for weakly nonlinear water waves can be obtained by employing the Hamiltonian theory in variational calculus (Broer, 1974). Radder and Dingmans (1985) had shown that the canonical equations of the Hamiltonian theory can be reduced to Stokes' wave form in deep waters and reduced to a Boussinesq-type equation in shallow waters. However, Radder and Dingmans did not derive an explicit, nonlinear equation for wave propagation. In this paper, employing Taylor's series expansion of free surface displacement and keeping the terms up to the third-order, we derive a unified nonlinear model equation for wave propagation. Validity of present nonlinear model is demonstrated theoretically by comparing model equations for different regimes of applications. Present nonlinear model is applied to calculate waves propagating over a submerged bar and a rectangular step in the third section. Discussions of present nonlinear wave model are followed.

Mathematical Formulation

For self-completeness of this paper, we give a brief derivation following Broer (1974), and Radder and Dingmans (1985).

For water body defined between bottom, $z = -h$, and free surface ζ , the canonical equations of Hamiltonian theory can be expressed as:

$$\frac{\delta H}{\delta \phi} = \frac{\partial \zeta}{\partial t} \quad (1)$$

$$\frac{\delta H}{\delta \zeta} = -\frac{\partial \phi}{\partial t} \quad (2)$$

where ϕ is the free surface velocity potential, and ζ is the free surface displacement. H is a functional and represents the total energy of water body.

$$H = \iint H_0 dx dy \quad (3)$$

where H_0 is the energy density function and can be written as:

$$H_0 = \frac{1}{2}g\zeta^2 + \frac{1}{2} \int_{-h}^{\zeta} [(\nabla\Phi)^2 + \left(\frac{\partial\Phi}{\partial z}\right)^2] dz \quad (4)$$

where the velocity potential at any point, Φ , is related to the velocity potential at the free surface by a distribution function in z -direction.

$$\Phi = f(z)\phi \tag{5}$$

with

$$f(z) = \frac{\cosh k(z+h)}{\cosh k(\zeta+h)} \tag{6}$$

It is noted that $f(\zeta) = 1$ and k is a characteristic value. When ζ is dropped from the equation, the distribution function reduces to the same one as linear cases and the characteristic value k represents wave number.

Assuming that change rates of water depth and characteristic value are negligible when slope of water bottom is mild, eqs.(1) and (2) after integrating from the bottom to the free surface can be expressed as:

$$\begin{aligned} \frac{\partial \zeta}{\partial t} = & (D + E\zeta)\nabla\phi \cdot \nabla\zeta + (F + G\zeta + H\zeta^2)\phi + I\phi(\nabla\zeta)^2 \\ & - \nabla \cdot [(A + B\zeta + C\zeta^2)\nabla\phi + (D + E\zeta)\phi\nabla\phi] + O(\zeta^4) \end{aligned} \tag{7}$$

$$\begin{aligned} \frac{\partial \phi}{\partial t} = & -[g\zeta + \frac{1}{2}(\nabla\phi)^2(B + 2C\zeta) + E\phi\nabla\phi \cdot \nabla\zeta + \frac{1}{2}\phi^2(G + 2H\zeta)] \\ & + \nabla \cdot [(D + E\zeta)\phi\nabla\phi + I\phi^2\nabla\zeta] + O(\zeta^4) \end{aligned} \tag{8}$$

where

$$\begin{aligned} A &= k \tanh kh \\ B &= k(k - k \tanh^2 kh) \\ C &= \frac{2kh + \sinh 2kh}{4k \cosh^2 kh} \\ D &= \frac{\cosh kh - kh \sinh kh}{\cosh^3 kh} \\ E &= \frac{-4kh + 2kh \cosh 2kh - 3 \sinh 2kh}{4k \cosh^4 kh} \\ F &= \frac{k(-2kh + \sinh 2kh)}{4 \cosh^2 kh} \\ G &= \frac{k^3 h \tanh kh}{\cosh^2 kh} \\ H &= \frac{k^3(4kh - 2kh \cosh 2kh + \sinh 2kh)}{4 \cosh^4 kh} \end{aligned} \tag{9}$$

The free surface, ζ , is related to the velocity potential, ϕ ,

$$\begin{aligned} \zeta = & -\frac{1}{g} \frac{\partial \phi}{\partial t} - \frac{1}{2g} [(B - \frac{2C}{g} \frac{\partial \phi}{\partial t})(\nabla\phi)^2 - \frac{2E}{g} \phi \nabla(\frac{\partial \phi}{\partial t}) \cdot \nabla\phi + (G - \frac{2H}{g} \frac{\partial \phi}{\partial t})\phi^2] \\ & - \frac{1}{g} \nabla \cdot [(-D + \frac{E}{g} \frac{\partial \phi}{\partial t})\phi\nabla\phi + \frac{I}{g} \phi^2 \nabla(\frac{\partial \phi}{\partial t})] + O(\zeta^4) \end{aligned} \tag{10}$$

Combining eqs.(7) and (8), a nonlinear equation of velocity potential can be obtained as:

$$\begin{aligned}
& \frac{1}{g} \frac{\partial^2 \phi}{\partial t^2} + \frac{1}{2g} \frac{\partial}{\partial t} \left[\left(B - \frac{2C}{g} \frac{\partial \phi}{\partial t} \right) (\nabla \phi)^2 - \frac{2E}{g} \phi \nabla \left(\frac{\partial \phi}{\partial t} \right) \cdot \nabla \phi + \left(G - \frac{2H}{g} \frac{\partial \phi}{\partial t} \right) \phi^2 \right] \\
& + \frac{1}{g} \frac{\partial}{\partial t} \nabla \cdot \left\{ \left[-D + \frac{E}{g} \frac{\partial \phi}{\partial t} \right] \phi \nabla \phi + \frac{I}{g} \phi^2 \nabla \left(\frac{\partial \phi}{\partial t} \right) \right\} \\
& = \frac{-1}{g} \left[-D - \frac{E}{g} \frac{\partial \phi}{\partial t} \right] \nabla \left(\frac{\partial \phi}{\partial t} \right) \cdot \nabla \phi - \left\{ \frac{I}{g^2} \left[\nabla \left(\frac{\partial \phi}{\partial t} \right) \right]^2 + F - \frac{G}{g} \frac{\partial \phi}{\partial t} - \frac{GB}{2g} (\nabla \phi)^2 \right. \\
& \quad \left. - \frac{G^2}{2g} \phi^2 - \frac{G}{g} \nabla \cdot (D \phi \nabla \phi) + \frac{H}{g^2} \left(\frac{\partial \phi}{\partial t} \right)^2 \right\} \phi + \nabla \cdot \left\{ \left[A - \frac{B}{g} \frac{\partial \phi}{\partial t} - \frac{B^2}{2g} (\nabla \phi)^2 - \frac{GB}{2g} \phi^2 \right. \right. \\
& \quad \left. \left. + \frac{B}{g} \nabla \cdot (D \phi \nabla \phi) + \frac{C}{g^2} \left(\frac{\partial \phi}{\partial t} \right)^2 \right] \nabla \phi - \frac{1}{g} \left[-D + \frac{E}{g} \frac{\partial \phi}{\partial t} \right] \phi \nabla \left(\frac{\partial \phi}{\partial t} \right) \right\} + O(\zeta^4) \quad (11)
\end{aligned}$$

In shallow water, where the parameter of $kh = \mu$ is small, we expand the coefficients of A, B, C, D, E, F, G, H and I in eq.(9) up to the accuracy of $O(\mu^3)$ of Taylor series. For one-dimensional cases, when normalized variables, $\varepsilon = a/h$ (a : amplitude), $x' = kx, t' = k\sqrt{gh} t, \zeta' = \zeta/a, \phi' = k\phi/\varepsilon\sqrt{gh}$ are introduced, and ε and μ^2 are assumed in the same order of magnitude, eq.(11) can be reduced to:

$$\phi'_{t't'} + \varepsilon(2\phi'_{x't'}\phi'_{x't'} + \phi'_{t'}\phi'_{x't'}) - \phi'_{x't'} = O(\varepsilon^2, \mu^3) \quad (12)$$

This is a nonlinear equation of Boussinesq type for waves propagating over shallow water depths.

Using Stokes expansion,

$$\begin{aligned}
\zeta &= a_1 \cos \theta + (a_{20} + a_{21}) \cos 2\theta + a_3 \cos 3\theta \\
\phi &= b_1 \sin \theta + b_2 \sin 2\theta + b_3 \sin 3\theta + O(a_1^4) \quad (13)
\end{aligned}$$

where $\theta = kx - \omega t$, ω is the radian frequency, we obtain the following coefficients in terms of amplitude, a_1 , up to the accuracy of $O(a_1^4)$:

$$\begin{aligned}
a_{20} &= -\frac{ka_1^2}{2 \sinh 2kh} \\
a_{21} &= \frac{8kh - 4kh \cosh 2kh + 12 \sinh 2kh + \sinh 4kh}{4(-2kh + \sinh 2kh) \sinh 2kh} ka_1^2 \\
b_1 &= \frac{g}{\omega} \left[a_1 + \frac{k^2(66 \cosh kh - 3 \cosh 3kh + \cosh 5kh - 52kh \sinh kh - 4kh \sinh 3kh)}{16(-2kh + \sinh 2kh) \sinh 2kh \cosh kh} a_1^3 \right] \\
b_2 &= \frac{g}{\omega} \frac{k(7 \cosh kh + \cosh 3kh - 4kh \sinh kh)}{4(-2kh + \sinh 2kh) \cosh kh} a_1^2 \\
a_3 &= k^2 a_1^3 (932kh \cosh kh - 246kh \cosh 3kh - 30 \cosh 5kh \\
& \quad + 541 \sinh kh - 264k^2 h^2 \sinh kh + 616 \sinh 3kh + 72k^2 h^2 \sinh 3kh \\
& \quad + 78 \sinh 5kh + 3 \sinh 7kh) / [128(-2kh + \sinh 2kh)^2 \sinh kh \cosh^2 kh] \quad (14)
\end{aligned}$$

with the nonlinear dispersion relation:

$$\begin{aligned}
\frac{\omega^2}{g} &= k \tanh kh \left[1 \right. \\
& \quad \left. + \frac{32kh - 16kh \cosh 2kh - 4kh \cosh 4kh + 31 \sinh 2kh + 4 \sinh 4kh + \sinh 6kh}{8(-2kh + \sinh 2kh) \sinh 2kh^2} k^2 a_1^2 \right] \quad (15)
\end{aligned}$$

The quantity of a_{20} represents change of lower mean water level under nonlinear wave action and is the same as that derived by Bowen (1968) for wave set down.

When kh approaches infinity for deep water depth, those coefficients in eqs. (14), and nonlinear dispersion relation, eq.(15) reduces to:

$$\begin{aligned} a_{20} &= 0 \\ a_{21} &= \frac{1}{2}ka_1^2 \\ a_3 &= \frac{3}{8}k^2a_1^3 \\ \frac{\omega^2}{g} &= k(1 + k^2a_1^2) \end{aligned} \quad (16)$$

These results are identical to those in the Stokes wave theory.

When all the nonlinear terms are dropped and monochromatic waves are assumed, eq.(11) can be easily simplified to the mild-slope equation (Berkhoff, 1972) with linear dispersion relation of the characteristic value, k , defined as wave number.

The model equation, eq.(11), therefore unifies propagation of nonlinear waves from deep to shallow water depths which is accurate up to the third order of incident wave amplitude. We plausibly use eq.(11) to simulate nonlinear wave propagation.

Numerical Computations

Due to the complexity of the model equation and difficulty of determining the characteristic value for nonlinear waves of third order, we employ Stokes expansion for second order nonlinear monochromatic waves.

$$\zeta = Re\{\zeta_0 + \zeta_1e^{-i\omega t} + \zeta_2e^{-2i\omega t}\} + O(|\zeta_1|^3) \quad (17)$$

$$\phi = Re\{\phi_0 + \phi_1e^{-i\omega t} + \phi_2e^{-2i\omega t}\} + O(|\phi_1|^3) \quad (18)$$

The model equations for different orders can be written as:

$$\left(\frac{\omega^2}{g} - F\right)\phi_1 + \nabla \cdot (A\nabla\phi_1) = 0 \quad (19)$$

$$\zeta_1 = \frac{i\omega}{g}\phi_1 \quad (20)$$

$$\zeta_0 = \frac{-B}{4g}|\phi_1|^2(\nabla S_{\phi_1})^2 - \frac{G}{4g}|\phi_1|^2 \quad (21)$$

$$\begin{aligned} \left(\frac{4\omega^2}{g} - F\right)\phi_2 + \nabla \cdot (A\nabla\phi_2) &= \frac{D}{2}\nabla\phi_1 \cdot \nabla\zeta_1 + \frac{G}{2}\phi_1\zeta_1 - \nabla \cdot \left(\frac{B}{2}\zeta_1\nabla\phi_1 + \frac{D}{2}\phi_1\zeta_1\right) \\ &+ \frac{2i\omega}{g}\left[-\frac{B}{4}(\nabla\phi_1)^2 - \frac{G}{2}\phi_1^2 + \nabla \cdot \left(\frac{D}{2}\phi_1\nabla\phi_1\right)\right] \end{aligned} \quad (22)$$

$$\zeta_2 = \frac{2i\omega}{g}\Phi_2 - \frac{B}{4g}(\nabla\phi_1)^2 - \frac{G}{4g}\Phi_1^2 + \frac{1}{g}\nabla \cdot \left(\frac{D}{2}\Phi_1\nabla\phi_1\right) \quad (23)$$

where S is the phase function and the characteristic value, k , determined by the dispersion relation of

$$\frac{\omega^2}{g} = k \tanh kh \quad (24)$$

Wave field can be calculated by using eqs.(19), (20), (21), (22), and (23) for each component. The free surface displacement is obtained by employing eq.(17). For the case of nonlinear waves propagating over a submerged bar (Beji and Battjes, 1994), Fig. 1, incident waves with wave height 2cm , period 2sec . propagate from left to right. The constant depth before the bar is 0.40m and the Ursell number, ($U_r = (a/h)/(kh)^2$), is 0.054 . In the computational domain of 12m , 481 nodal points are used. For numerical calculations, eqs.(19) and (22) are discretized into finite difference equations. Radiation conditions of outgoing wave components are applied to both ends of the computational domain. The sloping bottom on the right hand side is assumed to absorb all of the wave energy. In experiments (Beji and Battjes, 1993), gage 1 indicated incident waves. We compare the numerical solutions with experimental results for waves over the submerged bar (Figs. 2, 3, 4, 5, 6 and 7). The numerical solutions are obtained by calculating amplitude distribution in space of each component and reconstructing the time history of free surface at each point. It can be observed that there is a significant difference between linear and nonlinear waves. The nonlinear behavior of waves due to change of water depth is captured by present nonlinear model quite nicely. However, discrepancy between numerical solutions and experimental results at wave troughs seems quite persistent.

We further extend present nonlinear model to calculate waves over a step, Fig.8 (Kittitanasuan et al., 1993). Although the slope at the step violate mild-slope assumption, waves evolve nonlinearly after the step. The depths before and after the step are 0.376cm and 0.113cm , respectively. Incident wave height is 1.63cm and period 1.85sec . The Ursell number in this case is 0.042 . Total nodal points of 601 are used in a 12m computational domain. The step is simulated by a sudden change of water depth between two nodes with a slope of 6.575 . Present numerical time histories of free surface at points after the step of 1m and 2m are compared with experimental results, Figs.9 and 10 (Kittitanasuan et al., 1993). Good agreement is observed except profiles at wave troughs. We also calculate free surface profile in space and compare with that of Kittitanasuan et al (1993). The step is located at the origin of x-axis. Waves behaves almost linearly before the step and evolve nonlinearly further away from the step. Present nonlinear model is in good agreement with theory of Kittitanasuan et al (1993).

Discussions and Conclusions

In this paper, we present a derivation of nonlinear model in the accuracy of $O(\zeta^4)$ for water wave propagation. It unifies nonlinear wave models for different depth regimes. Present nonlinear model reduces to the mild-slope equation in the linear case. It is shown that present model can be simplified to a Boussinesq equation for shallow water and Stokes waves when water

depth is deep. However, due the complexity of the governing equation and the difficulty in determining the characteristic value of dispersion relation, we calculate nonlinear waves up to the second order and compare present numerical solutions with experimental results in two one-dimensional cases. Good agreement is obtained. Discrepancy between present numerical solutions and experimental results of free surface profiles at wave troughs remains for future study.

CHAPTER 48

APPLICATION OF A DIGITAL PARTICLE IMAGE VELOCIMETRY (DPIV) SYSTEM TO BREAKING WAVES IN THE SURF ZONE

Kenneth R. Craig II¹ and Robert J. Thieke²

BACKGROUND

The modeling of cross-shore and longshore currents in the nearshore region has improved greatly over the past twenty years with accompanying advances in an understanding of the relevant physical processes in shallow water and the surf zone. The empirical guidance provided by numerous laboratory and field experiments has been an essential element in sustaining these advances. However good experimental data are still largely lacking for aspects of these flows, the most notable being the flow in waves following breaking, which coincidentally represents the single most important physical process in the nearshore region.

For the two-dimensional case of waves normally incident on a beach, a variety of techniques have recorded velocities in surf zone flows. Wang, et al. (1982) used tracer techniques incorporating particles and film to provide significant qualitative information, but it generally suffers from poor spatial resolution and generally provides lagrangian information where an eulerian perspective is desirable. The air entrainment associated with the free surface instability of breaking waves also inhibits these methods, particularly near the water surface. Jansen (1986) used fluorescent tracers and ultraviolet light to view particle trajectories in the aerated region of breaking waves, yet these measurements still suffer from the other previously mentioned shortcomings. More recently several investigators have employed velocity measurement using Laser Doppler Anemometry (LDA). Stive (1980) and Nadaokah and Kondoh (1982) have contributed some of the early significant data sets using this technique in the surf zone. LDA offers very high precision and spatial resolution but the time it requires generally precludes any truly synoptic measurements of the flow

field. However, the most significant drawback to LDA techniques is that the high levels of air entrainment typical of the upper surf zone cause such significant signal drop-out as to completely degrade the fidelity of the measurements in this region. For example, although Nadaoka and Kondoh (1982) provide measurements of the vertical distribution of cross-shore velocity at several stations through the surf zone, they do not provide measurements above the level of the wave trough, and aeration affects the velocity profiles below the trough in the inner reaches of the surf zone significantly. As a result even averaged quantities such as the shoreward directed mass flux (due to contributions above the wave trough level) are not measured directly but only inferred by integration of the corresponding below-trough velocity measurements. These restrictions inhibit the development of a complete picture of the vertical flow structure in this region.

DPIV THEORY

Willert and Gharib (1991) describe a system that digitally performs a process similar to the opto-mechanical method employed in particle image velocimetry. Neutrally buoyant particles are introduced into a fluid flow and video images are recorded and digitized. Sequential digital images (each frame capturing a single instance in time) are analyzed using frequency domain techniques. After digitizing, small sections of each image, called areas of interest (AOIs), are compared. The AOIs represent identical locations on each consecutive image.

Willert and Gharib used the mathematical definition of cross-correlation in the frequency domain

$$\Phi_{fg}(u,v) = F^*(u,v) \times G(u,v) \quad (1)$$

where F^* is the complex conjugate of the Fourier transform of $f(m,n)$ and $G(u,v)$ is the Fourier transform of $g(m,n)$. They employed fast Fourier transforms (FFT) to reduce processing time. After finding Φ , they performed an inverse FFT to return the data to the spatial domain.

Essentially the process tries to match the pattern found in the first AOI with that in the second after the pattern has shifted. The location of the peak value of the cross-correlation function represents the point that best correlates the particle positions in each AOI. The shape of the peak value depends on the noise level. Large amounts of noise tend to broaden the peak. Smaller peaks also occur due to some correlation between incorrect particle pairings. However, the maximum value found in Φ_{fg} indicates the best correlated displacement over the AOI. Particles generate noise as they move out of the AOI laterally, vertically or normal to the plane of view. Assumably the AOI is large enough to allow a majority of the particles in the first AOI to appear in the second. Figure 1 shows a typical example resulting from the application of the correlation technique for particles settling in the +y direction.

Figure 1 Graphical representation of pixel intensities within an area of interest in a) image 1 and b) image 2 and c) the inverse transformed correlation peak in the spatial domain. The maximum peak in c) indicates a displacement of approximately 4 pixels in the +y direction (downward).

Two different centroiding techniques may then be employed to examine the peak. A center of mass method (Kimura and Takamori, 1986) provides one pixel accuracy but depends on the threshold value used to determine the limits of the peak. The method Willert and Gharib suggest provides sub-pixel accuracy. In controlled experiments, they found a minimum uncertainty value of 0.01 pixels. However, in practice the uncertainty may reach an order of magnitude higher. The peak and each of the two neighboring data points are fitted with parabolic curves in both the vertical and horizontal directions. The distances from the origin to the location of the maxima of these parabolas determine the displacement vector to sub-pixel accuracy. Dividing the displacement vector by the known time difference between frames provides the velocity vector.

EXPERIMENTAL SETUP

All experiments were carried out by the authors at the University of Florida's Coastal and Oceanographic Engineering Laboratory in Gainesville, Florida, USA. Waves were generated in the multifunctional wave flume equipped with plate glass panels running the entire length on both sides providing flexible access to camera and lighting positions. Wave data were collected using a capacitance type wave gauge. Six separate tests were run: tests 1, 2, and 3 in approximately 30 centimeters of water and tests 4, 5, and 6 in approximately 23 centimeters of water. For each test series at a specific water depth, the wave periods varied from 0.85 to 2.13 seconds. The video tape and wave data were then analyzed to determine velocity fields, mean water level set-up and wave height distributions.

All video imaging employed gray scales rather than color because gray scales provide a higher spatial resolution and tangibly greater light sensitivity. Gray scale video equipment also costs substantially less than similar quality color equipment. The advantage of gray scale imaging is realized during processing because DPIV relies on pixel intensity values to distinguish particles. Color does not offer any advantage over gray scale for this process.

Mulifunctional Wave Flume

The internal wave flume—approximately 28 meters long, 58 centimeters wide and 1.4 meters deep—is equipped with both a flap type and piston type wave maker. The smaller Seasim RSP 60-20 Modular Piston Wave maker used during the experiments is computer controlled through a central electronic system with feedback loops to minimize reflections and generation of free second harmonics. The wave maker produced monochromatic waves propagating towards a fixed beach with slope 1 on 20. The horizontal bottom portion of the flume extends 15 meters from the wave maker. The fixed beach slope then extends for another 10 meters. The flume also comes with a remotely controlled carriage capable of transiting its entire length. A capacitance type wave gauge was attached to the movable carriage and cabled to a data acquisition computer.

Video equipment used at the experiment site included a Panasonic WV-5470 high resolution gray scale video monitor, a Panasonic AG-1970 super-VHS recording

VCR, and a Vicon VC2400 high resolution gray scale CCD video camera with variable shutter speed. The camera provides 570 lines of horizontal resolution (which is actually above super-VHS quality) and requires only 0.2 lux minimum illumination. Shutter speeds range from continuously open to 1/10,000 of a second. A shutter speed of 1/1,000th of a second minimized blurring of the particles and still allowed sufficient light to pass through the camera lens for adequate videotaping. Both zoom and wide angle lenses were available for use. Lens magnification depended upon the wave characteristics at each particular camera location. The goal was to fill the view with as much of the flow field as possible to maximize resolution during processing. Ambient light was controlled by placing a light shield made of flexible polyurethane coated nylon fabric around the position of the video camera and flume. The light shield covered three panes of glass and could be positioned anywhere along the flume. Removable side panels on the light shield provided access to the camera when necessary. All video was recorded on master quality double coated super-VHS video tapes.

The moveable chassis was equipped with the following items: a light source, a cylindrical focusing lens and a dispenser for the neutrally buoyant particles. The light source was a 500 watt electric bulb enclosed in a wooden box with a slit approximately 2 millimeters wide cut in the bottom. The slit was aligned with the long axis of the flume (i.e., direction of wave propagation) and allowed only a portion of the light from the bulb to escape the box as a quickly dispersing plane (see Figure 2 for a schematic of the experimental apparatus).

The light then passed through the cylindrical lens and focused into a tight plane perpendicular to the bottom of the flume. With the lens approximately 1 meter above the flume bottom, the focused light diffused to a width of 1 centimeter at the flume bottom. Notably the light only remained on for periods of a few minutes to minimize the chance of overheating caused by the high power consumption of the light source and the wooden box. Despite this safety precaution, the inside bottom of the box was charred by the end of the experiment. The use of a nonflammable material to construct the light box for future applications is recommended.

Pliolite, a granular material used as a road paint strengthening ingredient with a specific gravity of 1.04 was used for the neutrally buoyant particles. Bright white, Pliolite is readily visible under the lighting conditions used during the experiments. Pliolite's highly irregular shape traps a proportionately large amount of air, causing the Pliolite to remain on the water surface when first introduced. Therefore, the pliolite was first washed in liquid soap and stored under water to facilitate breaking the surface tension when the particles were introduced to the flume. Separating the fines from the pliolite left particles ranging in size from 0.5 to 2 millimeters.

The pliolite dispenser, located next to the light source, was designed to work like a hopper. A board was fixed diagonally across the inside of the dispenser to act as a chute for the released pliolite. A second hinged board was installed so that it would form a "V" with the fixed board. Two elastic bands maintained tension on the hinged board. The pliolite was placed along the intersection of these two boards and held there until being dispensed. The chute was positioned to distribute the particles

linearly near the intersection of the light plane and the water surface. The pliolite release mechanism, designed to overcome the tension of the elastic bands, was connected to the outside of the flume. Water from an elevated container located above the chassis was fed along the top of the fixed board by plastic tubing and released through a series of small holes directed down the chute. This water washed any pliolite out of the dispenser that gravity had not removed during the initial opening.

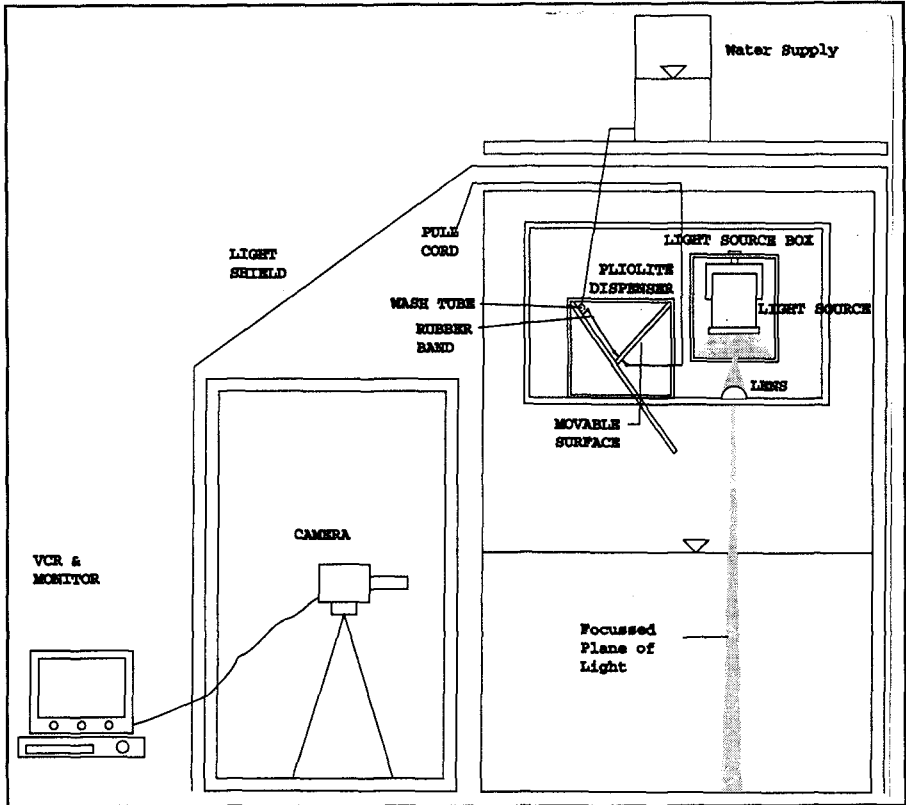

Figure 2 Experimental apparatus including video equipment location and movable chassis arrangement (cross section, long axis of tank).

To calibrate the video, a grid of 2 centimeter by 2 centimeter squares etched in clear Plexiglas was used to compensate for the magnification effects of filming through three types of media, namely air, glass, and water. Video of this grid was used to determine the number of pixels per centimeter as recorded by the camera. The bottom of the grid, tapered to the beach and held firmly to the slope, allowed the grid lines to be read vertically and horizontally.

Experiments began once the wave flume was filled to the appropriate water level and allowed to settle, after which a water depth reading was recorded from the flat portion of the flume. The wave maker then generated waves at the designated frequency. These waves were observed to determine the break point position and initial camera location. Wave gauge data were recorded along the flat portion for a deep water reading, at the beginning of the slope for initial shoaling data, and any appropriate locations outside and within the surf zone for setup and shoaling data.

The number of camera positions required for each test depended upon the field of view that could be achieved. The area from just outside the breakpoint to inside of the transition point was the focus of these experiments. The camera was placed inside the light shield at the proper location and the position of the center of the field of view along the flume was recorded. Next, the calibration grid was placed along the long axis of the flume in the field of view. The light source without the focusing lens illuminated the grid. This allowed filming the grid and minimizing any shadows the grid produced. It was found that the cylindrical lens created shadows too intense to provide any readings from the grid. The grid also allowed the camera to be focused to the proper location at the tank centerline. The pliolite was loaded into the dispenser and the flushing water source was connected to the dispenser and the focusing lens was replaced. At this point, the VCR began recording, the pliolite was released into the flume, and the light source was turned on. To produce an adequate ensemble average of flow characteristics required a minimum 30 cycles for each wave so taping lasted about two minutes for each test, at which point the light was shut off and the recording stopped. The camera was then moved to a location partially overlapping the field of view of the previous position and the process repeated until the transition point had been recorded.

When the taping ended the wave maker was stopped and the flume water level allowed to settle in order to eliminate any residual low frequency activity. Wave gauge data for still water levels were recorded for each station previously investigated. A second water level reading was taken in the flat portion of the flume to determine if any water was lost during the testing. The entire process was repeated for the next wave frequency.

DATA PROCESSING

All image digitization was carried out on a personal computer equipped with a 80486/66 MHz DX2 CPU. Computer peripheries included an EditLink 2200/TCG VCR controller card and a one megabyte frame grabber board as accessories. An image processing software package with macro language capabilities digitized and filtered the images. Several C language programs were written to control the VCR through the VCR controller card. The same super-VHS recording VCR and high resolution monitor were used during the digitization process.

The EditLink 2200/TCG can stripe a video tape with longitudinal Society of Motion Picture and Television Engineers (SMPTE) time code on one or both audio tracks. This was done after initial taping; however striping the tape before taping reduces the possibility of erasure. The EditLink manufacturers claim that the time

code can be used to locate any position on the video tape to an accuracy of +/- 1 frame. Trials of various positions on the tape confirmed this. Actually, each trial resulted in the EditLink finding the exact frame searched.

Macro files were written to automate the process of digitizing the video images by the frame grabber board. The images were processed in batches of 50. First, an image is digitized at a resolution of 640 columns by 480 lines. The 480 lines is the maximum allowable vertical resolution of the frame grabber card. A compiled C program called from the macro instructs the VCR controller card to advance the tape one frame. The next image is digitized and the process repeated. After 50 images have been digitized, a C program stops the VCR. This circumvents the automatic shut-off feature of the Panasonic AG-1970. This feature will shut the VCR off if it detects no "activity" for roughly three consecutive minutes. Unfortunately, it does not recognize frame advance as "activity." This 50 image limit actually provides an amount of data, about 15 megabytes, that most current hard disk drives can reasonably handle.

Next, the fifty images were filtered. The filtering process is based on a histogram analysis of the pixel values in each image. All pixel values lower than the 90th percentile are set to black or 0. All remaining pixels from the 90th to 99th percentile are linearly scaled from black to white (0 to 255). These filtered images were stored for later processing. A C program then directs the EditLink to find the next frame and digitizing continues.

The filtering process produced one of the most important advances in this research. Air bubbles entrained in the flow due to the breaking wave's impinging jet can be filtered out of the image. Given the lighting conditions used in the experiment, the bubbles have lower gray scale pixel intensities than do the pliolite. By visual inspection of the filtered images, the authors determined the histogram percentile range for the air bubbles and pliolite.

A Sun SPARC-LX workstation processed most of the velocity fields. The 486 microcomputer can process the velocity fields about 33% slower than the Sun workstation, so it was used to process only a small portion of the velocity fields. *Matlab*® by the Math Works, a matrix manipulation software package (also with macro language capabilities), was used to process the images on both the 486 microcomputer and the Sun workstation. All analysis of the velocity fields was done on the 486 microcomputer using this software package.

The filtered images were transferred to the Sun (or occasionally the 486) for DPIV processing. A series of M files (*Matlab*® macro language) were written to fully automate the process of analyzing the images and returning velocity fields. All data (i.e., filtered images and velocity field files) were stored on a high capacity magneto-optical (MO) disk in compressed format. The MO disk can store over 600 megabytes of data and currently contains over 200 MB of compressed velocity field data and over 300 MB of compressed filtered images.

A concern exists regarding the extent to which aeration of a broken wave crest, combined with the filtering process, may affect the velocity field determination in DPIV. The bubbles produced during wave breaking may distort the perceived

location of particles due to refraction/diffraction of the reflected light. To determine the net effect of this phenomenon, a mesh grid containing particles glued to fixed positions was videotaped in the highly aerated section of flow centered on the transition region. Velocity fields were then found for this video. In theory, particles held stationary should produce zero motion in the velocity fields. Analysis of the calculated velocity fields indicated that the distortional effects of the bubbles create a mean error of 1.0 pixels in the horizontal direction and 0.8 pixels in the vertical direction. A typical scaling scenario in the test conducted results in a converted 0.5 millimeter error in the calculated displacements.

VELOCITY FIELD RESULTS

Velocity field processing began by determining the calibration values used to convert pixels to centimeters for each camera position. This rather primitive method consisted of analyzing several frames from the grid video. Unfortunately, the grid lines were very difficult to observe in the still video frame. However, the outer edges of the grid—surrounded by an opaque paper coating—provided a known distance of 12 centimeters. The pixel columns values corresponding to the left and right edges were determined using a screen pointer and mouse. The difference of these two values divided by the 12 centimeter distance yields the horizontal calibration for that camera position. The vertical calibration was determined by multiplying the horizontal calibration by the pixel aspect ratio. Several frames were compared to evaluate the accuracy of the results. Each test showed slight variation from frame to frame due to slight grid movements on the order of one pixel. An average calibration value was selected after analyzing several frames.

All velocity field processing was done without converting from pixel displacements to actual centimeters per second velocity values. Doing so reduced the multiplicative error effects produced from numerous calculations using the less accurate length conversion from pixels to centimeters. Instantaneous displacement vectors were found in pixel units—final ensemble averages were then converted back to centimeters per second values using the calibrations taken from the recorded grid frames. Vertical and horizontal displacements were saved separately for each image pair processed. Mean flow velocity and turbulence intensities were the two principle derived quantities.

The raw velocity field data resulting from the DPIV method was analyzed using ensemble averaging techniques in an effort to separate the wave and turbulent parts of the motion. Consequently, the corresponding number of video frames per period for monochromatic waves had to be determined. Table 1 shows a summary of the values for the various tests and the relevant measured wave characteristics.

To calculate ensemble values for both mean flow and turbulence requires an appropriate value for the number of frames per cycle (i.e., wave period). Standard video records at 60 frames per second. Multiplying this value and the period and rounding to the nearest whole number yields the frames per cycle. Taking an ensemble average over all of the cycles corresponding to that point in the period then

Table 1 Experimental wave and frame data.

Test Number	Period (sec)	H _b (cm)	h _b (cm)	h _o (cm)	Frames/cycle	Total Frames Processed 30 cycles	Total Frames Processed 50 cycles
1B	0.85	4.85	4.7	31.2	51	N/A	2560
2C	1.42	6.52	4.2	30.7	85	2560	4266
3C	2.13	6.42	4.5	31.2	128	3840	N/A
4C	0.85	N/A	N/A	N/A	51	1536	2560
6A	2.13	8.86	8.4	23.2	128	3840	N/A

yields the mean velocities at each 1/60th of a second interval of the wave period. For example, to process a one second wave (corresponding to 60 frames per cycle) requires the average of frame 1, frame 61, frame 121... However, due to the limiting effect of the Nyquist frequency criterion in the DPIV method, certain sections of each velocity field are sometimes left without a value. In short, holes may exist in the data. This can occur if the area of interest contains a displacement greater than 1/3 its length. This is accounted for by keeping a running total of the number of valid values for each position in the velocity fields during the ensemble averaging. Therefore, to ensemble average 50 cycles requires independent totals for each position in the resulting velocity field. This improves the flawed values near free surfaces where small variations in the wave height produce a physical velocity value during only a few of the cycles. Care must be taken when analyzing the data near boundaries so as not to overstate the effect there. This method ensures that values within the main part of the flow are not understated as they would be if the summed values for, say, 48 cycles were actually averaged over 50 cycles. Both of the above effects become more pronounced for the longer period waves processed using only 30 cycles.

The time averaging analysis consisted of summing the ensemble averaged velocities over the entire period. Absent data are accounted for in the same manner as above. Time averaging the ensemble averaged velocity fields yields the mean flow velocities.

Turbulence was found using the ensemble averaged data for each point during the period. These values are subtracted from the instantaneous values of each velocity field used to find the ensemble average. These differences are squared and summed. Dividing the sum by a running total similar to that described above accounts for the nonexistent data. The turbulence values are then time averaged similar to the mean flow. Turbulence values are returned as squared values, their same form in the momentum conservation equations.

APPLICATION OF RESULTS

A total of 21,162 velocity fields were incorporated in the ensemble averaging during all of the tests. Actually, only 17,066 of these fields are completely independent because the fields found during the 30 cycle ensemble averaging in tests 2C and 4C were used as the first 30 cycles of the 50 cycle ensemble averaging. This allows a comparison of the effectiveness of increasing the number of cycles included in the ensemble averaging.

With the required number of digitized images known, digitization began. On average, images were digitized and fully filtered within 15 seconds. The filtered images were stored in compressed format on a magneto-optical disk and transferred to the workstation for processing. Given a sufficient data storage capacity available at the processing computer, one large data exchange will yield instantaneous velocities from the DPIV image processing method. This generally did not occur. Data transfer usually entailed transferring 200 images to the workstation while removing the previously processed velocity field files for the preceding 200 images. An example of a typical instantaneous velocity field is shown in Figure 3 (recall 1 cm is approximately 16 pixels).

Figure 3 Instantaneous velocity field from DPIV (Test 6C, Field 536)

After acquiring all of the required instantaneous velocity fields, ensemble averaging was performed according to criteria in Table 1. As described earlier, an ensemble average of the corresponding velocity fields for each 1/60th of a second interval in the period is determined and saved. These ensemble averages, when time averaged over the period, yield results similar to Figure 4. The first image in Figure 4 shows the resultant ensemble average velocity fields of the entire field of view, including “velocities” outside the flow. A digital stopwatch superimposed on the lower portion of the screen during videotaping accounts for most of the extraneous velocities. The data in the bottom portion of the field shows the correlated motion of the stopwatch numerals. Some spurious data are also present above the flow possibly due to splashing that occurs when the jet impinges the front face of the breaking wave. Instrument noise associated with the video equipment that occurs during digitization may provide another source of non-flow velocities. All data other than the desired flow data has been removed from the second image.

Figure 5 represents an enlarged section of the middle view for the 50 cycle case in test 4C. Profiles represent typical examples of the expected flow—for the first time measurements are included above and below the wave trough elevation. In

Figure 4 Ensemble time averaged velocity field with a) all non-flow data included and b) only flow related data included.

principle, mass (volume) should be conserved across any given vertical section (column) in this flow. Figure 5 indicates that mass is largely conserved in the measurements.

Figure 5 Columns 15-20 of ensemble, time-averaged velocity field from 50 cycle Test 6C indicating conservation of mass.

Ensemble turbulent r.m.s. velocity fluctuations are then calculated as described earlier. Observing the original video record determined the location of the relatively abrupt break in wave height change that signals the end of the transition region (or the location of the transition point). Albeit a somewhat subjective process, this technique provides greater accuracy than wave gauge data given the five centimeter gap between wave gauge stations. After determining the general location of the transition point, the average of each row in the three columns of horizontal turbulent velocity data on the offshore side of the transition point (toward the breakpoint) developed a depth varying profile of horizontal turbulent velocity fluctuations. Three column averaging thus provides two advantages: first, it further minimizes any effects that missing data may have on the ensemble averages and, second, increases the likelihood that the data represent values not only near the transition point but within the transition region. Figure 6 presents the depth varying values of the r.m.s. horizontal turbulent fluctuations (normalized by the local wave speed).

Figure 6 Dimensionless $u'_{r.m.s.}$ versus depth at the transition point.

Figure 6 shows that the below still water level (SWL) values of $u'_{r.m.s.}$ are fairly consistent within each test as well as between tests. For each test, the waves at the transition point are highly asymmetric about the SWL. This results in a majority of the crest appearing above the SWL. Mean values of the horizontal turbulent velocity

results above SWL were found and then normalized by the known breakpoint conditions.

CONCLUSION

The work presented here suggests the following:

1) Velocity measurements are now possible in the aerated crest of a broken wave within the transition region through the use of digital imaging and application of appropriate filtering techniques. The distortional characteristics of the bubbles produced during wave breaking somewhat affect the spatial resolution of these velocities. However, the errors introduced are on the order of one millimeter per frame and, considering the fairly coarse resolution of the velocities found with DPIV, are negligible.

2) Digital particle image velocimetry provides an effective alternative to standard PIV techniques and should improve as video technology and processing speeds advance.

3) The use of video for examination of large temporal data sets by ensemble averaging provides the most efficient and economical method currently available for applications in which the temporal and spatial resolution provided by video imaging are adequate.

4) DPIV can resolve turbulent velocity fluctuations over the entire water column. However to maintain accuracy requires a high particle seeding density in the crest region.

CHAPTER 49

Wave Gauging Networks Worldwide — An Overview

J. Michael Hemsley¹
PE, MASCE

Abstract

Throughout the history of society's attempts to build on the beach, waves have been the principal antagonist. Engineers soon learned that to be successful, they had to understand the nature of the waves that attacked their structures. That understanding has led to many efforts to measure or estimate waves to develop a climatology useful in coastal design.

Over the past 25 years, our ability to accurately and cost-effectively measure waves has improved considerably. This has resulted in an increasing number of gauging networks worldwide. This paper is a summary of many of those networks. Information on the networks will include, where available, the type gauges used, locations of stations, additional data collected, and data distribution means.

Introduction

Because many wave gauging programs are locally installed and operated, they are known only to their operators. Only a few of the networks are associated with the World Meteorological Organization (WMO) and have their data distributed worldwide on the Global Telecommunications System (GTS). Information about the networks operated by the U.S. National Data Buoy Center (NDBC), Canadian Atmospheric Environment Service (AES), and the United Kingdom Meteorological Office was relatively easy to acquire. The smaller networks have been a challenge. That challenge has been offset, though, by the willingness of most network operators, once identified, to share information.

To most coastal scientists and engineers, the small networks are the most interesting. The large networks, often funded by the country's weather service, are well known. But most network operators — or potential operators — must operate on a much smaller scale, so there is often much more to learn from others who manage data collection efforts within similarly restrictive budgets.

¹ Chief, Program Management Division, National Data Buoy Center, Building 1100, Stennis Space Center, MS 39529-6000, U.S.A.

Networks

In all, information has been received or obtained about wave measurement networks in 19 countries. Information has come from personal communications, papers or other publications, and, in several cases, from a "Guide to Moored Buoys and Other Ocean Data Acquisition Systems" (Data Buoy Cooperation Panel, in publication). Programs are likely to exist in countries other than those reported in this paper, particularly in countries such as Germany, The Netherlands, People's Republic of China, Portugal, and Sweden. Unfortunately, time ran out before all leads could be followed and information produced. It is hoped that this information will be useful to anyone who operates a wave gauging network or even a single station by providing information about the alternative hardware, techniques, and approaches available. A presentation of these alternatives should also help those who are interested in collecting wave data for research or engineering purposes.

Of the information that has been received, several networks stand out. Two particular examples of those that deserve mention are the efforts by Spain to establish their national network and the international effort to define the wave climate along the coasts of the Black Sea. The Clima Maritimo is the research and development department of the Puertos del Estado, which is responsible for coordinating the activities of 27 of Spain's ports. To provide data critical to their mission, they have installed and are operating a network of 20 nondirectional and 4 directional wave buoys. In the future, they will add three more directional wave buoys, five coastal wave radars, and six to nine oceanographic buoys that will report atmospheric information, current data, and temperature and salinity profiles, as well as wave data.

The international effort on the Black Sea, called NATO-TU WAVES, is supported by Russia, Turkey, the Ukraine, Bulgaria, and Rumania. Four nondirectional and six directional stations are being established to provide data needed for wave modeling and forecasting around the perimeter of the Black Sea.

The collection of wave data is important to coastal engineers and scientists. This overview is intended to be a minor reference for use when new networks are being planned or existing networks are updated. While an attempt has been made to ensure that the stations are currently in service, it is possible that some information may no longer be current. A consistent set of symbols will be used and will follow the key provided below. For simplicity, the only symbols used on the figures will be for directional and nondirectional systems. Where the information is available, the type of gauge will be mentioned in the discussion. The presentation to follow is organized alphabetically by country, except for the network in the Black Sea, which will be listed as NATO-TU WAVES because of its international nature.

Australia

Gauging networks in Australia are operated, primarily, by the states. This decentralization made identification of networks a bit more difficult than for countries with centralized control of their programs.

Three programs have been identified, those of Queensland, New South Wales, and Western Australia. In Queensland, wave data are collected at 13 locations (Figure 1). Nondirectional data are collected using Datawell Waverider buoys and from InterOcean S4 current meters, while directional data are collected from Datawell Directional Waverider buoys. All stations in the Queensland network are shown on Figure 1 as nondirectional, although several are likely to collect directional data. Data from the Waverider buoys are transmitted to shore via radio.

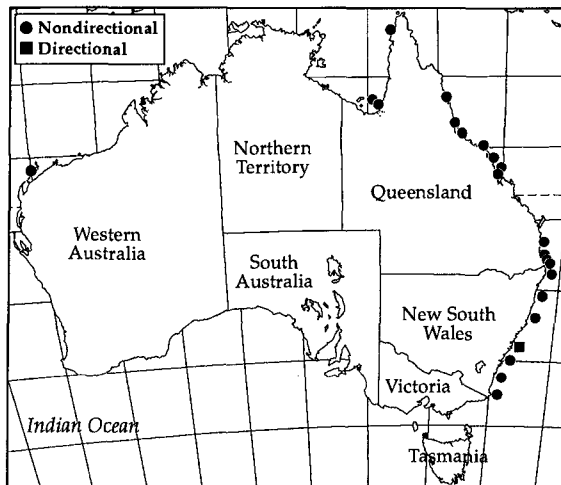

Figure 1. Australian Wave Gauging Networks

The wave data network in New South Wales presently consists of seven stations, one of which collects directional data (Figure 1). The oldest station in this network was installed in 1974; all stations have been operational since 1987. Datawell Waverider buoys are used at every station, and the data are transmitted to a shore station by radio.

There is one station in Western Australia for the past 4 years (Figure 1). A Datawell Waverider buoy is used to collect nondirectional data that are transmitted to shore by radio every 20 minutes. These data are used for "real" time ship operations.

Canada

There are two wave gauging networks in Canada. The first, and more traditional, is operated by the AES and has stations in the Atlantic and Pacific Oceans and in the Great Lakes and other major inland waters (Figure 2). The other network is operated in Quebec Province as a part of the James Bay Hydroelectric Project by the Societe d'Énergie de la Baie

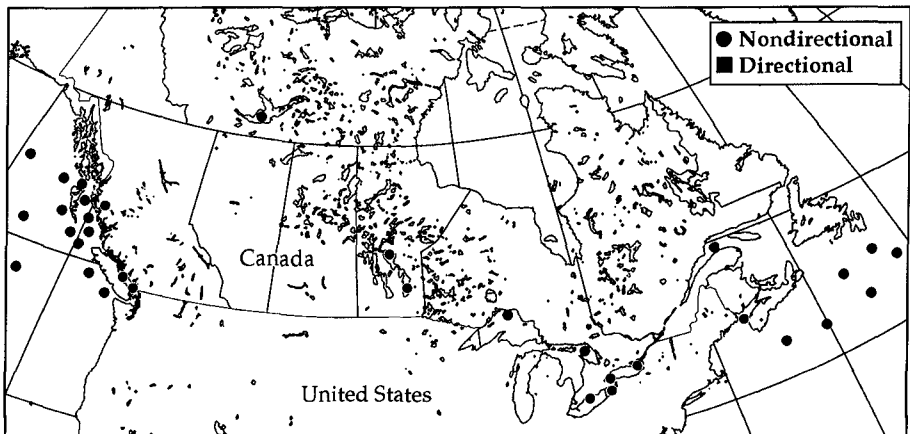

Figure 2. Canadian AES Buoy Network

James (Figure 3). The AES operates a total of 33 buoy stations, 8 in the Atlantic, 9 in the Great Lakes region, and 16 in the Pacific. The buoys in the Atlantic and Pacific consist of fifteen 3-m-diameter discus buoys in the nearshore areas and nine 6-m boat-shaped buoys offshore. In the Great Lakes region, two of the stations are occupied by 12-m-diameter discus buoys. All stations collect nondirectional wave spectral data as well as meteorological data such as wind speed and direction, pressure, and temperature. All data are transmitted hourly via the Geostationary Operational Environmental Satellite (GOES) and are available on the GTS.

In Quebec, four Endeco WaveTrack 1156 buoys are used to collect data from eight stations in the James Bay area. These buoys collect directional wave data that are transmitted hourly via an RF radio link to a base station. The buoys are deployed in a most unusual manner — by helicopter.

France

Meteo-France operates one buoy station in cooperation with the United Kingdom Meteorological Service. The buoy was developed and used by the UK Met Service and is operated by them. The station is located 300 km off the Brittany coast in 2,000 m of water. Additional information on the buoy used can be found in the section on the United Kingdom. Meteo-France plans to operate another buoy in the Bay of Biscay soon. Another plan to operate four additional stations, two in the Mediterranean Sea and two in the West Indies, is currently under study. Two directional Datawell Waverider buoys are currently deployed in the West Indies as a part of the Oceanilles project. The French Aids-to-Navigation Service (STNMTE), which operates its own network of ten wave buoys along the coast of France, assisted Meteo-France in the establishment of the stations in the West Indies (Data Buoy Cooperation Panel, in publication).

Iceland

The Icelandic Lighthouse and Harbour Authority operates a network of stations within the Information System on Weather and Seastate for Seafarers, an automated call-up voice information system (Figure 4). Among the stations are seven Datawell Waverider buoys reporting nondirectional wave data and nine harbor installations that report wave and

Figure 3. James Bay Hydroelectric Project Wave Gauging Network

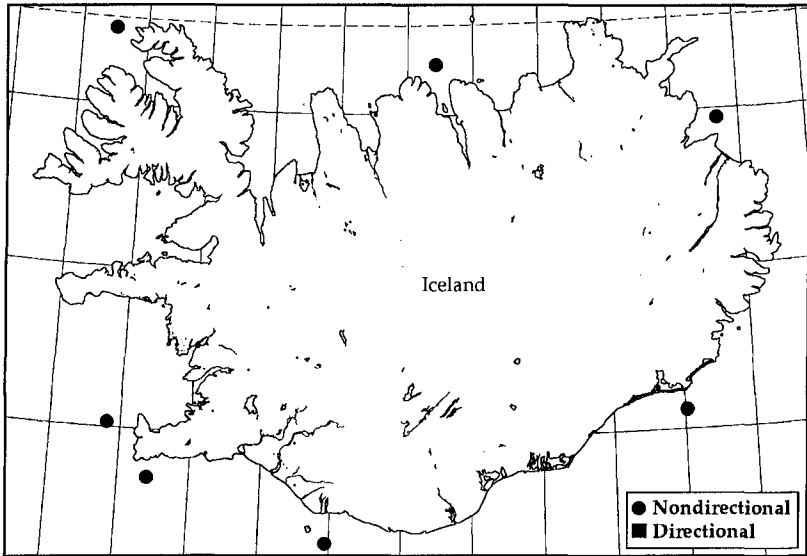

Figure 4. Icelandic Data Buoy Network

meteorological information. Another 12 automated weather stations are located on lighthouses. Waverider data are transmitted via radio link to a shore station (Data Buoy Cooperation Panel, in publication).

Israel

The Israel Meteorological Service operates a small network of directional Datawell Waverider buoys. The Waverider buoys are deployed in Haifa Bay and the ports of Asdod and Hadera. Data are received by direct radio link to a shore station (Data Buoy Cooperation Panel, in publication).

Italy

In an article in *History and Heritage of Coastal Engineering*, Professor Leopoldo Franco reports that there have been nearly 100 wave gauging stations on the Italian coast since 1974 (Franco, 1996) (Figure 5). Currently, there are 13 permanent stations. Eight of these are operated as a part of the National Wave Measurement Network. These stations are directional Datawell Wavec buoys reporting their data via polar orbiting satellites. The network is managed by the Italian Hydrographic and Tidal Service and has accomplished an average data acquisition rate of more than 90 percent since the network was established in 1989.

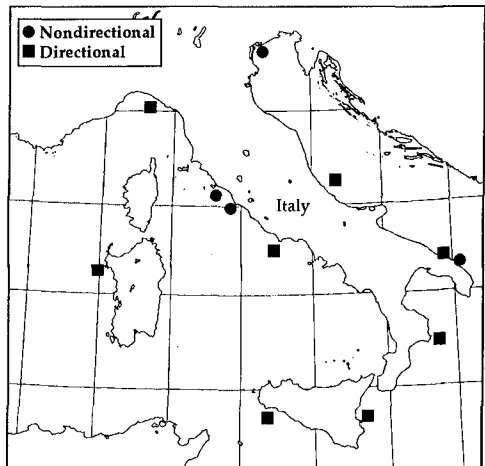

Figure 5. Permanent Wave Gauging Stations in Italy

Japan

For years, the Japanese have been leaders in coastal engineering research. Various agencies and research institutions have, therefore, operated networks of wave gauging stations. The diversity of organizations that have been involved in wave measurements has made the identification of all stations a bit difficult. Those stations that have been identified are reported here.

Japan's ocean data buoy program was initiated by the Japanese Meteorological Agency (JMA) in 1968. A total of seven 10-m-diameter discus buoys was eventually constructed. Four of these buoys remain in service, rotating among three stations (Figure 6). These buoys report data hourly via the JMA Geostationary Meteorological Satellite. Nondirectional wave data, as well as considerable meteorological data, are collected and reported. These data are published annually on CD-ROM in a report entitled "Data Report of Oceanographic Observations" available from JMA headquarters (Data Buoy Cooperation Panel, in publication).

A much more extensive network is operated and maintained by the Ports and Harbours Bureau of the Ministry of Transport. In particular, the Port and Harbour Research Institute (PHRI) operates a 42-station network of wave measurement stations called Nationwide Ocean Wave information network for Ports and HARbourS, or NOWPHAS (Figure 6). The network includes a variety of sensor types, some quite innovative. PHRI has deployed directional arrays, nondirectional buoys, measurements from towers, two acoustic meters, and a new Doppler-type wave directional meter. The Doppler meter is installed at three existing stations and one new research station.

NOWPHAS and JMA data are provided to a semi-governmental agency and from there to users. The Coastal Development Institute of Technology operates the Coastal Wave Information Center.

Figure 6. NOWPHAS and JMA Wave Measurement Stations

Korea

The Korean Meteorological Agency (KMA) and the Korean Maritime and Port Administration, the latter together with the PHRI in Japan, are cooperating in the establishment of a wave gauging network around the Korean peninsula. So far, the KMA has one buoy on station in the Yellow Sea—it is the northernmost buoy shown in Figure 7. The other stations are operated by the Maritime and Port Administration and include seven directional Datawell Waverider buoys and one directional pressure sensor and electromagnetic current meter (PUV) gauge—the northernmost station in the Sea of Japan. This PUV gauge is temporary and will be replaced by one of the Doppler meters being developed by the PHRI.

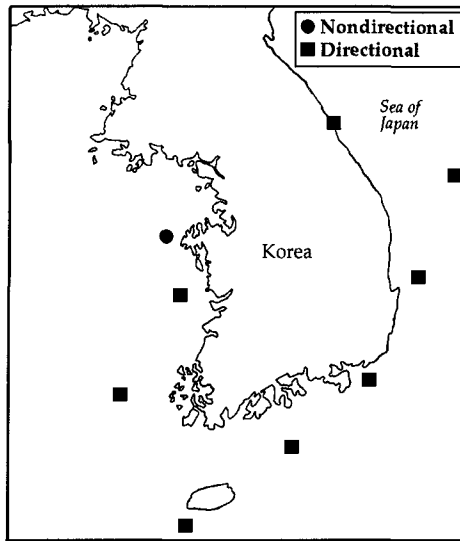

Figure 7. Korean Wave Gauging Networks

Kuwait

One directional wave station is maintained by the Hydraulics and Coastal Engineering Department of the Kuwait Institute for Scientific Research. Data are received by radio from the Endeco 1156 buoy located 6 km off the Fintas Coast in the Persian Gulf. The purpose of the station is to study deep-water waves in Kuwait's territorial waters.

NATO-TU WAVES

Bulgaria, Rumania, Russia, Turkey, and the Ukraine are cooperating in a program to better understand the wave climate affecting the Black Sea coastline and the Turkish coastline of the Mediterranean Sea. Partially funded by NATO, the program is being executed by four collaborating Turkish organizations and four institutes in the other Black Sea countries. A total of ten stations are collecting data, including six collecting directional wave data from directional Datawell Waverider buoys and four others from a Ukrainian-built wave staff that measure nondirectional waves (Figures 8 and 9). All buoy data are transmitted to shore using radio frequencies (Ozhan and Abdalla, 1993).

There is one additional station located in Turkish waters. A PUV gauge installed in conjunction with the Japanese International Corporation Agency — an installation supervised by the PHRI — is reporting directional wave data from a station at Filyos near Zongldak.

Figure 8. NATO-TU WAVES Black Sea Network

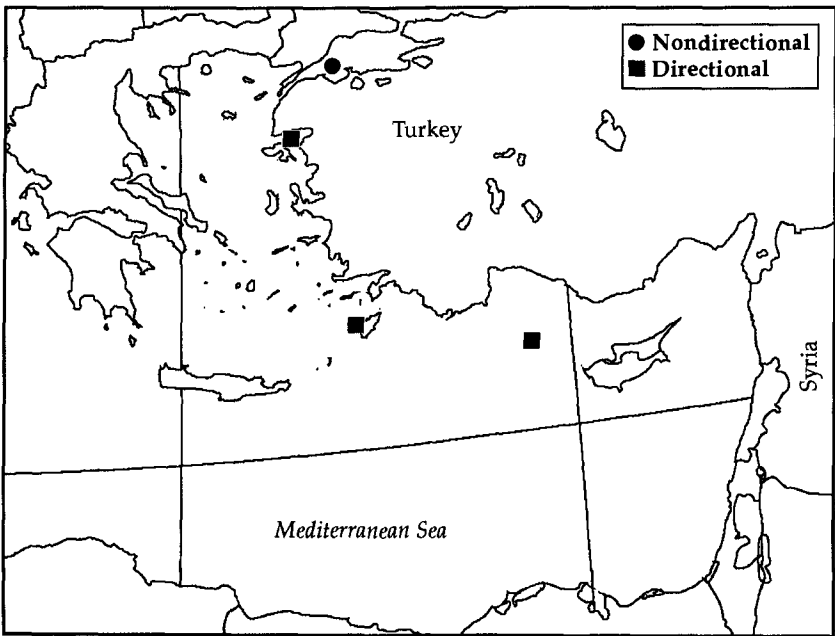

Figure 9. NATO-TU WAVES Mediterranean Sea Network

Spain

Clima Maritimo, the research department of the Puertos del Estado, is in the process of installing 21 nondirectional and 4 directional wave buoys (Figures 10 and 11). An additional four nondirectional stations are operated by other organizations. The scalar buoys are Datawell Waveriders, while the directional buoys are Seatex WaveScans. The data are collected to support the operation of Spain's harbors. Additional directional buoy stations and shore-based wave radars are planned for the future (Ruiz de Elvira, et al., date unknown).

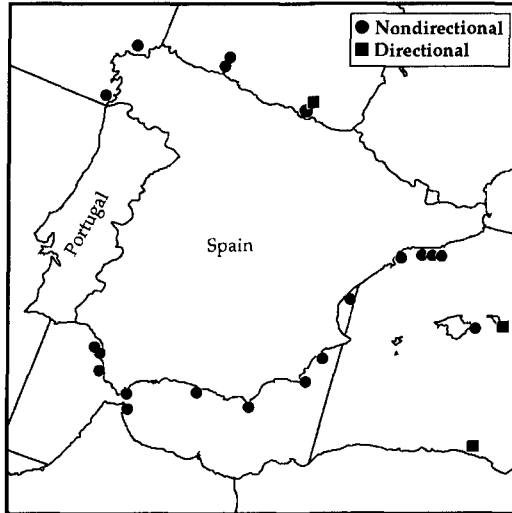

Figure 10. Spain's Coastal Wave Gauging Network

Figure 11. Spanish Wave Data Collection in the Canary Islands

Sri Lanka

An Endeco directional wave buoy has been operating offshore Galle on Sri Lanka's southwestern coast for 8 years. It was installed by the Sri Lanka Hydraulic Institute for the Coast Conservation Department.

Republic of China

A network of four directional stations is being established by the Central Weather Bureau around Taiwan. At least two, and probably all, of the stations are now in place. The current plan is to have Endeco 1156 WaveTrack buoys measuring directional waves at Bytougau at the northern tip of the island, Tonchiyu in the middle of the Taiwan Strait, Shaoliucho off Kaohsiung Harbor, and Chengkung on the southeastern coast facing the Pacific Ocean. Each of these stations reports by UHF to shore. Ultimately, the plan is to have a network of more than 20 stations ringing the island, including underwater ultrasonic wave gauges, shallow-water observation piles, buoys, and shore-based radars.

United Kingdom

The United Kingdom Meteorology Office has established a network of nondirectional data buoys off the British Isles in both relatively shallow water and in deep water off the continental shelf (Figure 12). Two types of buoys are used. Nearshore, a 2.5-m-diameter toroidal buoy transmits data via a VHF radio link to shore. Offshore, a new purpose-built buoy of less than 3-m-diameter (so it can be transported over public roads without special precautions) has been installed at four of the open-ocean locations. These buoys report via METEOSAT or GOES, and the data are distributed on the GTS (Bentley and Jones, 1993).

Figure 12. Wave Data Collection Off the British Isles

United States

Two agencies operate extensive networks of wave data collection stations in the United States, NDBC of the National Weather Service (NWS) and the U.S. Army Waterways Experiment Station Coastal Engineering Research Center (CERC). While buoys are the primary means of wave data collection for NDBC, laser wave systems are used on several Atlantic offshore platforms in the Coastal-Marine Automated Network. Buoys used by NDBC include the large 10- and 12-m discus buoys, 6-m boat-shaped hulls, 3-m-diameter discus buoys, and, on occasion, 2.4-m discus buoys. All NDBC's discus buoys are capable of collecting directional wave data, although those data are only collected at special locations. NWS sponsors many of the stations, but CERC, the Minerals Management Service, and the National Aeronautics and Space Administration fund a number of stations operated by NDBC as well. CERC is the primary sponsor of directional wave data from this network. In addition to wave data, NDBC buoys collect a full range of meteorological data and, occasionally, oceanographic data as well. All data are transmitted hourly from the buoys via GOES to the NWS Telecommunications Gateway and are distributed worldwide on the GTS (Figure 13).

While CERC operates wave gauging stations primarily in support of coastal projects, and therefore for short periods of time, they do fund or operate a network of relatively permanent stations (Figure 14). The principal operator of many of these stations is the Scripps Institution of Oceanography, University of California at San Diego. The Prototype Measurement and Analysis Branch of CERC operates the others. Their nondirectional stations are most often Waverider buoys; directional stations can be either PUV gauges or multiple pressure sensor arrays, including a linear array at the CERC Field Research Facility in Duck, NC. These data are usually either transmitted to shore by radio or cable where they are collected periodically by telephone connection (U.S. Army Corps of Engineers, Waterways Experiment Station, July 1996).

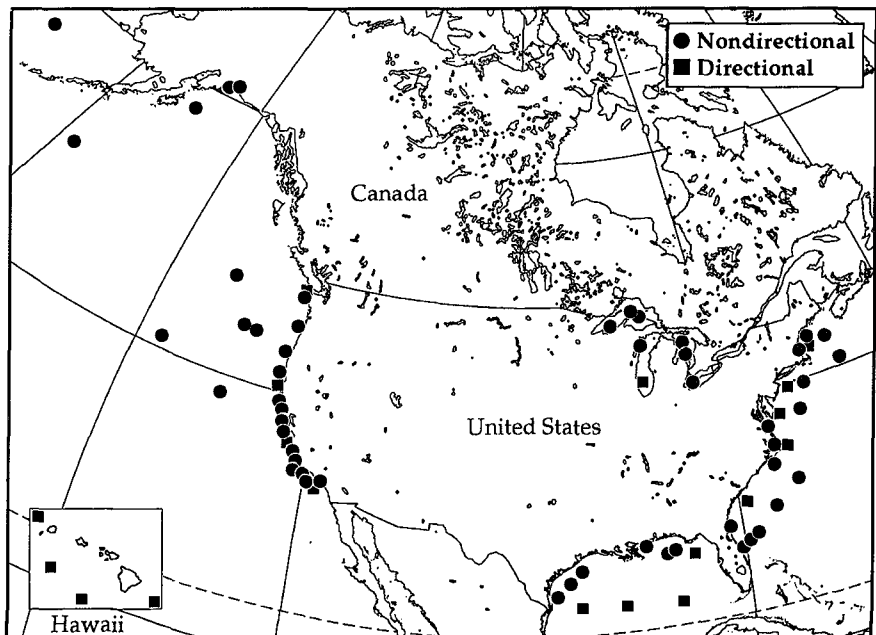

Figure 13. NDBC Wave Gauging Network

Figure 14. CERC Wave Gauging Network

Archival

Unfortunately, much of the wave data collected around the world is not archived outside the organizations that collect them. In the United States, for example, the National Oceanographic Data Center accepts all quality-controlled wave data collected, if they are sent to them. All NDBC data are archived in this way, but data collected in other agencies' programs are not always archived. So, someone searching for wave data often has to seek out a variety of sources. Internationally, there is no organization that exists to archive wave data from around the world. With proper coordination and cooperation, it is possible that this state could be corrected. The Intergovernmental Oceanographic Commission (IOC) and the WMO worked together to establish the Marine Environmental Data Service (MEDS) in Canada as the Responsible National Oceanographic Data Centre (RNODC) for drifting buoy data. All drifting buoy data transmitted on the GTS are archived by MEDS and are available to anyone who needs them. Possibly the same thing could be done for wave data and an RNODC established for them. It would seem that the IOC and WMO would have an interest in such a center.

Conclusion

Wave data are being collected by at least 19 countries around the world. This paper has attempted to summarize the programs the author could discover. Too many may have gone undetected. This is an indication that the results of many wave gauging efforts go unrecognized by others in the field, and valuable data lie unused after their initial purpose is served. These data do not decrease in value with time. It appears that the time has come for an international effort to provide an archive for wave data.

Acknowledgments

The author acknowledges the critical assistance he has received from those who provided the information that appears in this paper. Without the enthusiastic support of those who responded to requests for information, this paper could not have been successfully completed.

CHAPTER 50

Improvement of Submerged Doppler-Type Directional Wave Meter and its Application to Field Observations

Noriaki Hashimoto¹, Masao Mitsui², Yoshimi Goda³,
Toshihiko Nagai⁴, and Tomoharu Takahashi⁵

Abstract

This paper presents an improved submerged Doppler-type directional wave meter which has the capability of measuring water surface elevations and multiple current velocity components. These components are determined from Doppler frequency shifts of ultrasonic waves in water. The improved system has proven to be capable of successfully obtaining tide, current and directional wave data. In addition, this directional wave meter has accurately estimated directional wave spectra in severe sea conditions with the use of some techniques introduced in this paper.

1. Introduction

Field studies in coastal areas are indispensable not only for scientific research but also for pre- and post-construction monitoring of the effects of engineering projects. Particularly for the latter cases, field surveys often require not only a long observation period but also require the measurement of many parameters such as waves, currents, and tides to clarify the mutual interaction between those natural conditions and human activities. Many types of observational devices have been developed and improved on over the years. Most of them, however, were designed to measure specific parameters separately using their own techniques. To obtain meaningful results, it is necessary to measure the sea conditions comprehensively, i.e., the measurement of

many parameters at the same time and at the same location, because each item is mutually and closely interrelated.

Until recently, a simple instrument for directional seas has not yet been developed. In Japan, the commonly used wave meter is a submerged ultrasonic-type wave gage (USW) which can be installed in maximum water depths of 50m. A submerged ultrasonic-type current meter (CWD) has also been developed for measuring directional seas but it is limited to applications with maximum water depths of about 30m because of the decay of water particle velocities due to depth. For these reasons, the development of a well-combined measurement system has been anticipated in Japan.

With this background, we developed the submerged Doppler-type directional wave meter and introduced it at ICCE '94 in Kobe. This system, known as the DWM, is extremely convenient since it is a single instrument that can be used to obtain accurate observations of directional seas. It is considered to be one of the most useful measuring systems for investigating directional seas.

Since ICCE '94, further improvements have been made to the DWM and additional field experiments have been conducted to enhance the performance of the DWM from many aspects. In this paper, we introduce new features of the DWM-II (the improved DWM is hereafter called the DWM-II) with its validity and applicability demonstrated with experimental results. Some techniques for improving the performance of the DWM-II are also presented along with the results of field experiments.

2. System Description

An improved "submerged Doppler-type directional wave meter", the DWM-II, possesses the multiple functions of a wave meter, current meter and tide gage. The main components of the system are a submerged transducer, measurement section, and computation unit. The transducer is supported with gimbals and has oscillators which operate four acoustic beams. One beam is vertically directed and operates at a frequency of 200 kHz. The other three acoustic Doppler current profiler (ADCP) beams operate at a frequency of 500 kHz, each of which has an inclination of 30 degrees to the vertical.

To measure the water surface elevation, the transducer transmits upward-directed ultrasonic waves and receives that portion of the energy which is reflected off of the water surface. The water surface elevation is estimated by using the ultrasonic wave propagation time based on the known propagation speed in water.

By also transmitting ultrasonic waves upward in three directions, separated by an inclination of 30 degrees, current velocity components, $U_1(t)$, $U_2(t)$, $U_3(t)$, can be measured by receiving the acoustic waves reflected back from selected layers of water. The water particle velocity of each layer is estimated from the frequency shift caused

by the Doppler effect between the transmitted waves and the reflected waves. Using a time sharing system, all measurements are made every 0.125 seconds or at a sampling frequency of 8 Hz.

In addition, the DWM-II is equipped with a pressure sensor, compass and inclinometer in the transducer. These are used to monitor the conditions of the DWM-II itself and to check the quality of the measured data.

3. Field Testing

Field testing was carried out from August 1993 to March 1995 off the entrance of Kamaishi Port, as shown in **Figure 1**, where the conventional ultrasonic wave meter (USW) has been operational since 1983. The transducer of the DWM-II was positioned about 100m away from the USW at a height of 1.5m above the seabed where the water depth is 48m. The time series data consisted of water surface elevation and current velocity components that were measured at three different water depths of 10m, 23m and 38m below the water surface. These data were recorded on an optical magnetic disk at a sampling rate of 2 Hz for 20 minutes every two hours. Some statistical parameters, including the directional spectrum, were computed immediately after each observation and were recorded on the optical magnetic disk. In addition, a rotor-type current meter (RCM) was moored to a float and positioned 100m away to examine the validity of the DWM-II by comparing the results of both meters.

Figure 1 Field Observation Locations

4. Examples of Observational Results

Figure 2 shows some examples of the DWM-II time series of wave parameters such as significant wave height $H_{1/3}$, significant wave period $T_{1/3}$, mean wave direction $\bar{\theta}$, peak wave direction θ_p , mean spreading angle θ_N , and long-crestedness parameter γ .

Figure 2 Time Series of Wave Parameters

Figure 3 Time Series of the East-West and North-South Current Velocity Components by the DWM- II (solid line) and the RCM(dashed line)

Results have shown that wave parameters, such as significant wave height and period, measured by the DWM-II, show good agreement with those obtained by the USW. The current velocities, however, measured by the DWM-II, are very different than those obtained by the RCM as shown in **Figure 3**. It is important to note that the RCM is very vulnerable to the current induced by waves and, in fact, moves following the wave motions. This is demonstrated in **Figure 4**. The existing reports on the currents around the observation site show that the currents there are weak, i.e., 10 cm/s or less, which is consistent with the results of the DWM-II which are also shown in **Figure 4**. **Figure 5** shows the spectra of the currents of the east-west and north-south components measured by the DWM-II at the upper layer 10m below the mean free surface. As shown in **Figure 5**, two predominant tidal periods can be seen at the diurnal and the semi-diurnal frequencies. These predominant peaks were not observed in the spectra obtained by the RCM due to the limitations already discussed. Therefore, the DWM-II has an advantage over the RCM of measuring intrinsic current fields since it is relatively unaffected by waves.

Figures 6 (a) and (b) show the comparison of the tide level measurements obtained by a tide gage and estimates from the ultrasonic wave data and pressure data of the DWM-II, respectively. Three minute long ultrasonic measurements were made of the mean free surface every two hours at a sampling frequency of 2 Hz. The tide level was obtained by averaging each record. Pressure samples were obtained with the same sampling scheme. Corrections, with respect to the atmospheric pressure measured about 30km away from the observation site, were made to the tide level estimated by the pressure data. Both figures show high correlation.

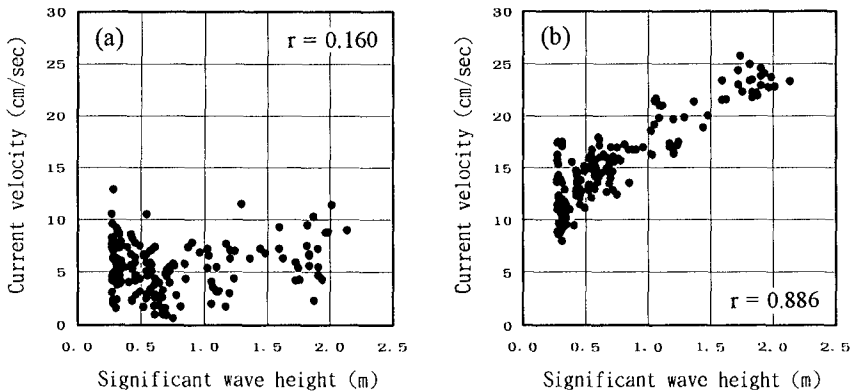

Figure 4 Significant Wave Height and Current Velocity Correlation Measured by the DWM- II (a) and the RCM (b)

Furthermore, **Figure 7** shows the relationship between the atmospheric pressure obtained from a barometer 30km away and the estimated atmospheric pressure from the DWM-II. Since the DWM-II pressure sensor measures the combined atmospheric pressure and hydrostatic pressure, the atmospheric pressure can be obtained by taking the difference between ultrasonic tide level data (hydrostatic pressure) and total pressure data. As seen in this figure, there was considerably high correlation. The fact that the atmospheric pressure can be estimated by the DWM-II, with a high degree of accuracy, further demonstrates the high quality of water surface elevation and water pressure data obtained by the DWM-II.

5. Proposed Techniques for Improving the Performance of the DWM-II

During this study to enhance the performance of the DWM-II, some new techniques have been introduced to mitigate some of its shortcomings. These techniques are presented in the following three sections.

5.1 Estimation of the Principal Wave Direction With Covariances

A disadvantage of measuring directional seas using wave arrays is that waves with lengths L less than two times the minimum separation distance, D_{\min} , of the array can not be analyzed to produce a directional spectrum. That is, if we wish to analyze waves of length L , the requirement of $2D_{\min} \leq L$ must be satisfied. However, if we measure x - and y -components such as (u, v) or (η_x, η_y) related to random wave motions in the same location, we can estimate the representative wave direction using the covariance method described below without being subjected to the above restriction on array spacing.

Longuet-Higgins defined the principal wave direction θ_p as the direction along which the root-mean-square (RMS) wave number is the largest or the wave crests are the densest. This can be expressed by the following relationship:

$$\theta_p = \frac{1}{2} \tan^{-1} \frac{2M_{11}}{M_{20} - M_{02}} \quad (1)$$

where the spectral moment M_{pq} of equation (1) can be evaluated by the following equation:

$$M_{pq} = \int_0^\infty \int_{-\pi}^\pi S(f, \theta) k^{p+q} \cos^p(\theta) \sin^q(\theta) d\theta df \quad (2)$$

The spectral moment defined by equation (2) can be alternatively evaluated with the covariance between the time series of several wave motion parameters (Goda, 1982).

By using covariances such as $\overline{u^2}$, $\overline{v^2}$, and \overline{uv} , the principal wave direction can be defined by:

$$\theta_p = \frac{1}{2} \tan^{-1} \frac{2\overline{uv}}{\overline{u^2} - \overline{v^2}} \tag{3}$$

The i -th water particle velocity component U_i measured by the DWM-II is expressed by:

$$U_i = a_i u + b_i v + c_i w \tag{4}$$

where u , v , and w are the orthogonal components of the water particle velocities at the measuring location U_i and a_i , b_i and c_i are the coefficients expressed by the following equations:

$$\left. \begin{aligned} a_i &= \sin \alpha_i \cos \beta_i \\ b_i &= \sin \alpha_i \sin \beta_i \\ c_i &= \cos \alpha_i \end{aligned} \right\} \tag{5}$$

where α_i , and β_i are the angles shown in **Figure 8**. Then the covariance of U_i is expressed by:

$$\overline{U_i^2} = a_i^2 \overline{u^2} + b_i^2 \overline{v^2} + c_i^2 \overline{w^2} + 2a_i b_i \overline{uv} + 2b_i c_i \overline{vw} + 2a_i c_i \overline{uw} \tag{6}$$

That is, the covariance $\overline{U_i^2}$ is expressed by the six independent covariances such as $\overline{u^2}$, $\overline{v^2}$, \dots , \overline{uw} . From the linear wave theory, however,

$$\overline{uw} = \overline{vw} = 0 \tag{7}$$

Therefore, Equation (6) reduces to;

$$\overline{U_i^2} = a_i^2 \overline{u^2} + b_i^2 \overline{v^2} + c_i^2 \overline{w^2} + 2a_i b_i \overline{uv} \tag{8}$$

In addition to equation (8), since the DWM-II measures free surface displacement $\eta(t)$, the covariances $\overline{w^2}$ can be estimated with the linear wave theory by the following equation:

$$\overline{w^2} = \int_0^\infty S_w(f) df = \int_0^\infty |H_w(f)|^2 S_\eta(f) df \tag{9}$$

Figure 8 Definition of Coordinate System

where $S_w(f)$ is the power spectrum of the vertical component of water particle velocity $w(t)$, $S_\eta(f)$ is the power spectrum of the free surface displacement $\eta(t)$ and $H_w(f)$ is the transfer function from $w(t)$ to $\eta(t)$.

Finally, the following simultaneous equations, with respect to the unknown values $\overline{u^2}$, $\overline{v^2}$ and \overline{uv} can be obtained:

$$\begin{pmatrix} a_1^2 & b_1^2 & 2a_1b_1 \\ a_2^2 & b_2^2 & 2a_2b_2 \\ a_3^2 & b_3^2 & 2a_3b_3 \end{pmatrix} \begin{pmatrix} \overline{u^2} \\ \overline{v^2} \\ \overline{uv} \end{pmatrix} = \begin{pmatrix} \overline{U_1^2 - c_1^2 w^2} \\ \overline{U_2^2 - c_2^2 w^2} \\ \overline{U_3^2 - c_3^2 w^2} \end{pmatrix} \tag{10}$$

By solving this set of simultaneous linear equations, the principal wave direction can be determined from the definition of Equation (3).

By using these techniques and measuring the water particle velocities, the DWM-II can estimate the principal wave direction, θ_p , even in calm sea conditions.

This means that even in short wave environments the principal wave direction can be estimated without being restricted by the minimum array spacing requirement. **Figure 9** shows examples of the comparison of the estimated principal wave directions (solid vertical line) and the directional spectra. It can be seen that the estimated principal wave directions compare favorably with the peak energy direction of the directional spectra.

Figure 9 Principal Wave Direction (solid line) and the Directional Spectrum Measured by the DWM- II

5.2 Surface wave Recovery From Subsurface Pressure Records

A disadvantage of utilizing ultrasonic waves in water is that they are severely scattered and absorbed by bubbles when the free surface is disturbed by strong winds or breaking waves. To overcome this limitation, the DWM-II measures pressure as an auxiliary parameter. A proper transformation can be performed to obtain surface wave information from subsurface pressure records. Although many researchers have

gone to great lengths to investigate the possibility of generating surface wave information from subsurface pressure records, and many methods have been proposed to date, almost all of the existing methods are supplemented with various empirical corrections.

Recently, we investigated the relationship between surface waves and subsurface pressure records in detail on the basis of weakly nonlinear directional wave theory. From this investigation we were able to propose a practical method to recover surface wave information by utilizing the shape of the subsurface pressure records. The use of directional spectra information is not required for this new method. This method can be applied for the recovery of surface waves by the DWM-II. The details of these techniques will appear in a paper soon to be published but an outline of this research and methods is presented below.

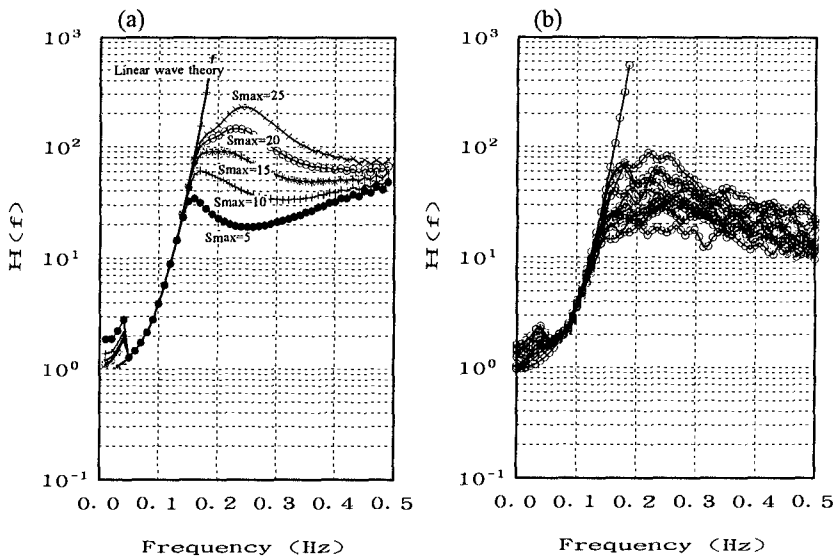

Figure 10 Examples of Theoretical (a) and Observed (b) Transfer Functions $H(f)$ in Water Depth of 50 Meters

Figures 10 (a) and (b) show examples of theoretical and observed transfer functions, $H(f)$, respectively, given by the square root of the ratio $S_{\eta}(f)/S_p(f)$ where $S_{\eta}(f)$ is the power spectrum of the water surface elevation and $S_p(f)$ is that of the subsurface pressure. Note the favorable comparison between the theoretical and observed transfer functions. The Bretschneider-Mitsuyasu type power spectrum and Mitsuyasu type directional spreading function are assumed for the directional spectrum of linear waves. As seen in the figures, the transfer function shows peculiarity in its lower and higher frequency ranges. The characteristics of the transfer functions in those ranges are dependent on the angular spreading parameter,

S_{\max} , of the directional spectrum and can be successfully explained on the basis of weakly nonlinear directional wave theory. This is due to the fact that k is a vector and ω is a scalar. That is to say, the second order nonlinear effect is a function of the wave propagation direction of each linear component wave. Therefore, accurate surface wave recovery, including the high frequency range, requires information of the directional spectrum. The wider the angular spreading function becomes, the greater the difference between the transfer function of the linear wave theory and that of the weakly nonlinear directional wave theory. However, by properly analyzing the shape of the subsurface pressure spectrum, sufficient information can be obtained to accurately recover the surface waves without obtaining the surface directional spectrum.

The proposed method is quite reliable for estimating a wide range of wave heights and periods for both calm and severe sea states.

5.3 Surface Wave Recovery from Current Velocity Component Records

In addition to recovering surface waves from subsurface pressure records, the DWM-II is capable of measuring surface waves, without obtaining information about the free surface displacement, $\eta(t)$, by properly transforming current velocities at several layers. This is useful since quite frequently, the ultrasonic waves used for measuring $\eta(t)$ are scattered and absorbed by bubbles at the surface.

The DWM-II can estimate the directional spreading function, $G(\theta|f)$, from a set of three current velocities, $U_1(t)$, $U_2(t)$ and $U_3(t)$ without information about the free surface displacement, $\eta(t)$.

$$G(\theta|f) = \frac{\kappa}{H^* \Phi^{-1} H} \quad (11)$$

where κ is a proportionality constant ensuring that $G(\theta|f)$ satisfies

$$\int_{-\pi}^{\pi} G(\theta|f) d\theta = 1 \quad (12)$$

H is the matrix comprised of the transfer functions from the i -th current velocity, $U_i(t)$, to the free surface displacement, $\eta(t)$, and is given by:

$$H_{U_i} = \frac{-i\omega \exp(-i\omega\Delta t)}{\Delta r k \sinh kh} \left[\cosh\{k(r \cos\alpha_i + z_0)\} \right. \\ \left. \times \exp\{ikr \sin\alpha_i \cos(\theta - \beta_i)\} \right]_{r_0 - \Delta r/2}^{r_0 + \Delta r/2} \quad (13)$$

Here α_i , β_i , and r_0 are the coordinates of the i -th current velocity from the coordinate system (α, β, r) shown in **Figure 8** and Δr is the "thickness" of the water volume shown in **Figure 8**. The DWM-II detects the current velocity, $U_i(t)$, by taking the average velocity of the water volume defined by α_i , β_i , and Δr . The water depth, wave number, angular frequency, wave propagation direction, and height at which the meter is situated above the seabed are represented by h , k , ω , θ and z_0 , respectively.

The time lag between the measurement of each velocity component and that of the water surface elevation is designated by Δt . Φ^{-1} is the inverse matrix of Φ consisting of the cross-spectra between each current velocity, $U_i(t)$;

$$\Phi = \begin{pmatrix} \phi_{U_1U_1} & \phi_{U_1U_2} & \phi_{U_1U_3} \\ \phi_{U_2U_1} & \phi_{U_2U_2} & \phi_{U_2U_3} \\ \phi_{U_3U_1} & \phi_{U_3U_2} & \phi_{U_3U_3} \end{pmatrix} \tag{14}$$

Equation (11) is the formula used to estimate the directional spreading by the Extended Maximum Likelihood Method (EMLM-Isobe, et al., 1984). Other methods such as the Bayesian Directional spectrum estimation Method (BDM-Hashimoto and Kobune, 1987) and the Extended Maximum Entropy Principle (EMEP-Hashimoto, et al., 1994) can also be applied to estimate the directional spreading function $G(\theta|f)$.

Using $G(\theta|f)$ as estimated by Equation (11), the power spectrum $S_\eta(f)$ of the free surface displacement, $\eta(t)$, can be estimated by:

$$S_\eta(f) = \Phi_{U_iU_j}(f) / \int_{-\pi}^{\pi} H_{U_i} H_{U_j} G(\theta|f) d\theta \quad (i = 1, 2, 3) \tag{15}$$

Multiplying $G(\theta|f)$ and $S_\eta(f)$ yields the directional spectrum $S(f, \theta)$,

$$S(f, \theta) = S_\eta(f) G(\theta|f) \tag{16}$$

Figure 11 Power Spectra of Free Surface Displacement

Figure 11 shows a comparison between the surface elevation power spectrum measured directly by the ultrasonic waves (indicated by a dotted line) and that obtained from the multiple current velocity components using Equation (15) (indicated by the three thin lines).

Although three power spectra can be estimated from Equation (15), by using $i=1,2,3$, all of the estimated power spectra show good agreement with the power spectrum measured by the ultrasonic waves around the spectral energy peak.

Figure 12 (a) shows a typical directional spectrum estimated by the EMLM where all of the measured quantities, $\eta(t)$, $U_1(t)$, $U_2(t)$, $U_3(t)$ were used to estimate the directional spectrum. **Figure 12 (b)** shows the directional spectrum for the same sea conditions estimated from the three current velocities, $U_1(t)$, $U_2(t)$, $U_3(t)$, using the present method without knowledge of the free surface displacement, $\eta(t)$. It can be seen that the two spectra compare favorably. The entrance of the experimental observation site faces East and the results clearly show that the waves propagate from the appropriate direction.

Figure 12 Estimated Directional Wave Spectra

Conclusions

Adequate knowledge of sea conditions is essential for clarifying various coastal engineering problems. Difficulties in measuring actual sea conditions, however, have resulted in a lack of critical information. Since the DWM-II can be employed to provide accurate information on directional waves, as well as currents and tides, with only one instrument, it is considered to be one of the most useful measuring systems for conducting research on actual sea conditions. By using techniques introduced in this paper, the auxiliary parameters of the DWM-II can be used to improve its performance. The DWM-II will contribute to increasing the reliability of long-term observations, especially in severe sea states, and will, therefore, lead to the enrichment of our knowledge of realistic sea conditions.

Acknowledgments

This research was jointly carried out by the Port and Harbour Research Institute, Ministry of Transport, and Japan Marine Surveyors Association under the direction of the Committee for the Development of a Submerged Doppler-Type Directional Wave Meter (Chairman, Professor Y. Goda, Yokohama National University) organized by Japan Marine Surveyors Association. The analyzed field wave data were contributed by the Second Port Construction Bureau, Ministry of Transport. Sincere gratitude is extended to all those involved in this study. We also wish to thank Sidney W. Thurston III, National Sea Grant Fellow of NOAA, who kindly gave us many valuable comments on this research work.

CHAPTER 51

COMPARISON OF DIRECTIONAL WAVE DATA QUALITY FROM TWO DIFFERENT MONITORING SYSTEMS

Lihwa Lin¹, Sidney Schofield², and Hsiang Wang³

ABSTRACT

A simple criterion was derived for evaluation and comparison of directional wave data quality from two underwater measuring systems – a point gage system consisting of a pressure transducer and a bi-axial current meter (PUV gage), and a slope array consisting of four pressure transducers. By using this criterion to the measured field data, it was demonstrated that directional wave data analyzed from PUV gage contain absolutely better quality than those from pressure array gages. Further examination of the pressure array data alone showed that the resolved directional wave quality was worse for long waves than short waves. However, the flaw of directional wave data quality from pressure array gages can be mended by forcing simple linear corrections on the analyzed directional data with a maximal tolerance to the criterion introduced in the present study.

1. INTRODUCTION

Directional wave data have been used widely in many coastal planning, designing, and operating projects. The data can be obtained from several sources: (1) measured directly in the coastal water, (2) measured at ocean and carried in numerically to the coastal area, (3) hindcast data, and (4) imitated data by numerical simulation. With no doubt, the measured directional data should be more representable to the real sea waves than the data from other sources. However, the usefulness of the measured directional data relies primarily on the quality and accuracy of the data being collected and analyzed.

Three basic types of measuring systems have been utilized today in finding directional wave information. They are: (1) a point gage system which will either measure the temporal changes of water surface slope in two horizontal principle directions, e.g., a pitch/roll buoy, or those of underwater horizontal wave orbital

1) Research Scientist, 2) Associate Engineer, 3) Professor, Dept. of Coastal and Oceanographic Engineering, University of Florida, Gainesville, FL 32611, USA.

velocity vectors, e.g., a biaxial current meter, (2) a slope array which measures the spacial changes of water surface elevations in several cross directions, and (3) casting images by remote sensing. In general, the first two systems are more applicable in the offshore area while the last one is useful in the nearshore area. In terms of the analysis, a directional wave spectrum is usually estimated based on a truncated Fourier series solved from the measured data. Nonetheless, this estimated directional spectrum presents only a limited directional information since a true spectrum shall include an infinite long Fourier series.

Comparison of directional wave data collected from different measuring systems is essential in order to know if the data quality is influenced by a particular instrumental system. Carrying out this comparison, however, can be difficult without clear criteria or standards to evaluate the data. A recent study by Corson and McKinney (1991), who compared the analyzed directional spectra from three different monitoring systems including a PUV gage, a slope array, and an ocean buoy, has addressed the difficulty of comparing the measured spectra without knowing the true spectrum.

The present study evaluates and compares the quality of directional wave data analyzed from two underwater measuring systems – a point gage consisting of a pressure transducer and a bi-axial current meter (PUV gage), and a slope array consisting of four pressure transducers. Evaluating directional wave data quality was carried out by examining the Fourier coefficients which are used to estimating a directional spectrum rather than a simple inspection of the spectrum itself.

2. BACKGROUND THEORY

A general but unique expression of directional spectrum, $E(f, \phi)$, is

$$E(f, \phi) = E(f)H(f, \phi), \quad (f = \text{frequency}, \phi = \text{direction})$$

where $E(f)$, the one-dimensional frequency spectrum, and $H(f, \phi)$, a directional distribution function, satisfy the following conditions:

$$E(f) = \int_0^{2\pi} E(f, \phi) d\phi; \quad \int_0^{2\pi} H(f, \phi) d\phi = 1, \quad \text{and} \quad H(f, \phi) \geq 0.$$

In terms of a Fourier Series,

$$H(f, \phi) = \frac{1}{\pi} \left[\frac{1}{2} + \sum_{n=1}^{\infty} a_n(f) \cos n\phi + \sum_{n=1}^{\infty} b_n(f) \sin n\phi \right],$$

where $a_n(f) = \int_0^{2\pi} H(f, \phi) \cos n\phi d\phi$, $b_n(f) = \int_0^{2\pi} H(f, \phi) \sin n\phi d\phi$

define the dimensionless, frequency-dependent Fourier coefficients.

It can be easily proved that $|a_n(f)| \leq 1$ and $|b_n(f)| \leq 1$ by using the facts of $|\cos n\phi| \leq 1$, $|\sin n\phi| \leq 1$, and integrating the quantities of $H(f, \phi) \cos n\phi$ and $H(f, \phi) \sin n\phi$, respectively, over the entire directional domain of $|\phi| \leq \pi$. However, a more rigid constraint on $a_n(f)$ and $b_n(f)$ also exists as a consequence of that $a_n(f)$ is related to $b_n(f)$ through the extant of $H(f, \phi)$. Since $(\cos n\phi \pm \sin n\phi)^2 = 1 \pm \sin 2n\phi \leq 2$, or $|\cos n\phi \pm \sin n\phi| \leq \sqrt{2}$, it can be shown by first multiplying $H(f, \phi)$ to both sides and then integrating over entire ϕ domain that

$$(i) \quad |a_n(f) \pm b_n(f)| \leq \sqrt{2}.$$

Now, for any real numbers of a and b , there is a binomial inequality:

$$-(a - b)^2 \leq 4ab \leq (a + b)^2.$$

Let $a = a_n(f)$, $b = b_n(f)$, and use the result from (i), it is further shown that

$$(ii) \quad |a_n(f)b_n(f)| \leq \frac{1}{2}.$$

Combining the results in (i) and (ii), and using the fact that $a_n(f)$ and $b_n(f)$ are resemblant in functional form, yields

$$(iii) \quad a_n^2(f) + b_n^2(f) \leq 1.$$

3. EVALUATION OF $a_n(f)$ AND $b_n(f)$ COEFFICIENTS

The methods used in evaluating $a_n(f)$ and $b_n(f)$ coefficients are different for the data collected by the PUV gage system and pressure array gages. Since these methods have been well developed and documented in the past, only the results from these methods are summarized here.

3.1 Submerged PUV Gage(1 pressure transducer and 1 biaxial currentmeter)Data

Based on a standard stochastic approach, only the first 2 pairs of $a_n(f)$ and $b_n(f)$ can be determined from the PUV data (Cartwright, 1963; Long, 1980):

$$a_1(f) = \frac{R_{pu}(f)}{\sqrt{R_{pp}(f)[R_{uu}(f) + R_{vv}(f)]}}, \quad b_1(f) = \frac{R_{pv}(f)}{\sqrt{R_{pp}(f)[R_{uu}(f) + R_{vv}(f)]}},$$

$$a_2(f) = \frac{R_{uu}(f) - R_{vv}(f)}{R_{uu}(f) + R_{vv}(f)}, \quad b_2(f) = \frac{2 R_{uv}(f)}{R_{uu}(f) + R_{vv}(f)},$$

where $R_{xy}(f)$ is the measured cospectrum of the random variables of $X(t)$ and $Y(t)$. The subscripts p , u , and v are corresponding to the measurements of underwater dynamic pressure, and two orthogonal horizontal wave orbital velocity components, respectively.

3.2 Submerged Pressure Transducer Array Data

By means of a standard stochastic approach, the cross spectrum of simultaneous measurements of water surface elevation from two horizontally spaced gages can be expressed as (Borgman, 1969)

$$\begin{aligned} E_{1,2}(f) &= R_{1,2}(f) + iQ_{1,2}(f) = \int_0^{2\pi} E(f, \phi) \exp[ikD_{1,2} \cos(\phi - \beta_{1,2})] d\phi \\ &= E(f) \{ J_0(kD_{1,2}) + 2 \sum_{n=1}^{\infty} [a_n(f) \cos n\beta_{1,2} + b_n(f) \sin n\beta_{1,2}] (i)^n J_n(kD_{1,2}) \}, \end{aligned}$$

where $i = \sqrt{-1}$ denotes the imaginary unit, k is the wave number, $Q_{1,2}(f)$ is the quadrature spectrum presenting the imaginary part of $E_{1,2}$, $D_{1,2}$ is the distance between two gages 1 and 2, $\beta_{1,2}$ is the angle of the vector from Gages 1 to 2, and

$$J_n(z) = \frac{1}{\pi(i)^n} \int_0^\pi \exp[iz \cos \phi] \cos n\phi d\phi$$

is the Bessel function of the first kind of order n . For N gages, a total of $2(N, 2) = N(N-1)$ equations are available for evaluation of $a_n(f)$ and $b_n(f)$ coefficients. These equations are

$$\begin{aligned} \frac{R_{jm}}{E(f)} &= J_0(kD_{jm}) + 2 \sum_{n=1}^M (-1)^n J_{2n}(kD_{jm}) [a_{2n}(f) \cos 2n\beta_{jm} + b_{2n}(f) \sin 2n\beta_{jm}], \\ \frac{Q_{jm}}{E(f)} &= 2 \sum_{n=1}^M (-1)^{n-1} J_{2n-1}(kD_{jm}) [a_{2n-1}(f) \cos(2n-1)\beta_{jm} + b_{2n-1}(f) \sin(2n-1)\beta_{jm}], \end{aligned}$$

where $j, m = 1, 2, \dots, N$, $j \neq m$ and $M = N(N-1)/4$. Here, M is the total number of pairs or harmonics of $a_n(f)$ and $b_n(f)$ existing in the above equations. This method of evaluating $a_n(f)$ and $b_n(f)$ is also valid on the source data from submerged pressure measurements instead of water surface elevations by calculating the cross spectrum and one-dimensional frequency spectrum from the measured pressure data.

In practice, it is preferable to solve $a_n(f)$ and $b_n(f)$ less than M harmonics. This is because that solving a finite number of $a_n(f)$ and $b_n(f)$ from a set of cross spectrum equations can be contaminated by the possible existence of directional wavelets higher than M harmonics. The contamination is deemed to be more severe to $a_n(f)$ and $b_n(f)$ with higher harmonics than lower harmonics being solved from the cross spectrum equations. Now, to solve for a less number of $a_n(f)$ and $b_n(f)$ than M harmonics, a least squared method can be used. This is the case of solving $\{x\}$ in the matrix system of $[A]_{m \times n} \cdot \{x\}_{n \times 1} = \{y\}_{m \times 1}$, with $m > n$ (more equations than unknowns). Utilization of a least squared method, which minimizes the quantity of $\|[A]\{x\} - \{y\}\|^2$, leads to the solution:

$$\{x\} = ([A]^T[A])^{-1} \cdot ([A]^T\{y\}), \text{ where } [A]^T = \text{the transpose of } [A].$$

Table 1: Coastal wave monitoring stations (1995).

Station	Depth(m)	Gage Type	Operating Period
Cape Canaveral	8.5	PUV P-array	Oct.,Nov. Feb.-Apr.
Palm Beach	3.5	PUV	Apr.-Jun.
Miami	6.5	PUV P-array	May-Jun. Jan.,Feb.,Apr. Nov.-Dec.

4. FIELD EXPERIMENTS

Wave data for use in the present study were measured from a number of PUV gages and pressure transducer arrays deployed in three coastal stations at Cape Canaveral, Palm Beach, and Miami Beach, Florida, in 1995. The data were collected four times daily, each containing a 20-minutes of measurements with a sampling rate of 1 Hz. The employed PUV gage is a submerged point gage system consisting of a pressure transducer and a bi-axial current meter. The slope array consists of four pressure transducers fixed by an aluminum tripod anchored on the sea floor. The geometry of the slope array is an equilateral triangle with one pressure transducer located at the center and three others at each corner of the triangle. This slope array setup is known as the star array geometry using four pressure transducers. The distances between the center and side transducers, and between any two side transducers, are 2m and 3.4m, respectively (Figure 1). Figure 2 shows the locations of wave monitoring stations and Table 1 lists the water depth, type of gage, and operating period of the stations.

5. COMPARISON OF DIRECTIONAL WAVE QUALITY

Directional wave data quality from both PUV and slope array data measurements was evaluated by examining $a_n(f)$ and $b_n(f)$ which are used in the estimation of directional spectrum rather than a simple inspection of the spectrum itself. The comparison of directional data quality is carried out for $a_1(f)$, $b_1(f)$, $a_2(f)$, and $b_2(f)$, based on the criterion of $a_n^2(f) + b_n^2(f) \leq 1$ shown earlier in Condition (iii). Table 2 presents a summary of the result of evaluation and comparison of these data. It is seen that directional data obtained from a PUV gage have absolutely better quality than those from a slope array. The worse quality of the latter is caused by the aliasing of higher directional wave modes to a finite number of $a_n(f)$ and $b_n(f)$ solved based on the slope array data. Figure 3 shows the histograms of directional data quality, based on the data satisfying the criterions of $a_1^2(f) + b_1^2(f) \leq 1$ and $a_2^2(f) + b_2^2(f) \leq 1$ over the frequency domain of $0 \leq f \leq 0.32$ Hz, for all the slope array data collected from Cape Canaveral and

Miami Beach stations. The analyzed results of slope array data show that $a_2(f)$ and $b_2(f)$ have much worse quality than $a_1(f)$ and $b_1(f)$. The results further indicate that all of these coefficients, regardless of $a_1(f)$, $b_1(f)$ or $a_2(f)$, $b_2(f)$, show overall worse quality for longer waves than shorter waves. Therefore, directional wave data quality measured from slope array gages is expected to be worse in shallow water than in deep water.

In fact, the quality of directional data measured from a slope array depends also on the total number of pressure gages employed and displacement geometry of the gages in the array. However, the degree of improvement of directional wave quality from the use of more gages in a slope array will always be affected by the finite number of $a_n(f)$ and $b_n(f)$ solved from the data.

Although the slope array measurements are seen to yield less satisfactory directional data quality, the analyzed data can be modified according to the criterion of $a_n^2(f) + b_n^2(f) \leq 1$ when the criterion is violated. A simple modification is proposed in the present study to multiply a common factor of γ to both $a_n(f)$ and $b_n(f)$ such that

$$(iv) \quad (a_n)' = \beta a_n, \quad (b_n)' = \beta b_n, \quad \beta = \frac{\gamma}{\sqrt{a_n^2 + b_n^2}},$$

where γ has a magnitude between 0 and 1. Again, without knowing the true directional spectrum, it is not possible to find γ . However, it is clear that γ approaching to 1 indicates a narrower directional band while γ approaching to 0

implies a broader directional distribution. Therefore, when Condition (iii) is violated, the sea is likely to have a quite narrower distribution of directional waves and the correction factor of γ shall have a value close to its upper limit of 1. A constant value of $\gamma = 0.99$ has been adopted in the present study for modifying the less perfect directional data quality from the pressure transducer arrays.

An example is presented here comparing the directional spectra analyzed for the data collected at midnight of 95/04/12 by a PUV gage from West Palm Beach station and a pressure transducer array system from Cape Canaveral station. At this particular time, waves may have reached to an equilibrated state under relatively strong winds with consistent magnitude and direction within the interval of ± 12 hrs (Figure 4). Figures 5 and 6 present the computed one-dimensional frequency spectra and Fourier coefficients of $a_1(f)$, $b_1(f)$, $a_2(f)$, $b_2(f)$ from the measured data. It is seen that all of these Fourier coefficients computed from PUV gage data satisfy Criterion (iii) whereas those from pressure transducer array can violate the same criterion. In order to compute the directional spectrum, the coefficients of $a_1(f)$, $b_1(f)$, $a_2(f)$, $b_2(f)$ determined based on the pressure transducer array data were modified according to the equations presented in (iv) if they violate Condition (iii). The computation of directional spectrum is, based on a Maximum Entropy approach (Kim *et al.*, 1993),

$$E(f, \phi) = E(f) \cdot \exp[-\lambda_0 - \lambda_1 \cos \phi - \lambda_2 \sin \phi - \lambda_3 \cos 2\phi - \lambda_4 \sin 2\phi],$$

where λ_i , the Lagrange's multipliers, can be approximated by

$$\lambda_1 = 2a_1a_2 + 2b_1b_2 - 2a_1(1 + a_1^2 + b_1^2 + a_2^2 + b_2^2),$$

$$\lambda_2 = 2a_1b_2 - 2b_1a_2 - 2b_1(1 + a_1^2 + b_1^2 + a_2^2 + b_2^2),$$

$$\lambda_3 = a_1^2 - b_1^2 - 2a_2(1 + a_1^2 + b_1^2 + a_2^2 + b_2^2),$$

$$\lambda_4 = 2a_1b_1 - 2b_2(1 + a_1^2 + b_1^2 + a_2^2 + b_2^2),$$

and

$$\lambda_0 = \ln \left[\int_{-\pi}^{\pi} \exp(-\lambda_1 \cos \phi - \lambda_2 \sin \phi - \lambda_3 \cos 2\phi - \lambda_4 \sin 2\phi) d\phi \right].$$

Figure 7 compares the directional spectra computed based on the PUV and pressure transducer array data. The computed spectra show that the associated wave systems are mainly moving westward against the coastal shore. The comparison shows that the two computed spectra are very similar in size and shape except that the one measured from Cape Canaveral station has the spectral tail twisted more towards NW direction than the spectrum from West Palm Beach station. This twisting in spectral direction is due to the effect of wave refraction in shallow water. The refraction effect is stronger for the spectrum measured at West Palm Beach station where the water depth is much shallower than Miami station.

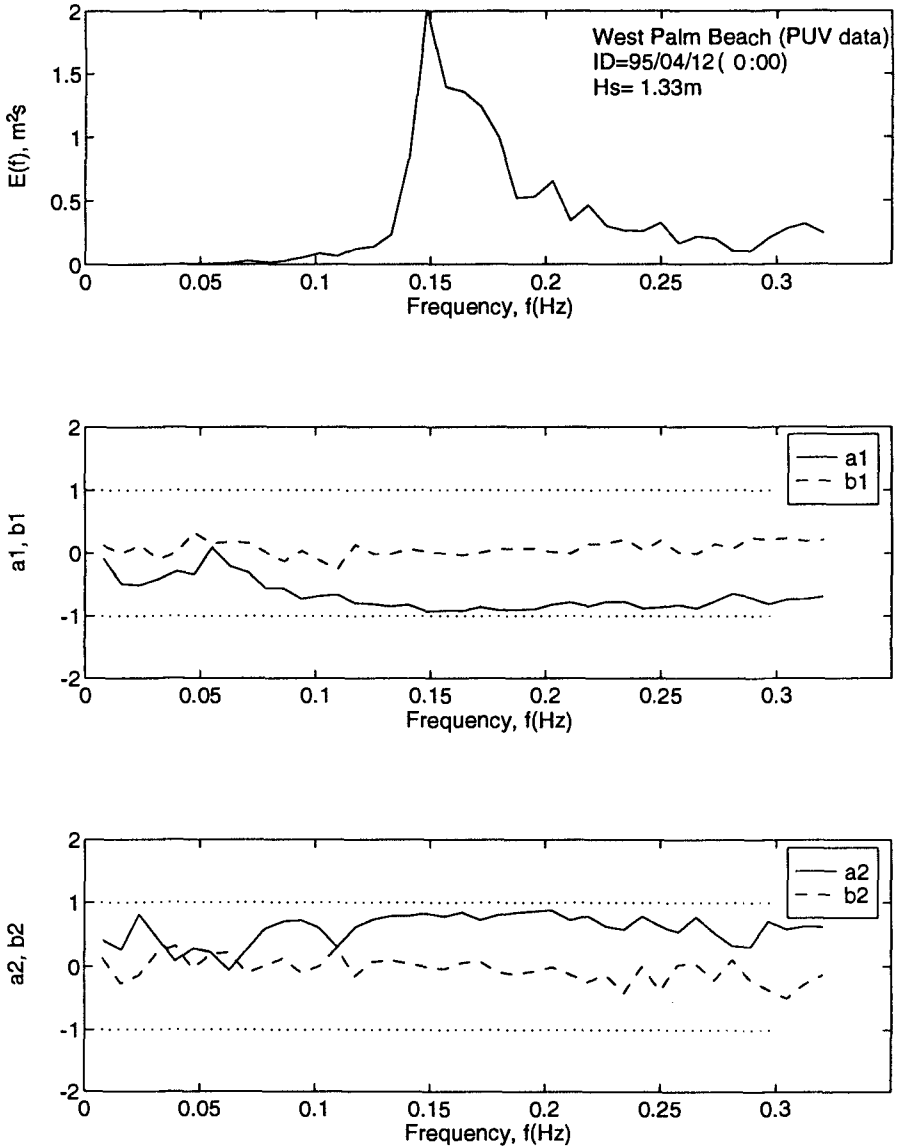

Figure 5: Wave information analyzed from West Palm Beach gage data.

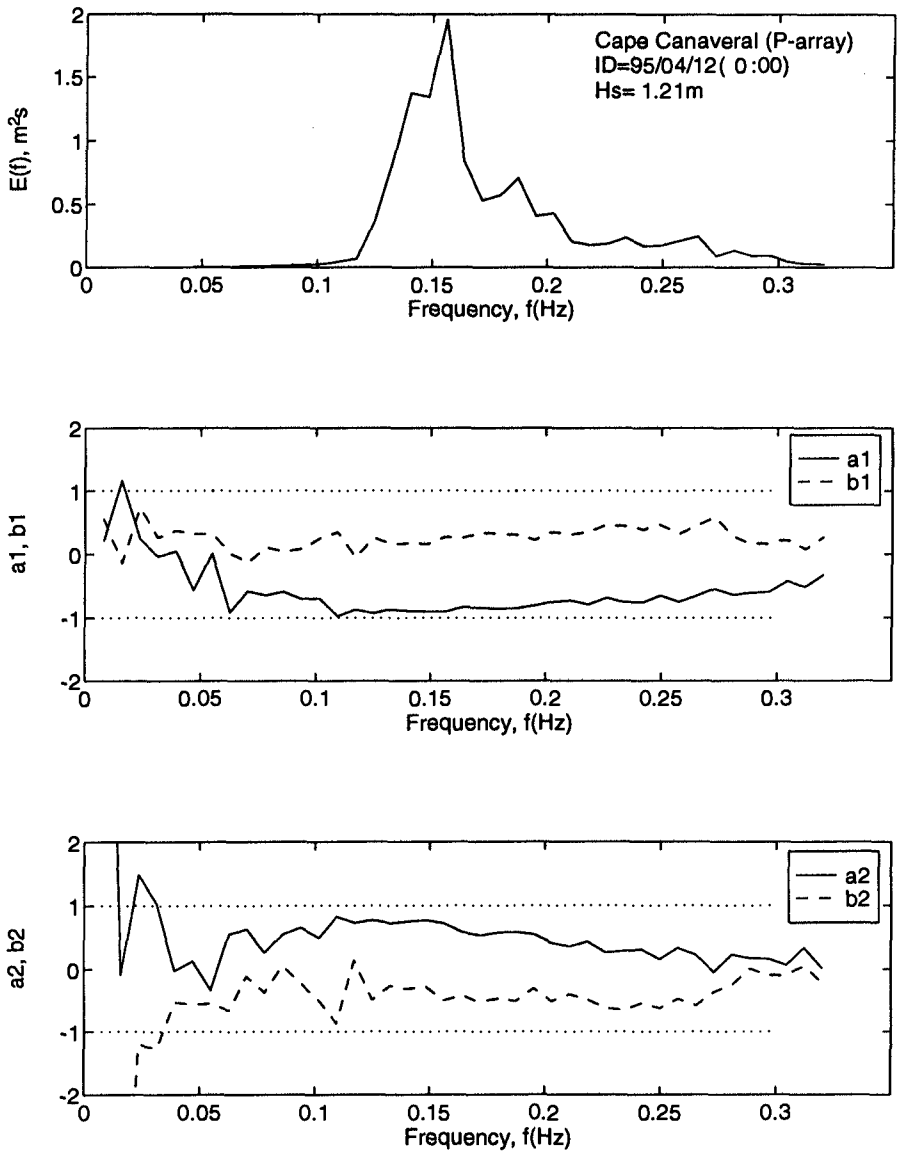

Figure 6: Wave information analyzed from Cape Canaveral gage data.

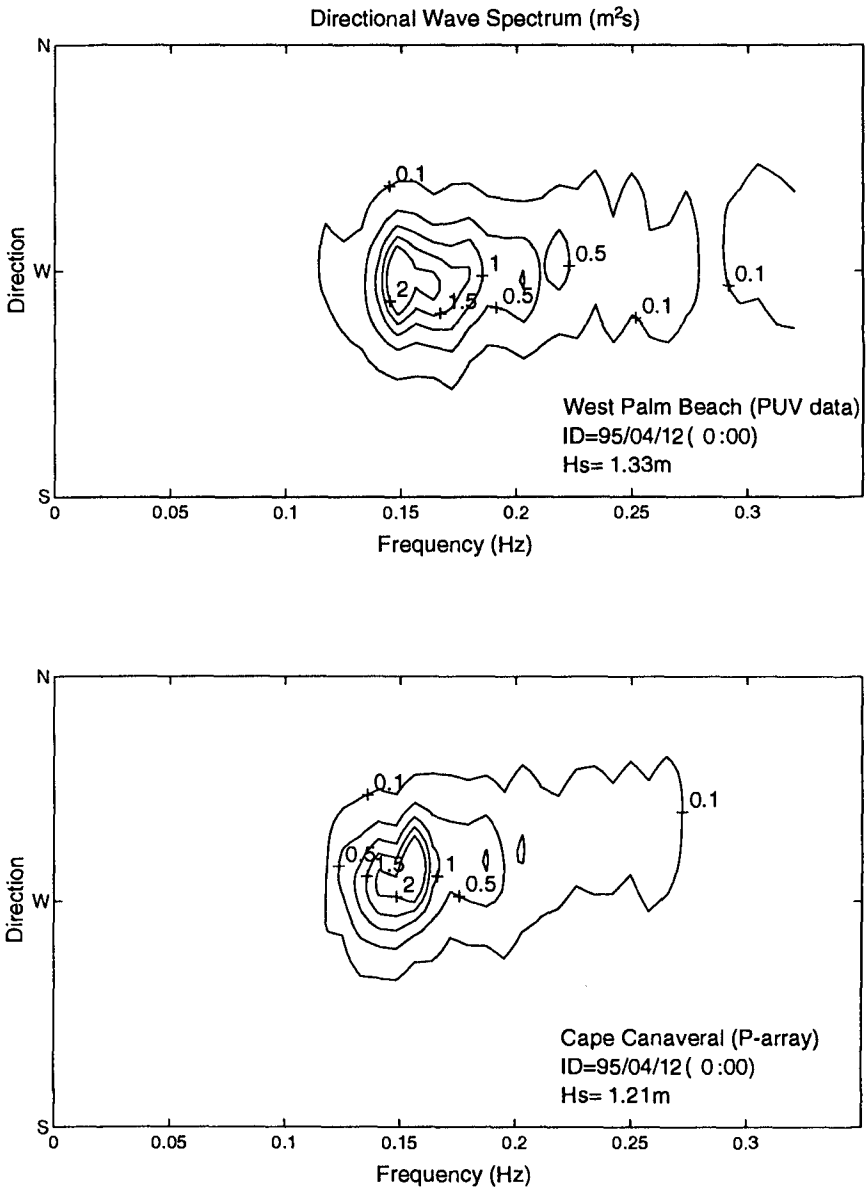

Figure 7: Comparison of analyzed directional wave spectra.

6. CONCLUSION

The conclusion drawn from this study is summarized as follows:

(1) Directional sea wave data need to satisfy the condition:

$$a_n^2(f) + b_n^2(f) \leq 1.$$

(2) The analyzed directional wave data based on PUV measurements show absolutely better quality than those based on P-array data (100% vs 75%), according to the criterion presented in (iii).

(3) The analyzed pressure gage array data show that the coefficients of a_2 , b_2 have much worse quality than a_1 , b_1 . Nevertheless, all of these coefficients show worse quality for longer waves in the range of shallow water condition.

(4) Corrections to the slope array directional wave data from

$$(a_n)' = \beta a_n, \quad (b_n)' = \beta b_n, \quad \text{with } \beta = \frac{\gamma}{\sqrt{a_n^2 + b_n^2}}, \quad \gamma = 0.99$$

have shown to yield directional spectra similar to those from PUV gage data.

CHAPTER 52

THE DIGITAL SIMULATION OF NON-LINEAR RANDOM WAVES

Kyungmo Ahn *

Abstract

This paper presents the method for the digital simulation of the second-order nonlinear random waves including strongly nonlinear shallow water waves and near breaking waves, which can be considered to be non-Gaussian random process. The method generates time series of the second order nonlinear random waves from the given energy spectrum and bispectrum obtained from the wave records. Numerical examples indicate that the procedure is basically worked well and generated time series of waves having the similar target spectral density function and probability distribution function. The proposed method has a wide range of applicability to problems involving the second-order nonlinear systems where outputs have strongly nonlinear and non-Gaussian characteristics.

Introduction

The time series simulation of nonlinear random waves has many practical applications in many engineering problems. For example, the simulated waves can be used for the analysis of the response of offshore structures excited by irregular waves (Duncan and Drake, 1995) and also can be used as wave-board control signals to generate nonlinear random waves (Klopman and Leeuwen 1990; Yasuda et al. 1994).

For the realistic reproduction of coastal waves, it is necessary to include the effects of the second-order nonlinear waves associated with the sum and difference frequency

* Assistant Professor, School of Construction and Environmental Engineering,
Handong University, 3 Namsong-ri, Pohang, Kyungbuk, 791-940, Korea

components of linear waves. For weakly nonlinear waves, the second-order random wave theory derived from the perturbation method using potential theory can be used to derive formulas for the generation of second-order random waves (Sharma and Dean, 1979; Klopman and Leeuwen 1990). However, the method cannot be used to generate strongly nonlinear waves in shallow water.

Recently, Ochi and Ahn (1994) developed a method to separate bound harmonic wave components from free linear wave components by applying the concept of the bicoherence spectrum. When various spectral components interact with one another due to nonlinearities, the resulting components are phase coherent with the primary components. Therefore, those components are not considered to be statistically independent. The bispectrum, which measures the statistical dependence of three spectral components whose sum frequency is zero, may therefore be a useful tool to investigate the nonlinearities of random waves especially in shallow water waves. By applying the concept of a bicoherent spectrum, it is possible to separate the linear free wave spectral component from the spectrum obtained from the measured wave profile record. Then, by using the separated linear spectrum and bispectrum, we can digitally simulate the strongly non-linear random waves which have the similar stochastic characteristic of the target waves.

Digital Generation of Second-Order Nonlinear Random Waves.

In this paper, a method is presented to generate time series of strongly nonlinear waves from the linear energy spectrum and bispectrum of surface elevation obtained from the wave record. For this, we first write surface profile of second-order random waves in finite water depth as follows:

$$y(t) = \text{Re} \sum_{k=1}^N c_k e^{i(2\pi f_k t + \varepsilon_k)} + \text{Re} \sum_{k=1}^N \sum_{l=1}^N c_k c_l \left[q_{kl} e^{\{2\pi(f_k + f_l)t + (\varepsilon_k + \varepsilon_l)\}} + r_{kl} e^{\{2\pi(f_k - f_l)t + (\varepsilon_k - \varepsilon_l)\}} \right] \quad (1)$$

where f = frequency, ε = phase lag, q_{kl} = wave-wave sum interaction coefficient associated with $f_k + f_l$, and r_{kl} = wave-wave difference interaction coefficient associated with $f_k - f_l$.

According to Ahn (1993), wave-wave interaction coefficients q_{kl} and r_{kl} can be

represented as follows:

$$q_{kl} \approx \frac{m}{s_k^2 s_l^2} B_s(f_k, f_l) \tag{2}$$

$$r_{kl} \approx \frac{m}{s_k^2 s_l^2} \{B(f_l, f_k - f_l) - B_s(f_k, f_l)\} \tag{3}$$

where $m = 1$ for $k \neq l$, $m = 2$ for $k = l$, $s_k^2 = c_k^2 / 2$, $s_l^2 = c_l^2 / 2$ represent the discrete linear spectral wave energy components at frequencies f_k and f_l , respectively. $B(f_k, f_l)$ denotes the bispectrum which is formally defined as the Fourier transform of the second-order covariance function (Hasselmann et al., 1963). The bispectrum can also be expressed in terms of Fourier coefficients (Kim and Powers, 1979) as follows:

$$B(f_k, f_l) = E[Y(f_k)Y(f_l)Y^*(f_k + f_l)] \tag{4}$$

where $y(f_k)$ is the complex Fourier coefficient for frequency f_k and the asterisk denotes the complex conjugate. $B_s(f_k, f_l)$ represents the portion of the bispectrum which is due to wave-wave interactions of sum frequency components.

From Equations (1) through (3) we can generate the time series of nonlinear random waves for given linear energy spectrum and bispectrum.

Numerical Example Problem

To verify the method proposed, a numerical example is given. We generated 64 records of test waves which involve three primary linear wave components at frequencies f_1, f_2 and f_3 and non-linear wave components generated from interactions of components at frequencies f_1, f_2 and f_3 .

Let's consider a test waves such that

$$\begin{aligned} y(t) &= \operatorname{Re} \sum_{k=1}^3 c_k e^{i(2\pi f_k t + \varepsilon_k)} + \operatorname{Re} \sum_{\kappa=1}^2 \sum_{l=1}^2 c_\kappa c_l [q_{\kappa l} e^{i\{(2\pi f_\kappa + 2\pi f_l)t + (\varepsilon_\kappa + \varepsilon_l)\}} + r_{\kappa l} e^{i\{(2\pi f_\kappa + 2\pi f_l)t + (\varepsilon_\kappa - \varepsilon_l)\}}] \\ &= c_1 \cos(2\pi f_1 t + \varepsilon_1) + c_2 \cos(2\pi f_2 t + \varepsilon_2) \\ &\quad + c_1^2 r_{11} \cos(4\pi f_1 t + 2\varepsilon_1) + c_2^2 r_{22} \cos(4\pi f_2 t + 2\varepsilon_2) \\ &\quad + 2c_1 c_2 r_{12} \cos((2\pi f_1 + 2\pi f_2)t + (\varepsilon_1 + \varepsilon_2)) \\ &\quad + 2c_1 c_2 q_{12} \cos((2\pi f_1 - 2\pi f_2)t + (\varepsilon_1 - \varepsilon_2)) \end{aligned} \tag{5}$$

where $f_3 = f_1 + f_2$. The phases of each wave were independently taken from a set of uniformly distributed random numbers between 0 and 2π . Fig.1 shows the energy spectrum of test waves $y(t)$. The wave energy in the spectrum corresponds to frequencies from the lowest to the highest frequency $f_2 - f_1$, $f_1, f_2, 2f_1, f_3 = f_1 - f_2$, and $2f_2$ respectively. The wave energy at $2f_1, 2f_2$ and $f_2 - f_1$ is entirely due to self-interactions of f_1 and f_2 and difference interactions of f_1 and f_2 . A portion of the energy at $f_3 = f_1 + f_2$ is due to the sum interaction of waves at f_1 and f_2 and the rest of the energy at f_3 is due to the free linear wave component.

The wave-wave difference interaction coefficient r_{ke} in Eq(3), can be obtained from the bispectrum and corresponding linear energy spectral components. In evaluating the interaction at the frequency $f_1 - f_2$, it is assumed that the spectral energy density at frequencies smaller than the minimum frequency f_s is entirely due to the nonlinear interactions associated with the difference between various combinations of the two frequency component at f_1 and f_2 . Furthermore, noting that $Y(f_k) = Y^*(-f_k)$ for real $y(t)$, it can be shown that the bispectrum has the following symmetry relations:

$$\begin{aligned} B(f_1, f_2) &= B(f_2, f_1) = B(f_1, -f_1 - f_2) \\ &= B(f_1, -f_1 - f_2) = B(f_2, -f_1 - f_2) = B(-f_1, -f_2, f_2) \end{aligned} \quad (6)$$

By the above symmetry relations and definition of f_s , the difference interaction coefficient r_{ke} , can be obtained in the unique bifrequency space, $B - B_s$ as shown in Fig 2. Fig.3 shows the real part of the bispectrum obtained for $y(t)$ by using MATLAB, higher order spectral analysis toolbox.

The analytically computed bispectral values for $y(t)$ are also shown as follows:

$$\mathbf{B}(f_1, f_1) = E[Y(f_1)Y(f_1)Y^*(2f_1)] = \frac{c_1^4 r_{11}}{8} \quad (7a)$$

$$\mathbf{B}(f_2, f_2) = E[Y(f_2)Y(f_2)Y^*(2f_2)] = \frac{c_2^4 r_{22}}{8} \quad (7b)$$

$$\mathbf{B}(f_1, f_2) = E[Y(f_1)Y(f_2)Y^*(f_1 + f_2)] = \frac{c_1^2 c_2^2 r_{12}}{4} \quad (7c)$$

$$\mathbf{B}(f_2, f_1 - f_2) = E[Y(f_2)Y(f_1 - f_2)Y^*(f_1)] = \frac{c_1^2 c_2^2 q_{12}}{4} \quad (7d)$$

Fig.1 The energy spectrum of $y(t)$

Fig.2 Domains for computing $B(f_k, f_l)$ and $B(f_l, f_k - f_l)$

$$\mathbf{B}(f_1 + f_2, f_1 - f_2) = E[Y(f_1 + f_2)Y(f_1 - f_2)Y^*(2f_1)] = \frac{c_1^4 c_2^2 r_{11} r_{12} q_{12}}{2} \quad (7e)$$

$$\mathbf{B}(2f_2, f_1 - f_2) = E[Y(2f_2)Y(f_1 - f_2)Y^*(f_1 + f_2)] = \frac{c_1^2 c_2^4 r_{22} r_{12} q_{12}}{2} \quad (7f)$$

The plan view of the bispectrum is drawn in Fig.4 to identify the bispectrum in the unique bifrequency space. As can be seen in the figure and from Eq.(7d), the difference interaction coefficient q_{12} is obtained from $\mathbf{B}(f_2, f_1 - f_2)$. Since bispectral values $\mathbf{B}(f_1 + f_2, f_1 - f_2)$ and $\mathbf{B}(2f_2, f_1 - f_2)$ in Eq.(7a,b) are order of magnitude smaller than $\mathbf{B}(f_2, f_1 - f_2)$, we may neglect the terms in evaluating difference interaction coefficient.

The energy spectral component at frequency f_3 is due to free linear wave component $c_3 \cos(2\pi f_3 t + \varepsilon_3)$ as well as the nonlinear sum interaction of waves at f_1 and f_2 . The separation of the nonlinear energy from the total spectrum can be achieved approximately by applying the method proposed by Kim and Power(1979) and Ahn(1993) as following:

$$S(f_m) = S_L(f_m) + \sum_{f_m=f_k+f_l} b^2(f_k, f_l) S(f_m) \quad (8)$$

where the bicoherence squared spectrum is defined as

$$b^2(f_k, f_l) = \frac{|B(f_k, f_l)|^2}{E[|Y(f_k)Y(f_l)|^2] E[|Y(f_m)|^2]} \quad (9)$$

Fig.5 shows the bicoherence squared spectrum. The computed bicoherence for the sum interaction is $b^2(f_1, f_2) = 0.14$ which implies that only 14% of the energy at f_3 is due to the nonlinear sum interaction of the waves at f_1 and f_2 . The computed bicoherences for the self interactions and difference interaction are $b^2(f_1, f_1) = 0.9969$, $b^2(f_2, f_2) = 0.9989$ and $b^2(f_2, f_1 - f_2) = 0.9980$, respectively, which implies that the energy at $2f_1$, $2f_2$ and $f_1 - f_2$ are entirely due to the nonlinear interactions.

Fig.3 Real part of bispectrum

Fig.4 Plan view of bispectrum

Digital simulation of non-linear waves

The time series and the histogram of $y(t)$ in Eq.(4) are shown in Fig.6 and Fig.7, respectively. In these figures, the wave profile shows a definite excess of high crests and shallow troughs, which is a typical feature of nonlinear waves (non-Gaussian random process). In the previous section, we computed the linear energy spectrum and bispectrum of $y(t)$. We now demonstrate the simulation of time series of the second-order random waves from the given linear energy spectrum and bispectrum. The digitally simulated waves should have similar stochastic characteristics such as the spectral density function and the probability distributions. Fig.8, shows the digitally simulated waves by the method proposed. Fig.9 and Fig.10 show the energy spectral density and the histogram of the simulated waves. The digitally simulated waves have good agreement with the target spectral density function and the probability density function of $y(t)$ (compare Fig.9 and Fig.10 with Fig.1 and Fig.6). Therefore the simulated waves is proved to satisfy both the target spectral density and probability distribution function. The following table shows the statistical values of the target time series and the simulated time series of waves. The agreement between them is satisfactory.

	Target time series $y(t)$	Simulated time series
Variance	2.48	2.83
Skewness	1.11	1.05
Kurtosis	4.17	3.71

Conclusions

A method to digitally generate the time series of second-order nonlinear random waves applicable to strongly nonlinear shallow water waves is developed. For the given bispectrum and the bicoherence spectrum, the linear spectrum is separated from the measured spectrum. Then, the wave-wave interaction coefficients associated with various pairs of sum and difference frequency components can be evaluated from the bispectrum. Time series of the second-order nonlinear waves are then digitally simulated using linear spectral components and wave-wave interaction coefficients derived from the bispectrum. The simulated waves have the similar spectral density function and probability distribution

function. A numerical example is used to verify the method developed. The simulated time series of waves closely reproduce the target spectral density function and probability distribution function. It is noted that the proposed method can be applied to wide range of outputs produced by the quadratic nonlinear system. The method could be applied to many practical engineering fields.

CHAPTER 53

THE "SWAN" WAVE MODEL FOR SHALLOW WATER

N. Booij¹, L.H. Holthuijsen¹ and R.C. Ris¹

ABSTRACT

The numerical model SWAN (Simulating WAves Nearshore) for the computation of wave conditions in shallow water with ambient currents is briefly described. The model is based on a fully spectral representation of the action balance equation with all physical processes modelled explicitly. No a priori limitations are imposed on the spectral evolution. This makes the model a third-generation model. In Holthuijsen et al. (1993) and Ris et al. (1994) test cases for propagation, generation and dissipation have been shown without currents. Current effects have now been added and academic cases are shown here. The model is also applied in a fairly academic case of a shallow lake (Lake George, Australia) and in a complex, realistic case of an inter-tidal area with currents (Friesche Zeegat, the Netherlands). The results are compared with observations. A new development to formulate the model on a curvi-linear grid to accommodate linkage to hydro-dynamic circulation models is presented and a first test is shown.

INTRODUCTION

Over the last decade, the traditional wave ray models in coastal engineering to compute waves in nearshore conditions are being replaced by models that formulate the wave evolution in terms of a spectral energy balance on a regular grid (or the action balance in the presence of ambient currents). In third-generation versions of such models the wave spectrum is allowed to evolve free of any a priori limitations and all relevant physical processes are represented explicitly in a discrete spectral formulation. Such a wave model (the SWAN model), with the inclusion of ambient currents is described here. Conceptually it is an extension of deep water third-generation wave models but the physical processes and the numerical techniques involved are more complicated. The SWAN wave model has been conceived to be a computationally feasible third-generation spectral wave model for waves in shallow water (including the surf zone) with ambient currents in a consulting environment with return times of less than 30 min on a desk top computer.

¹ Delft University of Technology, Department of Civil Engineering, P.O. Box 5048, 2600 GA Delft, Netherlands.

THE SWAN WAVE MODEL

The SWAN wave model (Ris et al., 1994) is a fully discrete spectral model based on the action balance equation which implicitly takes into account the interaction between waves and currents through radiation stresses (e.g., Phillips, 1977):

$$\frac{\partial}{\partial t} N(\sigma, \theta) + \nabla_{x,y} \cdot [c_{x,y} N(\sigma, \theta)] + \frac{\partial}{\partial \sigma} [c_{\sigma} N(\sigma, \theta)] + \frac{\partial}{\partial \theta} [c_{\theta} N(\sigma, \theta)] = \frac{S(\sigma, \theta)}{\sigma}$$

The first term in the left-hand side is the rate of change of action density in time, the second term is the rectilinear propagation of action in geographical x -, y -space. The third term describes the shifting of the relative frequency due to currents and time-varying depths with propagation velocity c_{σ} in σ -space. The fourth term represents the propagation in θ -space (depth- and current-induced refraction) with propagation velocity c_{θ} . The term $S(\sigma, \theta)$ at the right hand side of the action balance equation is the source term representing the growth by wind, the wave-wave interactions and the decay by bottom friction, whitecapping and depth-induced wave breaking.

To reduce computer time, we remove time from the action balance equation (i.e., $\partial/\partial t = 0$). This is acceptable for most coastal conditions since the residence time of the waves is usually far less than the time scale of variations of the wave boundary conditions, the ambient current, wind or the tide. For cases in which the time scale of these variations becomes important, i.e., variable incoming waves at the boundary, or variable winds or currents, a quasi-stationary approach can be taken by repeating the computations for predefined time intervals.

The formulations for the generation, the dissipation and the quadruplet wave-wave interactions are taken from the WAM model (WAM Cycle 3, WAMDI group, 1988 and optionally WAM Cycle 4, Komen et al., 1994 as presently operational at the European Centre for Medium Range Weather Forecasting). For the present study the formulations from WAM Cycle 3 are used. These are supplemented with a spectral version of the dissipation model for depth-induced breaking of Battjes and Janssen (1978) (with the maximum wave height to depth ratio from Nelson, 1987) and a recently formulated discrete interaction approximation for the triad wave-wave interactions (Eldeberly and Battjes, 1995).

Fully implicit numerical schemes are used in the SWAN model for propagation in both geographic space and spectral space (an iterative, forward-marching, four-sweep technique, Ris et al., 1994). This scheme is unconditionally stable in contrast with the explicit schemes of conventional spectral wave models which are only conditionally stable and which require therefore very small time steps in shallow water (typically 10 s for 100 m resolution in water depth of 10 m where in the SWAN model the time increment may be as large as 15 min). The formulation is basically in terms of finite differences on a regular, rectangular grid. This is inconvenient in regions with highly variable scales such as tidal inlets, tidal flats and

estuaries. Nesting of grids with decreasing resolution is the conventional approach in such cases but it requires extra computations. A variable resolution grid would avoid such extra computations, in particular if the grid would conform to the topography of the region. It would also accommodate the linkage with hydrodynamic circulation models which are often formulated on such grids. Such a curvilinear approach is implemented in the SWAN model by considering in the numerical scheme of each spatial grid point, two separate, non-equidistant finite up-wind differences in each of two orthogonal directions. For the x -direction this is for grid point i, j (the grid points are ordered in x, y -space):

$$\frac{\partial C_x N}{\partial x} \approx \left[\frac{[c_x N]_{i,j} - [c_x N]_{i-1,j}}{\Delta \bar{x}_1} \right] + \left[\frac{[c_x N]_{i,j} - [c_x N]_{i,j-1}}{\Delta \bar{x}_2} \right]$$

where $\Delta \bar{x}_1 = \Delta x_1 - (\Delta y_1 / \Delta y_2) \Delta x_2$, $\Delta \bar{x}_2 = \Delta x_2 - (\Delta y_2 / \Delta y_1) \Delta x_1$. The increments are $\Delta x_1 = x_{i,j} - x_{i-1,j}$, $\Delta x_2 = x_{i,j} - x_{i,j-1}$, $\Delta y_1 = y_{i,j} - y_{i-1,j}$ and $\Delta y_2 = y_{i,j} - y_{i,j-1}$.

PROPAGATION TESTS

In Holthuijsen et al. (1993) the excellent agreement for academic cases is shown between computed wave propagation and analytical solutions and wave ray solutions of the linear wave theory without ambient currents. A similar good agreement with ambient currents added is shown here. For this, consider current-induced refraction in deep water, of monochromatic, long-crested waves with a (significant) wave height of 1 m and a (peak) frequency of 0.1 Hz. In the SWAN computation these waves are simulated with a Gaussian-shaped frequency spectrum with 0.01 Hz standard deviation and a $\cos^{500}(\theta)$ -directional distribution. Consider first these waves propagating from a uniform up-wave boundary over a distance of 4000 m in a following or opposing current of which the speed increases from 0 m/s to 2 m/s in the down-wave direction (current direction 0° or 180° direction relative to the mean wave direction). Only whitecapping is activated in the computations (although its effect is marginal). The computational results in terms of (significant) wave height for this current-induced shoaling test are shown in Fig. 1. The agreement for these cases with linear theory is excellent as the computational errors are less than 0.5% for the significant wave height and less than 0.1° for the mean wave direction (both differences hardly noticeable in Fig. 1). Consider next the same waves slanting across a 4000 m wide current field of which the current speed increases from 0 m/s to 2 m/s across the width and the current direction is constant and parallel to the straight current field boundaries. The wave direction is either $+30^\circ$ or -30° relative to the current direction. The results for the significant wave height and the wave direction are also shown in Fig. 1. The agreement for these cases with linear theory is as good as in the current-induced shoaling test.

The propagation with the curvilinear formulation is tested here by comparing the computational results on a rectangular grid with those on a curvilinear grid near

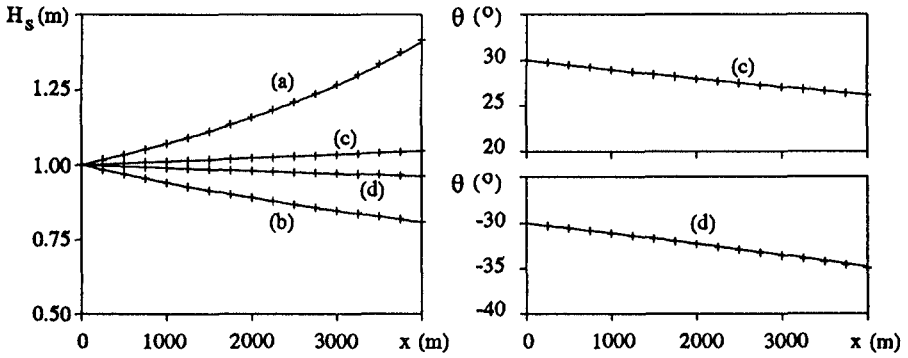

Fig. 1 Current-induced shoaling and refraction for monochromatic, long-crested waves for travelling against an opposing current (line a), a following current (line b) and a slanting current with incident wave direction $\theta_o=30^\circ$ (line c) and $\theta_o=-30^\circ$ (line d). Left panel: significant wave height H_s (m). Right panel: mean wave direction θ ($^\circ$), (—) analytical solutions and (+ + +) results from the SWAN model.

Fig. 2 The propagation of a short-crested wave field around a barrier island; significant wave height with contour line interval of 0.1 m and mean wave direction. The depth increases from the shore line over a distance of 4500 m to a constant water depth of 10 m. Left panel: computational results on a rectangular grid. Right panel: computational results on a curvi-linear grid (grid points at start of each vector).

a hypothetical barrier island (Fig. 2). All source terms are de-activated in these computations. The incoming waves are characterized with a JONSWAP spectrum with a $\cos^4(\theta)$ -directional distribution. The significant wave height and the mean wave period are 2.0 m and 6.0 s, respectively. The results of the computation on the curvi-linear grid agrees well with the results on the rectangular grid (Fig. 2).

WIND-WAVE GENERATION IN SHALLOW WATER

The observations of Young and Verhagen (1996) in the shallow Lake George (Australia) provide an excellent opportunity to test the generation of waves in the SWAN model in shallow water. These observations were carried out at eight wave stations in the lake, the bathymetry of which is fairly flat with an average depth of 2m (Fig. 3).

Fig. 3 Bathymetry of Lake George and the locations of the eight wave stations. Isolines represent depth contours (interval 0.5 m).

One case with a relatively high wind speed of $U_{10}=15.2$ m/s (at station 6 on 02-11-1992 at 16:00 local time) from northerly directions is chosen to demonstrate the performance of the SWAN model. From wind measurements at other stations it was found that the wind speed varied slightly along the north-south axis of the lake. This variation is calculated with the simple expression of Tayler and Lee (1984) proposed for these cases by Young and Verhagen (1996). As the up-wave coast line was not very well defined in this case (due to a very gentle bottom slope) the up-wind boundary condition was taken to be the observed wave spectrum at station 1. Fig. 4 shows the good agreement between the observed

significant wave height and peak frequency (I.R. Young and L.A. Verhagen, private communication, 1996) and the computational results. The inclusion of depth-induced wave breaking in modelling such conditions is unusual. Its effect is determined here by repeating the computation with this process de-activated in the model. The effect is significant only at the down-wind end of the lake (Fig. 4) and only for these high wind speeds (computations with wind speeds less than 10 m/s do not show this effect).

Fig. 4 Model results and observations of the significant wave height (left panel) and peak frequency (right panel) at the observation stations in Lake George for $U_{10}=15.2$ m/s. (+) measurements, (o) SWAN results, (v) SWAN results with depth-induced wave breaking de-activated.

APPLICATION

The performance of the SWAN model is shown here for a field case with wind and complex bottom and current patterns and 95% reduction in wave energy. It is a case in the Friesche Zeegat (the Netherlands) where a system of narrow channels (10 km length scale) runs from the North Sea into an area of tidal flats (the Wadden Sea, Fig. 5, the two main channels are about 10 m and 14 m deep). The waves were measured with one WAVEC pitch-and-roll buoy (station 1) at the deep water boundary of the area and five Waverider buoys (stations 2 to 6) located along the two channels (see Fig. 5). The observations that have been selected from the extensive data set for this verification are a flood current case which occurred on 09-10-1992 at 05:00 UTC (J.G. de Ronde and J.H. Andorka Gal, private communication, 1996). The reasons for this selection are that (a) at this time relatively high waves were observed (significant wave height about 2.5 m) which were generated by a storm in the northern North Sea, (b) during the period of observation the wind speed and direction were nearly constant, (c) the frequency spectrum was uni-modal and (d) tidal currents and water levels were measured. The wind velocity of $U_{10}=11.5$ m/s and direction of 320° are assumed to be uniform over the Friesche Zeegat area. The corresponding currents and water levels in the area were computed with a shallow water circulation model, resulting in a maximum current speed of about 1 m/s.

The spectrum at the up-wave boundary in deep water for the computations is taken equal to the frequency spectrum observed by the WAVEC buoy at station 1. It is taken uniform along a straight line through the location of the WAVEC buoy and roughly parallel with the 20 m depth contour. The observed significant wave height is $H_s = 2.24$ m and the mean wave period is $T_{m01} = 5.6$ s. The observed overall mean wave direction is 328° (nautical convention) and the overall directional width of the waves is 31° . The directional distribution is correspondingly

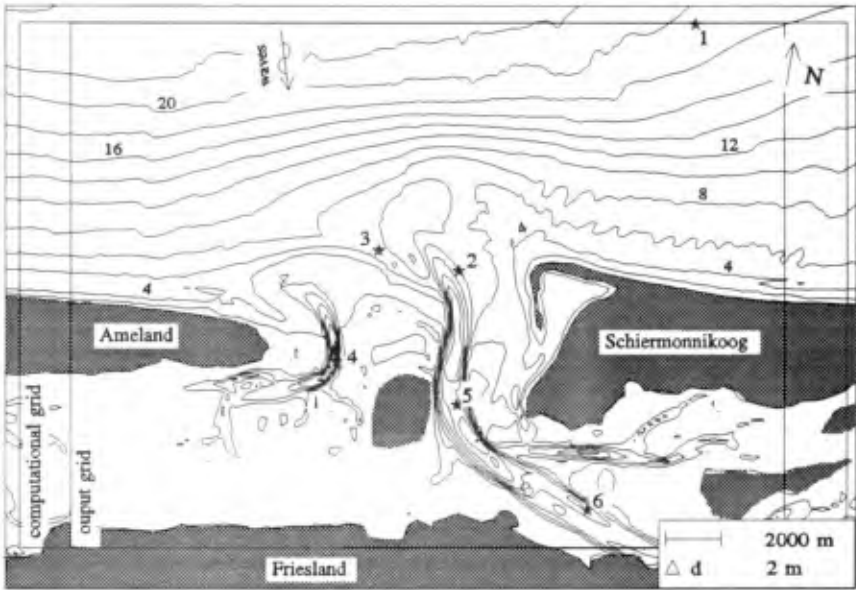

Fig. 5 The bathymetry of the Friesche Zeegat with the locations of the six stations. The isolines represent depth contours (interval 2 m). All water depths are in m.

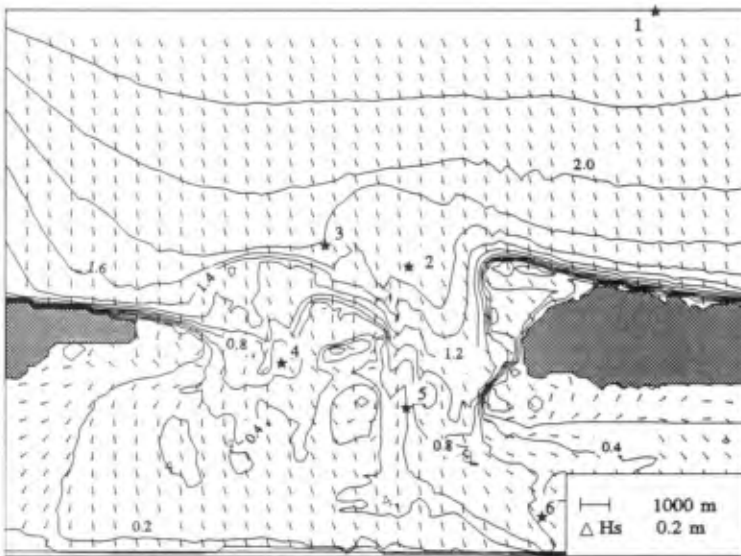

Fig. 6 Computed wave height pattern and mean wave direction (denoted with vectors) for a flood current case in the Friesche Zeegat. The isolines represent wave height contours (interval 0.2 m).

Fig. 7 Computed and observed significant wave height (left panel) and mean wave period (right panel) at the observation stations for the flood current case in the Friesche Zeegat: (+) observations, (o) SWAN results, (v) SWAN results without currents.

approximated with a $\cos^{2.1}(\theta)$ -directional distribution at all frequencies. The computed pattern of the significant wave height is shown in Fig. 6. This pattern is consistent with the pattern of the observations: the wave height gradually decreases between the deep water boundary and the entrance of the tidal inlet. Due to depth effects, more wave energy penetrates into the deeper eastern entrance than into the shallower western entrance of the tidal inlet (roughly 20 % lower wave height near station 4 than in the other entrance). As the waves penetrate through the tidal gap into the inlet they refract laterally to the shallower parts of the tidal inlet. They completely reverse direction behind the two barrier islands. The mean wave period (not shown here) follows roughly the same pattern. The effect of currents is shown with results of computations without currents (Fig. 7). This effect is evident but generally not very important in this case.

The calculated significant wave heights and mean wave periods at the six observation stations are given in Fig. 7. The agreement with the observations is fairly reasonable although the model tends to underestimate the mean wave period.

CONCLUSIONS

The SWAN wave model, which has been conceived as a computationally feasible third-generation spectral wave model for waves in shallow water (including the surf zone) with ambient currents for engineering consultancy has been implemented. It accounts for all relevant processes of propagation, generation, dissipation and nonlinear wave-wave interactions (except diffraction but including depth-induced wave breaking, triad wave-wave interactions and the effects of currents). Tests so far in academic conditions and in realistic field conditions show good agreement between computational results and observations although the present version of the model tends to slightly underestimate the mean wave period.

The present computation time is 6×10^{-5} s per grid point in x -, y -, σ -, θ -space per iteration on a HP 9000/735 work station (without currents; three times more than this when currents are included). A typical engineering application (without currents) of 100×100 geographic (water covered) grid points, 24 frequencies and 36 directions with 3 to 5 iterations will therefore take typically between 30 and 45 min computation time. With the expected performance of desk-top computers presently entering the market this will reduce to less than 15 - 30 min within the next few years. The operational goal has therefore been achieved. Future versions of the SWAN model (presently under development) will be non-stationary, formulated on a curvi-linear grid, and optionally formulated in spherical coordinates with a higher-accuracy propagation scheme and possibly include the effects of diffraction and reflections.

ACKNOWLEDGEMENTS

We gratefully acknowledge the generosity of I.R. Young and L.A. Verhagen of the University of New South Wales in Australia and of J.G. de Ronde, J.H. Andorka Gal and their colleagues from the Ministry of Transport and Public Works in the Netherlands in sharing their data from Lake George and the Friesche Zeegat, respectively. We are equally grateful to B.A.J. Les from the Delft University of Technology who (at the Ministry of Transport and Public Works) carried out the calculations for the currents and water levels in the Friesche Zeegat.

CHAPTER 54

Generation Depths from Water Wave Data

J. Ernest Breeding, Jr.¹

Abstract

It is shown that by determining wave group back tracks for recorded data it is possible to determine whether the waves were generated in deep, intermediate, or shallow water depths. The general movement of a storm can be tracked if a storm moves through water of intermediate depths. For the examples shown reasonable results were obtained by approximating the geometric group velocity by the conventional group velocity.

Introduction

When water waves are generated the depth of the water where the waves begin becomes a characteristic trait of the waves. Through the use of simple refraction concepts it is possible to determine from recorded data whether the waves originated in deep, intermediate, or shallow water depths. If the waves were generated in intermediate water depths the actual water depths can be determined.

It is assumed that initially the wave groups and the individual waves within the groups have the same direction where the waves are generated. In shoaling water, refraction causes the groups and the individual waves to have different directions because of their differing velocities. This difference is used to determine the water depths where the waves are generated, i.e., the generation depths. The method is based on determining back tracks from the measurement site to the source of wave generation.

Breeding (1978, 1986) found that the paths of wave groups are determined

¹Research Physicist, Code 7183, Naval Research Laboratory, Stennis Space Center, MS 39529-5004

according to Snell's law with the geometric group velocity. The geometric group speed G is defined

$$G = U \cos \phi \quad (1)$$

$$U = d\omega/dk \quad (2)$$

$$\phi = \theta - \gamma \quad (3)$$

where U is the conventional group speed, ω is the angular frequency, k is the wave number, θ is the wave group direction, and γ is the direction that the individual waves move within the group. The direction γ is given by Snell's law with phase velocity.

This concept can be used to explain a number of physical processes in coastal waters that cannot be explained on the basis of a single refraction law. For example, when both refraction laws are used together it is possible to show (Breeding, 1981b) that the widely occurring sinuous shoreline is part of an equilibrium beach form.

The primary objective in this paper is to determine the generation depths of recorded waves. A second objective is to demonstrate that under certain conditions good results can be obtained if the conventional group velocity is used as an approximation to the geometric group velocity. This approach can be highly desirable for many practical applications since it greatly simplifies the ray equations and the complexity of the computer program for ray tracing.

Wave Group Directions and Trajectories from Wave Data

The directions obtained in a directional-power spectral analysis of wave measurements are those of the individual waves. It is necessary to compute the corresponding wave group directions. If the water depth contours are parallel the wave group directions can be determined through the use of Snell's laws. For the wave group Snell's law can be stated

$$(\sin \theta_m)/G_m = (\sin \theta_g)/G_g \quad (4)$$

where the subscript m denotes the measurement site and the subscript g refers to the place of wave generation. Snell's law for the individual waves is given by

$$(\sin \gamma_m)/v_m = (\sin \gamma_g)/v_g \quad (5)$$

where $v = \omega/k$ is the phase speed. It is assumed that $\theta_g = \gamma_g$. When (4) and (5) are combined it is found that

$$\tan \theta_m = (J \sin 2\gamma_m) / [2(1 - J \sin^2 \gamma_m)] \quad (6)$$

$$J = (v_g / U_g) (U_m / v_m) \quad (7)$$

The ratio of U_m/v_m is determined by the water depth at the measurement site for a given wave period. So θ_m is a function of γ_m and the ratio of U_g/v_g . For a given wave period the latter ratio depends on the water depth of wave generation. If this depth is known the wave group directions are readily determined. If the water depth where the waves are generated is not known, then this depth and the wave group directions can be determined together by trial and error for a range of wave periods.

The best way to illustrate how the method works is to consider some simulated examples. It will be assumed that water waves have been generated at a distant location where the water depth is 200 m. The directions of the individual waves are presumed to have been determined with high accuracy for a range of wave periods from data obtained at a water depth of 15 m near shore. The water depth contours are parallel. Now assume that the water depth where the waves were generated is unknown. The objective is to work backwards using the measured individual wave directions to determine the corresponding wave group directions and the water depth of wave generation. Equations (6) and (7) are used to calculate wave group directions at the measurement site for a range of wave periods and for trial values of water depths of wave generation. Back tracks produced from the measurement site will determine which trial value of water depth of wave generation is consistent with the wave source. In Figure 1a wave group back tracks are shown for wave periods of 7.7, 8.3, 9.1, 10.0, 11.1, 12.5, and 13.3 s for an assumed depth of wave generation of 50 m. Since the rays are seen to diverge and not go back together to a common source the trial value of generation depth must be incorrect. In Figure 1b the wave group directions at the measurement site were determined on the assumption that the waves were generated in water of 100 m depth. Although the results are better than in the previous example, they are not entirely consistent. The correct answer is obtained in Figure 1c where the assumed depth of wave generation is 200 m. The wave group back tracks are seen to go back together to a common source and to be parallel at the 200 m water depth. The wave group directions determined for this example using (6) and (7) also have to be correct.

Determination of Water Depths of Wave Generation from Field Data

Two field data sets will be used to further illustrate the theory and methodology for determining water depths of wave generation and wave group

Figure 1. Wave group back tracks for assumed water depths of wave generation of (a) 50 m, (b) 100 m, and (c) 200 m. Soundings in meters.

trajectories. In both cases the waves were measured (Bennett, et al, 1964; Breeding, 1972) with an array of up to six pressure sensors on the sea floor in 31.7 m of water 17.7 km from shore near Panama City, Florida. In the array a pressure sensor was located at each corner of a pentagon of side 35.8 m, and these sensors were located 30.5 m from a sensor at the center of the array. Directional power spectra with 60 degrees of freedom were computed for time series records about 30 minutes in length by Bennett (1972) based on the method of Munk, et al (1963).

The water depth contours for the region of interest are shown in Figure 5. Over much of the region the water depth contours are approximately parallel. Accordingly, in determining wave group back tracks two approximations are made in the calculations. Firstly, the wave group directions at the measurement site are determined on the assumption that the water depth contours are parallel. And secondly, the conventional group velocity is used as an approximation to the geometric group velocity. The latter approximation can be made since Breeding (1981a) has shown for parallel water depth contours that G does not differ from U by more than 14%. The difference is usually much less. When G is replaced by U and the Snell's law equations are combined it is found that

$$\sin \theta_m = J \sin \gamma_m \quad (8)$$

This equation is used as an approximation to (6).

The wave group back tracks for the field data examples are determined using a ray curvature expression for nonparallel water depth contours based on the conventional group velocity U . Details are given in Breeding (1972). The approximations noted above greatly simplify the analysis.

Summer Storm

In the first example, waves measured on June 1, 1965 are considered. The directional power spectra computed from the waves are presented in Figure 2. This "3-D" representation is due to Bennett (1968). The bottom of each arrow gives both the frequency and bearing of the waves. Note that the frequency increases in the form of concentric circles moving outward from the center. The direction north (N) represents magnetic north. To obtain true north one adds 3 degrees. The tip of each arrow indicates the log power density of the waves at the depth of measurement. In this example the waves have small amplitudes.

In Figure 2 it can be seen that the directional power spectra near 0.1 Hz varies in a smooth fashion indicating that the waves are due to a common source.

Figure 2. Directional power spectral for summer storm.

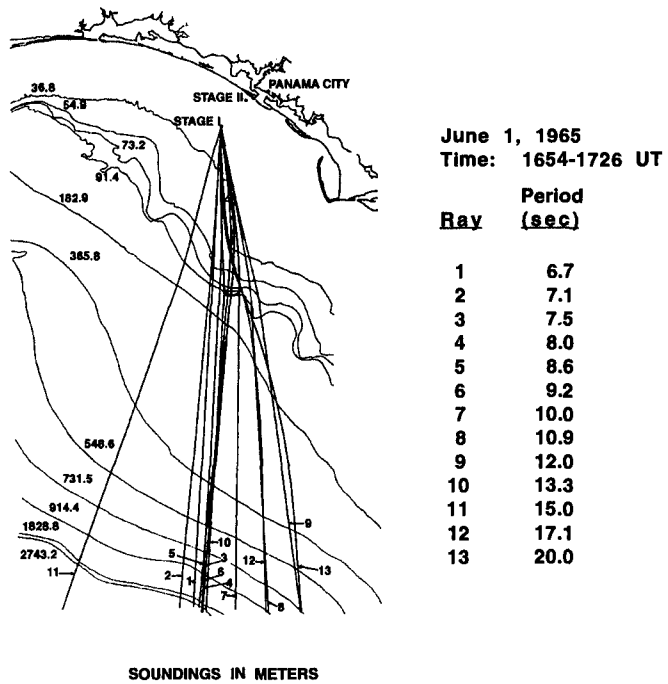

Figure 3. Wave group back tracks for summer storm.

The wave periods which are too short to be affected by refraction indicate the waves come from near south. Back tracks were produced for wave groups assuming that the waves had a deep water source and using (8) to determine the wave group directions at the measurement site. The resulting back tracks, which are shown in Figure 3, are generally consistent with a common source in the Caribbean Sea. All but two of the group rays go back through the Yucatan Channel, and only one misses badly.

Hurricane Betsy

In the second example, an investigation is made of waves measured in September 1965 due to Hurricane Betsy. The storm crossed the tip of South Florida and entered the Gulf of Mexico at about 1500 UT (Greenwich mean time) on September 8. After making a curved path the hurricane entered land at the Mississippi Delta near New Orleans, Louisiana at about 0400 UT on September 10. Over much of the storm path water waves were generated in intermediate water depths.

Figure 4 is an example of the directional power spectra (Bennett, 1972) for September 9 for the time period 1359 - 1430 UT. This is an example of a very energetic source.

The wave group back tracks and water depths of wave generation have to be determined by trial and error for each wave period. The general procedure is as follows. A water depth of wave generation is assumed as a trial value, the initial direction of the back track is calculated, and the ray traced. If the ray does not take a path which crosses water of the depth assumed the depth assumption must be rejected. If the location of the storm is known from meteorological records the range of possible depths is readily restricted. Once a few depths have been tried it is usually easy to decide which values to try next. Further, the answer found for one wave period must be consistent with the results found for other wave periods. After ray trajectories are drawn for the various wave periods a final check is made by comparing travel times computed along the paths to the region of wave generation. The computed travel times should agree with the known movement of the storm.

Equation (8) was used to determine the wave group directions at the measurement site. The corresponding back tracks and the water depths of wave generation are shown in Figure 5. The rays emanate from the measurement site, and they are continued until they reach either shore or a boundary of the water depth grid. Tick marks have been placed on the rays at five hour intervals of travel time. The course of Hurricane Betsy is indicated along the bottom of the illustration. The back tracks appear reasonable when viewed with respect to the hurricane path.

Figure 4. Directional power spectra for Hurricane Betsy.

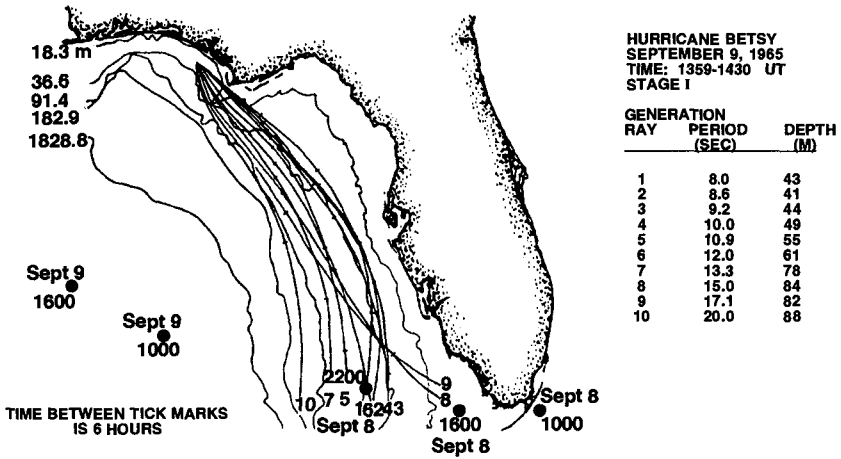

Figure 5. Wave group back tracks for Hurricane Betsy.

Consider, for example, ray number five which has a wave period of 10.9 s. Back tracking along this ray for fifteen hours gives water depths near the determined generation depth of 55 m. Timewise this corresponds to September 8 at 2300 UT. This time and location compare favorably with the record of the storm and its counterclockwise wind pattern.

It can be observed that portions of the wave group trajectories in Figure 5 are nearly parallel with the water depth contours. Although this would not be possible for monochromatic trajectories, it is not unusual for wave group trajectories. For wave group trajectories Breeding (1981a, 1986) has shown that the ray curvature goes to zero for rays parallel as well as perpendicular to the water depth contours.

Water depths of wave generation and wave group back tracks were also determined for the time periods 0800 - 0829 and 1816 - 1847 UT on September 9. The water depths of wave generation for the three wave measurement periods are presented in Table 1. For the first measurement period the waves were generated close to the Florida coast and were in the initial stages of development. For the second and third measurement periods the waves had become quite large. Note that for a given measurement time the water depths of wave generation generally increase with wave period. This result is what one would expect for dispersed gravity water waves due to a storm moving toward deeper water, as was the case. Observe further that for a given wave period the generation depths generally increase with the measurement recording time. This is clearly in agreement with the meteorological record.

Table 1. Water Depths of Wave Generation, 9 September 1965

Period (sec)	Time UT, Generation Depths in m		
	<u>0800 - 0829</u>	<u>1359 - 1430</u>	<u>1816 - 1847</u>
8.0	44	43	depth > 50
8.6	44	41	depth > 58
9.2	46	44	depth > 66
10.0	47	49	67
10.9	47	55	72
12.0	47	61	82
13.3	50	78	93
15.0	50	84	88
17.4	48	82	85
20.0	---	88	111

Monochromatic Trajectories

Monochromatic back tracks are presented in Figure 6 for comparison with the wave group back tracks shown in Figure 3 for the summer storm. The same individual wave directions were used to produce both results. The monochromatic rays were determined using the numerical method for nonparallel water depth contours developed by Wilson (1965). These back tracks are not at all consistent with a common wave source.

In Figure 7 monochromatic back tracks are shown for the same individual wave directions used to determine the wave group back tracks presented in Figure 5 for Hurricane Betsy. The Wilson (1965) program was used to determine the rays. It is seen that the monochromatic rays are in poor agreement with the path of the storm.

Conclusions

If the directions of the individual waves of a group are determined from wave data as a function of wave period, and if some simple refraction concepts are used for parallel water depth contours, it is possible to determine: (1) the wave group directions at the measurement site, (2) the wave group back tracks to their sources, and (3) the depths of water where the waves were generated. A wave example was presented where the apparent source of the waves was in deep water. Waves due to Hurricane Betsy (September 1965) were analyzed, and by determining the wave group back tracks and the corresponding water depths of wave generation, it was possible to track the general movement of the storm as it passed through intermediate water depths. For the cases considered reasonable results were obtained using the conventional group velocity as an approximation to the geometric group velocity. Finally, monochromatic wave back tracks are not consistent with the wave sources for the examples considered.

Acknowledgments

The data were collected and the spectral analysis was done at the Naval Coastal Systems Center, Panama City, Florida by George B. Austin and Carl M. Bennett, respectively. I thank them for their help and suggestions. I was particularly indebted to the late Franklyn C. W. Olson for many hours of constructive criticism. I also thank Donald R. Del Balzo, Christopher T. Mullins, Sheryl L. Goynes, Leslie M. Tarter, and Christy Vise for their help in the preparation of this paper. The research was supported by the Office of Naval Research.

CHAPTER 55

WAVE CLIMATE ASSESSMENT IN THE SOUTH AEGEAN SHELF

Spiros Christopoulos¹, Christos Solomonidis²

Abstract

Wave climate parameters are estimated in a coastal area in the South Aegean Sea with the use of wave hindcast, wave transformation and spectral transformation models. The relative performance of these models is judged with the aid of a field measurements campaign. It is shown that most models can give the correct prediction in the intermediate depth waters, whereas only models taking into account nonlinear phenomena can match the measurements in the very shallow water area.

Intoduction

The correct estimation of the wave climate parameters such as wave height and period both in deep waters and in the coastal zone, is of paramount importance for the design of offshore and coastal works, safe navigation and the operation of marine systems such as fisheries.

For the determination of the wave conditions in deep and intermediate depth waters, a series of hindcast models have been developed and validated by many researchers. Second generation hindcast models are already used by various meteorological centres, as is the UK Met. Office, for daily prediction of the wave conditions, usually updated every 6 hours. Even third generation hindcast models, like the WAM, are used for hindcasts in European waters. The use of third generation models for operational purposes has been explored extensively (Komen et al., 1994).

Numerical models for wave transformation in the nearshore area have been used for many years for research and for coastal engineering design purposes as well. A large number of monochromatic wave models, based either on Berkoff's Mild Slope Equation (Berkhoff, 1976) or on geometrical physics (ray tracing) are widely used in applications. Spectral models based

on the energy balance equation are also used, whereas spectral models, which solve Boussineq type equations, including non-linear energy dissipation processes (Madsen et al., 1991) are gaining popularity recently. Research is under way for the refinement of these models in order to include the non-linear interaction of spectral ordinates (Komen et al., 1994).

Despite the variety of numerical wave models, not much work has been done for their calibration with simultaneous wave measurements, and even less in the direction of assimilating the measurements in the models themselves. The recent abundance of satellite imagery is facilitating though this task.

In the work which is presented in this paper, the wave climate in an area of the South Aegean Sea (North Coast of Crete), is assessed with the aid of wave hindcast and numerical wave transformation models as well as semi-analytical (spectral transformation) methods, in conjunction with in situ wave measurements.

Wave Measurements

A field campaign of wave measurements was conducted in the context of MAST2-WAVEMOD project at a site near Rethymno, in the North coast of Crete, Greece. The field

Figure 1. Rethymno Bay bathymetric grid and locations of the wave riders

campaign was conducted by the French Insitute IFREMER, subcontracting to METEOMER, with the collaboration of MARTEDEC and the Institute of Marine Biology of Crete. Two directional and one non-directional wave riders (all by Datawell) were used for the wave measurements, deployed along the predominant direction of wave attack, at three locations of different depths (100m and 10m for the directional waveriders, 20m for the non-directional). The campaign lasted for a period of 10 months, in particular from the 1st of February to the 28th November 1994. Next to each waverider, a current meter was deployed; two AANDERA RCM 7 were used at the 100 and 20 m locations, and a S4DW current and wave measuring instrument, by InterOcean, was used at the 10 m location (Solomonidis 1995, Paillard 1995).

At the same time, a fully equipped land based station was installed in a public building and overlooking the area of the experiment. The raw data (timeseries of heave and N-S & E-W translation), as well as spectral data processed on board the wave riders, were continuously transmitted via VHF to the land based station. The sampling rate for the directional buoys was 1.28 Hz, recording for 20 min every 30 min, and 2.56 Hz for the non-directional buoy, recording for 20 min every 20 min. The bathymetry of the area as well as the locations of the instruments is shown in Figure 1.

Intense climatic incidences were recorded during February (11-13), March (5-6, 10-14), October (10-16) and November (15-16, 20-24), with significant wave heights H_s from 3 - 6 m, peak periods T_p from 9 to 10 sec and predominant directions North to North West. In Figure 2 the significant wave heights H_s recorded at the location of the offshore buoy are shown.

Figure 2. Time history of H_s from the 100m wave rider.

Wave Hindcast Model

The wave climate in the broader area is assessed with the aid of a second generation wave model (Christopoulos & Koutitas, 1991). The model AUT simulates the wave energy balance equation, which for deep water is written as

$$\frac{\partial F}{\partial t} + c_g \cos \theta \frac{\partial F}{\partial x} + c_g \sin \theta \frac{\partial F}{\partial y} = S_{in} + S_{nl} + S_{ds} \quad (1)$$

where $F(f,\theta;x,y;t)$ is the spectral energy density of the wave component (f,θ) at location (x,y) and time t , c_g the group velocity, S_{in} the wind input, S_{nl} the nonlinear wave energy transfer and S_{ds} the wave dissipation due to white capping.

The equation is solved using the fractional step method, where for the advection a first order upwind scheme is adopted. For the wind input the Bight of Abaco result is used, while the wave dissipation is represented by means of Komen's et al. (1984) explicit formula. The nonlinear energy transfer between the various wave components is estimated implicitly through the redistribution of the wave energy, after the above steps, according to a Jonswap spectrum having the same wave energy.

The model is implemented in the whole area of Aegean Sea with grid resolution of 1/6 of a degree. For the wind data, the ECMWF data from analysis results are used. The model output is compared with the results from

the deep buoy for the storm of March 1994 (Figure 3). As it can be seen, there is a good agreement for the characteristic wave parameters of the significant wave height and the mean wave period.

Figure 3. AUT model results for 3-17 March 1994

Numerical Wave Transformation Models

The offshore wave climate is specified either from the deep water wave hindcast model results or from the offshore wave buoy data. From the offshore location the deep water waves propagating to the coastal zone, are transformed to the shallow water waves through various physical processes like refraction, shoaling, diffraction, wave breaking, bottom friction and nonlinear energy transfer. For the simulation of these transformation processes three different numerical models are used, a shallow spectral model, an elliptic mild slope model and a Boussinesq wave model. The spectral model is a version of the AUT hindcast wave model, while the other two are belonging to DHI's suite of programs MIKE 21, namely MIKE 21 EMS (Elliptic Mild Slope) and MIKE 21 BW (Boussinesq).

The results of the models in the vicinity of the two inner buoys locations are compared with the corresponding measurements of the buoys. A short description of the numerical wave transformation models, as well as the way in which they are used in the present work, will be given in the following paragraphs.

Shallow Spectral Model

The shallow spectral model SAUT is a modified version of the AUT deep water wave model. The governing equation is

$$\frac{\partial F}{\partial t} + c_g \cos \theta \frac{\partial F}{\partial x} + c_g \sin \theta \frac{\partial F}{\partial y} + \partial \{ (c_g \cdot \nabla \theta) F \} / \partial \theta = S_{bf} + S_{ds} \quad (2)$$

where the refraction term is added on the left-hand side of the equation, while the processes of the bottom friction and wave dissipation are taken into account on the right-hand side.

The refraction term is based on Snell's law and after some manipulations is solved through

$$c_g \cdot \nabla \theta = -\frac{1}{k} \left(\frac{\partial H}{\partial x} \sin \theta - \frac{\partial H}{\partial y} \cos \theta \right) \left(\frac{-k^2 \operatorname{sech}^2 kH}{\tanh kH + kH \operatorname{sech}^2 kH} \right) \quad (3)$$

where k is the wave number and H the water depth. For the full refraction term the upstream difference in θ is expressed in flux form with the upstream direction determined by the sign of $c_g \cdot \nabla \theta$. The resulting difference for a single component may be written (Golding, 1983)

$$\begin{aligned} [\Delta F]_\theta &= -\frac{\partial}{\partial \theta} \{ (c_g \cdot \nabla \theta) F \} \Delta t \\ &= \left\{ \left[\min \begin{pmatrix} c_g \cdot \nabla \theta \\ 0 \end{pmatrix} \cdot F \right]_{\theta+\Delta\theta} + \left[\max \begin{pmatrix} c_g \cdot \nabla \theta \\ 0 \end{pmatrix} \cdot F \right]_{\theta-\Delta\theta} - [(c_g \cdot \nabla \theta) F]_\theta \right\} \frac{\Delta t}{\Delta \theta} \quad (4) \end{aligned}$$

The bottom friction is calculated using the Collins formula, while the calculated wave heights are checked using the following wave breaking criterion (Battjes & Janssen, 1978)

$$H_m = 0.88 k^{-1} \tanh(0.78 kH / 0.88) \quad (5)$$

The model is implemented on the area of Rethymno Bay with space step of 200m and time step of 15 sec. Results for the episode of March 1994 - date 03052300 (MMDDhhmm) are shown in Figure 4.

Figure 4. SAUT simulation, input $H_s=2.98\text{m}$, $T_z=6.3\text{sec}$, $\theta=185^\circ$

Elliptic Mild Slope Model

This program simulates the propagation of monochromatic waves over a gently sloping bathymetry. It basically solves numerically the Elliptic

Mild Slope equations (Berkhoff, 1976) which take into account the combined effects of shoaling, refraction, diffraction and back-scattering. The equations have been generalised in order to include the internal generation of waves, absorption by sponge layers, partial reflection by breakwaters or other structures, and energy dissipation due to bed friction and wave breaking.

The basic set of equations which are numerically solved in this model (MIKE 21 EMS manual) are the following:

$$\begin{aligned} \lambda_1 \frac{\partial S}{\partial x} + \lambda_2 S + \frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} &= SS \\ \lambda_1 \frac{\partial P}{\partial x} + \lambda_3 P + c_g^2 \frac{\partial S}{\partial x} &= 0 \\ \lambda_1 \frac{\partial Q}{\partial y} + \lambda_3 Q + c_g^2 \frac{\partial S}{\partial y} &= 0 \end{aligned} \quad (6)$$

where S, P and Q are complex variables of x , y , t expressing surface elevation and flux densities (in x and y directions) respectively, SS is the source magnitude per unit horizontal area, whereas the λ coefficients are terms which include frictions due to porous structures and sponge layers, and energy dissipation effects.

These equations are solved by implicit finite difference techniques. The double sweep algorithm is utilised, which is a form of the Gauss elimination.

The bathymetric grid which was used for the model extends to the line of -50m, which is sufficient so as to be considered as deep water conditions. A number of sponge layers is introduced in order to absorb wave energy.

Two parameters in the model set-up can be used for calibration purposes. One is the *bed friction*. For Rayleigh distributed wave heights, the energy dissipation is (MIKE21 EMS manual):

$$\frac{dE}{dt} = \frac{-1}{8\pi^{1/2}} \frac{f_e/2}{g} \left(\frac{\omega H_{rms}}{\sinh(kd)} \right)^3 \quad (7)$$

where H_{rms} is the rms value of wave height. The energy loss factor f_e is a function of the Nikuradse roughness parameter, k_N .

The other calibration factor are the friction coefficients which are used in the model to specify the partial reflection from breakwaters or from the surrounding area (in our case it is the later). The simulations showed that there is a sensitivity in the variation of these friction coefficients which specify the reflections from the rocks surrounding the area of interest.

A series of simulations were performed. Wave breaking was included in all of the simulations. The energy dissipation due to wave breaking is calculated by the Battjes and Janssen formulation.

The program calculates the maximum wave height at all grid points. In Figure 5, contour plots of the maximum wave heights are shown. In this simulation spectral parameters recorded at the 100m buoy location at 03052317 (MMDDhhmm) were used as input to the model ($H_s=3.65m$,

$T_p=9.09\text{sec}$, $\theta=359\text{ deg}$). The reflection coefficients which were used are 0.20, 0.10,0.25.

Figure 5. EMS simulation, contours of maxH, input $H=3.65\text{m}$, $T=9.09\text{sec}$, $\theta=359^\circ$.

Boussinesq Wave Model

This model is based on the numerical solution of the two-dimensional Boussinesq equations. These equations include non-linearity and frequency dispersion. In the classical form of the Boussinesq equations there is a very restrictive limitation on the maximum water depth in the simulation area ($\max d/L_0 = 0.22$). In the new forms of the equations, which are used in DHI's MIKE21 BW model, this ratio can go up to $d/L_0=0.5$ (Madsen et al., 1991).

Most wave transformation processes are taken into account in this model shoaling, refraction, diffraction and partial reflection from breakwaters and structures. Bed friction can also be included in the simulation. The only shortcoming of this model is wave breaking, which is not included in the energy dissipation processes. The basic equations, which are solved, are the continuity, the x -Momentum and the y - Momentum (Mike21 BW User Guide & Manual):

$$nS_t + P_x + Q_y = 0 \quad (8)$$

$$nP_t + \left(\frac{P^2}{h}\right)_x + \left(\frac{PQ}{h}\right)_y + n^2ghS_x + n^2P \left[\alpha + \beta \frac{\sqrt{P^2 + Q^2}}{h} \right] + \frac{gP\sqrt{P^2 + Q^2}}{C^2h^2} + n\Psi_1 = 0$$

$$nQ_t + \left(\frac{Q^2}{h}\right)_y + \left(\frac{PQ}{h}\right)_x + n^2ghS_y + n^2Q \left[\alpha + \beta \frac{\sqrt{P^2 + Q^2}}{h} \right] + \frac{gQ\sqrt{P^2 + Q^2}}{C^2h^2} + n\Psi_2 = 0$$

where S , P , Q are surface elevation, and flux density in x -direction and flux density in y -direction respectively; subscripts denote partial differentiation, h is total depth, resistance coeffs, porosity, etc are included, whereas the non-linear Boussinesq terms Ψ_1 and Ψ_2 are cross terms of derivatives of fluxes and elevation. The equations are solved by implicit finite difference techniques, with variables defined on a space staggered rectangular grid.

Due to restrictions which are imposed by the model, the bathymetry which is used in BW simulations is modified: by choosing as a minimum wave period (cut-off frequency of the spectrum) $T_{\min} = 6.02\text{sec}$, the maximum depth which can be allowed in the modelled area (assumption $d/L_0 = 0.60$, including deep water correction terms) is $d_{\max} = 34$ m, whereas with the given grid spacing $\Delta x = 5$ m and the assumption $L/\Delta x = 7$, the minimum water depth d_{\min} is 4 m. The time step Δt which is used in the simulations is chosen on the basis of the resolution and the *Courant* criteria and is set as $\Delta t = 0.18\text{sec}$.

Bed Resistance is included in the model by means of a uniform number for the whole area of simulation (Chezy number C). Sponge layers all along the coastline were introduced in the BW simulations, in order to compensate for the energy absorption due to wave breaking, which cannot be modelled here.

Storm cases from March and November were chosen to demonstrate BW modelling. As input to the models (boundary conditions) time series of flux densities generated from the spectra of the heave time series recorded at the deep water (100m) buoy were used. The spectra were truncated at $T_{\min} = 6.02\text{sec}$ or $f_{\text{cut}} = 0.17\text{Hz}$.

The output of these simulations are time series of wave elevation at all grid points of the modelled area. Contours of the significant wave heights, calculated as the RMS of the elevation time series for the whole period of simulation can also be drawn. In Figure 6 contour maps of significant wave heights H_s are plotted for the case date = 03052317, $H_s = 3.65\text{m}$, $T_p = 9.09\text{sec}$.

Spectral Transformation Methods

Spectral transformation techniques which focus on saturation, shoaling and refraction processes are also assessed by means of utilising them for the transformation of wave spectra recorded at the offshore location (100m) and comparing the resulting shallow water spectra with the ones measured at the two inner locations, for corresponding instances. Two methods are used, the TMA spectrum and the spectral slicing and reconstruction.

Figure 6. BW simulation, contours of H_s , input $H_s = 3.65\text{m}$, $T_p = 9.09\text{sec}$, $\theta = 359^\circ$

TMA spectrum

The TMA spectrum yields an extension of the shelf-similar JONSWAP shape to finite water depth using the expression (Bouws et al., 1983)

$$E_{TMA}(f, H) = E_j(f) \Phi_{\kappa}(\omega_H) \tag{9}$$

where $E_j(f)$ is the well known JONSWAP spectrum and $\Phi_{\kappa}(\omega_H)$ is a transformation factor calculated through the relation

$$\Phi = \tanh^2(kH) \left\{ 1 + \frac{2kH}{\sinh(2kH)} \right\}^{-1} \tag{10}$$

For a given spectrum, ie an output of the hindcast wave model or a measured spectrum at the offshore location, a JONSWAP spectrum with equivalent wave energy is estimated following the procedure, which is given in details elsewhere (Müller, 1976). Then the transformation factor for a specific depth is calculated and thus we obtain the TMA spectrum at a specific shallow site.

Spectral slicing and reconstruction

The incident wave energy spectrum, corresponding to a measurement at the outer location, is sliced to a number of discrete frequencies f_1, f_2, \dots, f_n , so that the total incident wave energy is given as:

$$m_0 = \int_0^\infty S(f)df = \sum_{i=1}^n S(f_i)\Delta f_i = E_1 + E_2 + \dots + E_n \tag{11}$$

Each component is introduced to a linear numerical wave transformation model as a monochromatic wave with the frequency of this component. The relative wave height k_i or wave disturbance coefficient for every frequency f_i is calculated at every grid point in the studied area, and the resulting wave disturbance coefficient (of the pseudo-random wave) is consequently calculated by the formula:

$$k_{res} = \sqrt{\sum_{i=1}^n \alpha_i k_i^2} \tag{12}$$

where $\alpha_i = E_i/m_0$ is the percentage of wave energy which belongs to this particular discrete frequency f_i . The coefficients k_i are weighted either by the percentage of the total wave energy on this frequency (Equal Frequency method), or by the width of the frequency band it represents (Equal Energy), and then are superimposed.

Finally, the whole spectrum at a particular location P in the shallow area can be reconstructed, using the relation:

$$S(f_i, p) = |H(f_i, p)|^2 S(f_i) = k^2_{pi} \cdot S(f_i) \text{ or } S(f_i, p) = \frac{E_i}{df_i} k^2_{pi} \tag{13}$$

where k_{pi} is the disturbance coefficient for component frequency i . In Figure 7 comparisons are shown between a measured spectrum in shallow water, a reconstructed with the equal frequency slicing method spectrum, and a TMA spectrum. We can observe that for the 20m location the agreement is good, although the slicing method cannot reconstruct the tail of the spectrum (which is expected since only a limited number of frequencies were included).

At the 10m location, the TMA grossly underestimates the spectral peak

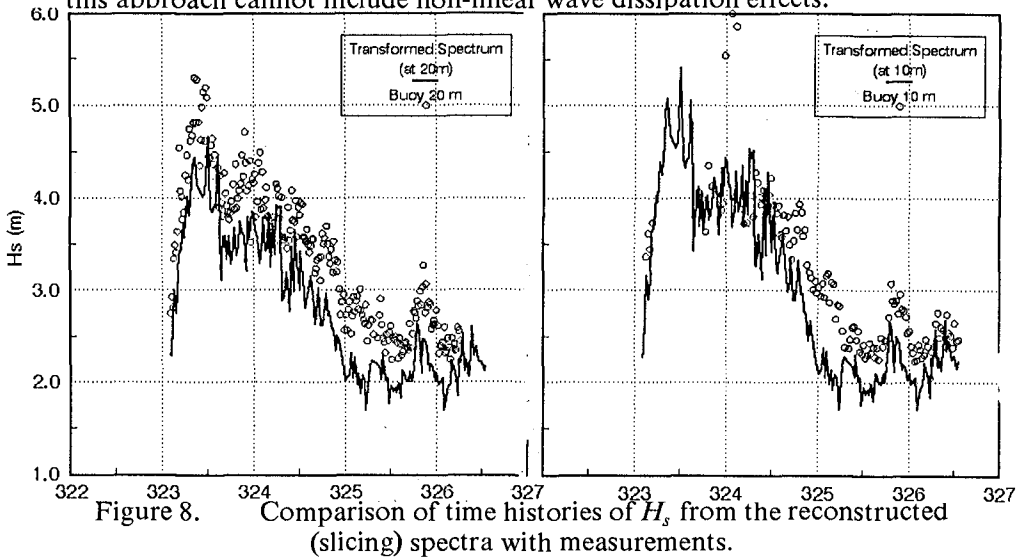

Figure 7. Comparison of reconstructed (slicing) and TMA spectra with measurements.

In Figure 8 the H_s calculated from the zero-th moment of the spectrum (slicing and reconstruction method) as $H_s=4*m_0^{1/2}$ is compared with the H_s of the measured spectrum, for a number of recordings in November 1994, for both the 20m and the 10m locations. We can see that the agreement is in general good, with some discrepancies appearing in the 10m location, since this approach cannot include non-linear wave dissipation effects.

Comparison of the methods

The methods which were employed in this work for the estimation of some of the nearshore wave climate parameters, are comparatively assessed in this section. In particular, the calculated wave heights, as they result from the numerical modelling are compared with the two inner buoys (20m and 10m) measured parameters. Transects, cutting perpendicularly to the coast are drawn on the contour maps of the solutions, whereas the corresponding measured parameters are marked on the same graphs.

In Figure 9 the case of date= 03052317, $H_s=3.65\text{m}$, $T_p=9.09\text{sec}$ and $\theta=359$ deg is presented; the results which are superimposed on the same graph are from the following simulations:

- EMS simulation with input parameters measured at the offshore location.
- BW simulation with input parameters measured at the offshore location.
- AUT shallow water simulation with input parameters calculated from the AUT hindcast model at the offshore location.
- BW simulation with input parameters calculated from the AUT hindcast model at the offshore location

It can be seen that whereas at the 20 m location most methods predict correctly the wave height, for the 10 m they overestimate it, which can be explained by the fact that they cannot include energy dissipation due to wave breaking. The BW simulation gives a better approximation, as it takes into account modal interactions. The SAUT model gives lower values overall due to initial underestimation at the offshore location.

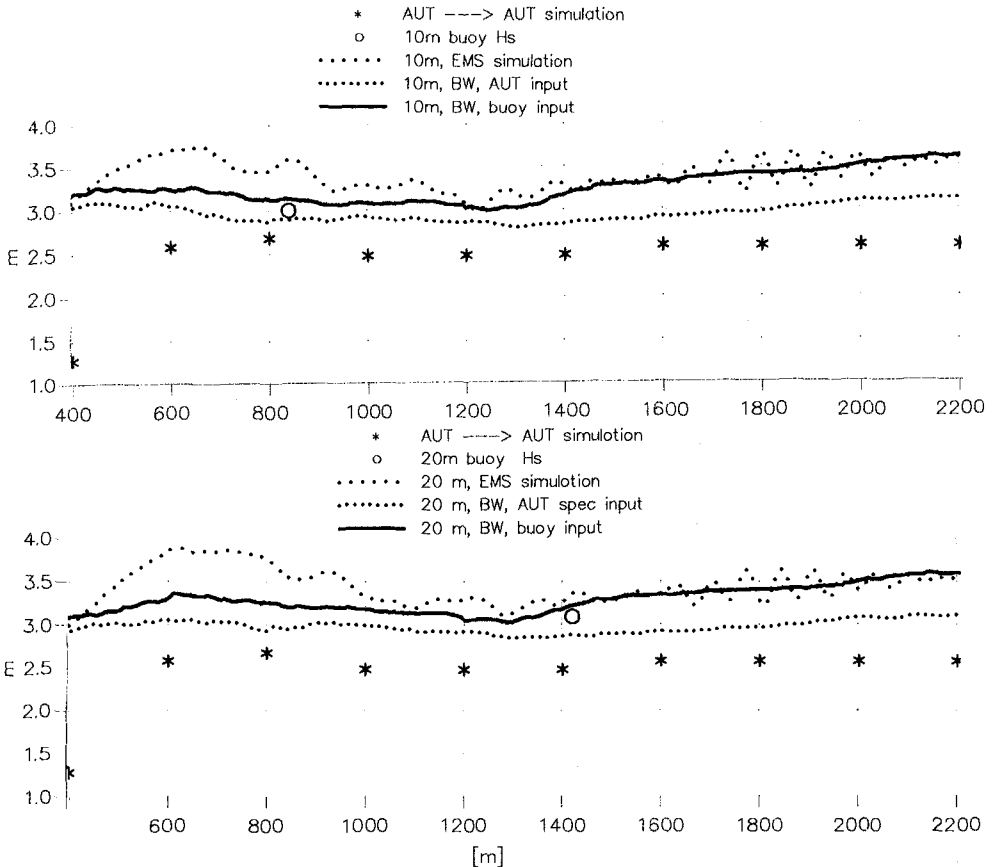

Figure 9. Comparison of estimated wave heights from various methods with measurements

In Figure 10 a comparison of the calculated disturbance coefficients for the case of date= 11201512, $H_s=4.54\text{m}$, $T_p=9.09\text{sec}$ and $\theta=0$ deg. is presented. The results which are superimposed on the same graph are from the following simulations:

- EMS simulation with input parameters measured at the offshore location.
- BW simulation with input parameters measured at the offshore location
- The Pseudo-random simulation (slicing and reconstruction)

It can be seen that whereas for the 20 m location the prediction is correct from all methods, for the 10m location the pseudo-random method is grossly overshooting, which can again be attributed to the omission of both wave breaking and the interaction between modes.

Conclusions

Wave hindcast, numerical wave transformations and spectral transformation methods are employed for the assessment of the wave climate in a coastal area. The models are calibrated with the use of 10 month's duration of in situ wave measurements.

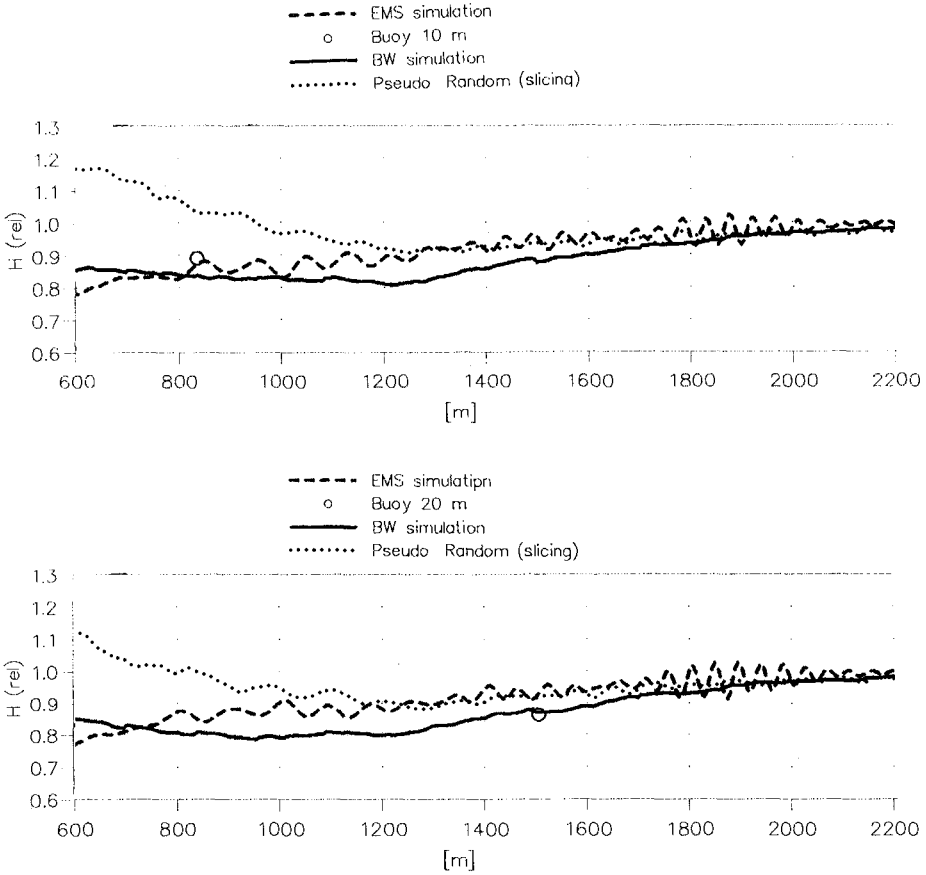

Figure 10. Comparison of estimated wave disturbance coeffs from various methods with measurements

The results of the deep water wave hindcast model compare well with the measured parameters. The results of the numerical wave transformation models match the measurements at the 20m and 10m buoys. It was found that, particularly for the monochromatic model (EMS), there is a sensitivity in the reflections from the area bordering the water. Despite the difference in scale (Δx and Δt) between the AUT shallow water model, and the BW and EMS models, they all predict correctly the wave parameters, as juxtaposed to the measurements.

Spectral transformation methods (TMA and slicing) seem to work well for the intermediate depth but not so well for the very shallow water. This is attributed to the lack of modelling both wave dissipation effects (breaking) and non-linear interactions. Great computational efficiency can be achieved though by using these methods.

CHAPTER 56

SEA STATE PARAMETERISATION USING EMPIRICAL ORTHOGONAL FUNCTIONS

Witold Cieřlikiewicz¹ and Jerzy Graff¹

Abstract

In this paper the development of a parametric transformation linking the meteorological conditions with the sea response for the Irish Sea and the southern North Sea regions is presented. The method of *empirical orthogonal functions* and *system identification* procedures are used to develop the parameterisation. The reference data sets used in the investigation consist of high quality hindcast data (41 storm events) and field measurements (13 years) covering meteorological and sea state parameters. The method of empirical orthogonal functions is applied to the wind velocity field and it is shown that the wind field time history can be adequately represented by the first few principal components. These wind field principal components together with atmospheric pressure parameters are used to synthesise the meteorological input for system identification. The system identification procedures are then applied to develop a new efficient form of parametric model linking spatial meteorological data with sea state response.

1. Introduction

This study is a part of the NEPTUNE project (see Graff & Cieřlikiewicz 1996, and Graff *et al.* 1995) under the EU MASTII framework. It is concerned with the requirement to develop a fast and efficient scheme to predict the sea state response during extreme storms using wind field and atmospheric pressure field data. The project methodology involves a cause-effect process chain, the first part of which links the storm meteorological variables field \mathbf{M}_t and the offshore sea state variables \mathbf{X}_t . In the project a relatively long data set is available for meteorological variables \mathbf{M}_t . This is the *Norwegian Meteorological Institute—DNMI* 6-hourly gridded pressure field \mathbf{p}_t and wind field \mathbf{W}_t for the North Sea – NE Atlantic covering the period 1955–1993. In order to create long time series of offshore variables \mathbf{X}_t the parametric transformation $\mathcal{F} : \mathbf{M}_t \rightarrow \mathbf{X}_t$ has to be developed. In this paper we present a new approach to derive the parametric transformation models \mathcal{F} .

There are many classic methods for prediction of sea state determined by local winds under prescribed conditions of fetch and wind duration. The simplest assume a uniform and steady wind blowing over a limited fetch or over an unlimited ocean for time t after a sudden onset. These are cases of fetch-limited and duration-limited waves, respectively. Those methods provide a very useful first look at the wave field,

¹ British Maritime Technology Limited, 7 Ocean Way, Ocean Village, Southampton SO14 3TJ, England

but the assumption of a uniform wind field is generally unrealistic and is often a source of considerable error. Examination of regional wind fields over relatively small areas, e.g. the Irish Sea, during hurricane type storms shows that the wind field is not uniform. The variation of both the magnitude and the direction of wind velocity vector, which influences the wave field, is small but significant. The spatial pattern of the wind velocity field reflects the circulation of the air in the cyclonic direction around the centre of a moving pressure depression (see Fig. 1). Over the larger areas, the non-uniformity of the wind field is much more pronounced and the sea state wave forecasts based on fetch-limited or duration-limited algorithms cannot be usually accepted. A further limitation of these methods is their difficulty in reflecting the *dynamic* features of the metocean system, i.e., the fact that the current sea state depends not only on the current meteorological conditions but also on their history.

In this study we seek a fast and efficient prediction scheme as an alternative to conventional numerical modelling. The scheme must be capable of taking into account the non-uniformity of the wind field and should incorporate the most characteristic features of its spatial distribution concerning storm track history. Moreover it should also reflect the dynamic features of the metocean system.

When long historical time series of metocean parameters are available it becomes possible to apply *system identification* (SI) techniques to investigate the required types of prediction schemes. In this study, the available data consist of the DNMI 6-hourly gridded meteorological data \mathbf{W}_t , \mathbf{p}_t and the offshore variables \mathbf{X}_t describing the sea state in terms of both hindcast data (41 storm event periods) and 3-hourly field measurements extending over 13 years 1979–1991 at five monitoring stations near the Dutch coast (provided by the *National Institute for Coastal and Marine Management of Rijkswaterstaat—RIKZ*). The parameters selected from the RIKZ data set consist of time series of significant wave height $H_S(t)$, mean wave period $T_z(t)$, principal wave direction $\theta_0(t)$, astronomical tide and the observed still water level. The difference between the latter two was taken as the surge level $S(t)$.

The application of the SI technique in sea response modelling, when the non-uniform wind field over selected area is taken as the input data, will lead to very large model dimensions and to enormous amounts of data involved. For example, in this study for the southern part of the North Sea the area covered by a sector of 221 DNMI grid points was selected. This leads to 442 time series of wind components, each 37984 data points long. This amount of input information which has to be processed in the

Fig. 1. DNMI wind field at elevation 10 m at 0:00h on 12 Nov 1977. DNMI grid coordinates and study areas.

SI modelling may be well beyond the capabilities of most desktop computer systems available nowadays. However, the question arise: is all that input information equally important? Certainly not. It will contain noise and, moreover, it is possible that part of that information is in a some way redundant. In order to reduce the volume of input wind data and still preserve its salient features, while filtering out most of the noise and redundant information, the *empirical orthogonal functions* (EOF) analysis is used. EOF analysis in time domain, has been variously used in meteorological, environmental, and oceanographic studies for some two decades (see e.g. Prandle & Matthews 1990, Ng 1993). It is applied here to analyse and decompose the DNMI wind field time series over two selected areas, namely the Irish Sea and the southern North Sea.

In the EOF analysis, the temporal and spatial variation of the wind field is partitioned into orthogonal spatial patterns, so called EOF modes \mathbf{e}_m , which are constant in time domain and principal components $P_m(t)$ (corresponding to each EOF mode). Each principal component $P_m(t)$ is given as a time series describing the time evolution of the corresponding EOF mode. The importance to this study is the fact that the wind field time history can be determined with sufficient accuracy by a few principal components only. Those few principal components and not the wind time series itself, are taken as the SI stimuli and are used to build the parametric models linking the meteorological parameters field \mathbf{M}_t with the offshore sea state variables \mathbf{X}_t .

We assume that input-output variables are related by a *linear dynamic system* and we use SI models in multi-input, single-output version, i.e. each component of the offshore parameters vector \mathbf{X}_t is modelled one by one. The estimated models $\mathcal{F}_{\mathcal{L}}^X : \mathbf{Q}_t^X \rightarrow X_{\mathcal{L}}$ link the meteorological input \mathbf{Q}_t^X with the output $X_{\mathcal{L}}$ which is one of the sea state parameters: $H_S(t)$, $T_z(t)$, $\theta_0(t)$ or $S(t)$ at offshore monitoring station indicated by the location index \mathcal{L} . The input \mathbf{Q}_t^X is composed using the first few wind field components $P_m(t)$ and the atmospheric pressures p_i in the selected grid points indexed by i . We use superscript X to emphasise the fact that the model input may be prepared differently for different output variables. For example, when the surge is modelled we use atmospheric pressure, which is however not the case for the wind wave variables.

Summarising, there are two important elements in this study: The EOF analysis, and SI procedure. Both are schematically depicted on Fig. 2. The EOF prepares the input data by reducing the amount of input information, i.e., by extracting only that information which is most significant. Then, the SI deals with the actual problem of building a mathematical model of a dynamical metocean system in which the sea response is stimulated by the meteorological conditions.

2. EOF analysis of wind field

2.1 Basics

Let \mathbf{W}_t denote the complex state vector formed by the M complex functions of time $W_m(t)$

$$W_m(t) = U_m(t) - \langle U_m \rangle + i(V_m(t) - \langle V_m \rangle) \quad (1)$$

where $U_m(t)$, $V_m(t)$ are the wind velocity components in m th of M locations and $\langle \cdot \rangle$ denotes the expected value of a quantity enclosed in the angle brackets. As the covariance matrix \mathbf{H}

$$\mathbf{H} = \langle \mathbf{W}_t \mathbf{W}_t^+ \rangle \quad (2)$$

is Hermitian (the cross denotes the transpose complex conjugate) it has M real eigenvalues λ_m and complex unitary eigenvectors \mathbf{e}_m which are called EOF modes and may be normalised: $\mathbf{e}_m^+ \mathbf{e}_n = \delta_{mn}$

The EOF modes \mathbf{e}_m , as eigenvectors, form a complete and orthonormal basis for \mathbf{W}_t . Thus the original wind field state vector \mathbf{W}_t may then be expanded in terms of the EOF modes

$$\mathbf{W}_t = \sum_n P_n(t) \mathbf{e}_n \quad (3)$$

The so called principal components $P_n(t)$ are obtained as

$$P_n(t) = \mathbf{e}_n^+ \mathbf{W}_t \quad (4)$$

It can be shown that the principal components compose a set of orthogonal vectors satisfying the relation $\sum_{\nu=1}^N P_{\nu\mu}^* P_{\nu\lambda} = N \lambda_n \delta_{nm}$ which shows the principal components corresponding to different

modes are uncorrelated in time and that $\lambda_m = (\sum_{\nu=1}^N |P_{\nu m}|^2)/N$ is the mean energy contained in the EOF mode \mathbf{e}_m . The fraction χ_m of the total variance (total in the sense that this is the local variance of wind velocity summed over all locations, i.e. $\text{Tr}(\mathbf{H})$) corresponding to the EOF mode \mathbf{e}_m , with the eigenvalue λ_m , is given by

$$\chi_m = \lambda_m / \text{Tr}(\mathbf{H}) \quad (5)$$

We shall assume henceforth that EOF modes are ranked in descending order according to that fraction.

Concluding, the EOF analysis separates the space-time variation of the wind field state vector into the space variation of the EOF modes which are constant in time and uncorrelated over space and the time variation of the principal components that do not depend on location in space and are uncorrelated in time. The time evolution of each EOF mode \mathbf{e}_m is described by a time series of the principal component $P_m(t)$ defined in (4). The observed wind field pattern at a given time in the study region is given by the sum of the mean wind velocity vector and EOF modes, each being modulated by the complex value of the corresponding principal component at that time. It is assumed in this study that those EOF modes that account for small fractions of total variance are not important for the physical process which is modelled. In that sense the EOF technique provides an effective way to reduce, or compress, the data and filter out most of the noise whilst retaining the most relevant information to be incorporated into the analysis.

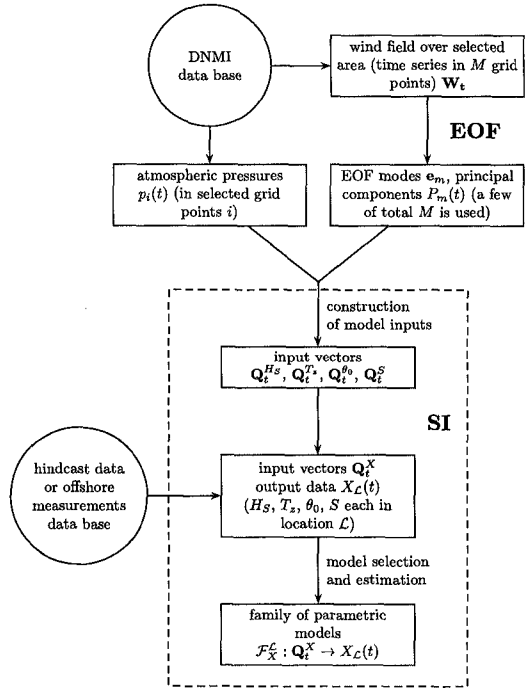

Fig. 2. Methodology for the study.

2.2 Application of EOF analysis

The DNMI 6-hourly gridded pressure field and wind field data which cover the North Sea and NE Atlantic are given in a rectangular grid on a polar stereographic projection with grid size 75 km at 60° N. The area covered by the DNMI data base and the grid used are presented on Fig. 1. In the project NEPTUNE two distinct demonstrator zones were established, one on the west coast of Great Britain and the other on the Dutch coast. The EOF analysis of wind field data was applied for both demonstrator zones. In both cases the rectangular areas for EOF analysis were selected. They are marked on Fig. 1. The area covering the Irish Sea consists of 5×5 grid points, i.e., $M = 25$. In the case of the Dutch zone, because of the open character of North Sea, much more wind time series have been subjected to the EOF analysis. The area selected for the Dutch zone consists 13×17 grid points resulting in $M = 221$.

In this section, as an example, the result of EOF analysis performed for two storm events and for two whole years over the Irish Sea is presented. Over the southern North Sea the results of EOF analysis performed for the 13 year period are described in greater detail. In Table 1 the fractions χ_m of the total variance corresponding to the first four EOF modes for the Irish Sea area are presented.

Table 1. First four EOF modes of the wind velocity field over the Irish Sea.

Mode	Percent of total variance			
	1977		1983	
	7 Nov – 17 Nov	whole year	25 Jan – 6 Feb	whole year
1	93.88	90.08	93.07	92.71
2	2.69	4.10	4.32	3.55
3	2.26	3.37	2.07	3.10
4	0.42	0.58	0.23	0.28

On Fig. 3 (a) the mean wind velocity field during the storm period 7–17 November, 1977 is shown. Fig. 3 (b) presents the associated first two modes. The most important first EOF mode containing 94% of total variance appeared to be almost uniform with characteristic “cyclonic twist” clearly visible. On Fig. 3 (c) the time histories of the first two principal component vectors during the storm are shown. The orientation of vectors is related to DNMI grid co-ordinates.

It was found that the EOF analysis performed for each of the whole year periods results in spatial patterns very similar to those obtained for the storm event only. Of course, the mean wind field over the whole year differs significantly from that calculated for storms only. The first EOF mode still consists about 90% of the total variance (see Table 1), which suggests possible usage of the EOF technique for describing the continuous time history of the wind field over the longer period covered by DNMI data set. In the case of the southern North Sea the first four EOF modes for 6 year and 13 year periods were calculated and compared. They proved very similar and it was decided to utilise the result of EOF analysis for 13 year period in further SI work.

The period 1979–1991 covered by RIKZ offshore parameters data base was selected. To adjust the 6-hourly wind velocity time series to the 3-hourly RIKZ measurements the interpolation suitable for SI analysis was performed first. Because of the greater number of the wind time series taken into the analysis ($M = 221$) and the wider area

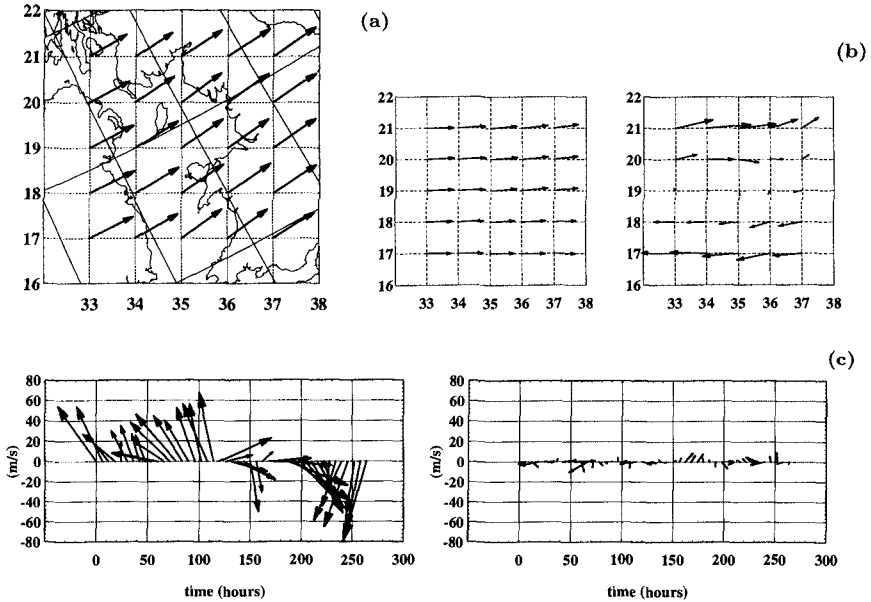

Fig. 3. EOF analysis of wind velocity field over the Irish Sea during the storm period 7 Nov – 17 Nov, 1977; (a) mean wind velocity field, scale: upper-left vector has length 10.70 m/s; (b) first (left) and second (right) EOF modes, scale: upper-left vector in the first mode has the length 0.20 (vectors of EOF modes are dimensionless); (c) evolution of first (left) and second (right) principal components, scale: left-hand side vector in the first component has the length 66.29 m/s. Time is counted starting from 0:00h of first day of storm period.

covered, the 90% of the total variance is distributed over the first eight EOF modes. The numerical values for the first eight EOF modes are given in Table 2. On Fig. 4(a) the mean wind velocity field over the area covering the 221 DNMI grid points used for the EOF analysis over 13 years is presented. Fig. 4(b) shows the first four EOF modes. Similar to the Irish Sea area case, the first mode shows the cyclonic twist characteristic for storm events determined by the depressions situated North of the Dutch coast. Also the second EOF mode is similar to the second mode of the Irish Sea case. It becomes clear that the EOF modes reflect certain characteristic features of the storm climate of both the Irish Sea and the southern North Sea areas. This is demonstrated for short storm periods and for longer one year periods as well as for the relatively long 13 year period.

Table 2. First eight EOF modes of the wind field over the southern North Sea.

Mode	1	2	3	4	5	6	7	8
Percent of total variance	59.50	15.15	9.68	3.55	2.22	1.57	1.34	1.01

On Fig. 4(c) the time series of the first four EOF principal components for one of the extreme storms selected within the study for Dutch demonstrator zone are presented for illustration.

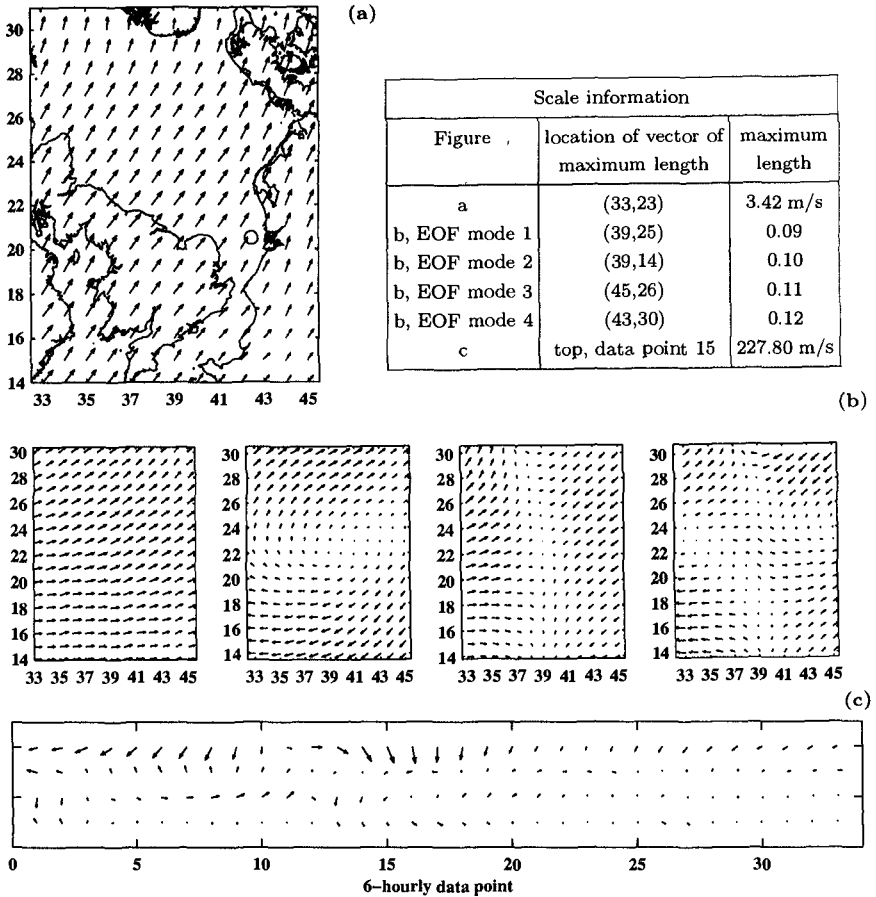

Fig. 4. EOF analysis of wind velocity field over 13 years 1979–1991 for the southern North Sea; (a) mean wind velocity field. Location of station EUR is marked with \circ ; (b) first four EOF modes (from left to right); (c) 8 days (storm No 9, Table 3) extracted from 13 year long 6-hourly time series of first four principal components (first at the top to fourth at the bottom).

In order to verify the results of EOF analysis the comparison of original wind field data \mathbf{W}_t with the wind field reproduced, according to equation (3), by the first four and eight EOF modes and principal components was performed. Examples of this comparison are shown on Figs. 5 (a) and (b). Fig. 5 (a) shows the comparison of time histories of the wind velocity at a selected grid point while Fig. 5 (b) shows the comparison of spatial distribution of the wind velocity field at a selected time instant. It can be seen that reasonably good agreement exists when the first four EOF modes are utilised and becomes very good when the first eight EOF modes are taken into account. The remarkably good agreement reflects the fact that the first eight EOF modes contain 95% of the total variance of analysed wind velocity time series, i.e., total variance calculated using reproduced wind will be equal to 95% of total variance

Fig. 5. Results of EOF analysis of wind data over the southern North Sea; (a) comparison of original DNMI wind velocity time series (*) with those recalculated via EOF method using first four (+) and first eight (o) principal components. Time series extending over 8 days (storm No 9, Table 3) are given in grid point (43, 24); (b) spatial distribution of DNMI wind velocity field at 12h on 12 Dec, 1990 (peak of the storm, data point 15); original distribution (to left), and recalculated using first eight principal components (in the middle) and first four (to right).

of the original wind field. This also indicates the scale of reduction in the volume of data that should be handled in further SI procedures. Namely, it shows that using 8 of the 221 EOF modes and 8 of the 221 principal components, one is able to reproduce the information contained in the original data base to a reasonably high level. In other words, using only 3.6% of the whole data set we are still able to retrieve most of the information contained within it.

3. System identification

3.1 Background

The metocean system and basic input-output configuration may be symbolically depicted as in Fig. 6. The output data $X(t)$ across the locations \mathcal{L} are the offshore sea state parameters. The principal components of wind field and atmospheric pressures compose the input data vectors Q_t of N_Q dimension. There is also some unmeasurable random disturbance \mathcal{N}_t that influences the output. We shall include that disturbance as an additive filtered white-noise \mathcal{E}_t .

We assume in this study that the metocean system can be described by a linear time-invariant model which is specified by the sequence of impulse response series

Fig. 6. Basic input-output configuration of metocean system being modelled.

$g_q(k)$, $q = 1, \dots, N_Q$ and the weighting function $h(k)$ of random additive disturbance, $k = 0, 1, \dots, \infty$, and, possibly, the probability density function of the white-noise \mathcal{E}_t .

It is worth noting, that despite the assumption of linear model we are still able to incorporate in a system the nonlinearities that have the character of a static nonlinearity at the input side, while dynamics itself is linear. In case the nonlinearity is known, say as function F , the input can be transformed as $Y(t) = F(X(t))$ and the system can be treated as linear. We have such a situation in this study were the moduli of the wind field principal components are taken as stimuli rather than the principal components themselves.

A complete model is given by the following relationship (see e.g. Ljung 1987)

$$X(t) = \mathbf{G}(f)\mathbf{Q}(t) + \mathcal{N}(t) \quad (6)$$

in which f is the forward shift operator, \mathbf{G} is the transfer function of the system and $\mathbf{G}(f)\mathbf{Q}(t)$ is short for

$$\sum_{q=1}^{N_Q} G_q(f)Q_q(t) = \sum_{k=0}^{\infty} \sum_{q=1}^{N_Q} g_q(k)Q_q(t-k) \quad (7)$$

and for any $q = 1, 2, \dots, N_q$

$$G_q(f) = \sum_{k=0}^{\infty} g_q(k)f^{-k}; \quad f^{-1}Q_q(t) = Q_q(t-1) \quad (8)$$

As mentioned above, we assume that the disturbance \mathcal{N} can be described as filtered white-noise, so

$$\mathcal{N}(t) = H(f)\mathcal{E}(t) \quad (9)$$

where

$$H(f) = 1 + \sum_{k=1}^{\infty} h(k)f^{-k} \quad (10)$$

Within SI we work with the structures that permit the specification of \mathbf{G} and H in terms of a finite number of numerical values. As it is common, we assume that $\mathcal{E}(t)$ is Gaussian, in which case the PDF is specified by the first and second moments. Thus, a particular model (6) is entirely determined in terms of a number of numerical

coefficients which are included as parameters to be determined. The purpose of SI is to determine the values of those parameters. If we denote the parameters in question by the vector θ , and if we take into account equation (9), the basic description for the modelled system becomes

$$X(t) = \mathbf{G}(f, \theta)\mathbf{Q}(t) + H(f, \theta)\mathcal{E}(t) \quad (11)$$

$p_{\mathcal{E}}(\cdot, \theta)$, the PDF of $\mathcal{E}(t)$; $\mathcal{E}(t)$ white-noise

which is a set of models, each of them associated with a parameter value θ .

One of a commonly used way of parameterising G_q and H is to represent them as rational functions of f^{-1} and specify the numerator and denominator coefficient in some way (see e.g. Ljung 1987). Such model structures, which are known as *black-box models*, were utilised in this study. A few different model structures were tested. However, in the limited frame of the present paper we are not able to present the modelling results for all of them. The examples demonstrating the results of SI with the simplest ARX model structures for the significant wave height and surge will be presented. Those models were estimates using *least-squares methods*.

ARX model structure

If in (11) we assume

$$G_q(f, \theta) = \frac{B_q(f)}{A(f)} \quad \text{for } q = 1, \dots, N_Q, \quad H(f, \theta) = \frac{1}{A(f)} \quad (12)$$

where

$$A(f) = 1 + a_1 f^{-1} + \dots + a_{N_A} f^{-N_A} \quad (13)$$

and for $q = 1, 2, \dots, N_Q$

$$B_q(f) = b_0^q + b_1^q f^{-1} + b_2^q f^{-2} + \dots + b_{N_{B_q}}^q f^{-N_{B_q}} \quad (14)$$

we obtain one of the simplest model structures, i.e., the autoregressive with extra input model (ARX). If (11) is rewritten as $A(f)X(t) = \mathbf{B}(f)\mathbf{Q}(t) + \mathcal{E}(t)$, $A(f)X(t)$ is the autoregressive part while $\mathbf{B}(f)\mathbf{Q}(t)$ is the extra input of the ARX model.

The vectorial parameter θ to be determined is in this case

$$\theta = [a_1, a_2, \dots, a_{N_A}, b_0^1, b_1^1, \dots, b_{N_{B_1}}^1, b_0^2, b_1^2, \dots, b_{N_{B_2}}^2, \dots, b_0^{N_Q}, b_1^{N_Q}, \dots, b_{N_{B_{N_Q}}}^{N_Q}] \quad (15)$$

where $N_A, N_{B_1}, N_{B_2}, \dots, N_{B_{N_Q}}$ are the orders of the multi-input ARX model.

By substituting (12) into (11) the following input-output relationship is obtained

$$X(t) + a_1 X(t-1) + \dots + a_{N_A} X(t-N_A) = b_0^1 Q_1(t) + b_1^1 Q_1(t-1) + \dots + b_{N_{B_1}}^1 Q_1(t-N_{B_1}) + \dots + b_0^{N_Q} Q_{N_Q}(t) + b_1^{N_Q} Q_{N_Q}(t-1) + \dots + b_{N_{B_{N_Q}}}^{N_Q} Q_{N_Q}(t-N_{B_{N_Q}}) + \mathcal{E}(t) \quad (16)$$

which is the *linear difference equation*. The ARX model represented by (16) is sometimes called an *equation error model* because of the way in which the white-noise term $\mathcal{E}(t)$ enters the difference equation (16).

3.2 Application in modelling of significant wave height and surge

As mentioned in the introduction, we use the RIKZ measurements as the output data for the purpose of SI. Those 3-hourly measurements covering the 13 year period 1979–1991 were recorded at five offshore monitoring stations.

In this paper, as examples demonstrating the SI carried out within the study, the modelling of significant wave height $H_S(t)$ and surge $S(t)$ in the location of the station EUR are presented. The position of the EUR station is marked on Fig. 4 (a).

Table 3. Selected extreme storms.

Storm no.	Year	Start (00:00 hrs)	End (24:00 hrs)
1	1981	21 Nov	28 Nov
2	1982	13 Dec	18 Dec
3	1983	15 Jan	22 Jan
4	1983	29 Jan	5 Feb
5	1984	11 Jan	18 Jan
6	1989	11 Feb	18 Feb
7	1990	22 Jan	29 Jan
8	1990	23 Feb	2 Feb
9	1990	9 Dec	16 Dec

Within the NEPTUNE project 41 storms over the Irish Sea and the southern North Sea were selected in order to study in a very extensive way the historical extreme coastal events. 9 of the 20 storms selected for the southern North Sea region overlap the 13 year period of the Dutch measurements. They are listed in Table 3. We use those 9 storms to present the results of SI. Namely, both the synthetic data produced by the estimated models and the measured data are plotted and the standard deviations of differences between measured and modelled values are given for the 9 storms listed in Table 3.

In order to select the structure of the model, i.e., to set up the input-vectors and decide about the combination of model orders, a *cross-validation* procedure was utilised. Namely, the data series covering the 13 year period were split into independent *working* and *validation* data sets. The working data (covering 7 years) were used for the estimation while the validation data (covering 6 years) were used to evaluate an estimated model's properties. That evaluation was done mainly by comparison of the simulated and measured output time series, and computing of the sum of squared prediction errors. The model structure resulting in the smallest sum was selected and then estimated again using the whole 13 year long data set. The synthetic data produced by those re-estimated models, for the 9 storms listed in Table 3, are shown in Figs. 7 and 8.

Below we describe the construction of the input-vectors used in SI procedures applied in the modelling of the significant wave height $H_S(t)$ and surge $S(t)$.

Significant wave height

In the modelling of significant wave height H_S the principal components of the wind velocity field for the 13 year period were taken as the only system stimuli. The units of the wind velocity field principal components P_m are, as in the case of wind velocity itself, m/s (EOF modes e_m are dimensionless). The dimensional analysis applied to the significant wave height H_S and principal components P_m suggests that the squares of the latter should be used as input in SI. However, slightly better results were obtained when $|P_m|$ to the first power were also incorporated.

The analysis of equation (3) together with the examination of the spatial patterns shown by the first and second EOF modes with reference to the geographical features of the southern North Sea led to the conclusion that the first EOF mode should have

Fig. 7. Comparison between modelled (solid line) and recorded (stars) time series of significant wave height $H_S(t)$ for 3 of the 9 storms listed in Table 3: storms No 1, 5 and 8 (from top to the bottom).

greatest influence when it is rotated by an angle of about $\alpha_1 = -70^\circ$ and also $\beta_1 = 45^\circ$, while for the second EOF mode, the rotation angle of about $\alpha_2 = -80^\circ$ was selected. As a result, the projections of the first principal component P_1 on α_1 and β_1 , and the second principal component P_2 on α_2 were used in the construction of the input-vector rather than their arguments. The projection directions were then subjected to the cross-validation procedure (by varying the projection angles over the ranges around the initially selected values) which confirmed the goodness of the initial guess. In addition, the cross-validation procedure showed it was useful to introduce the second projection also for the second principal component P_2 , namely $\beta_2 = 35^\circ$.

Interestingly, it was found by cross-validation, with the projections of P_1 and P_2 taken into account, that there was no improvement arising from the greater number of components involved in the input-data vector. However, by taking the higher model orders, the modelling was improved, namely, when 7 past input values were taken into account. This suggests that the most important input information in the modelling of the sea response is involved in the first two principal components, despite the fact that they compose only about 75% of the total variance. However, longer history of the dynamic metocean system (21 hours in our case) should be taken into account.

Finally, the following input-vector \mathbf{Q}^{H_S} was selected to model the significant wave height:

$$Q_q^{H_S} = \begin{cases} |P_q| & \text{for } q = 1, 2 \\ |P_{q-2}|^2 & \text{for } q = 3, 4 \\ \Re(P_{q-4} \exp(-i\alpha_{q-4})) & \text{for } q = 5, 6 \\ \Re(P_{q-6} \exp(-i\beta_{q-6})) & \text{for } q = 7, 8 \end{cases} \quad (17)$$

in which $\Re(\cdot)$ denotes the real part of a complex number enclosed in the brackets, with the orders:

$$N_A = 0; \quad N_{B_1} = N_{B_2} = \dots = N_{B_8} = 7 \quad (18)$$

Fig. 7 demonstrates the result of ARX modelling with the structure given by (17) and (18). The standard deviation of the differences between the synthetic and measured significant wave heights are listed in Table 4.

Fig. 8. Comparison between modelled (solid line) and recorded (stars) time series of surge $S(t)$ for 3 of the 9 storms listed in Table 3: storms No 1, 5 and 8 (from top to the bottom).

Surge

In its simplest form the SI can be considered to take the form of regression techniques applied in past years to examine and estimate storm surges (see e.g. Ovadia 1980 and Amin 1982). In this section the results of surge modelling using the ARX structure with the principal components of wind velocity field and local atmospheric pressure taken as the system stimuli are presented. The dimensional analysis applied to the surge S , principal components P_m and local pressure p suggests to use the squares of principal components and the atmospheric pressure to the first power. The input-

Table 4. Standard deviations of differences between modelled and recorded time series.

Calculated for	Variable and model used	
	H_S	S
	ARX (17) & (18)	ARX (19) & (20)
Storm 1	0.37	0.19
Storm 2	0.45	0.13
Storm 3	0.52	0.16
Storm 4	0.51	0.24
Storm 5	0.69	0.16
Storm 6	0.48	0.28
Storm 7	0.55	0.14
Storm 8	0.60	0.22
Storm 9	0.66	0.29
Average of 9 storms	0.54	0.20
13 years: 1979–1991	0.46	0.12

vector \mathbf{Q}^S was selected in the same manner as for significant wave height H_S (with the first two principal component projections) with additional component being the local atmospheric pressure. However, in this case, contrary to H_S case, the cross-validation analysis suggested not to take into account the first powers of the principal component moduli. Finally, the input-data vector \mathbf{Q}^S was constructed as

$$Q_q^{H_S} = \begin{cases} |P_q|^2 & \text{for } q = 1, 2 \\ \Re(P_{q-2} \exp(-i\alpha_{q-2})) & \text{for } q = 3, 4 \\ \Re(P_{q-4} \exp(-i\beta_{q-4})) & \text{for } q = 5, 6 \\ p & \text{for } q = 7 \end{cases} \quad (19)$$

with the orders:

$$N_A = 0; \quad N_{B_1} = N_{B_2} = \dots = N_{B_7} = 7 \quad (20)$$

The local pressure p was computed from the DNMI pressure data base by bi-linear interpolation of the time series taken from the four neighbour DNMI grid points.

The surge time series created by the ARX model with the structure given in (19) and (20) are demonstrated in Fig. 8. The standard deviations of errors are listed in Table 4.

4. Conclusions

Comparison between the modelled and observed time series of both significant wave height and surge level present a sufficiently good agreement to prove effectiveness of the new approach. In the case of significant wave height for 9 storms examined, the standard deviations of differences between the predicted and observed values appeared to be of the same order as those found for the second generation numerical wave forecasting model utilised within the project. Extreme values are found to be underestimated which may be due to possible inconsistency between the input and output data, i.e., the DNMI synthetic wind field and the Dutch field measurements. Further research is being directed to improve the modelling of individual extremes.

This study was carried out as a part of the NEPTUNE project funded by the Commission of the European Communities, Directorate General for Science, Research, and Development under MAST contract No. MAS2-CT94-0081. The Royal Norwegian Meteorological Institute and the National Institute for Coastal and Marine Management (RIKZ) provided data utilised in this study. We are especially grateful to Dr John de Ronde of RIKZ for his permission to access the Dutch offshore station data.

CHAPTER 57

Fully Nonlinear Properties of Periodic Waves Shoaling over Slopes

Stéphan T. Grilli¹, M. ASCE, and Juan Horrillo²

ABSTRACT : Shoaling of finite amplitude periodic waves over a sloping bottom is calculated in a *numerical wave tank* which combines : (i) a Boundary Element Model to solve Fully Nonlinear Potential Flow (FNPF) equations; (ii) an exact generation of *zero-mass-flux Streamfunction Waves* at the deeper water extremity; and (iii) an *Absorbing Beach* (AB) at the far end of the tank, which features both free surface absorption (through applying an external pressure) and lateral active absorption (using a piston-like condition). A feedback mechanism adaptively calibrates the beach absorption coefficient, as a function of time, to absorb the period-averaged energy of incident waves.

Shoaling of periodic waves of various heights and periods is modeled over 1:35, 1:50, and 1:70 slopes (both plane and natural), up to very close to the breaking point. Due to the low reflection from both the slope and the AB, a quasi-steady state is soon reached in the tank for which local and integral properties of shoaling waves are calculated ($K_s, c, H/h, kh, \eta_m, S_{xx}, \dots$). Comparisons are made with classical wave theories and observed differences are discussed. Parameters providing an almost one-to-one relationship with relative depth kh in the shoaling region are identified. These could be used to solve the so-called *depth-inversion problem*.

INTRODUCTION

In the coastal region, incident ocean waves propagating towards the shore (in direction x ; Fig. 1) increasingly feel the effects of the reducing depth $h(x)$, due to the sloping ocean bottom. These effects induce significant changes in wave shape, height H , length L , and phase celerity c , while the wave period T stays closely constant. Predicting such changes (usually referred to as *wave shoaling*) up to the point waves become unstable and break (breaking point; BP) is one of the important tasks of coastal

²Graduate Student, same address

engineering. Characteristics of waves at the BP indeed are used to design coastal structures and predict littoral sediment transport; detailed wave kinematics at the BP is also needed for surfzone models which are increasingly used in coastal engineering research and design. In the more specific problem referred to as *depth inversion*, one seeks to predict the nearshore bottom topography based on observed characteristics of shoaling waves (e.g., through remote sensing). Hence, simple relationships between these and $h(x)$ are sought after.

In most wave transformation models used so far, shoaling of deep water waves is calculated based on linear or weakly nonlinear theories (e.g., modified Boussinesq eqs.) and using semi-empirical breaking criteria to locate the BP. Such theories, however, despite their satisfactory predictions in deep and intermediate water, may not be sufficiently accurate close to the BP where wave height reaches a significant fraction of the depth. Highly nonlinear waves have been modeled using a higher-order Fourier steady-wave theory (FSWT), e.g., by Sobey and Bando³ (1991). In the latter work, up to three conservation equations for mass, momentum, and energy flux, are expressed to propagate incident waves over a mildly sloping bottom. In such an approach, however, the bottom slope is replaced by a cascade of horizontal steps and, hence, wave profiles do not take the characteristic skewed shape observed in experiments before breaking occurs. As a result, wave kinematics and dynamics cannot be well represented close to the BP⁴. Finally, in this approach, breaking corresponds to the highest wave which is stable over constant depth. This is quite unrealistic since, as we will see, skewness and unsteadiness allow waves to reach a larger height before they break.

To accurately predict wave properties close to the BP, we will show that, in addition to full nonlinearity, even for mild slopes, the influence of bottom topography on wave shape must be included in shoaling models. Time dependent models based on fully nonlinear potential flow (FNPF) theory have this capability, provided proper wave generation and absorption methods are implemented (e.g., 2D : Klopman, 1988; Grilli *et al.*, 1989; Cointe, 1990, Cooker, 1990; Ohyama and Nadaoka, 1991; 3D : Romate, 1989; Broeze, 1993). Hence, with such models, a "numerically exact" solution can be obtained for waves shoaling over an arbitrary bottom geometry, for which no approximation other than potential flow theory is made.

NUMERICAL MODEL

The two-dimensional FNPF model by Grilli, *et al.* (1989, 1990, 1996) will be used to compute characteristics of periodic waves shoaling over both plane and natural slopes, up to a very high fraction of the breaking height (Fig. 1). FNPF computations can

³Also see their detailed review of other similar works. Note, Johnson and Arneborg (1995) followed a similar approach using a fourth-order perturbation method.

⁴The authors nevertheless assume that integral properties should be insensitive to such details and are thus well predicted by a FSWT. The latter assumption is quite questionable, since radiation stresses, for instance, are strongly influenced by wave skewness.

Figure 1: Sketch for FNPF computations of a periodic wave shoaling over a plane slope s , in a “numerical wave tank”.

model overturning waves but, by nature, are limited to prior to the time touch-down of a breaker jet first occurs. This does not pose problems when solitary waves are used in the analysis, as it has often been the case in the past⁵. For periodic or irregular waves, however, an *absorbing beach* (AB) must be used to absorb the energy of incident waves, hence eliminating reflection and preventing these from breaking at the top of the slope.

Grilli and Horrillo (1996) implemented such an AB in the model over a shallower region located in the upper part of the slope whose geometry was specified somewhat similar to natural bars on beaches⁶ (Fig. 1). Energy absorption combined both free surface and lateral absorption with an adaptive calibration of the absorption coefficient : (i) an exterior counteracting pressure is specified on the AB free surface, proportional to the normal particle velocity (Cointe, 1990; Cao *et al.*, 1993), to create a negative work against incident waves; this is shown to absorb high frequency wave energy well; (ii) a piston-like (active) absorbing boundary condition is specified at the tank extremity Γ_{r2} (“absorbing piston”, AP), which is shown to absorb low frequency wave energy well (Clément, 1996); (iii) the AB’s absorption coefficient is adaptively calibrated in time to absorb the period-averaged energy of incident waves entering the beach at $x = x_l$. Grilli and Horrillo developed and tested this AB and showed that wave reflection could be reduced to a few percent only. Hence, in a “numerical wave tank” such as sketched in Fig. 1, computations for periodic waves can reach a quasi-steady state for which properties of shoaling waves can be calculated, up to very close to the BP, and compared to results of other shoaling methods (theory or models), which usually assume there is no reflection from the slope or beach. [In the present method, reflection from the slope still occurs as it does in nature.]

Incident waves can be arbitrary in the model but, for sake of comparison with other wave theories, permanent form wave solutions of the FNPF problem are generated on the leftward boundary (Γ_{r1} , Fig. 1). These are so-called streamfunction waves

⁵In such cases, FNPF calculations can predict characteristics of breaking solitary waves within 2% of experimental measurements (Grilli *et al.*, 1994, 1997)

⁶In this case, gradual deshoaling of waves occurs in the AB which helps absorbing wave energy.

(SFW; Dalrymple 1974; Dean and Dalrymple 1984) which, unlike finite amplitude waves produced by a wavemaker, do not exhibit the generation of higher harmonics and the beat phenomenon observed in wave tanks as they propagate over constant depth (e.g., Chapalain *et al.*, 1996). Since SFW's have a non-zero mass flux, they are generated in the model together with a mean current, equal and opposite to their period-averaged mass transport velocity (Grilli and Horrillo, 1996). Hence, volume stays constant within the "numerical wave tank" as it would on a beach for which the undertow current balances the incident mass flux at some distance from the shore.

Details of model equations, numerical methods and validation applications can be found in the above-referenced papers. It will just be mentioned that Laplace's equation is solved in the model, over domain Ω , based on a higher-order Boundary Element Method (BEM) derived from Green's 2nd identity. Boundaries are discretized using N nodes and M higher-order elements are specified to interpolate in between the nodes. Quadratic isoparametric elements are used on lateral and bottom boundaries (Γ_{r1} , Γ_{r2} , Γ_b) and cubic elements ensuring continuity of the slope are used on the free surface boundary Γ_f (Grilli and Subramanya 1996). The nonlinear free surface kinematic and dynamic boundary conditions are time integrated using second-order Taylor series expansions expressed in terms of a time step Δt and of the Lagrangian time derivative. Numerical errors are kept to a very small value by adaptively selecting the time step based on a mesh Courant number $C_o(t)$ (Grilli and Svendsen, 1990; Grilli and Subramanya 1996). In shoaling computations, as waves become increasingly steep towards the top of the slope, discretization nodes may get quite close to each other and create quasi-singular values for the BEM integrals, leading to poor accuracy. Hence, the adaptive regridding method developed by Grilli and Subramanya (1996) is used to automatically regrid nodes three by three when the distance between two nodes is either more than 4 times or less than 0.25 times the distance between the previous two nodes. In the following applications, a minimum of 20 nodes per wavelength is maintained throughout shoaling.

APPLICATIONS

Figure 1 illustrates a typical set-up for shoaling computations : (i) incident zero-mass-flux SFW's are generated on Γ_{r1} (in depth h_o , with height H_o and period T ; o-indices denote deep water values); (ii) waves propagate up the sloping bottom and are absorbed in the AB/AP; (iii) since reflection is very small from both the sloping bottom and the beach, computations soon reach a quasi-steady state for which successive waves undertake similar transformations (see Grilli and Horrillo, 1996, for a detailed discussion of numerical parameters and results); (iv) model parameters are tuned-up to let incident waves shoal up to impending overturning before they are absorbed in the AB. Numerical "wave gages" are specified at several fixed locations, $x = x_g$, over the slope where wave characteristics are calculated, both on the free surface (e.g., elevation $\eta(x_g, t)$) and as a function of depth z (e.g., velocity $u(x_g, z, t)$, dynamic pressure $p_D(x_g, z, t)$).

Figure 2: (a) shoaling coefficient $K_s = H/H_0$; (b) celerity c ; and (c) left/right asymmetry s_2/s_1 , for periodic waves shoaling over a 1:50 slope, with $H'_0 = H_0/h_0 =$ (- - -) 0.04, (- - -) 0.06, and (—) 0.08, and $T' = T\sqrt{g/h_0} = 5.5$: (n) FNP results; (s) Sobey and Bando's (1991) FSWT results; (---) LWT results; (c) CWT results. $c_0 = gT/(2\pi)$ is the (linear) deep water celerity.

Local wave properties

After quasi-steady state is reached, successive incident waves are identified and tracked in the results : (i) envelopes of crest and trough elevations are calculated, from which wave height $H(x)$ and shoaling coefficient $K_s(x) = H/H_o$ are obtained; (ii) phase velocity $c(x)$ is calculated from the time derivative of crest trajectories; (iii) to quantify wave skewness, forward and backward normalized wave slopes are calculated as, $s_2(x) = H_2/(s_o L_2)$ and, $s_1(x) = H_1/(s_o L_1)$, respectively, in which (L_1, L_2) and (H_1, H_2) denote horizontal and vertical distances from a crest to the previous and next troughs, respectively, and $s_o = 2H_o/L_o = k_o H_o/\pi$. Results show that these quantities are quite well reproduced as a function of x , for successive incident waves (Grilli and Horrillo, 1996); in the applications, however, to eliminate small variations, ensemble averages of these quantities for each x are calculated over at least 4 successive waves.

In the model, waves are found to shoal up the slope, qualitatively, as expected from linear wave theory (Fig. 1) : (i) both wavelength L and celerity $c = L/T$ continuously decrease; (ii) deshoaling first occurs, with a reduction in wave height, followed by shoaling and an increase in wave height up to the top of the slope where waves almost reach overturning before entering the AB and decaying.

More specifically, in Fig. 2, K_s , c , and s_2/s_1 have been plotted as a function of normalized depth $k_o h$, for a bottom slope $s = 1:50$ and three incident waves of normalized incident height $H'_o = H_o/h_o = 0.04, 0.06, \text{ and } 0.08$, and normalized period $T' = T\sqrt{g/h_o} = 5.5$ ($k_o = (2\pi)^2/(gT^2)$ is the (linear) deep water wavenumber). Results of linear (LWT) and cubic (CWT) Stokes wave theories are also indicated. For $k_o h < 0.5$, significant differences are observed between FNPF results and the wave theories; this also corresponds to $kh = 2\pi h/L < 0.77$ (or $H/h > 0.10$; see Fig. 4b). For diminishing depths, due to increased nonlinearity, both K_s and c become significantly larger than predicted by LWT (Figs. 2a and 2b) and, as could be expected, increasingly so with the incident wave height. CWT predicts celerity better for shallower depths but diverges in very shallow water. The more accurate FSWT performs reasonably well for predicting celerities (Fig. 2b) but does quite poorly for wave heights (Fig. 2a). This is likely due to the lack of skewness in modeled waves whereas FNPF results for s_2/s_1 (Fig. 2c) show that waves are significantly skewed—i.e., forward tilted, left/right asymmetric—for very shallow water (see also Fig. 1 for spatial wave profiles).

The significant differences observed in Fig. 2 between FSWT and FNPF results show that, even for a very mild slope, the influence of actual bottom shape on local wave properties is important. Fig. 3 now investigates how this influence varies with bottom slope. An incident wave with $H'_o = 0.06$ and $T' = 5.5$ is shoaled up three plane beaches of slopes $s = 1:35, 1:50, \text{ and } 1:70$, and a “natural beach” geometry with an average slope of 1:50. The natural beach has a depth variation defined according to Dean’s equilibrium beach profile, $h = A(x^* - x)^{2/3}$, with x^* denoting a constant, function of the location of the toe of the slope in depth h_o , and A depending on the

Figure 3: FNPF results for : (a) shoaling coefficient; (b) celerity; and (c) left/right asymmetry, for periodic waves with $H'_o = 0.06$ and $T' = 5.5$, on : 1:35 (curve a); 1:50 (curve b); 1:70 (curve c), plane (—) or natural (----) beaches. (---) LWT results; (- - -) CWT results.

specified average slope. This “natural beach”, hence, has a milder slope in deeper water and a steeper slope in shallower water. For the wave height and celerity, Figs. 3a and 3b show fairly small differences between results calculated for the same depth on various slopes, for most of the shoaling region. The wave left/right asymmetry— s_2/s_1 , shown in Fig. 3c—seems to be more sensitive to bottom slope, becoming larger for the shallower parts of the (steeper) 1:35 slope and the “natural beach”. Overall, however, no major differences are observed provided wave properties are compared for the same normalized depth.

Results in Fig. 3 imply that, for a given depth, local wave properties vary little for the same wave propagating over a range of mild slopes from 1:35 to 1:70. Hence, a broader parametric study will be carried out on a 1:50 slopes only, for 9 waves combining heights, $H'_o = 0.04, 0.06, \text{ and } 0.08$ and period, $T' = 5.5, 6.5, \text{ and } 7.5$. Results for each wave are given in Fig. 4 as a function, this time (due to the varying wave period), of the relative local depth kh . First, in Fig. 4a, we see that, for the phase celerity normalized by the linear wave celerity, $c_l = c_o \tanh kh$, the larger the incident wave height and the smaller the period (or similarly the larger $k_o H_o$) then, for a given kh , the larger the celerity increase with respect to c_l . Such results illustrate the well known amplitude dispersion effects due to increasing wave steepness⁷ kH which, for the studied cases in shallow water ($kh < \pi/10$), lead to a 40 to 85% maximum increase in celerity with respect to linear wave theory. In Fig. 4b, we see that, in all cases, the wave height to depth ratios H/h reach $\mathcal{O}(1)$ values in the shallow water region, confirming the very strong nonlinearities. A similar analysis of shoaling coefficients would show that linear wave theory significantly underpredicts wave height for depths corresponding to $H/h > 0.2$ (which also corresponds to the region where celerity is significantly underpredicted in Fig. 4a); for the studied cases this underprediction of K_s is up to 55%. With regard to these results, it is anticipated that the quantity, $kH/(k_o H_o) = K_s/(c/c_o)$, i.e., the local wave steepness normalized by the deep water steepness, should exhibit somewhat less variations (i.e., overprediction) with respect to linear wave results, since underprediction of wave height and celerity should compensate each other to some extent. This is confirmed in Fig. 4c where we see, first of all, that all FPNF results follow quite a similar increase as a function of kh , up to maximum steepness, and that results of LWT (i.e., $K_s/\tanh kh$) are a better predictor of normalized wave steepness, with a maximum underprediction of only 11%, than for the other wave properties discussed above. Considering the many differences in wave shape, height and length, and kinematics, observed between FPNF and LWT results, the latter result is somewhat unexpected.

Integral wave properties

These are the mean water level η_m , the mean undertow current U_m , the energy flux E_f , and the radiation stress S_{xx} . In the model, integral properties are computed at

⁷Such effects are predicted at third-order by Stokes theory (CWT).

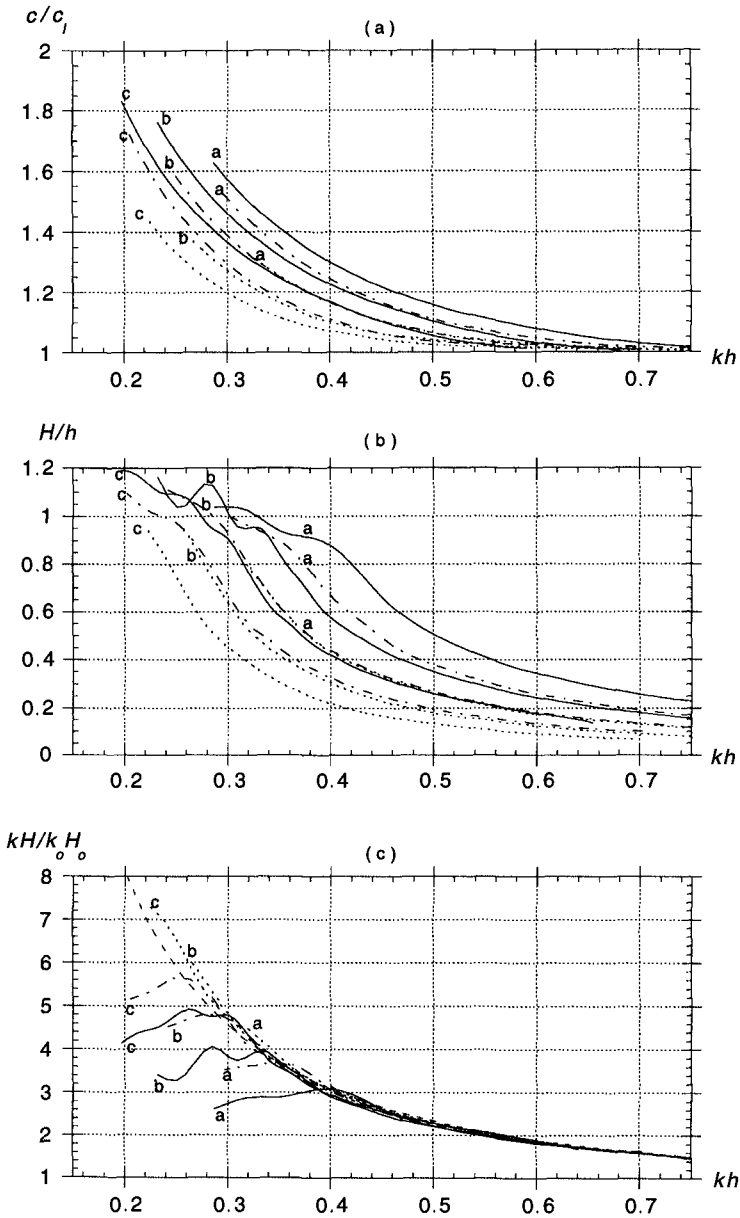

Figure 4: Periodic waves shoaling over a 1:50 slope. $H'_o = (- - -)$ 0.04, $(- \cdot - \cdot)$ 0.06, and (—) 0.08, and $T' = : 5.5$ (curves a); 6.5 (curves b); 7.5 (curves c). $(- - -)$ LWT results; $c_l = c_o \tanh kh$, is the linear wave celerity.

Figure 5: Normalized (a) mean water level $\eta'_m = \eta_m/h_o H_o'^2$; and (b) radiation stress $S'_{xx} = S_{xx}/\rho g H_o'^2$ (with ρ the fluid density), for three periodic waves shoaling over a 1:50 slope. Symbols and definitions are as in Fig. 2. Results have been averaged over $3T$ in the quasi-steady regime. Symbols (\circ) denote locations $x = x_g$ of "numerical gages". Corrections, $\Delta\eta'_{mo} = -0.0274$ and $\Delta S'_{xxo} = h'_o(\Delta\eta'_{mo}) + (\Delta\eta'_{mo})^2/2$, have been applied to the linear results for η'_m and S'_{xx} , respectively, to account for the actual mean water level in depth h_o in the FNPF results.

Figure 6: Normalized amplitudes of first three harmonics (a,b,c), a_i ($i = 1,2,3$), for three periodic waves shoaling over a 1:50 slope. Definitions are as in Fig. 2.

“numerical gages” located at $x = x_g$ above the sloping bottom using classical equations, i.e., through depth integrations and wave period-averaging involving, $\eta(x_g, t)$, $\mathbf{u}(x_g, z, t)$ and $p_D(x_g, z, t)$. To account for the non-zero mean Eulerian velocity in the model (resulting from specifying zero-mass-flux incident waves at boundary Γ_{r1}), and for the set-down η_m , expressions of integral properties are corrected following Klopman (1990) and Jonsson and Arneborg (1995). In the model, time averaging is performed at time t , for the results calculated from time $t - T$ to t . Time series of integral properties are thus obtained for each gage location x_g . When computations reach a quasi-steady state, integral properties stabilize to fairly constant values in time for each gage location. To eliminate small time fluctuations and oscillations of integral properties with respect to these constant values, averages are calculated over $3T$, before results are analyzed.

In all cases, the energy flux is found to be very close to constant at the gages located in the region where wave height increases (e.g., over the shoaling parts of curves in Figs. 2a and 3a). This indicates that reflection is small from both the sloping bottom and from the AB. As depth decreases, the mean undertow current increases roughly proportionally to $1/h$, as expected from the period-averaged continuity equation, and then decreases when wave height starts decreasing.

Mean water level and radiation stress results are given in Fig. 5, for the same three waves as in Fig. 2, shoaling over a 1:50 slope. As expected, the normalized η_m in Fig. 5a follows a trend opposite to S_{xx} in Fig. 5b, first setting-down over the slope and then stabilizing towards the top of the slope and increasing in the AB due to wave height reduction. In shallow water, the set-down becomes relatively larger, the smaller the incident wave, as a result of the steeper drop in radiation stresses for the larger waves. Results obtained from a first-order nonlinear perturbation of LWT

(FNLT; Dean and Dalrymple, 1984) and adjusted to match the initial FNPF set-down in depth h_o , show reasonable agreement with FNPF results. In the shallower region at the top of the slope, however, FNLT results do not capture the leveling-up of η_m . Radiation stresses in Fig. 5b gradually increase while wave height increases and depth decreases, following the expected pattern from FNLT, which predicts results quite well in the deeper water region. At some stage, however, FNPF results become smaller than FNLT results, and more so, for a given depth, the larger the incident wave height. A more detailed analysis of these results would show that this decrease in S_{xx} is strongly correlated with the increase in "skewness index" s_2/s_1 , shown earlier in Fig. 2c for $k_o h < 0.45$; this confirms that radiation stresses are quite sensitive to wave shape.

Fourier analysis

Another way of analyzing how wave shape changes during shoaling is to calculate Fourier transforms of wave surface elevations $\eta(x_g, t)$ obtained at fixed gages at $x = x_g$. Harmonic amplitudes can then be plotted as a function of x_g . This was done in Fig. 6 which shows normalized amplitudes of the first three harmonics a_i ($i = 1, 2, 3$), for the same three waves as in Fig. 2 shoaling over a 1:50 slope. In all cases, in the shoaling region where wave height increases (Fig. 2a), after a slight initial increase, a_1 decreases while a_2 and a_3 continuously increase. This indicates that, in shoaling periodic waves, energy is being continuously transferred to higher-order harmonics, as a result of nonlinear interactions. As could be expected, for a given depth, this nonlinear energy exchange is stronger, the larger the incident wave height, and the energy transfer to the higher-order harmonics thus starts occurring in deeper water. Not surprisingly, variations of the "skewness index" s_2/s_1 in Fig. 2c are strongly correlated with variations of a_2 and (particularly) of a_3 in Fig. 6.

Conclusions

A numerical wave tank was used to model finite amplitude periodic waves shoaling over a sloping bottom. Periodic waves of various heights and periods, covering the range $k_o H_o = [0.028, 0.105]$, were modeled over 1:35, 1:50, and 1:70 slopes (both plane and natural), up to very close to the breaking point. Due to the low reflection from the slope and the AB, a quasi-steady state was soon reached in the tank for which both local and integral properties of fully nonlinear shoaling waves were calculated (K_s , c , s_2/s_1 (left/right asymmetry), H/h , kH , η_m , S_{xx}).

For a shallow enough normalized depth ($k_o h < 0.5$ or $kh < 0.77$), significant differences are observed between FNPF results and 1st (LWT), 3rd (CWT), and higher-order steady wave (FSWT) theories. For the first two theories, low-order nonlinearity is clearly the main reason for the observed differences in a region where $H/h = \mathcal{O}(1)$; in the latter theory, the lack of wave skewness and the representation of the bottom by horizontal steps likely explain the observed differences.

Despite the significant effects of actual bottom shape on the results, for the range of tested mild slopes, FNPF results are found fairly similar for the same wave taken at the same normalized depth ($k_o h$ or kh). This, hence, allows us to use kh as the *unique parameter* describing a mild bottom variation and to compute additional results on a unique mild slope (1:50). In these results, for the range of tested waves, the normalized wave steepness, $kH/k_o H_o$, shows an almost one-to-one relationship with kh in the shoaling region. Steepness thus could be used to solve the so-called *depth-inversion problem*. Quite surprisingly, due to a partial compensation of nonlinear effects for the wave height and celerity, LWT is found quite a good predictor of this parameter (maximum difference is 11%), whereas discrepancies for H and c reach 55 and 85%, respectively.

For the tested waves, set-down is quite well predicted by the first-order perturbation of LWT, except in the shallower region, where it is smaller, following the steep drop in radiation stresses. [This could also be partly due to the mean undertow current. More work remains to be done about this.]. Radiation stresses are overpredicted by the first-order theory in the region where wave left/right asymmetry s_2/s_1 (i.e., skewness) becomes large, confirming the sensitivity of this parameter to wave shape. Otherwise, agreement with the theory is quite good. A Fourier analysis of surface profiles $\eta(x_g, t)$ calculated for gages located at $x = x_g$ shows a continuous transfer of energy from the fundamental to higher-order harmonics in the shoaling region, illustrating nonlinear interactions in the shoaling wave field. The 3rd-harmonic amplitude a_3 is strongly correlated with s_2/s_1 .

CHAPTER 58

WATER WAVE FLUCTUATIONS INDUCED BY IRREGULAR BATHYMETRY

Lulin Guo¹ and Robert A. Dalrymple²

Abstract: Small irregular water depth variations may cause relatively large variations of the wave field, which may affect the results of various water wave models. Statistical properties of depth variation are obtained from real bathymetry and idealized water depths are generated to study this influence on wave fields. An angular spectral model and a parabolic model are examined for their sensitivity to depth variations. It is shown that diffraction and nonlinear effects are dominant to the wave energy scattering. Correlation functions, especially correlation lengths, play an important role in the wave field variation.

INTRODUCTION

In shallow water, waves are strongly affected by depth variations, yet the water depth near a site of interest is often not well known and may vary rapidly in time and space. Slight depth variations can cause relatively large variations of the wave properties particularly after significant propagation distance. Recent studies showed that some models are very sensitive to bathymetry variation; fluctuations of depth can lead to chaotic patterns in the wave field (Brown *et al.* 1991; ray tracing model).

An important input to numerical wave models is a bathymetric grid, containing digitized water depths. These digitized depths may contain errors caused by sounding errors, errors in digitizing the chart, unknown variation in depth between survey points and bottom variation since the sounding. These errors can be regarded as random depth variations. The influence of the random variations can be fairly large depending on the model, the initial wave field, the systematic bottom bathymetry, and the statistical properties of the random bottom variation. The statistical properties can be described by distribution function and correlation functions.

A variety of numerical models, which differ in their underlying theories and their numerical implementations, are used to simulate wave fields. Results exist for a wave ray model, mild-slope equation, Boussinesq equations, an Eulerian

¹Graduate student, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA.

²Professor and Director, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA.

model, which is a stationary model based on the action balance of short-crested waves (Holthuijsen *et al.*, 1989), and some other models. The traditional ray tracing model does not consider diffraction and nonlinearity effects. It is not applicable for the study on wave fluctuations when these effects are important to be neglected. Other models contain effects of refraction, diffraction and nonlinearity, and their sensitivity to the random bottom variation are different. Numerical methods include finite element, spectral, pseudo-spectral and parabolic methods. The WANGLE model (Dalrymple *et al.* 1989) is an angular spectrum model to solve the modified mild-slope equation. It permits wide wave propagation angles which could appear in the situations when the refraction and diffraction of the waves are strong. The nonlinearity is included through the nonlinear dispersion relationship. The REF/DIF model (Kirby and Dalrymple, 1992) is a parabolic model originating from the mild-slope equation with the influence of current added. The sensitivity of these two models are examined.

Some studies of the influence of bottom variation have been done recently. Brown *et al.* (1991) showed that a ray tracing model is very sensitive to the bottom perturbations. When the bottom fluctuations are 20% of the mean water depth, the wave field can become chaotic. Holthuijsen and Booij studied the effects of the water depth variations using HISWA (Holthuijsen and Booij, 1989), a predictive model for stationary, short-crested waves in shallow water, in 1994. Their results showed that the bottom-induced fluctuation may be a serious problem and the effects of bottom variations on long-crested waves was more dominant than on short-crested waves. Reeve (1992) applied an analytical method and Monte Carlo simulations. Some quantitative results were obtained with the help of the angular spectrum of the bathymetry variation.

In this paper, we examine the influence of the random variability of the ocean bottom on waves in shallow water and the sensitivity of various numerical models to these depth variations. Some idealized bathymetries and the measured bathymetry near Duck, North Carolina is used for the numerical simulation. The REF/DIF and WANGLE models are examined. Statistical analyses of the bathymetry will be done. Bathymetries with the same statistical properties will be used to obtain the average wave properties and the fluctuations of the wave field. Results are compared with that of the traditional wave ray model. The relationship between the fluctuation in the wave field and the randomness of water depth is obtained.

GENERATION of WATER DEPTH

As an exact complete measurement of real bathymetry is almost impossible, a statistical analysis of the properties of bathymetry, such as the distribution of the depths and the correlation length scales in different directions, are needed. For the numerical study, different water depth profiles with different statistical properties are needed to study the wave field response.

The depth variation can be described statistically by its distribution and its correlation function. First we generated depth variations with uniform distribution, whose correlation function is the Dirac delta function (white noise) on a rectangular horizontal grid. The standard deviation is controlled to be some ratio of the mean water depth. Such variations are not related to the horizontal distance as the depths are taken firstly to be uncorrelated, and they lead unfortunately to rapid changes of water depth between grid points. As the grid size is reduced, larger depth gradients occur.

We also generated depth variations with Gaussian distributions and smooth correlation functions. Figure 1.a shows the generated correlation function in a 2-dimensional case. Its form is roughly similar to that of the bathymetry in Duck, NC. Correlation length is defined by the length at which the correlation function has the value around 0.6. It describes the relationships among the randomly varied depths. We will compare the correlation length to wave length to determine if there is an effect (such as Bragg scattering) when they are similar. The following formulae are used to calculate the generated depth variations.

Figure 1: A sampled correlation function and a generated water depth variations for 2-D case. a). Correlation function; b). Water depth variation. The correlation length is about 30 grid sizes.

$$h(x) = \sum_{i=1}^N A_i \sin(i\Delta kx + \epsilon_i)$$

$$A_i = \sqrt{2F(c)_i}; \Delta k = 2\pi/L$$

where N is the number of grids, the correlation function $c(x_1-x_2) = \langle h'(x_1)h'(x_2) \rangle$ is the ensemble average of $h'(x_1)h'(x_2)$ and it is assumed a function of $x_1 - x_2$, where h' is the depth variation and x_1 and x_2 are two locations, $F(c)$ is the Fourier transform of c , L is the length of the domain, and $\epsilon \in [0, 2\pi]$ is an uniformly distributed which serves as the random phase. Using different ϵ , we can obtain different results of the same probability properties. Figure 1.b shows one of the results.

The 3D case is similar to that of 2D. A correlation function is used to generate the depth variation. Note that the correlation function has two arguments x and y , and there are two correlation lengths, in x and y direction. We are going to compare these two lengths to the incident water wave length separately to see which one is more important. Figure 2 shows the results. The formulae used are

$$h(x, y) = \sum_m \sum_n A_{mn} \cos(k_{mx}x + k_{ny}y + \epsilon_{mn})$$

Figure 2: A sampled correlation function and a generated water depth variations for 3-D case. a). Correlation function; b). Water depth variation. The correlation lengths in the two directions are about 3 and 4.5 grid sizes, respectively.

$$A_{mn} = \sqrt{F(c)_{mn}}; kmx = \Delta k_x \cdot m; kny = \Delta k_y \cdot n; \epsilon_{mn} \in [0, 2\pi]$$

where $\Delta k_x = 2\pi/L_x$, $\Delta k_y = 2\pi/L_y$ and L_x and L_y are the size of the domain in x and y directions, respectively. The correlation function is $c(x_1 - x_2, y_1 - y_2) = \langle h'(x_1, y_1)h'(x_2, y_2) \rangle$.

NUMERICAL EXPERIMENTS AND RESULTS

Both REF/DIF and WANGLE models involve the effects of refraction, diffraction and shoaling. Weak nonlinearity can also be included. We examined the sensitivity of the two models, and then we studied the fluctuations of wave field response to different bottom changes. To demonstrate the importance of refraction and diffraction, we did two cases, one of which included only shoaling effects and the other included refraction, diffraction and shoaling effects. To study the model sensitivity, we compared Holthuijsen and Booij's results with our results obtained by REF/DIF and WANGLE models. Their results showed quantitatively that long-crested waves were affected more than short-crested waves by the bottom variation. In our cases, we only used plane waves for the comparison.

To study water wave fluctuations induced by the bottom randomness, we did some numerical experiments using the generated water depth and the measured bathymetry in Duck, NC.

Figure 3 shows the comparison of shoaling effect and the combination of refraction, diffraction and shoaling effects. We used the bathymetry in Duck, NC measured in August, 1994. (Thanks to Casey Church who supplied the data to us) In Fig. 3.a, the normalized amplitude variation calculated from the alongshore-averaged bathymetry by the REF/DIF model is shown. The incident wave is normal to the shoreline, so only shoaling effect is involved. The wave amplitude increases from 1 to about 1.09, a 9% increase. In Fig 3.b, we used the real bathymetry, with its alongshore variation. Now the fluctuation of the wave amplitude is much larger than that with shoaling effect only. The largest amplitude increase is about 55%, over 6 times larger larger than the shoaling-only case.

When water waves propagate in shallow water toward the shoreline, the water depth variation in the propagation direction causes the waves to shoal, while the variation in the transverse direction causes refraction and diffraction. It is the transverse variations that cause the variation of wave direction scattering and wave focusing. The transverse variation, rather than the onshore variation, is more important to the wave scattering.

Figure 3: REF/DIF model, nonlinear version. Wave period = 10 sec. a). Upper: Normalized wave amplitude; Lower: Alongshore-averaged water depth (Duck, NC); b). Comparison of shoaling effect and refraction, diffraction and effects. Real bathymetry

Figure 4: Results obtained by the HISWA model (Holthuijsen and Booij, 1994.) for the circular shoal. a). Wave heights along centerline profile for circular shoal with unperturbed bottom; b). The standard deviations of the wave height for the perturbed bottom.

Holthuijsen and Booij studied an idealized case numerically using the HISWA model. The bathymetry is a isotropic Gaussian-shaped shoal superimposed on

an otherwise flat horizontal bottom. The ambient depth is 20 m and the minimum depth over the shoal is 17 m. The width of the shoal is 6 km. The presence of the shoal causes the waves to focus behind it. For the cases when the bottom is perturbed, the superimposed variation on the bathymetric grid points is Gaussian uncorrelated noise of 0.5 m standard deviation, 2.9% of the minimum depth. The wave height of the incident wave is 5 m and the wave period is 10 sec. Holthuijsen and Booij considered both long- and short-crested incident waves. Only long-crested waves were simulated in our experiments. Their results are shown in Figure 4. Fig. 4.a shows the results of unperturbed bottom, the bathymetry profile and the wave amplitude profiles of long- and short-crested incident waves along the centerline which is parallel to the initial wave propagation direction and crosses the top of the shoal. Fig. 4.b shows the depth perturbation induced wave height standard deviations on the centerline, averaged by the results of 25 cases.

We can see both long- and short- waves focus at the same position, about 20,000 m behind the shoal. The wave height at the focusing point is 12.5 m for long-crested wave, 2.5 times larger than the initial wave height of 5 m. The standard deviation of the wave height is 2.5 m, half as the initial waves. But for short-crested waves, the focusing wave height and the wave fluctuation are much smaller.

Figure 5: Results obtained by the nonlinear version of the REF/DIF model for the circular shoal. a). Wave height along the centerline with unperturbed bottom and the average of the results of 25 perturbed bottoms; b). The standard deviation of the wave height for the perturbed bottom.

Using the REF/DIF and WANGLE models, both the linear and nonlinear versions, we replicated the same case. We obtained the wave field with an unperturbed bottom for each model and version. Then 25 cases were run with different perturbed bottoms to get the ensemble-averaged water wave height and standard deviation. The ensemble-averaged wave height was calculated by averaging the 25 cases. The ensemble-averaged standard deviation was calculated by computing the standard deviation for each of the 25 cases, as compared to the unperturbed case, and then averaging the results.

Results obtained by the nonlinear version of the REF/DIF model are shown in Fig. 5. The wave height at the focusing point is 6.3 m, 26% larger than that

Figure 6: Results obtained by the nonlinear version of the REF/DIF model for the circular shoal. Same conditions as that for Fig. 5.

of the incident wave. The maximum standard deviation is about 0.8 m, 16% of the initial wave height. It is even smaller than the result of HISWA model of the short-crested waves. The focusing happens earlier due to diffraction and nonlinear effects. These effects help to transfer wave energy to different locations and smooth down the roughness of the wave field.

Figure 7: Results obtained by the nonlinear version of the WANGLE model for the circular shoal. Same conditions as that for Fig. 5.

Fig. 6 shows the results obtained by the linear version of the REF/DIF model. For the unperturbed bottom, there seems to be wave breaking when waves are focusing behind the shoal. But there is no wave breaking with the perturbed bottom. The reason is that the random depth variations make wave refract and diffract before focusing behind the shoal. Wave energy is scattered to other directions and eventually the wave height at the focusing position is reduced, avoiding breaking. The breaking position is further behind the shoal than the focusing position obtained by the nonlinear version model. The only

difference between the two experiments is that nonlinear effect is not involved here. Nonlinearity can smooth down the amplitude variation, transfer wave energy to the area right behind the shoal, and make results more reasonable. The standard deviation shown in Fig. 6.b is very large around the breaking area due to the big difference between breaking and non-breaking waves.

We also studied the same case with WANGLE model. Fig.7 and Fig. 8 show the results of WANGLE model of nonlinear and linear versions, respectively.

Figure 8: Results obtained by the nonlinear version of the WANGLE model for the circular shoal. Same conditions as that for Fig. 5.

We can see the focusing is still very large, about 15m here, larger than than of HISWA model. However, the standard deviation is smaller even than that obtained by REF/DIF model. For these cases, WANGLE is not very sensitive to bottom perturbation, so it does not suffer as much from bathymetry errors. Results of the linear and the nonlinear versions are not quite different. WANGLE model is an angular spectrum model that is supposed to be applicable to those cases where the wave direction varies widely. It emphasizes diffraction and refraction effects.

As mentioned above, we generated two kinds of water depth variations to superimpose on flat bottoms: uniformly distributed uncorrelated variations and Gaussian distributed correlated variations. Using the generated water depth and the nonlinear REF/DIF model, we did some numerical studies on depth variation influence. Fig. 9 and Fig. 10 are the results of the first kind of variations. They are the normalized standard deviations of wave height for bottom perturbations of different orders and different gradients, respectively. We choose bottom perturbations as 1%, 5% and 10% related to the mean depth. The corresponding normalized amplitude standard deviations are 10%, 30% and 50% of the incident wave, respectively. It is not surprising to see the larger the perturbation is, the larger the amplitude fluctuation is. But the ratio between amplitude variation and bottom perturbation becomes smaller as the perturbation increases. The reason is that as the bottom variation increases, the diffraction and nonlinearity effects becomes larger and they scatter and transfer wave energy, hence reduce the relative wave height fluctuation. To get the results in Fig. 10, we used the same water depth but different grid sizes, 5m, 2.5m and 1.25m, decreasing by half. The grid sizes are much smaller than the wave length. After waves propa-

Figure 9: Amplitude standard deviations for different depth perturbations on a flat bottom, 1%, 5% and 10% of the mean water depth, respectively. Wave period = 5 sec. Mean water depth = 5 m. Grid size = 5 m. Incident wave amplitude = 0.5 m. REF/DIF, nonlinear version.

Figure 10: Amplitude standard deviations for different grid sizes, 5m, 2.5m and 1.25m, respectively. Wave period = 5 sec. Mean water depth = 5 m. Incident wave amplitude = 0.5 m. Depth perturbation = 5% of the mean depth. REF/DIF, nonlinear version.

gate over a very long distance, about 300 wave lengths, the amplitude variations approach roughly the same value. For large gradients, or rougher bottom surface, there are more grid points in one wave length and the wave field is more sensitive.

Results of the normal distributed and correlated water depth variations are shown in Fig. 11. The figures show the amplitude profiles in sections perpendicular to the initial wave direction. A normally distributed water depth can be described by its correlation function. We used water depths with different correlation lengths in different directions and examined how the wave field responds when the wave length (L) is similar to the correlation lengths in the wave propagation and the transverse directions (L_x and L_y). In Fig. 11.a, we fixed L_y and varied L_x ; in Fig. 11b, L_x was fixed and L_y was varied. The results of wave focusing of the three cases shown in Fig. 11a are not very different and bottom variation correlation length in wave direction does not affect the wave field much. Fig. 11.b shows that when L_y is much longer than wave length, the focusing is relatively small. When the two lengths are the same, focusing is large. So correlation length in the direction perpendicular to wave propagation is an important factor to the wave field. When the correlation length is much shorter than the wave length, the focusing is also fairly dominant. This is because for this case, the bottom is rougher, as there are more grid points in one wave length, and the wave fields are sensitive to this in short wave propagation distance.

Figure 11: Cross-section amplitude profiles obtained by the REF/DIF model, nonlinear version. L : water wave length, L_x and L_y : water depth correlation lengths in wave propagation and transverse directions, respectively. Wave period = 5 sec, Mean water depth = 5 m. Standard deviation of water depth = 0.5 m. Distance from where waves start: 700 m.

We also used the bathymetry in Duck, NC to study the influence of bottom randomness of different statistical properties. The correlation length is about 150 m in both alongshore and cross-shore directions. We used waves of different wave length for numerical studies. The results are similar to what we got from the generated water depth. When correlation length and wave length are similar, the effects on wave field is dominant. This can be observed quantitatively by the amplitude standard deviations. After waves propagate for certain distances (1

Figure 12: Cross-section amplitude profiles obtained by the REF/DIF model, nonlinear version, for incident waves of different wave periods T . Bathymetry in Duck, NC is applied. Distance from the incident waves, left figure: 1 km; right figure: 2 km.

km and 2 km), the amplitude standard deviations are 0.0323, 4.4, 2.5 and 0.0982, 13.2, 8.6 for waves with time periods of 5sec, 10sec and 23.5sec, respectively. When the two lengths are the the most similar, the standard deviation is the largest.

DISCUSSION AND CONCLUSIONS

We have shown that small water depth perturbation can cause large wave fluctuations based on the wave model used. Different numerical models are sensitive to depth variation in different ways, and models involving nonlinearity, refraction and diffraction effects can be applied to study the effects of random bottom variations, such as the REF/DIF and the WANGLE models. Large and rapid water depth variations cause large wave field fluctuations, and with the same variance, different statistical water depths have different effects on wave field. The effects of a Gaussian distributed bottom variation on wave field depends on its variance and correlation function. The numerical results show that correlation length in the direction perpendicular to water waves direction is important to the wave fluctuations. When it is similar to the incident wave length, the wave fluctuation becomes larger.

CHAPTER 59

INTEGRAL CONTROL DATA ASSIMILATION IN WAVE PREDICTIONS

L.H. Holthuijsen¹, N.Booij¹, M. van Endt¹, S. Caires², C. Guedes Soares²

ABSTRACT

In the present study a technique for assimilating observed wave data in numerical wave predictions is developed that exploits (a) the efficiency of a limited number of integral control variables and (b) the effectiveness of variational (model-consistent) assimilation. The formal procedure is independent of the type of control variables and of the wave model. The integral control variables in this study are chosen to represent large-scale errors in the driving wind fields and uncertainties in the wave model. The assimilation technique is validated with observations of the ERS-1 satellite altimeter and two waverider buoys in two consecutive storms in the Norwegian Sea. The assimilation of the observations reduced the errors in the predicted significant wave height at the buoy locations typically from 25% to 15%. The technique is also demonstrated with an simulation of swell prediction in the Indian Ocean based on simulated buoy data and satellite data.

INTRODUCTION

Good quality wave forecasts are often required for estimating the workability for coastal and offshore activities. The quality of these forecasts, which are usually based on numerical wave models can be improved by assimilating wave observations (Komen et al., 1994). In simple assimilation techniques (sequential techniques), observed waves are used to correct the model wind and waves locally and instantaneously. The effect is short-lived as the corrections are quickly lost in the uncorrected wind and waves elsewhere in the model. In the more advanced variational assimilation techniques the observed waves are used to correct the entire space-time structure of the wind in detail, which is more effective. This requires very large computer capacity. However, this detail in the corrections is not required for two reasons. First, the wind errors that affect the waves are highly correlated in space and time and second, the waves are an integral effect of the wind in which

¹ Delft University of Technology, Department of Civil Engineering, P.O. Box 5048, 2600 GA Delft, Netherlands.

² Lisbon University of Technology, Av. Rovisco Pais, 1096 Lisbon, Portugal

details of the wind are lost. In the present study a variational technique is developed that exploits this correlated and integral character of wind and waves by using integral control variables. It is efficient and seems therefore operationally feasible (e.g., all experiments of the present study were carried out on a personal computer). The technique is validated with an application in the Norwegian Sea and it is demonstrated with simulated data in the Indian Ocean.

TECHNIQUE

The essence of data assimilation in wave forecasting is that wave observations just prior to the forecast are used to obtain wind fields and wave fields that are as consistent as possible with both the first-guess wind field and the observed waves. The forecast system, including the driving wind fields, thus continuously adapts to the wave observations.

Assimilation techniques for wave forecasting are commonly divided into sequential techniques and variational techniques (e.g., Komen et al., 1994). In the sequential techniques the wave observations are used to correct the wind and the waves at each time level of the model without regard for the previous states of the model. Since the space-time structure of the modelled wave field is not taken into account, the results are not consistent with the dynamics of the wave model. The variational techniques do take the dynamics of the wave model into account. Since the generation, dissipation and propagation of the waves in the entire geographic model domain is thus accounted for, the effect of these techniques is expected to be of longer duration. The most advanced of these techniques is the adjoint technique which determines a very large number of local corrections (in fact, every single wind vector in space and time, e.g., de las Heras, 1994). The variational technique presented here combines (a) the effectiveness of the variational techniques by correcting the driving wind field (consistency with the model dynamics) and (b) the efficiency of the sequential techniques using a relatively small number of corrections (compared with the conventional adjoint techniques). In the present study the chosen control variables are: (1) a shift in time and space of the wind field and (2) a common correction to all wind vectors and (3) a model coefficient representing wave dissipation. These control variables are taken to be constant in time and space during the assimilation period. To improve the subsequent forecast, the assimilated values of the control variables are extrapolated into the forecast.

The assimilation technique optimizes the driving wind field and the corresponding wave field taking into account (a) the differences between the observed and computed waves and (b) the confidence in the driving wind fields and the wave model itself. These aspects are quantified in a cost function J :

$$J = J^x + J^y \quad (1)$$

where J^x represents the differences (that need to be minimized) between the observed and the modelled waves and J^y represents the corrections (that will be

penalized) that are needed in the wind field and the wave model. These differences and corrections are quantified as follows.

- (i) In the following the observed wave field is represented by a set of observed wave parameters such as significant wave height, mean wave frequency etc. Each of these may be observed at different locations and times. They are indicated as χ_i^o where subscript i is the realization index. The modelled waves are similarly represented by the same set of wave parameters χ_i at the same locations and times as χ_i^o . The penalty is expressed as

$$J^x = \sum_i \sigma_{\chi_i}^{-2} (\chi_i^o - \chi_i)^2 \quad (2)$$

where σ_{χ_i} is the standard deviation of the error of the wave parameter χ_i .

- (ii) The corrections that are required in the driving wind fields and in the wave model can be represented as corrections of a set of control variables such as a shift in the location of a storm or a coefficient in the wave model. Each such control variable is indicated as ψ_j . Its value prior to the assimilation is indicated as its first-guess value ψ_j^f . Confidence in these values is expressed by penalizing the corrections that are needed in the assimilation, again with a quadratic measure with the variance of the errors in the control variables as weights:

$$J^\psi = \sum_j \sigma_{\psi_j}^{-2} (\psi_j - \psi_j^f)^2 \quad (3)$$

where σ_{ψ_j} is the standard deviation of the error of the control variable ψ_j (representing the confidence in the control variable).

The assimilation consists essentially of minimizing the cost function J which can be interpreted as adjusting the driving wind field and the wave model with a certain penalty, to produce the best-fit wave field. This minimum is estimated with one small perturbation per control variable in the driving wind field and in the wave model. The optimum values of the control variables thus obtained are used to carry out the fully assimilated wave forecast. Details of the method are given in Holthuijsen et al. (1996).

The assimilation is carried out with the original wave model (no adaptations). The computer storage capacity for this technique is therefore equal to that required for one conventional model run. It follows from the above that the number of model runs with the wave model is equal to the number of control variables plus one. The technique is therefore efficient only when a limited number of control variables is considered. This condition is fulfilled if only a few integral control variables are used.

VALIDATION

The technique is validated in two storms in the Norwegian Sea (1 - 10 March, 1993). For the data assimilation and the verification, observations of the significant wave height (values of up to 7.5 m) from two waverider buoys and from the altimeter of the ERS-1 satellite are used (Fig. 1). The wave model is the second-generation model DOLPHIN-B of Holthuijsen and de Boer (1988). The integral control variables that were chosen for this validation experiment, are the ones mentioned above. They were taken to be constant in time and space (extrapolated into the forecast).

Fig. 1 The area covered by the wave model with the locations SCOTT (S) and HALTENBANKEN (H) and the ERS-1 tracks that were used in this study during the assimilation period 3 - 8 March, 1993.

Several combinations of the buoy and satellite data have been used. The effect is evaluated by comparing the computed significant wave height (before and after assimilation) with the observed significant wave height both in the assimilation period and in the forecast (e.g. Fig. 2 for the HALTENBANKEN location). Table 1 presents some of the results in terms of the scatter index (rms-difference normalized with the mean observed significant wave height). Day 1 - 3 were used as spin-up of the wave model. Day 4 - 8 is the assimilation period. Day 9 - 10 is the forecast period. It is obvious that the agreement between computed and observed

waves improves considerably both in the assimilation period and in the forecast, in particular in the forecast at location SCOTT where the scatter index drops from 37.2% to 12.4% (buoy assimilated) or 17.1% (buoy and satellite assimilated).

Fig. 2 The observed significant wave height at HALTENBANKEN (waverider buoy) with the first-guess significant wave height and the assimilated significant wave height (HALTENBANK buoy only) in the assimilation period and in the forecast period.

DEMONSTRATION

The assimilation technique is demonstrated in the Indian Ocean with a simulated swell forecast at a near-shore location (10 km offshore) off Kerala (southern India, Fig. 3). All wave information in this demonstration has been simulated with the wave model. A period has been selected with a storm south of Madagascar that produced high swell conditions off Kerala in July of 1995 (Fig. 3). The aim of the assimilation is to improve the forecast of crossing the 1 m threshold of the swell wave height at the near-shore location. The observed swell wave height (defined as $H_{swell} = 4 m_{0.1}^{1/2}$ where $m_{0.1}$ is the variance of frequencies less than 0.1 Hz) is simulated with actual (not simulated) 12-hour wind forecasts of the European Centre for Medium Range Weather Forecasts (ECMWF, Reading, England). The "observed" swell wave heights at the near-shore location are given in Fig. 4. Two cases are considered. In the first case, simulated wave data from one buoy, located 200 km south-west off Kerala are used. In the second case, simulated wave data from the ERS-1 satellite are used. For the assimilation the same control variables are used as in the validation experiment, except the wave dissipation coefficient which is not included (wave physics cannot be inferred from simulated wave data; the value of this coefficient is set at the value obtained in the above validation experiment).

Fig. 3 The area covered by the wave model in the Indian Ocean with the wind field analysis of ECMWF showing the storm south of Madagascar that generated the high swell conditions at Kerala (India). The wave rays indicate great circles along which swell can propagate towards Kerala (the ones shown here are used in the wave model). Note the coinciding directions of wind and swell rays in the storm.

Fig. 4 The "observed" (simulated) swell wave height at the near-shore location off Kerala with the first-guess swell wave height and the assimilated swell wave height (off-shore buoy and satellite) in the assimilation period and in the forecast period.

The first-guess swell wave height (including the first-guess forecast) at the near-shore location is simulated with the wind analyses of ECMWF (to obtain wave fields that are somewhat different from the "observed" wave fields). It is obvious from Fig. 4 that this first-guess, at July 7, 00:00 UTC, predicts the crossing of the 1 m threshold on July 9th more than 24 hours too late. The result of assimilating the off-shore buoy data over a period of 5 days (sampled at 6 hour interval) is to predict the time of threshold-crossing only 9 hours late. This is an improvement of 17 hours. The scatter index of the swell wave height at the near-shore location reduces significantly e.g. in the forecast from 30.9% to 19.2% (Table 2). The satellite data were simulated at the actual tracks of the ERS-1 over a period of 23 days (15 days spin-up, 5 days assimilation and 3 days forecast) with the same wind fields but sampled every 30 min when the satellite was (a) over the Indian Ocean and (b) the observation was on a great circle through the near-shore location off Kerala (so that swell could potentially affect the Kerala location). This resulted in about 6 observations per day, or 88 in total during the 15 day assimilation period (Fig. 5). The effect of assimilating these data on predicting the threshold-crossing is somewhat uncertain as the corrected swell wave height fluctuates around this level (Fig. 4). In terms of the scatter index, the effect is small in the assimilation period but reasonable in the forecast period (Table 2). It is speculated that the poor performance in the assimilation period is due to the fact that 6 observations per day

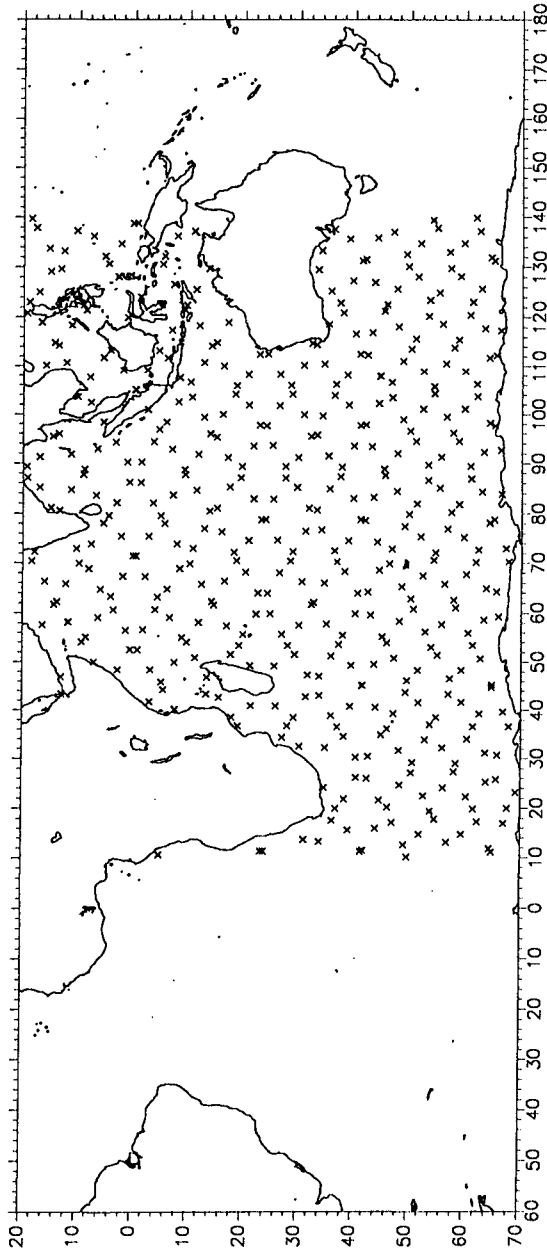

Fig. 5 Locations at which the wave data from the ERS-1 satellite were simulated for the demonstration in the Indian Ocean. The locations are at 30 min interval and on great circles centered at the near-shore location off Kerala (potentially affecting the waves there).

over such a large area is not sufficient to detect and correct rather local (on the scale of the Indian Ocean) errors in the wind field (the timing or location of the storm south of Madagascar that generated the swell).

CONCLUSIONS

A variational data assimilation technique has been developed based on the notion of integral control variables. It has been shown to be rather effective and efficient in the sense that the forecasts of the significant wave height in the validation experiment improved considerably with only a small fraction of the computer effort that is normally involved in variational techniques. Adding satellite data to the (buoy) assimilation in this validation experiment did not improve the forecasts at the buoy locations. This is possibly due to the fact that the satellite data contribute to the overall improvement of the wave field rather than to the improvement at one particular (buoy) location. The demonstration of the assimilation technique for swell forecasting in the Indian Ocean showed that for satellite data to be effective, more than only a few satellite observations per day are required over such extensive areas as the Indian Ocean.

ACKNOWLEDGEMENTS

We are grateful to DELFT HYDRAULICS, in particular H. Wensink for providing us with the buoy data at SCOTT and for obtaining the permission from the owners (Heeremac V.O.F.) to use the data. We are similarly indebted to S. Barstow of OCEANOR A/S who provided us with the buoy data of HALTENBANKEN. These data were collected in the framework of the SEAWATCH Europe project and put at our disposal under the terms of reference of the WAVEMOD project that was funded by the European Commission in the MAST-II programme under contract N°. CT92/0025. For permission to use these data we are indebted to OCEANOR A/S. The altimeter data were provided by the Faculty of Aerospace Engineering of the Delft University of Technology with the support and assistance of E. Wisse, R. Scharroo and M. Naeije who we sincerely thank for this. We also thank S. Kruisinga of the Royal Netherlands Meteorological Institute (KNMI) for providing us with the wind fields of ECMWF (the European Centre for Medium Range Weather Forecasts). Permission from KNMI to use these wind fields is gratefully acknowledged. This study was partly funded by the WAVEMOD project that was funded by the European Commission in the MAST-II programme under contract N°. CT92/0025.

CHAPTER 60

TWO-DIMENSIONAL ANALYSIS OF WAVE TRANSFORMATION BY RATIONAL-APPROXIMATION-BASED, TIME-DEPENDENT MILD-SLOPE EQUATION FOR RANDOM WAVES

Toshimasa Ishii¹, Masahiko Isobe² and Akira Watanabe²

ABSTRACT

The method for determining coefficients in the rational approximation is improved and a numerical method is developed for application of time-dependent mild-slope equation for random waves to two-dimensional wave fields. The validity of the method is verified through comparisons with analytical solutions in typical situations and an experimental result of wave transformation around a man-made island on a uniform slope.

1. INTRODUCTION

Time-dependent mild-slope equations for random waves were derived from Berkhoff's mild-slope equation by approximating frequency-independent expressions to frequency-dependent coefficients (Kubo *et al.*, 1992; Kotake *et al.*, 1992; Isobe, 1994). It can be used to simulate directly the time evolution of irregular waves. The approximation by a rational function (Padé approximation) has a high accuracy to the coefficient over a wide frequency range (Isobe, 1994). However, the method for determining the coefficients in the rational function and the numerical calculation method for applying to two-dimensional problems were not established. In this paper, a method was developed to apply the time-dependent mild-slope equation for random waves to practical problems. The results of calculations are compared with analytical solutions in typical situations and an experimental result of wave transformation around a man-made island on a uniform slope.

2. A TIME-DEPENDENT MILD-SLOPE EQUATION FOR RANDOM WAVES BASED ON RATIONAL APPROXIMATION

The governing equation is as follows:

$$\nabla^2 \tilde{\phi} - ia_1 \nabla^2 \left(\frac{\partial \tilde{\phi}}{\partial t} \right) + (b_0 + ic_0) \tilde{\phi} + i(b_1 + ic_1) \frac{\partial \tilde{\phi}}{\partial t} - b_2 \frac{\partial^2 \tilde{\phi}}{\partial t^2} = 0 \tag{1}$$

where t is the time, ∇ the differential operator in the horizontal two directions, i the imaginary unit and $\tilde{\phi}$ the unknown variable which is related to complex amplitude $\hat{\phi}$ as follows.

$$\tilde{\phi} = \hat{\phi} e^{-i\omega' t}, \quad \omega' = \omega - \bar{\omega} \tag{2}$$

where $\bar{\omega}$ is a representative angular frequency, ω and ω' the angular frequency and its deviation from $\bar{\omega}$, a_1, b_0, b_1 and b_2 the coefficients in the rational function in (4) which is approximated to k^2 (k : wave number) in a Helmholtz equation (3) (Radder, 1979), and c_0 and c_1 the energy dissipation term to model the wave breaking.

$$\nabla^2 \tilde{\phi} + k^2 \tilde{\phi} = 0 \tag{3}$$

$$k^2 = \frac{b_0 + b_1 \omega' + b_2 \omega'^2}{1 - a_1 \omega'} \tag{4}$$

3. IMPROVEMENT OF METHOD FOR DETERMINING COEFFICIENTS

3. 1. Condition of numerical stability

For monochromatic progressive waves, $\tilde{\phi}$ is expressed as

$$\tilde{\phi} = a e^{i(kx \cos \theta + ky \sin \theta - \omega' t)} \tag{5}$$

Then, equation(1) becomes

$$-k^2 + a_1 k^2 \omega' + (b_0 + ic_0) + (b_1 + ic_1) \omega' + b_2 (\omega')^2 = 0 \tag{6}$$

Equation(6) can be solved for ω' as

$$\omega' = \left\{ -(a_1 k^2 + b_1 + ic_1) \pm \sqrt{(a_1 k^2 + b_1 + ic_1)^2 - 4b_2(-k^2 + b_0 + ic_0)} \right\} / (2b_2) \tag{7}$$

To avoid numerical divergence, $Im\{\omega'\} \leq 0$. This requires that the magnitude of the imaginary part for $\sqrt{\quad}$ should not exceed c_1 . Let the real and imaginary parts in the $\sqrt{\quad}$ be denoted by X and Y , respectively, then the condition is written as

$$X \geq 0 \quad (c_1 = 0) \quad (8)$$

$$X \geq (Y/2c_1)^2 - c_1^2 \quad (c_1 > 0) \quad (9)$$

The above condition should be satisfied for an arbitrary k , which yields

$$b_1^2 - 4b_0b_2 \leq 0, \quad c_0 = 0 \quad (c_1 = 0) \quad (10)$$

$$\left(\frac{c_0}{c_1}\right)^2 - \left(\frac{b_1}{b_2}\right)\left(\frac{c_0}{c_1}\right) + \left(\frac{b_0}{b_2}\right) \leq 0 \quad (c_1 > 0) \quad (11)$$

In a previous study (Isobe, 1994), equal signs were taken for the sake of convenience within the above restrictions. Then,

$$b_2 = b_1^2/(4b_0) \quad (12)$$

$$c_1 = (2b_2/b_1)c_0 \quad (13)$$

However, numerical divergence occurs due to round-off error if the coefficients are determined by the above equations. An example is in the calculation of wave propagation over a submerged circular shoal. In the present study, the conditions were modified to avoid the numerical instability as follows:

$$b_1^2 - 6b_0b_2 \leq 0, \quad c_0 = 0 \quad (c_1 = 0) \quad (14)$$

$$\left(\frac{c_0}{c_1}\right)^2 - \left(\frac{b_1}{b_2}\right)\left(\frac{c_0}{c_1}\right) + \frac{3}{2}\left(\frac{b_0}{b_2}\right) \leq 0 \quad (c_1 > 0) \quad (15)$$

Within the above restrictions, we take equal signs. Then,

$$b_2 = b_1^2/(6b_0) \quad (16)$$

$$c_1 = (2b_2/b_1)c_0 \quad (17)$$

By considering the above two equations, independent parameters are a_1 , b_0 , b_1 and c_0 .

3. 2. Determination of coefficients

The coefficients a_1 , b_0 , b_1 and b_2 can be determined from three sets of ω' and k which satisfy the dispersion relation exactly and equation(16) which is the condition to avoid numerical divergence. In the previous method (Isobe, 1994),

equation(4) was applied piece by piece to three intervals of frequency range to approximate dispersion relation accurately, but it required extensive computational time for calculation of two-dimensional wave transformation of random waves. In the present study, equation(4) is applied for the whole range of frequency and the coefficients are determined by using three sets of ω' and k which satisfy the dispersion relation exactly on $f/f_p = 0.76, 1.22, 1.92$, where f is frequency, f_p the peak frequency. Figure 1 shows the dispersion relation which was obtained by applying equation (4). The relative error due to the method is at most 10 % in the range of $f/f_p = 0.68 \sim 2.07$ which occupies the major portion of wave energy in frequency spectrum.

When we determine the values of coefficients a_1, b_0, b_1 and b_2 , we compensate for the error included in the finite difference form of the equation in the ADI method of which the detail is given later. The finite difference expressions for each term in equation(1) are related with the corresponding derivatives as

$$\left. \frac{\partial^2 \tilde{\phi}}{\partial x^2} \right|_{\text{F.D.}} = \left(\frac{\sin(\frac{1}{2}k\Delta x \cos \theta)}{\frac{1}{2}k\Delta x \cos \theta} \right)^2 \left(\cos(\frac{1}{2}\omega'\Delta t) \right)^2 \frac{\partial^2 \tilde{\phi}}{\partial x^2} \quad (18)$$

$$\left. \frac{\partial^2 \tilde{\phi}}{\partial y^2} \right|_{\text{F.D.}} = \left(\frac{\sin(\frac{1}{2}k\Delta y \sin \theta)}{\frac{1}{2}k\Delta y \sin \theta} \right)^2 \left(\cos(\frac{1}{2}\omega'\Delta t) \right)^2 \frac{\partial^2 \tilde{\phi}}{\partial y^2} \quad (19)$$

$$\left. \frac{\partial^3 \tilde{\phi}}{\partial x^2 \partial t} \right|_{\text{F.D.}} = \left(\frac{\sin(\frac{1}{2}k\Delta x \cos \theta)}{\frac{1}{2}k\Delta x \cos \theta} \right)^2 \frac{\sin(\frac{1}{2}\omega'\Delta t)}{\frac{1}{2}\omega'\Delta t} \frac{\partial^3 \tilde{\phi}}{\partial x^2 \partial t} \quad (20)$$

$$\left. \frac{\partial^3 \tilde{\phi}}{\partial y^2 \partial t} \right|_{\text{F.D.}} = \left(\frac{\sin(\frac{1}{2}k\Delta y \sin \theta)}{\frac{1}{2}k\Delta y \sin \theta} \right)^2 \frac{\sin(\frac{1}{2}\omega'\Delta t)}{\frac{1}{2}\omega'\Delta t} \frac{\partial^3 \tilde{\phi}}{\partial y^2 \partial t} \quad (21)$$

$$\left. \tilde{\phi} \right|_{\text{F.D.}} = \left(\frac{2}{3} \cos \omega'\Delta t + \frac{1}{3} \right) \tilde{\phi} = \beta_0 \tilde{\phi} \quad (22)$$

Figure 1: Accuracy of Padé approximation to kh

$$\left. \frac{\partial \tilde{\phi}}{\partial t} \right|_{\text{F.D.}} = \frac{\sin \omega' \Delta t}{\omega' \Delta t} \frac{\partial \tilde{\phi}}{\partial t} = \beta_1 \frac{\partial \tilde{\phi}}{\partial t} \tag{23}$$

$$\left. \frac{\partial^2 \tilde{\phi}}{\partial t^2} \right|_{\text{F.D.}} = \left(\frac{\sin(\frac{1}{2} \omega' \Delta t)}{\frac{1}{2} \omega' \Delta t} \right)^2 \frac{\partial^2 \tilde{\phi}}{\partial t^2} = \beta_2 \frac{\partial^2 \tilde{\phi}}{\partial t^2} \tag{24}$$

where |_{F.D.} denotes the finite difference expressions. The wave directions θ at calculation grid points are assumed as 45°, which makes the values of correction factors the same for x - and y -directions and closer to unity. Under the condition that $\Delta x = \Delta y = \Delta l$, the finite difference expressions and correction factors are as follows:

$$\left. \begin{aligned} \left. \frac{\partial^2 \tilde{\phi}}{\partial x^2} \right|_{\text{F.D.}} = \alpha_1 \frac{\partial^2 \tilde{\phi}}{\partial x^2}, \quad \left. \frac{\partial^2 \tilde{\phi}}{\partial y^2} \right|_{\text{F.D.}} = \alpha_1 \frac{\partial^2 \tilde{\phi}}{\partial y^2} \\ \left. \frac{\partial^3 \tilde{\phi}}{\partial x^2 \partial t} \right|_{\text{F.D.}} = \alpha_2 \frac{\partial^3 \tilde{\phi}}{\partial x^2 \partial t}, \quad \left. \frac{\partial^3 \tilde{\phi}}{\partial y^2 \partial t} \right|_{\text{F.D.}} = \alpha_2 \frac{\partial^3 \tilde{\phi}}{\partial y^2 \partial t} \end{aligned} \right\} \tag{25}$$

$$\alpha_1 = \left(\frac{\sin(\frac{1}{2\sqrt{2}} k \Delta l)}{\frac{1}{2\sqrt{2}} k \Delta l} \right)^2 \left(\cos(\frac{1}{2} \omega' \Delta t) \right)^2, \quad \alpha_2 = \left(\frac{\sin(\frac{1}{2\sqrt{2}} k \Delta l)}{\frac{1}{2\sqrt{2}} k \Delta l} \right)^2 \frac{\sin(\frac{1}{2} \omega' \Delta t)}{\frac{1}{2} \omega' \Delta t} \tag{26}$$

Then, instead of equation (6), the finite difference equation for equation(1) implies

$$- \alpha_1 k^2 + a_1 \alpha_2 k^2 \omega' + b_0 \beta_0 + b_1 \beta_1 \omega' + b_2 \beta_2 \omega'^2 = 0 \tag{27}$$

for $c_0 = c_1 = 0$. By rearranging the equation with $b_2 = b_1^2/6b_0$, the equation is written

$$- b^* \alpha_1 k^2 + a^* \alpha_2 k^2 \omega' + \beta_0 + \xi \beta_1 \omega' + \frac{1}{6} \beta_2 \xi^2 \omega'^2 = 0 \tag{28}$$

where

$$b^* = 1/b_0, \quad \xi = b_1/b_0, \quad a^* = a_1/b_0 \tag{29}$$

Three independent parameters can be determined from three set of exact values.

Since equation (29) is linear in a^* and b^* , these parameters can be eliminated to yield a parabolic equation in terms of ξ . After solving for ξ , we can determine a_1, b_0, b_1 and b_2 by equations (16) and (29).

4. METHOD OF NUMERICAL CALCULATION

The ADI method is employed in the numerical calculation to achieve high accuracy in a reasonable computational time. The calculation is carried out alternately in the x - and y -direction. In the discretization by the ADI method, the term $\nabla^2 \tilde{\phi}$ cannot be ensured a second-order accuracy in time. In the present study, the term is averaged over time to ensure the accuracy. The finite difference equations of the equation (1) in the x - and y -directions are written

(t+1 time step : x -direction)

$$\begin{aligned}
 & \frac{1}{2} \left(\frac{\tilde{\phi}_{i-1,j}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i+1,j}^{t+1}}{(\Delta x)^2} + \frac{\tilde{\phi}_{i-1,j}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i+1,j}^t}{(\Delta x)^2} \right) \\
 & - ia_1 \frac{(\tilde{\phi}_{i-1,j}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i+1,j}^{t+1}) - (\tilde{\phi}_{i-1,j}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i+1,j}^t)}{(\Delta x)^2 \Delta t} \\
 & + \frac{1}{2} \left(\frac{\tilde{\phi}_{i,j-1}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i,j+1}^t}{(\Delta y)^2} + \frac{\tilde{\phi}_{i,j-1}^{t-1} - 2\tilde{\phi}_{i,j}^{t-1} + \tilde{\phi}_{i,j+1}^{t-1}}{(\Delta y)^2} \right) \\
 & - ia_1 \frac{(\tilde{\phi}_{i,j-1}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i,j+1}^t) - (\tilde{\phi}_{i,j-1}^{t-1} - 2\tilde{\phi}_{i,j}^{t-1} + \tilde{\phi}_{i,j+1}^{t-1})}{(\Delta y)^2 \Delta t} \\
 & + (b_0 + ic_0) \frac{\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i,j}^t + \tilde{\phi}_{i,j}^{t-1}}{3} + i(b_1 + ic_1) \frac{\tilde{\phi}_{i,j}^{t+1} - \tilde{\phi}_{i,j}^{t-1}}{2\Delta t} \\
 & - b_2 \frac{\tilde{\phi}_{i,j}^{t+1} - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i,j}^{t-1}}{(\Delta t)^2} = 0
 \end{aligned} \tag{30}$$

(t+2 time step : y-direction)

$$\begin{aligned}
 & \frac{1}{2} \left(\frac{\tilde{\phi}_{i-1,j}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i+1,j}^{t+1}}{(\Delta x)^2} + \frac{\tilde{\phi}_{i-1,j}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i+1,j}^t}{(\Delta x)^2} \right) \\
 & - ia_1 \frac{(\tilde{\phi}_{i-1,j}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i+1,j}^{t+1}) - (\tilde{\phi}_{i-1,j}^t - 2\tilde{\phi}_{i,j}^t + \tilde{\phi}_{i+1,j}^t)}{(\Delta x)^2 \Delta t} \\
 & + \frac{1}{2} \left(\frac{\tilde{\phi}_{i,j-1}^{t+2} - 2\tilde{\phi}_{i,j}^{t+2} + \tilde{\phi}_{i,j+1}^{t+2}}{(\Delta y)^2} + \frac{\tilde{\phi}_{i,j-1}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i,j+1}^{t+1}}{(\Delta y)^2} \right) \\
 & - ia_1 \frac{(\tilde{\phi}_{i,j-1}^{t+2} - 2\tilde{\phi}_{i,j}^{t+2} + \tilde{\phi}_{i,j+1}^{t+2}) - (\tilde{\phi}_{i,j-1}^{t+1} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i,j+1}^{t+1})}{(\Delta y)^2 \Delta t} \\
 & + (b_0 + ic_0) \frac{\tilde{\phi}_{i,j}^{t+2} + \tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i,j}^t}{3} + i(b_1 + ic_1) \frac{\tilde{\phi}_{i,j}^{t+2} - \tilde{\phi}_{i,j}^t}{2\Delta t} \\
 & - b_2 \frac{\tilde{\phi}_{i,j}^{t+2} - 2\tilde{\phi}_{i,j}^{t+1} + \tilde{\phi}_{i,j}^t}{(\Delta t)^2} = 0
 \end{aligned} \tag{31}$$

where (i, j) is the grid number in the (x, y) coordinate system, t the time, Δx and Δy the grid size in x - and y -direction, respectively.

5. NUMERICAL RESULTS

As for the frequency spectrum and the directional spreading function, the Bretschneider-Mitsuyasu-type and the Mitsuyasu-type were employed. The incident waves consisted of 1000 components and were given by the single summation method.

5. 1. Refraction

The present method was applied to the calculation of refraction of multi-directional irregular waves on 1/50 slopes. The significant deepwater wave height and period are 1.0m and 8.0s. The principal wave direction is normal to the shoreline (0°). The maximum directional concentration parameter, S_{max} , is 10 in deepwater. In this case, the analytical solution can be obtained by means of linear superposition of the spectral components by Snell's law. Figure 2 and 3 compare the two-dimensional and cross-shore distributions of the significant wave height, respectively. Dashed lines show analytical solution and solid lines represent the results of numerical calculation. Good agreement is observed.

Figure 2: Significant wave height distribution due to refraction

Figure 3: Significant wave height cross-shore distribution due to refraction

5. 2. Diffraction

Diffraction coefficients of multi-directional irregular waves for a semi-infinite breakwaters and through a breakwater gap have been calculated by Goda *et al.* (1978) by superposing analytical solutions. In the calculation, Bretschneider-Mitsuyasu-type frequency spectrum and Mitsuyasu-type directional distribution function are used. Dashed lines in Figures 4 and 5 show the results with the maximum directional concentration parameter, $S_{max} = 10$. In Figure 4, L denotes the wavelength corresponding to the significant wave period. In Figure 5, B denotes the gap width and this figure shows the case of $B/L=8$. Solid lines represent the results of the present method. These lines agree well with the dashed lines.

Figure 4: Diffraction coefficient around a semi-infinite breakwater for irregular waves

Figure 5: Diffraction coefficient around a breakwater gap for irregular waves (A gap width of 8 significant wavelength)

5. 3. Submerged circular shoal on a constant bottom

When waves propagate over a submerged circular shoal, the phenomenon of combined refraction-diffraction of waves occurs. To illustrate the capability of the present numerical model for the phenomenon, we compared the present results with that obtained by using the parabolic equation for a submerged circular shoal (Serizawa *et al.*, 1990). Figure 6 shows a submerged circular shoal on a constant depth. The constant water depth is 15m, the water depth at the peak of the circular shoal with radius 160m is 5m. Serizawa *et al.* (1990) calculated for this case. The significant wave height and period are 1.0m and 5.1s. The principal wave direction is in the positive y -axis (0°). The maximum value S_{\max} of the parameter S in the Mitsuyasu-type directional spreading function was 10. Significant wave height distributions are presented in Figures 7 and 8, to compare with the previous numerical result. Good agreement is observed.

Figure 6: Sketch of submerged circular shoal on a constant bottom

5. 4. Wave breaking

Breaking wave model used is the same as Isobe (1987). The calculation of wave breaking was carried out in the cross-shore wave transformation problem for uni-directional irregular waves. The slope is 1/50. The significant wave period is 8.0s. The significant deepwater wave heights are 2.0m and 4.0m. In Figure 9, dashed lines show the results of calculation and solid lines show the results by Goda (1975). In the figure, H_0 is the significant wave height in deep water and h the water depth. The effect of wave nonlinearity and wave setup in shallow water is neglected in the present method. By considering this, the results seems to be in reasonable agreement with the results by Goda.

6. WAVE HEIGHT DISTRIBUTION AROUND A MAN-MADE ISLAND

Numerical calculation of wave transformation around a rectangular man-made island on 1:50 slope is performed. It is an island of 1km long in the alongshore direction and 0.5km wide, and located about 1km from the coastal line. Hydraulic model tests with a multi-directional wave maker were carried out by Central Research Institute of the Electric Power Industry, Japan (Ikeno *et al.*, 1995) to investigate effects of the irregularity and directional spreading of waves behind the man-made island. The model is 1/150 in scale and the island is 6.6m long and 3.3m wide. The water depth at the man-made island is 20m at prototype scale which corresponds to 15cm at model scale. Side walls in the laboratory basin are installed on the slope along both edges of the wave maker, preventing waves from being diffracted.

Numerical calculation is performed under the same condition as that of the experiment. The offshore significant wave height and period are 9.2m and 14.3s. As for the frequency spectrum and the directional spreading function, the Bretschneider-Mitsuyasu-type and the Mitsuyasu-type were employed. The maximum values S_{\max} of the parameter S in the Mitsuyasu-type directional spreading function were 25. The incident waves consisted of 512 components and were given by the single summation method, whereas input signal to each segment of wave maker was computed by superposing component waves with 512 frequencies and 90 directions by the double summation method.

Figure 10 and 11, respectively, depict the numerical result and the experimental result (Ikeno *et al.*, 1995) for significant wave height distribution. Figure 12 compares the longshore distributions of the significant wave height. The validity of the numerical model is verified through comparison with the experimental result.

7. CONCLUSION

We have proposed a method for determining coefficients in the rational approximation and an efficient numerical calculation method for applying the time-dependent mild-slope equation for random waves to two-dimensional problems. The results of numerical calculations were compared with analytical and experimental results, which confirmed the validity of the present method.

Figure 10: Calculation result (The ratio of significant wave height to incident wave height, $(H_{1/3})_0 = 9.2\text{m}$, $T_{1/3} = 14.3\text{s}$, $S_{\text{max}} = 25$, $\theta_p = 0^\circ$)

CHAPTER 61

NONLINEAR WAVE TRANSFORMATION DUE TO A SUBMERGED BREAKWATER

Masahiko Isobe¹, Akira Watanabe¹ and Shogo Yamamoto²

Abstract

A nonlinear model of wave transformation due to a submerged breakwater is developed on the basis of the nonlinear mild-slope equations. Numerical computation shows that significant amount of wave energy can be transferred from the fundamental component to higher harmonics by adjusting configuration of the submerged breakwater. In case of oblique incidence, wave direction as well as wave period changes due to the breakwater. These results implies the possibility to control wave period and direction as well as wave height.

1 Introduction

When waves propagate in a region of rapidly changing depth such as over a submerged breakwater, higher harmonic components are generated due to nonlinear effect. Various numerical simulations have been carried out for nonlinear wave transformation due to a submerged breakwater (Ohyama and Nadaoka, 1992, 1994; Tsubota *et al.*, 1994). This implies that submerged breakwaters can change and control characteristics of waves such as wave height, period and direction, which can be utilized in coastal engineering. Since floating breakwaters are, in general, effective for controlling only short period waves, combination of submerged and floating breakwaters may become an efficient breakwater system. Change of frequency spectrum over an offshore bar is an essential factor in predicting wave field and resultant wave-induced nearshore current. These indicate the importance to study wave transformation due to a submerged breakwater.

Since generation of higher harmonics is a strongly nonlinear phenomenon, it cannot be reproduced by linear or weakly nonlinear wave theories. Isobe (1994) derived a set of nonlinear mild-slope equations which includes full nonlinearity and full dispersion. In the present study, numerical simulations are performed based on the nonlinear mild-slope equations to examine the function of a submerged breakwater to control not only wave height but also wave period and direction.

2 Basic Equations and Boundary Conditions

2.1 Nonlinear mild-slope equation

Fully nonlinear and fully dispersive wave theories have been developed by Nadaoka *et al.* (1994), Nochino (1994) and Isobe (1994) among which the nonlinear mild-slope equations derived by Isobe (1994) is employed in the following numerical simulation.

¹Dept. of Civil Eng., Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan.

²Penta-Ocean Construction Inst. of Tech., Nishinasuno-machi, Nasu-gun, Tochigi 329-27, Japan.

In deriving the nonlinear mild-slope equations, the velocity potential, ϕ , is expanded into a series in terms of a set of vertical distribution functions, Z_α , which are given a priori:

$$\phi(\mathbf{x}, z, t) = \sum_{\alpha=1}^N Z_\alpha(z; h(\mathbf{x})) f_\alpha(\mathbf{x}, t) \equiv Z_\alpha f_\alpha \quad (1)$$

where h is the water depth, $\mathbf{x} = (x, y)$ the horizontal coordinates, z the vertical coordinate, t the time, and N the total number of terms.

By substituting the above expression into the Lagrangian defined by Luke (1967), applying the variational principle, and neglecting terms of the second order in bottom slope, the following equations can be obtained:

$$g\eta + Z_\beta^\eta \frac{\partial f_\beta}{\partial t} + \frac{1}{2} Z_\gamma^\eta Z_\beta^\eta \nabla f_\gamma \nabla f_\beta + \frac{1}{2} \frac{\partial Z_\gamma^\eta}{\partial z} \frac{\partial Z_\beta^\eta}{\partial z} f_\gamma f_\beta + \frac{\partial Z_\gamma^\eta}{\partial h} Z_\beta^\eta f_\gamma \nabla f_\beta \nabla h = 0 \quad (2)$$

$$Z_\alpha^\eta \frac{\partial \eta}{\partial t} + \nabla(A_{\alpha\beta} \nabla f_\beta) - B_{\alpha\beta} f_\beta + (C_{\beta\alpha} - C_{\alpha\beta}) \nabla f_\beta \nabla h + \frac{\partial Z_\beta^\eta}{\partial h} Z_\alpha^\eta f_\beta \nabla \eta \nabla h = 0 \quad (3)$$

where η is the water surface elevation, g the gravitational acceleration and

$$Z_\alpha^\eta = Z_\alpha|_{z=\eta} \quad (4)$$

$$A_{\alpha\beta} = \int_{-h}^{\eta} Z_\alpha Z_\beta dz \quad (5)$$

$$B_{\alpha\beta} = \int_{-h}^{\eta} \frac{\partial Z_\alpha}{\partial z} \frac{\partial Z_\beta}{\partial z} dz \quad (6)$$

$$C_{\alpha\beta} = \int_{-h}^{\eta} \frac{\partial Z_\alpha}{\partial h} Z_\beta dz \quad (7)$$

Unknown functions in Eqs. (2) and (3) are f_α ($\alpha = 1$ to N) and η which yield $N + 1$ unknowns, whereas the total number of equations is also $N + 1$. No assumptions other than expanding the velocity potential into a series are made in deriving the equations. Therefore, the nonlinear mild-slope equations can be used to simulate even strongly nonlinear and strongly dispersive wave transformation.

2.2 Vertical distribution functions

Since the present study deals with wave transformation in shallow water, even-order polynomial functions are chosen as vertical distribution functions:

$$Z_\alpha = \left(\frac{h+z}{h} \right)^{2(\alpha-1)} \quad (8)$$

Then, Eqs. (4) to (7) become

$$Z_\alpha^\eta = \zeta^{2(\alpha-1)} \quad (9)$$

$$A_{\alpha\beta} = h \frac{\zeta^{2(\alpha+\beta)-3}}{2(\alpha+\beta)-3} \quad (10)$$

$$B_{\alpha\beta} = \frac{4(\alpha-1)(\beta-1)}{h} \frac{\zeta^{2(\alpha+\beta)-5}}{2(\alpha+\beta)-5} \quad (11)$$

$$C_{\alpha\beta} = 2(\alpha - 1) \left[\frac{\zeta^{2(\alpha+\beta)-4}}{2(\alpha + \beta) - 4} - \frac{\zeta^{2(\alpha+\beta)-3}}{2(\alpha + \beta) - 3} \right] \quad (12)$$

where

$$\zeta = \frac{h + \eta}{h} \quad (13)$$

In the following calculation, the series is truncated at the second term ($N=2$) as

$$\phi(x, y, z) = f_1(x, y, t) + \left(1 + \frac{z}{h}\right)^2 f_2(x, y, t) \quad (14)$$

so that Eqs. (2) and (3) are rewritten in more specific forms:

$$g\eta + \frac{\partial f_1}{\partial t} + \frac{(h + \eta)^2}{h^2} \frac{\partial f_2}{\partial t} + \frac{1}{2} \left[\nabla f_1 + \frac{(h + \eta)^2}{h^2} \nabla f_2 \right]^2 + \frac{1}{2} \left[\frac{2(h + \eta)}{h^2} f_2 \right]^2 - \frac{2\eta(h + \eta)}{h^3} f_2 \left[\nabla f_1 + \frac{(h + \eta)^2}{h^2} \nabla f_2 \right] \nabla h = 0 \quad (15)$$

$$\frac{\partial \eta}{\partial t} + \nabla \left[(h + \eta) \nabla f_1 + \frac{(h + \eta)^3}{3h^2} \nabla f_2 \right] + \frac{(h + \eta)^2(h - 2\eta)}{3h^3} \nabla f_2 \nabla h - \frac{2(h + \eta)\eta}{h^3} f_2 \nabla \eta \nabla h = 0 \quad (16)$$

$$\frac{(h + \eta)^2}{h^2} \frac{\partial \eta}{\partial t} + \nabla \left[\frac{(h + \eta)^3}{3h^2} \nabla f_1 + \frac{(h + \eta)^5}{5h^4} \nabla f_2 \right] - \frac{4(h + \eta)^3}{3h^4} f_2 - \frac{(h + \eta)^2(h - 2\eta)}{3h^3} \nabla f_1 \nabla h - \frac{2(h + \eta)^3}{h^5} f_2 \nabla \eta \nabla h = 0 \quad (17)$$

2.3 Boundary condition

We first consider one-dimensional (on-offshore) wave transformation. At the onshore boundary, waves propagate only shoreward (i.e., positive x direction) with wave celerity, C so that for any independent variable, Φ ($= \eta, f_1$ or f_2),

$$\Phi = \Phi(x - Ct) \quad (18)$$

At the offshore boundary, waves consist of incident and reflected waves denoted by Φ_{in} and Φ_r , respectively:

$$\Phi = \Phi_{in}(x - Ct) + \Phi_r(x + Ct) \quad (19)$$

where the incident waves are given and the reflected waves are unknown.

Differentiating the above two equations with respect to x and t , we obtain the following boundary conditions:

$$\frac{\partial \Phi}{\partial t} + C \frac{\partial \Phi}{\partial x} = 0 \quad (\text{at onshore boundary}) \quad (20)$$

$$\frac{\partial \Phi}{\partial t} - C \frac{\partial \Phi}{\partial x} - 2 \frac{\partial \Phi_{in}}{\partial t} = 0 \quad (\text{at offshore boundary}) \quad (21)$$

The water surface elevation, η_{in} , due to the incident waves can be given from an appropriate progressive wave theory from given water depth h , wave period T , and wave height H . The functions, f_{1in} and f_{2in} , should also be able to be given from the same wave theory, but an explicit expression is not available in any wave theory. However, since nonlinearity is normally negligible at the offshore boundary, linear relationships between η_{in} , and f_{1in} and f_{2in} are derived as follows.

One-dimensional linearized forms of Eqs. (15) to (17) for a constant depth are written as follows:

$$g\eta + \frac{\partial f_1}{\partial t} + \frac{\partial f_2}{\partial t} = 0 \quad (22)$$

$$\frac{\partial \eta}{\partial t} + h \frac{\partial^2 f_1}{\partial x^2} + \frac{h}{3} \frac{\partial^2 f_2}{\partial x^2} = 0 \quad (23)$$

$$\frac{\partial \eta}{\partial t} + \frac{h}{3} \frac{\partial^2 f_1}{\partial x^2} + \frac{h}{5} \frac{\partial^2 f_2}{\partial x^2} - \frac{4}{3h} f_2 = 0 \quad (24)$$

which result in an eigenvalue problem for η , f_1 and f_2 . To solve the problem, we seek for a non-trivial solution of the following forms:

$$\eta = a e^{i(kx - \omega t)} \quad (25)$$

$$f_1 = a_1 e^{i(kx - \omega t)} \quad (26)$$

$$f_2 = a_2 e^{i(kx - \omega t)} \quad (27)$$

where ω ($= 2\pi/T$) is the angular frequency to be given, k the wave number to be determined from the eigen value, and a , a_1 and a_2 are the amplitudes.

By differentiating Eq. (22) with respect to t and substituting it into Eqs. (23) and (24), η can be eliminated:

$$-\frac{1}{g} \left(\frac{\partial^2 f_1}{\partial t^2} + \frac{\partial^2 f_2}{\partial t^2} \right) + h \frac{\partial^2 f_1}{\partial x^2} + \frac{h}{3} \frac{\partial^2 f_2}{\partial x^2} = 0 \quad (28)$$

$$-\frac{1}{g} \left(\frac{\partial^2 f_1}{\partial t^2} + \frac{\partial^2 f_2}{\partial t^2} \right) + \frac{h}{3} \frac{\partial^2 f_1}{\partial x^2} + \frac{h}{5} \frac{\partial^2 f_2}{\partial x^2} - \frac{4}{3h} f_2 = 0 \quad (29)$$

Then substitution of Eqs. (26) and (27) into the above two equations yield the following two equations:

$$\frac{\omega^2}{g} (a_1 + a_2) - hk^2 a_1 - \frac{hk^2}{3} a_2 = 0 \quad (30)$$

$$\frac{\omega^2}{g} (a_1 + a_2) - \frac{hk^2}{3} a_1 - \frac{hk^2}{5} a_2 - \frac{4}{3h} a_2 = 0 \quad (31)$$

To obtain a non-trivial solution, the determinant of the above simultaneous equations should vanish, from which we can determine the wave number as

$$k^2 = \frac{6h^2\omega^2 - 15gh \pm \sqrt{(6h^2\omega^2 - 15gh)^2 + 60gh^3\omega^2}}{2gh^3} \quad (32)$$

in which positive sign should be selected because positive and negative signs, respectively, yield positive and negative values of k^2 corresponding to progressive and evanescent waves. Then the normalized eigenvector, (r_1, r_2) , becomes

$$r_1 = \frac{a_1}{a_1 + a_2} = \frac{3\omega^2}{2ghk^2} - \frac{1}{2} \quad (33)$$

$$r_2 = \frac{a_2}{a_1 + a_2} = \frac{3}{2} - \frac{3\omega^2}{2ghk^2} \quad (34)$$

By considering Eqs. (22), (25) to (27), (33) and (34), we finally obtain the following relationships:

$$f_{1in} = \frac{g}{i\omega} \left(\frac{3\omega^2}{2ghk^2} - \frac{1}{2} \right) \eta_{in} \quad (35)$$

$$f_{2in} = \frac{g}{i\omega} \left(\frac{3}{2} - \frac{3\omega^2}{2ghk^2} \right) \eta_{in} \quad (36)$$

The above relationships will be used even when a nonlinear wave theory such as Stokes or cnoidal wave theory is employed to give incident waves because nonlinearity is normally not so strong at the offshore boundary.

3 Computational Method and Condition

Eqs. (15) to (17) are solved numerically by an implicit finite difference scheme. The initial condition is still water and the time evolution of η , f_1 and f_2 is calculated by these equations as well as the boundary conditions (20) and (21). Spatial derivatives are evaluated at the center of the old and new time steps. This necessitates an iteration procedure, for which the Newton-Raphson method is employed in the present study.

The computational domain is 500m long including a submerged breakwater or a step. The grid size is 1/64 of the wavelength, and the time increment is 1/64 of the wave period. This fine grid size assures the accuracy of the numerical solution for the nonlinear mild-slope equations.

To give incident waves, a third-order Stokes wave theory and a second-order cnoidal wave theory (Isobe and Kraus, 1983a, b) are employed depending on the Ursell parameter. Stokes wave theory is employed when the Ursell parameter is less than 25, and cnoidal wave theory is employed otherwise.

The incident wave conditions for close examination of the numerical result are shown in **Table 1**.

Table 1 Incident wave condition for numerical experiment

	wave period (s)	wave height (m)	water depth (m)
Case 1	7.1	1.0	10.0
Case 2	7.1	2.0	10.0

Two types of bottom configuration are employed: step type and submerged breakwater type. Samples are shown in **Figure 1** and detailed dimensions used are shown in **Table 2**.

Figure 1 Examples of calculated distribution of the water surface elevation, wave height, mean water level, and energy flux.

4 Result for 1-D Calculation

Figure 1 shows examples of calculated distribution of the water surface elevation at two different time steps, wave height, mean water level, and energy flux. Waves are incident from left to right. (a) is for a submerged breakwater, and (b) is for a step. The energy flux is kept constant except for a small fluctuation which may have resulted from the error due to insufficient number of terms in the series expansion of the velocity potential. As can be seen from the water surface elevation, wave disintegration on the breakwater or step is significant.

To examine the nonlinear wave disintegration, the temporal change of water surface elevation is transformed into a Fourier series at every point. Figure 2 shows the distribution of amplitude of the first six components. Spatial change of amplitudes on the step are periodic.

The spacing between two adjacent peaks of the second harmonics is derived theoret-

(a) Submerged

breakwater Case 1, $\tan \theta = 1/3, h_s/h = 0.3, b/h = 4$

(b) Step

Case 1, $\tan \theta = 1/3, h_s/h = 0.3$

Figure 2 Distribution of amplitude of various harmonics.

ically as (Massel, 1983)

$$\lambda_2 = 2\pi/(k_2 - 2k_1) \quad (37)$$

where k_1 and k_2 are the wave numbers corresponding to the linear dispersion relation for ω and 2ω , respectively:

$$\omega^2 = gk_1 \tanh k_1 h \quad (38)$$

$$4\omega^2 = gk_2 \tanh k_2 h \quad (39)$$

The present result agrees well with the above theory, which implies the return spacing is predicted theoretically. However, the amplitude cannot be predicted accurately especially for strongly nonlinear cases. Thus, it is examined in the present study in detail.

Figure 3 shows the relation between the maximum amplitudes, $|\eta_n|$ ($n = 1$ to 3), of the first three harmonics, and the slope, $\tan \theta$, of the offshoreward face of a step. The maximum amplitude of higher harmonics increases with increasing slope. The effect of the water depth on a step is shown in **Figure 4**. In the figure, h_s/h is the ratio between the water depth, h_s , on the step and that, h , in the offshore region. Results are plotted for non-breaking cases for which $h_s/h \geq 0.3$ for Case 1 and $h_s/h \geq 0.5$ for Case 2. The maximum amplitudes of higher harmonics increase with decreasing water depth on the step.

As can be expected from the periodicity of the amplitude of higher harmonics on the step which is shown in **Figure 2(b)**, the amplitudes of various harmonics behind a submerged breakwater oscillate significantly with the width. **Figure 5** shows the average amplitudes of the first three harmonics behind a submerged breakwater. (a) is for the incident waves of Case 1 and $h_s/h = 0.3$, (b) for Case 1 and $h_s/h = 0.5$, and (c) for Case 2 and $h_s/h = 0.5$. For each figure, the return spacing, λ_2 , of the second harmonics agrees well with that predicted by Eq. (37). The amplitude behind the breakwater becomes maximum for $b = m\lambda_2$ ($m = 1, 2, \dots$), and minimum for $b = (m - 1/2)\lambda_2$, and the difference between the maximum and minimum values increases with

Figure 3 Relation between the maximum amplitude of various harmonics and the slope of the offshoreward face of a step.

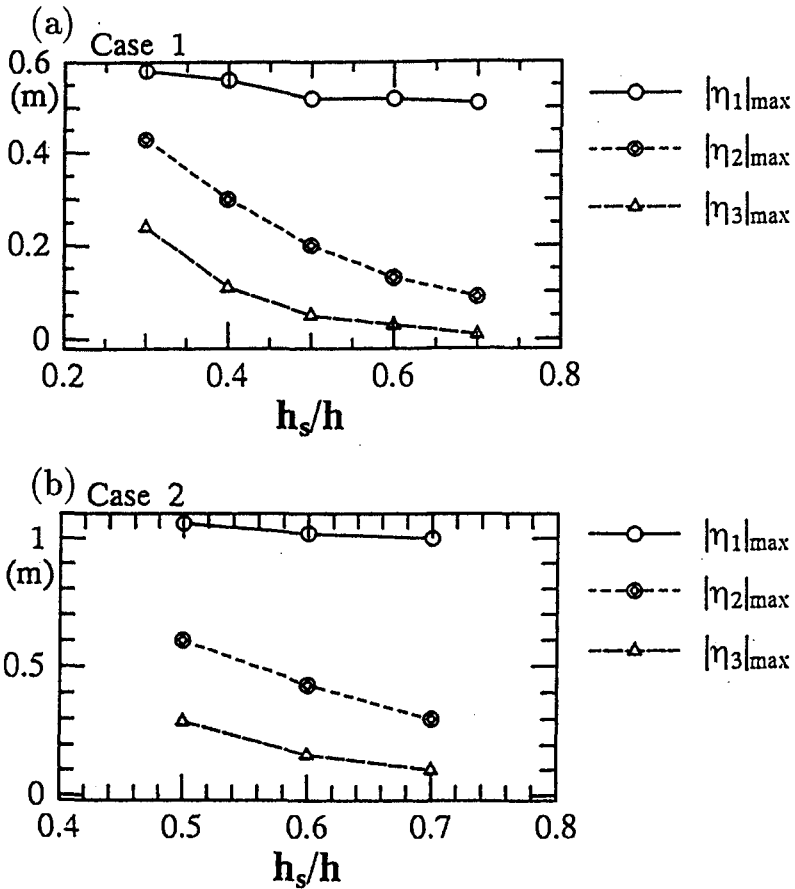

Figure 4 Relation between the maximum amplitude of various harmonics and the water depth on a step.

decreasing crown water depth. By comparing between (b) and (c), it is understood that the ratios of amplitudes of higher harmonics to the first harmonics grow larger for larger incident wave steepness.

The above results imply that significant amount of wave energy is transferred from the fundamental component to higher harmonics and the amplitude of the second harmonics can become comparable or larger than that of the first harmonics behind a submerged breakwater by adjusting its configuration.

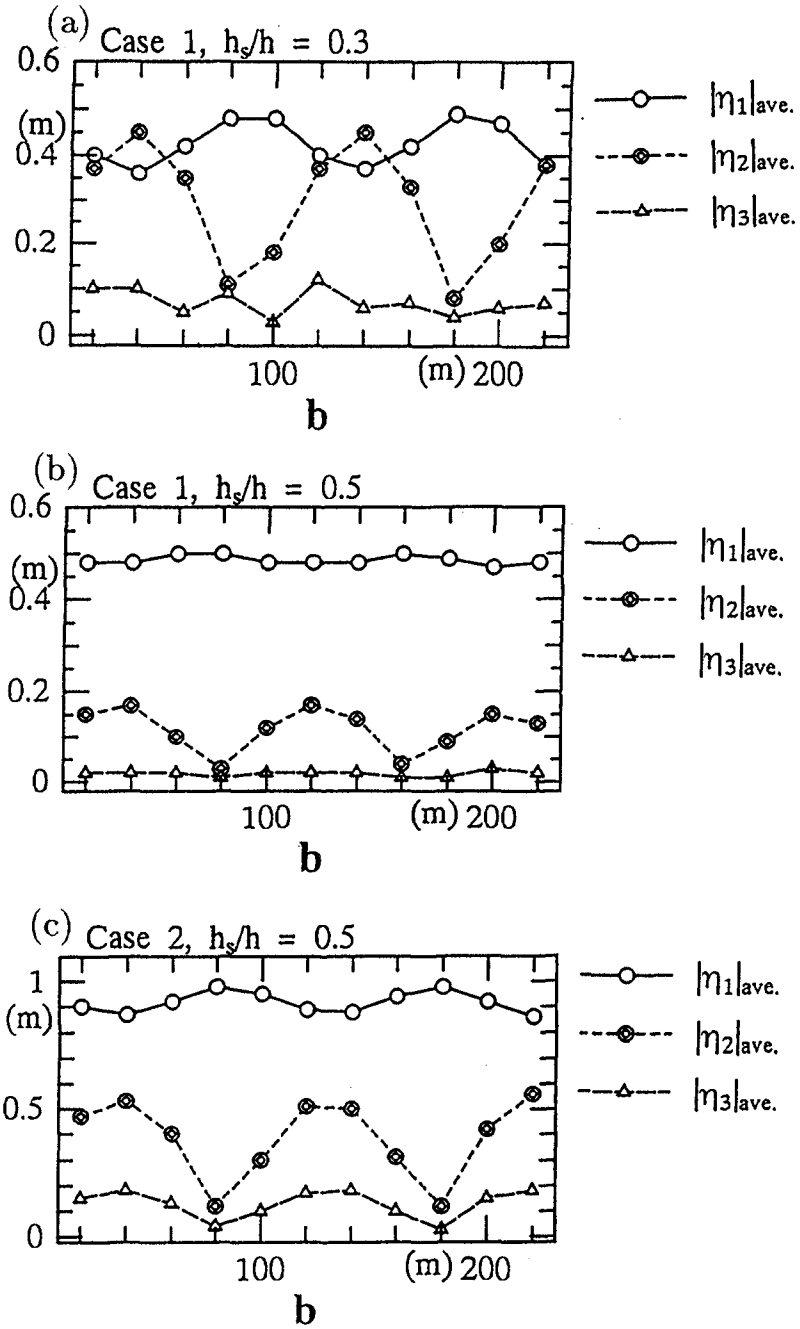

Figure 5 Relation between the average amplitude of various harmonics and the crown width of a submerged breakwater.

5 Basic Equations for Obliquely-Incident Waves

When waves are incident obliquely to a region with parallel depth contours, the celerity, C_y , in the alongshore direction, y , becomes constant throughout the depth. The quantity C_y is evaluated at the offshore boundary as

$$C_y = \frac{C_o}{\sin \theta_o} \quad (40)$$

where C_o and θ_o are the wave celerity and direction at the offshore boundary. Then the derivative with respect to y is converted to that with respect to t :

$$\frac{\partial}{\partial y} = \frac{1}{C_y} \frac{\partial}{\partial t} \quad (41)$$

If Eq. (41) is substituted into Eqs. (15) to (17), independent variables become only x and t . However, numerical solution could not be obtained due to numerical instability because the equations include the second-order derivatives with respect to t . Therefore, by considering the linear relationships (35) and (36), the following equations are used to eliminate the second-order derivatives:

$$\frac{\partial^2 f_1}{\partial t^2} = -gr_1 \frac{\partial \eta}{\partial t} \quad (42)$$

$$\frac{\partial^2 f_2}{\partial t^2} = -gr_2 \frac{\partial \eta}{\partial t} \quad (43)$$

Then Eqs. (15) to (17) become

$$g\eta + \frac{\partial f_1}{\partial t} + \frac{(h+\eta)^2}{h^2} \frac{\partial f_2}{\partial t} + \frac{1}{2} \left[\frac{\partial f_1}{\partial x} + \frac{(h+\eta)^2}{h^2} \frac{\partial f_2}{\partial x} \right]^2 + \frac{1}{2} \frac{1}{C_y^2} \left[\frac{\partial f_1}{\partial t} + \frac{(h+\eta)^2}{h^2} \frac{\partial f_2}{\partial t} \right]^2 + \frac{1}{2} \left[\frac{2(h+\eta)}{h^2} f_2 \right]^2 - \frac{2\eta(h+\eta)}{h^3} f_2 \left[\frac{\partial f_1}{\partial x} + \frac{(h+\eta)^2}{h^2} \frac{\partial f_2}{\partial x} \right] \frac{\partial h}{\partial x} = 0 \quad (44)$$

$$\begin{aligned} & \frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \left[(h+\eta) \frac{\partial f_1}{\partial x} + \frac{(h+\eta)^3}{3h^2} \frac{\partial f_2}{\partial x} \right] \\ & + \frac{1}{C_y^2} \left[\left\{ \frac{\partial f_1}{\partial t} + \frac{(h+\eta)^2}{h^2} \frac{\partial f_2}{\partial t} - gr_1(h+\eta) - gr_2 \frac{(h+\eta)^3}{3h^2} \right\} \frac{\partial \eta}{\partial t} \right] \\ & + \frac{(h+\eta)^2(h-2\eta)}{3h^3} \frac{\partial f_2}{\partial x} \frac{\partial h}{\partial x} - \frac{2(h+\eta)\eta}{h^3} f_2 \frac{\partial \eta}{\partial x} \frac{\partial h}{\partial x} = 0 \end{aligned} \quad (45)$$

$$\begin{aligned} & \frac{(h+\eta)^2}{h^2} \frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \left[\frac{(h+\eta)^3}{3h^2} \frac{\partial f_1}{\partial x} + \frac{(h+\eta)^5}{5h^4} \frac{\partial f_2}{\partial x} \right] \\ & + \frac{1}{C_y^2} \left[\left\{ \frac{(h+\eta)^2}{h^2} \frac{\partial f_1}{\partial t} + \frac{(h+\eta)^4}{h^4} \frac{\partial f_2}{\partial t} - gr_1 \frac{(h+\eta)^3}{3h^2} - gr_2 \frac{(h+\eta)^5}{5h^4} \right\} \frac{\partial \eta}{\partial t} \right] \\ & - \frac{4(h+\eta)^3}{3h^4} f_2 - \frac{(h+\eta)^2(h-2\eta)}{3h^3} \frac{\partial f_1}{\partial x} \frac{\partial h}{\partial x} - \frac{2(h+\eta)^3\eta}{h^5} f_2 \frac{\partial \eta}{\partial x} \frac{\partial h}{\partial x} = 0 \end{aligned} \quad (46)$$

The numerical solution method for the above equations is the same as that for normal incidence previously described.

6 Result for Obliquely-Incident Waves

Once a numerical solution is obtained in terms of x and t as $\Phi(x, t)$, the solution in terms of x , y and t is written as $\Phi(x, t - y/C_y)$. **Figure 6** shows the pattern of wave crests near an infinitely-long submerged breakwater with a trapezoidal cross section. Waves are incident obliquely from the lower boundary.

For **Figure 6(a)**, wave direction changes on the breakwater due to refraction, and secondary crests appear due to the nonlinear effect, but the secondary crests disappear behind the breakwater and the wave direction turns back to that of the incident waves. However, for **Figure 6(b)** in which the amplitude of the second harmonics grows larger than that of the first harmonics, secondary crests remain behind the breakwater and the wave direction is different from that of incident waves. The reason is as follows. Since celerities of all component waves must be the same in the y direction, higher harmonics, of which the wave celerities are smaller than that of fundamental component, should propagate in the direction closer to the shore-normal. Therefore, the predominant direction changes when higher harmonic components dominate behind the breakwater.

7 Conclusion

Numerical scheme for the nonlinear mild-slope equations is developed to examine wave transformation due to a submerged breakwater for normal and oblique incidence.

Generation of higher harmonics for normal incidence to a step and a submerged breakwater is first examined. The amplitudes of higher harmonics on a submerged breakwater are larger for steeper offshoreward slope and for smaller crown water depth. The amplitudes of higher harmonics behind a submerged breakwater become maximum for $b = m\lambda_2$ ($m = 1, 2, \dots$), and minimum for $b = (m - 1/2)\lambda_2$. When the nonlinearity of incident waves is stronger, higher harmonics grow larger.

Higher harmonics appear also for obliquely incident waves. When higher harmonics dominate behind the submerged breakwater, predominant wave direction changes to keep the alongshore celerity constant.

These results imply that, utilizing a submerged breakwater, we can control wave period and direction as well as wave height.

Case 1, $\theta_0 = 45$, $\tan \theta = 1/10$, $h_s/h = 0.3$, $b/h = 8$

Case 1, $\theta_0 = 45$, $\tan \theta = 1/3$, $h_s/h = 0.3$, $b/h = 4$

CHAPTER 62

Observed and Modeled Wave Results From Near-Stationary Hurricanes

Charles L. Vincent, PhD¹ and Robert E. Jensen, PhD²

Abstract

Wave conditions in hurricanes have been difficult to study because of a lack of high-quality wave data and poor descriptions of the wind field. In the 1994 and 1995 hurricane seasons, two Category 1 hurricanes (Gordon and Felix) approached the North Carolina coast and stalled for a period of about 2 days. Although the storms were minimal hurricanes they produced large swell that persisted for several days. A wave gauging network of two to five directional instruments in water depths ranging from 8 to 50 m operated throughout the storms. Because of their proximity to land, both storms were extensively observed by radar and aircraft so that the wind fields are well described. The data set offers an opportunity to evaluate two prediction methods to examine the wave field during these most unusual hurricanes.

Introduction

In 1994 and 1995, Hurricanes Gordon and Felix approached the U. S. Army Engineer Waterways Experiment Station's Field Research Facility (FRF) at Duck, NC (Figure 1), stalled, and then eventually moved away. Of the two, Felix was by traditional meteorological measures the stronger (Categories 1 and 2) on the Saffir-Simpson scale but produced lower wave heights in the vicinity of the FRF than Gordon (tropical storm to brief Category 1) which produced some of the largest wave heights recorded at National Data Buoy Center (NDBC) Buoy 44014 located 90 km to the northeast of the FRF.

²Res. Hyd. Eng., USAE Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Rd., Vicksburg, MS 39180-6199.

This paper investigates the wave fields in the two storms by comparing simple and complex simulation models of the wind and wave fields to observations in order to determine if the wave field in Gordon was indeed anomalous. Most engineering models of hurricane wind fields assume a symmetric vortex that is uniformly propagated at a forward speed, so that when a vector is added to the vortex, the asymmetric wind field of a moving storm is produced. Thus, when hurricanes became nearly stationary, they would be expected to be similar to the simple vortex. Observations provide an opportunity to understand how well the simulation technology can estimate the stationary case, as well as the approaching and receding storm cases. Waves in each storm were estimated by (1) using the procedure described in the *Shore Protection Manual* (1984) termed SPM84, and (2) simulation with Cycle 4 of the wave model WAM (Komen et al. 1995) driven by an analyzed wind field provided by Oceanweather, Inc.

The concept of the paper is to apply two types of simulation approaches to wave estimation in the two storms using routine approaches for obtaining input meteorologic information. These are used with fairly standard wave estimation procedures to obtain an estimate of the waves. In this study the wind and wave models were not iteratively run to obtain a best estimate of the wave field by providing feedback corrections to the wind field model. The goal is to understand results obtained using routine approaches, because this is closer to a case where extensive wave data would not be available for hindcast or forecast, which is typical of many design situations.

Wave Observations

Locations of the wave buoys and arrays used in the study are shown in Figure 1. All except the Waverider buoy and Linear Array at the FRF are NDBC buoys emplaced for routine measurements or in the case of Gordon for the DUCK94 experiment (e.g. Birkemeier 1994, Jensen 1994). Table 1 provides a summary of the location and water depths of the buoys and gauges. The height, period, direction, and spectral data used in the study were produced by the routine analysis procedures of NDBC (Steele et al. 1992) or the FRF reported in Leffler et al. (1993) and Long and Oltman-Shay (1991).

Wind-Field Simulations

The wind field required for SPM84 is an internal element of the wave field parameterization of the wave estimates and requires central pressure,

Table 1. Measurement Sites for 3GWAM Comparisons

BUOY #	GORDON	FELIX	LONGITUDE	LATITUDE	DEP.
41001	X	X	72° 39' 46"	34° 42' 06"	4444
41002	X		75° 14' 26"	32° 17' 42"	3658

FRF-WR	X	X	75° 41' 59"	36° 10' 05"	18
FRR-LA	X	X	75° 44' 43"	36° 11' 16"	8.5

which the wave model equations are integrated. The method used by Oceanweather, Inc. (e.g. Cardone, Greenwood, and Greenwood 1992; Cox et al. 1994) assumes that the hurricane wind field can be simulated by a vortex embedded in an overall large-scale pressure gradient field. The wind field is estimated from the gradient wind approximations. An interactive optimal kinematic analysis (IOKA) procedure is then applied to modify the estimated winds so that they better match observed winds in the vicinity of the wave field. This solution was obtained at snapshots of the storm's history and then interpolated in time and space to give the required input to the wave model. For these simulations, the snapshots were taken every 3 hours (interpolated to 1 hour using a moving center algorithm preserving the storm's center), and data were output on a 0.5-deg grid. The NDBC buoys and FRF have wind field records for the storms. However these data have been used in the IOKA as an essential ingredient of the windfield analysis. Since they cannot provide independent validation of the wind field, they will not be presented here.

SPM84 Procedure

The method for producing hurricane wave estimates in deep water is relatively straightforward. The method has an equation of significant wave height H_s and period T_s

$$H_s = 5.03 \exp(R\Delta p/4700) [1 + 0.29 \alpha V_r / (U_R)^{0.5}]$$

$$T_s = 8.6 \exp(R\Delta p/9400) [1 + 0.145 \alpha V_F / U_R^{0.5}]$$

where R is radius of maximum winds (km), Δp is the pressure drop, α is the forward speed coefficient (about 1 for a slow-moving storm), V_F is the forward speed (m/s), and U_R is the maximum sustained wind speed at the 10-m elevation. Once these values are obtained, the SPM84 provides a generalized nomogram (in terms of r/R : radius of the local r relative to the eye over the radius to maximum winds) that displays the wave height pattern in reference to the eye and the direction of movement.

WAM Model Set-up

WAM Cycle 4 was set up on a 0.25-deg grid for the entire region shown in Figure 1 using 25 frequencies ($f_{i+1} = 1.1 \cdot f_i$) and 24 directions (15 degree bins). The refraction and shoaling routines were turned on. The model received wind input every hour and was interpolated to the 0.25-deg grid in space and 600 s in time (WAM propagation time-step). Both hurricane fields were generated 3 days prior to the test period for spin-up of the wave model domain.

Hurricane Gordon

Gordon formed in the Caribbean and moved into the Gulf of Mexico across Florida into the Atlantic. Our analysis begins with the movement of the storm into the Atlantic near Cape Canaveral, FL at which point it was a tropical storm. The tropical storm moved northeastward from November 17, 1994, until early on the 18th when it slowed its movement and began to drift to the west approximately 200 km to the south of Cape Hatteras. As the storm was blocked from further northward movement, it intensified to a minimal hurricane for about 1 day, and then rapidly moved southward towards the Bahamas and lost strength.

SPM Method: The SPM84 calculations were made at a point when the storm was nearly stationary and had peak winds of 35-38 m/s. In the region of maximum winds, SPM84 (Table 2) indicates a maximum wave height of 7.7 m with a period of 12 s. The height and period at buoy 41002 - just north of the eye of the storm (r/R of 1.6) were estimated to be 5.7 m at 12 s compared to a buoy observation of 5-5.7 m and 10-12 s for the times bracketing the analysis (eight buoy observations are missing). At buoy 41001 at an r/R of 2.4 northeast of the eye, the estimate via SPM84 is a height of 5.7 m with a period of 12 s. The buoy observations are significantly larger, 11 m and 13 s.

Table 2. Wave Height Results, SPM84 and WAM

STORM	LOC	SPM84	WAM	NDBC Obs.
GORDON	Max. Wind	7.7m / 12s*	10m / 13s*	---
	41001	5.7m / 12s*	7m / 11s*	11m / 13s
	41002	5.7m / 12s*	6.9m / 11s*	5m / 11s
	44014	3.8m / 12s*	6m / 12s*	9m / 15s
FELIX	Max. Wind	9m / 12s*	10m / 13s*	---
	44004	5.4m / 12s* 7.2m / 12s**	6.0m / 12s* 5m / 12s**	6.0m / 12s* 8.0m / 12s**
	44009	3.6m / 12s*	4.0m / 12s	3.8m / 12s*
	44014	5.4m / 12s* 7.6m / 12s**	4.0m / 12s* 6.2m / 14s**	4.0m / 12s* 6.8m / 15s**
	41001	6.3m / 12s* 7m / 12s**	5.2m / 9s* 8.0m / 14s**	5.8m / 9s* 7.8m / 15s**

* Stationary

** Closest Approach

At buoy 44014, 90 km northeast of the FRF and at an r/R of 5.4, the estimate was 3.8 m with a 12-s period, compared to the buoy observations of 9 m and 15 s.

Thus the SPM84 provided an estimate consistent with the observations near the center of the storm if the missing observations were similar to the ones bracketing it. However, the SPM84 technique dramatically missed the wave heights at 41001 and 44014, which were more to the east and northeast of 41002 and much further from the storm. Orientation of the nomogram was varied relative to the storm motion, but no significant improvement was obtained. The only way to achieve the size answers at 41001 and 44014, given the SPM84 method, would be to greatly increase the wind speed (and pressure drop) which was unsupported by the meteorological estimates.

WAM Simulations: The WAM simulations provide a detailed history of the waves over the entire region with hourly output. The input wind field has far more detail and asymmetry than is possible with the SPM approach. Figure 2 provides the wave height traces for 41002, 41001, and 44014. Results at the peak times are also provided in Table 2. Estimated peak wave conditions for the storm on the 18th were 10 m with a peak period of 13 s - substantially larger than the SPM84 estimate. The trace at 41002 indicates that the simulation and observations were fairly close on the 17th and the latter half of the 18th. On the morning of the 18th, the simulation suggests waves of 7 m, but the buoy failed

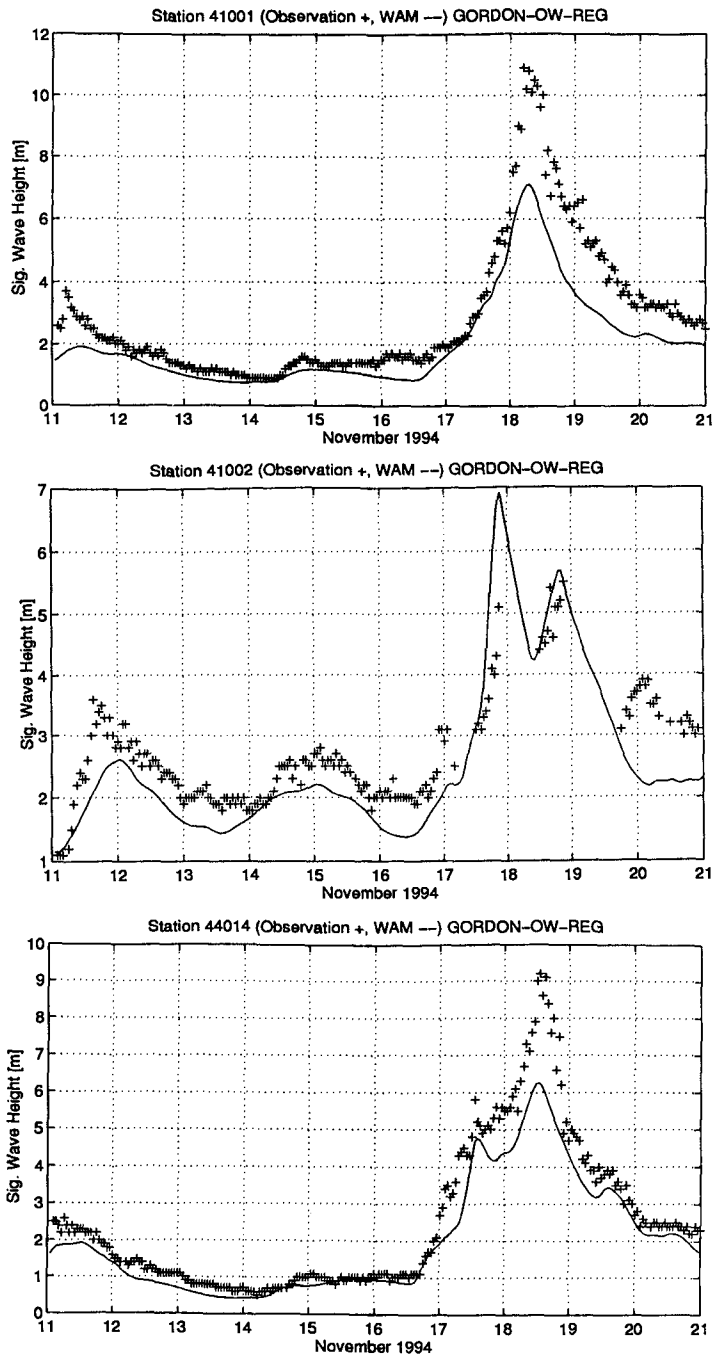

Figure 2. Comparison of WAM (solid line) versus measurements (+) at Buoys 41001 (top), 41002 (middle), and 44014 (bottom).

to collect data. At 41001, the simulation trace is fairly close to the observations until the morning of the 18th, at which time the model peaks at 7 m, but the observations continue to climb to 11 m and 13 s. The trace comparison at 44014 is fairly similar in that the simulation significantly underestimates the peak wave conditions (6 m predicted versus 9 m observed).

The WAM simulations provide larger wave heights than the SPM84 simulations, but it is clear that although the observations near the center of the storm (41002) are not poorly predicted, those to the east and northeast were badly underpredicted. If just the observations at 41002 and 41001 are compared (the buoys are about 150 km apart), the waves at 1200 on the 18th are about 4.5 m at 41002 versus 11 m at 41001. So there is a very rapid variation in conditions depending upon location with respect to the eye (both radial distance and quadrant), as is generalized in SPM84.

Hurricane Felix

Felix originated in the eastern Atlantic and moved steadily towards the United States. Our interest begins on the August 13, 1995 as the storm enters the computational grid some 4 days before closest approach to Cape Hatteras, NC. The storm moved steadily to the northwest towards Cape Hatteras as a Category 2-3 hurricane. By the 17th, the storm's northwest movement has been greatly reduced and the storm moves slowly to the north, then recurves to the east, looping on the 19th and 20th offshore of the Outer Banks of NC. Finally, on the 21st, the storm moves rapidly to the northeast as it becomes a tropical storm. In the region of Cape Hatteras, the storm remained a medium Category 1.

SPM Method: The SPM84 was applied several times. The first was when the storm was nearly stationary, and additional estimates were made when the storm was at closest approach 41001 and 44014 to the buoy (Table 2). The estimated maximum wave was 9 m at 12 s for the stationary case. SPM84 and buoy observations were fairly close - normally within a meter. Wave periods were low for the closest approaches at 41001 and 44014. Based on this very simple approach, the SPM method appeared to give a satisfactory estimate for this storm.

WAM Simulations: Results of the WAM simulations are given in Table 2. The simulated wave heights and periods based on stationary and closest approach times compare favorably with the observations. Comparisons of the wave height traces to the observations provides more mixed results (Figures 3 and 4). At 41001 (Figure 3), where the hurricane passed right over, the simulations are quite reasonable until 1200 on the 16th. After that time the observed heights fall more quickly than the simulated. From the 18th on, the simulations are 1-2 m

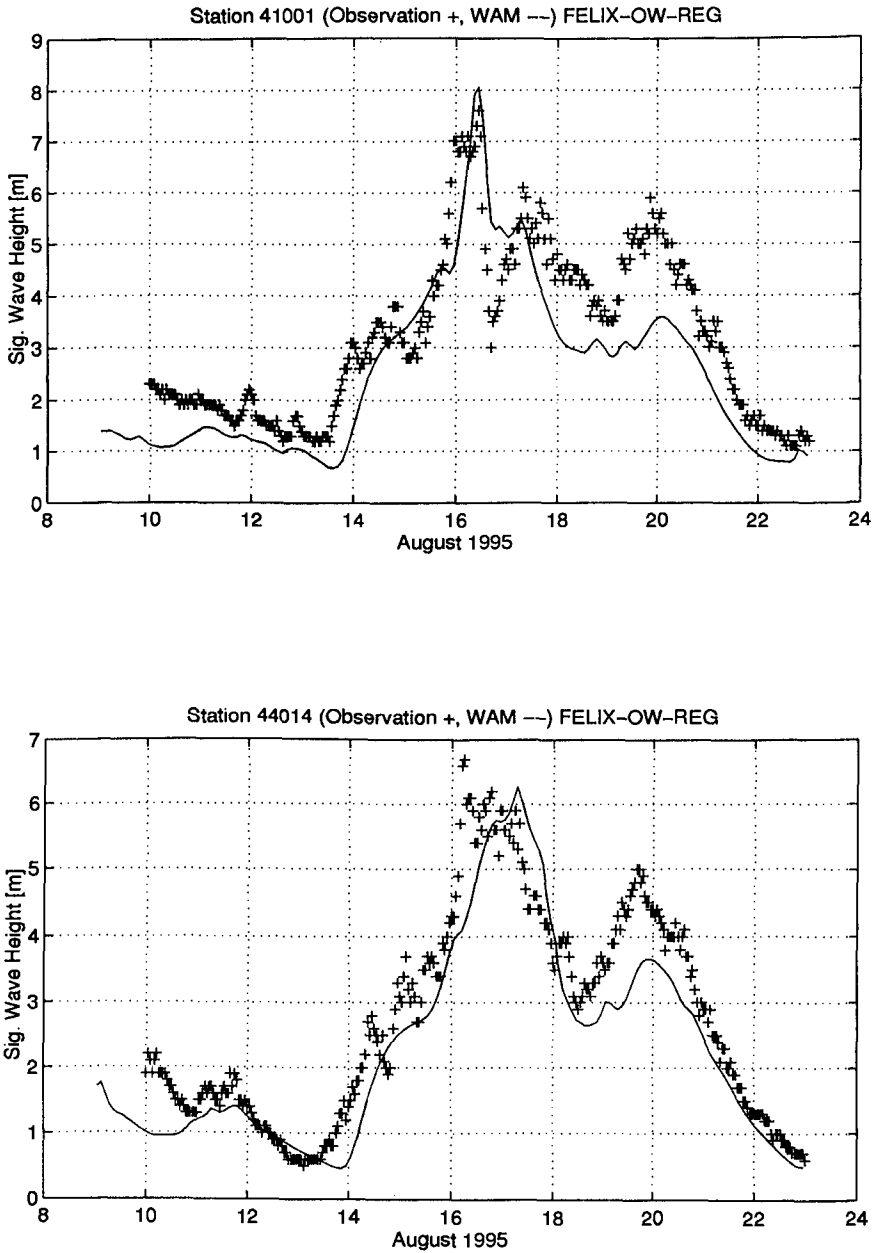

Figure 3. Comparison of WAM (solid line), and measurements (+), at 41001 (top), and 44014 (bottom) panel.

lower than the observed. At this time, the hurricane is in the looping process. At 44014 (Figure 3), the pattern is fairly similar. The simulations produce a similar peak height though the largest waves appear to arrive earlier than indicated by the simulation. The simulated decay of the storm is excellent until the 18th, when the observations rise more than the simulated values with a difference of 1 to 2 m seen. At 44009 (Figure 4), which lies in fairly shallow water off of Delaware bay, the pattern is similar to 44014, although the waves do not get as large as at 44014. Comparison of the simulation results to observations at 44004 (Figure 4), which is several hundred kilometers off of Delaware Bay and just to the north of the storm path, is by far the worst. The simulations completely underestimate large waves on the 16th and underestimate waves by nearly 3 m on the 18th-21st. Ship observations near 44004 recorded during the time of Felix were on the order of 2 to 4 m lower than the buoy wave heights. This suggests the potential of other factors such as the Gulf Stream influencing the measurements at 44004.

Thus, even though comparison of the WAM and SPM84 results to the observations at closest approach and when the storm was stationary are fairly good, comparison of the simulated history of wave heights shows that the WAM results underestimated (as much as 4 m) the storm when it was in the looping phase.

Discussion

Objectives of this paper were to understand (1) if Gordon was in some sense anomalous, and (2) how well two wave estimation approaches (one very simple, one very complex) performed with the typical level of information available for many forecasts and hindcasts. In judging the prediction approaches, it must be stated that any error is an integrated error for both wind field specification/modeling and wave model physics and numerics.

In considering Hurricane Gordon, it is best to contrast results to Hurricane Felix. In Felix application of both prediction methods gave fairly satisfactory results for peak quantities in the storm at most locations. Felix had consistently stronger winds and a somewhat smaller physical size. Felix at most produced 8 m waves at the buoys it passed by. Gordon, although generally weaker, produced waves larger than Felix by 3 m at 41001 and 2 m at 44014. At 41002, the simulation results from WAM and the observations were in reasonable agreement. Thus, although some systematic error in WAM or SPM84 cannot be ruled out, the authors hypothesize that Gordon must have been highly asymmetric with a region of larger winds to the east of the storm that is not caught in the current meteorological specification of the storm.

Figure 4. Comparison of WAM (solid line), and measurements (+), at 44009 (top) and 44004 (bottom) panel.

With regard to Felix, it appears that simulation methods do reasonably well when the storm is moving in a more or less straight line, but that the combination in wind field and WAM does not replicate what happened in the turning and looping situation. One can postulate two reasons for the problem. First, the simple vortex model approach may not be adequate when the storm is wobbling in a loop. Second, the ability of a model such as WAM to handle such radically turning winds and mixed sea-swell conditions has never been proven.

The principal lesson learned of engineering consequence is that fairly weak-appearing storms can produce unexpected high wave heights if the storm stalls or loops, with the error for a weak hurricane/strong tropical storm approaching 3-4 m in significant wave height. Moreover, forecast/hindcast of the wave height trace in the stalling/looping storms may produce errors of 1-2 m.

CHAPTER 63

Estimation of Persistence Statistics of the Waves Observed on Japanese Coast in the Light of Recent Studies

Hajime Kato¹, Hisamichi Nobuoka²

Abstract

The NMI method proposed by Kuwashima and Hogben (1986) for estimating the wave persistence statistics and Mathiesen's Model (1994) which was expected to develop the NMI method were applied to the wave data observed at four sites at Japanese coast to investigate the validity of the models. Mathiesen's model was found not to be superior to NMI method. We show the modification of the NMI parameters based on the data improve the accuracy of the estimated persistence statistics.

1. Introduction

The estimation of wave height duration statistics is needed in various engineering fields such as planning and execution of maritime construction works as well as oil industry operations. For the case when continuous data sequences are not available Graham (1982) proposed an approximate method based on the probability distribution of significant wave height. Kuwashima and Hogben (1986) generalized the method using mainly North Sea wave data, and proposed an empirical method which they called the NMI method. Recently Mathiesen (1994) proposed a theoretically founded parametric model for the estimation of duration statistics for wave height. Although he suggested that his study established a theoretical basis for the development of NMI method, the fact was not confirmed.

In this study we estimate the wave persistence statistics from the wave data observed at the coasts of Japan using both NMI and Mathiesen's method. We pay attention to the local differences of persistence statistics examining the applicability of the two methods to the present wave data of Japanese area.

2. Data and method of analysis

2.1 Wave data used

We used the wave data observed at the four sites in the Japanese coast. Fig.1 shows the locations of the four sites. Hitachinaka and Kashima are at the coast of Ibaraki facing to the Pacific Ocean, and Sakata and Wajima are in the Sea of Japan. They are hereafter abbreviated as HI, KA, SA and WA. The name of Ibaraki will also be used to denote both HI and KA. Those data are measured every two hours and the time spans are 13 years for HI and 8 or 9 for other sites.

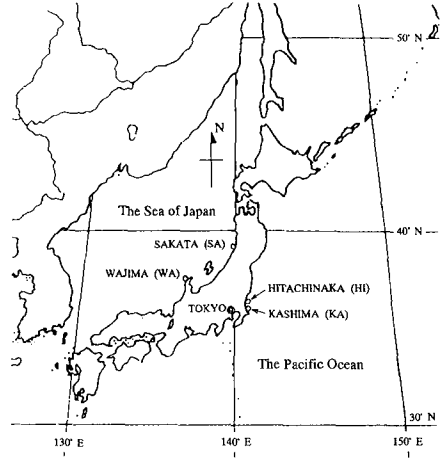

Fig.1 Map of the sites of the wave data used in this study.

2.2 Estimation of wave height persistence statistics by the NMI method

In the NMI method, the input data used are cumulative probability distributions of significant wave height H_s which is written for the case of height exceedance as $Q(\geq H_s)$. The mean duration of exceedance waves $\bar{\tau}_g$ for a threshold height H_s' are expressed as:

$$\bar{\tau}_g = A[-\ln Q(\geq H_s')]^{-\beta} \tag{1}$$

where A and β are constants and Q is cumulative probability distribution for a threshold H_s' . The equation (1) was originally proposed by Graham (1982) with constants $A=20.0$ and $1/\beta = 1.3$ for the North Sea wave data.

Kuwashima and Hogben (1986) allowed variations in the parameters A and β by deriving empirical relations (based on exceedance data) between the parameters and a shape parameter γ for the input distribution defined in terms of a 2 parameter Weibull distribution. At first the distribution is written in terms of the normalized significant wave height defined by $H_n = \bar{H}_s / H_s$ as:

$$Q(\geq H_n) = \exp(-B H_n^\gamma) \tag{2}$$

where the parameter B and γ are related by

$$B = [\Gamma(1+1/\gamma)]^\gamma \tag{3}$$

and Γ is a gamma function. Then the relevant relations of A and β with γ have been obtained from many data sets as follows:

$$A=35 \gamma^{-0.5}, \quad \beta=0.6 \gamma^{0.287} \tag{4a,b}$$

Although Eqs.(4a,b) are empirical formulas, they are expected applicable to any world wide sites since the wave statistics is well represented by the

parameter γ . When $\bar{\tau}_g$ is obtained from Eq.(1), then the mean duration of non-exceedance waves $\bar{\tau}_l$ is obtained as

$$\bar{\tau}_l = \bar{\tau}_g [1 - Q(\geq H_s')] / Q(\geq H_s') \quad (5)$$

The cumulative distribution of duration for exceedance and non-exceedance waves are also expressed in terms of a 2-parameter Weibull distribution. Writing $x = \tau / \bar{\tau}$ where $\bar{\tau}$ is the mean duration, the distribution is written as:

$$Q_g(\tau / \bar{\tau}_g) = Q_g(\geq x_g) = \exp[-C_g x_g^{\alpha_g}] \quad (6a)$$

$$Q_l(\tau / \bar{\tau}_l) = Q_l(\geq x_l) = \exp[-C_l x_l^{\alpha_l}] \quad (6b)$$

The shape parameters α_g and α_l of the above equations are also given in the following empirical forms:

$$\alpha_g = 0.267 \gamma (H_s' / \bar{H}_s)^{0.4} \quad (7a)$$

$$\alpha_l = 0.267 \gamma (H_s' / \bar{H}_s)^{-0.4} \quad (7b)$$

C_g and C_l of Eq.(6) are related to α_g and α_l as :

$$C_g = [\Gamma(1+1/\alpha_g)]^{\alpha_g} \quad (8a)$$

$$C_l = [\Gamma(1+1/\alpha_l)]^{\alpha_l} \quad (8b)$$

If we know the probability distribution of wave height for a certain area, then from the cumulative probability distribution $Q(\geq H_s')$ and the shape parameter γ of a 2-parameter Weibull distribution, we can estimate the mean duration $\bar{\tau}_g$ (or $\bar{\tau}_l$) and the cumulative probability of duration Q_g (or Q_l) of exceedance (or non-exceedance) wave for a threshold wave height by using the equations stated above.

2.3 Mathiesen's model

Mathiesen (1994) assumed that the time variation of significant wave height is a continuous stationary process and applied a level crossing theory for water waves to the time series of wave heights. In this section we write a significant wave height H_s simply as H and a threshold wave height H_s' as H_c .

The average number of exceedances or level-upcrossings per unit time $\nu(H)$ is given by:

$$\nu(H) = (1/2) \int_{-\infty}^{\infty} |H'| |p(H, H')| dH' \quad (9)$$

where $H' = dH/dt$ and $p(H, H')$ is the joint probability of H and H' . Then Mathiesen obtained the relation:

$$\nu(H) = (1/2) f(H) S(H) \tag{10}$$

where $f(H)$ is the probability density function for H , and $S(H)$ the average absolute rate of change of significant wave height H . That is, he showed that the duration statistics depended not only on $f(H)$ but also $S(H)$, the average absolute rate of change of H . Considering the equation of mean duration of exceedance $\bar{\tau}_g$:

$$\bar{\tau}_g = T Q(\geq H_c) / N \tag{11}$$

where N is the number of up-crossing for the total time length T , then $\bar{\tau}_g$ is given as :

$$\bar{\tau}_g = 2 Q(\geq H_c) / [f(H) S(H)] \tag{12}$$

$f(H)$ and $Q(H)$ are evaluated in the 3-parameter Weibull form as follows:

$$f(H) = (\gamma' / X_0) ((H-a) / X_0)^{\gamma'-1} \exp[- ((H-a) / X_0)^{\gamma'}] \tag{13}$$

$$Q(H) = \exp[- ((H-a) / X_0)^{\gamma'}] \tag{14}$$

where γ' is the shape parameter, a the local parameter which was set as zero in practice and X_0 the scale parameter.

Mathiesen (1994) found that $S(H)$ could be expressed as

$$S = q (H/H_0)^R, \quad (H_0=1.0m) \tag{15}$$

where q and R are constants different between the locations.

From Eqs.(11) to (15) and Eq.(3), the NMI parameters A and β are found to become to A_M and β_M in the following equations:

$$A_M = 2 / [\gamma' (X_0 / H_0)^{R-1} (q / H_0)] \tag{16}$$

$$\beta_M = (\gamma' + R - 1) / \gamma' \tag{17}$$

It is seen that the parameters A_M and β_M depend on both the shape of the distribution $Q(H)$ and the average absolute rate of change $S(H)$ in Mathiesen's model.

3. Applicability of the NMI method to the present wave data

In this study we used the measured wave data for calculating the wave height persistence statistics in three ways; (a) data sets of each year, (b) seasonally divided data sets for four years, and (c) monthly divided for 9 (KA and HI) or 8 (SA and WA) years. For testing the reliability of the NMI method Kuwashima and Hogben (1986) showed comparisons of the estimated persistence statistics with those directly derived from measured data in cumulative distribution form. We made the same comparisons for the test of

applicability of the NMI method to the present wave data. Figure 2 is one of the results which are calculated for a 4-year data set of HI (Hitachinaka). The upper one is for exceedance waves and the lower one non-exceedance. As seen from these figures the NMI method yielded moderately good but slightly deviated results. More or less, this was the case for most of other data sets.

This may be due to the fact that the parameters A , β , α , etc. given by Eqs.(4) and (7) does not sufficiently fit to the present wave data. So following Kuwashima and Hogben (1986) we tried to obtain more suitable expressions from the measured data in stead of Eqs.(4) and (7). To complete this, we calculated A , β , α_M (value of α for $H_s' = \bar{H}_s$) from the measured wave data and plotted them against the parameter γ as Fig.3 in which the original values of NMI method are shown with dotted lines. Although there are considerable

Fig. 2 Comparison of the estimated persistence statistics by NMI method with those directly derived from the measured wave data.

Fig. 3 Plots of NMI parameters A , β , α_M against γ
 Seasonal dataset of HI for 4 years were used.

scatter, we obtained the empirical relations instead of Eqs.(4). For example the relations for HI are as follows:

$$A=32.3 \gamma^{-0.464}, \quad \beta=0.552 \gamma^{0.100} \tag{18a,b}$$

$$\alpha_M = 0.202 \gamma \tag{19}$$

The relation of A is almost the same as that of NMI. However the values of β are smaller than those of NMI about by 2.0 and α_M is as small as nearly 3/4

of NMI values.

Figure 4 shows the variations of α_g and α_l of HI normalized by α_M against various threshold height H_s' in the form of Eqs.(7a,b). From the results of these figures we can obtain the following relations:

$$\alpha_g = 0.202 \gamma (H_s' / \bar{H}_s)^{0.318}, \tag{20a}$$

$$\alpha_l = 0.202 \gamma (H_s' / \bar{H}_s)^{-0.044} \tag{20b}$$

When we used Eqs.(18) and (19) in estimating persistence statistics for HI we found that the agreement of the estimated values with those calculated from the measured data increased in most cases. Figure 5 shows the results corresponding to the previous figure 2 and it is seen that the modification of coefficients such as Eqs.(18) to (19) yields better agreements.

We conducted the similar procedures for the monthly divided data sets. Figure 6 shows the calculated values of A , β , α_M for KA and HI, the location of which are the Pacific Ocean side. Since no different tendency was found between the values of HI and KA, both quantities are plotted together and the

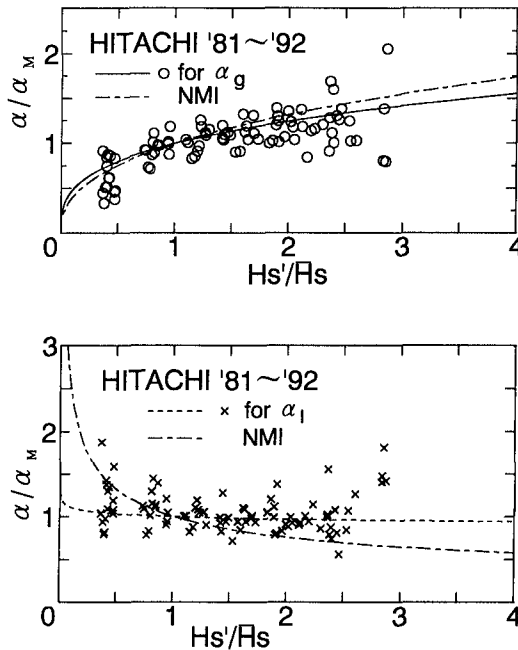

Fig. 4 Plots of α_g and α_l against threshold wave heights.

relations common to the two sites were obtained. Figure 7 shows the variation of α normalized by α_M for HI and KA. From these monthly data we obtained the following relations:

Fig. 5 Comparison of the estimates by the improved NMI formula with those directly derived from the measured wave data.

$$A=32.5 \gamma^{-0.439}, \quad \beta = 0.618 \gamma^{0.0052} \quad (21a,b)$$

$$\alpha_M = 0.195 \gamma \quad (22)$$

$$\alpha_g = 0.195 \gamma (H_s' / \bar{H}_s)^{0.163} \quad (23a)$$

$$\alpha_l = 0.195 \gamma (H_s' / \bar{H}_s)^{-0.150} \quad (23b)$$

Optimum parameter formula for SA and WA

When we applied the NMI method for the wave data of SA and WA in the coast of the Sea of Japan, good agreements were not found similarly to HI and

KA in the coast of the Pacific Ocean. Therefore in the similar way as HI and KA, we tried to obtain the optimum relations for SA and WA. The results of A , β , α_M calculated from the measured data are plotted in Fig.7. Concerning A and β we may take the common formula, that is

$$A=31.1 \gamma^{-0.451}, \quad \beta=1.05 \gamma^{-0.453} \quad (24a,b)$$

Since, however, the magnitude of α_M are slightly but distinctly different between SA and WA, the different relations may be obtained as:

$$\alpha_M = 0.398 \gamma \quad (\text{SA}) \quad (25)$$

$$\alpha_M = 0.355 \gamma \quad (\text{WA}) \quad (26)$$

Fig. 6 Plots of A , β , α_M against γ . Monthly data of HI and KA.

Fig.7 Plots of A , β , α_M against γ . Monthly data of SA and WA.

For reference we show α_g and α_l for SA and WA:

$$\alpha_g = 0.398 \gamma (H_s' / \bar{H}_s)^{0.185} \quad (\text{SA}) \quad (27a)$$

$$\alpha_l = 0.396 \gamma (H_s' / \bar{H}_s)^{-0.137} \quad (\text{SA}) \quad (27b)$$

$$\alpha_g = 0.355 \gamma (H_s' / \bar{H}_s)^{0.176} \quad (\text{WA}) \quad (28a)$$

$$\alpha_l = 0.355 \gamma (H_s' / \bar{H}_s)^{-0.232} \quad (\text{WA}) \quad (28b)$$

It is noted that the magnitude of α_M in the Pacific coast is smaller than that of the NMI method, while it is larger in the Sea of Japan coast as seen from the bottom ones in Figs. 6 and 7. The variability of the estimates by the NMI method are discussed further in the later section.

4. Applicability of Mathiesen's model

Mathiesen (1994) found that the average absolute rate of change of significant wave height S could be expressed by Eq.(15). Figure 8 shows an example of $S(H)$ calculated from the wave data of HI. We can see that the relation of Eq.(15) holds well. Although for the same site the constants q and R in Eq.(15) slightly vary month to month, we neglected the monthly changes similarly to Mathiesen. The mean values of q and R for each location are shown in Table - 1.

Fig.8 Average absolute rate of change of significant wave height at HI.

The values of A and β calculated from Mathiesen's Eqs.(16) and (17) are compared with those of the NMI method and its improved (data-fitted) equation in Fig.9 (HI:upper, SA:lower) in which the monthly average

significant wave heights H_m are also shown. The suffix M and NMI denote Mathiesen's and NMI method, respectively and no suffix the improved equation method. It is noted that A_M are in general different from A_{NMI} and A , and especially too small in summer.

Some examples of the estimated mean durations by the three methods for

Table-1 Constants in Eq.(7)

Station	q	r
HI	0.045 m/h	1.02
KA	0.045	0.98
SA	0.062	0.85
WA	0.055	0.89

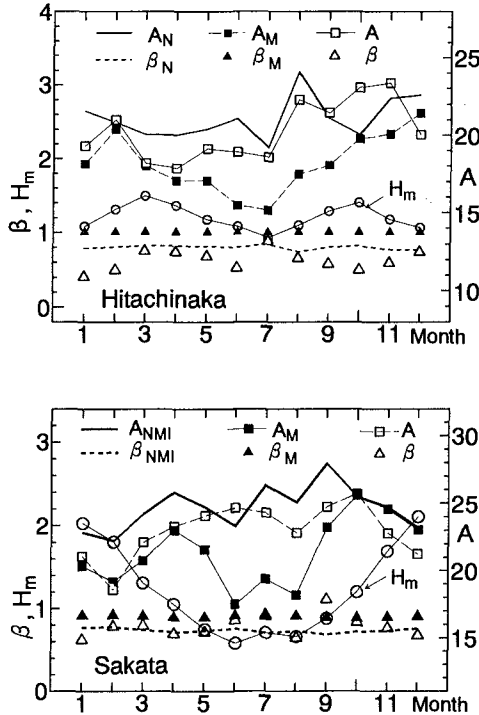

Fig.9 A and β for three method; NMI, improved NMI and Mathiesen at HI (upper) and SA (lower). Suffix N or NMI: NMI method, M: Mathiesen's, no suffix: Improved NMI.

exceedance (GE) and non-exceedance (LT) waves are shown together with those calculated directly from the measured data in Fig.10.

Contrary to our expectation Mathiesen's method generally did not show the better agreement with the measured data than NMI method. Improved NMI method which utilized the relations like Eq.(4) yielded the best agreement.

We tried to find the reason why Mathiesen's model showed rather worse results than the NMI method. The relation of Eq.(9), which Mathiesen used

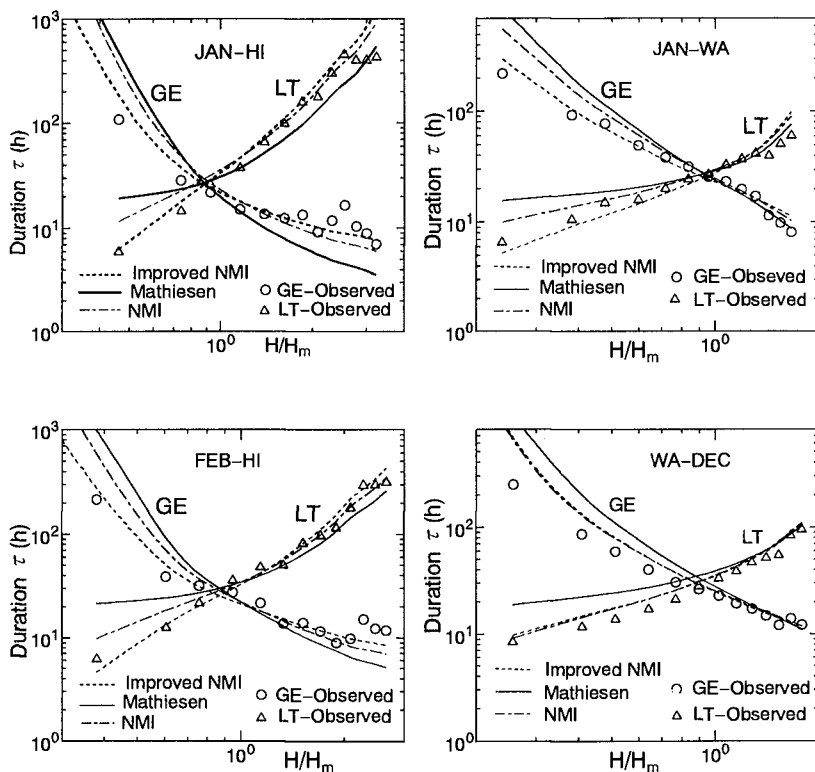

Fig. 10 Comparison of estimates by Mathiesen’s method with NMI and improved NMI method. (Mean duration for exceedance and non-exceedance waves for HI and WA.)

as the foundation of his model, is originally valid to the time series of surface displacement of water waves and $\nu(0)$ coincides with a reciprocal of the zero up-cross wave period. With regard to the time series of wave eight which we used, it was found that the validity of Eq.(9) became poor at the wave height apart from the mean height. It was also found that the degree of accuracy of Eq. (10) was reduced depending on the month.

5. Discussion

Figure 11 shows the monthly values of γ for 4 sites analyzed in this study. As seen from this figure, the values of γ for the two sites (SA and WA) in the Sea of Japan are, except the months in winter, smaller than those of the two sites (HI and KA) in the coast of Pacific Ocean.

In the figures 3, 6 and 7, etc. from which the expressions of A and β were

obtained in terms of γ , the point were scattered considerably. So it may give an impression that the estimates by NMI method or improved NMI method include a great deal of errors. The figure such as Figs. 2 and 5 is not suitable to grasp the general degree of agreement. In order to see the accuracy of the estimated values compared with the observed values, we prepared Fig.12. It shows the cumulative frequency (times/month) of the non-exceedance waves ($H \leq 1.0\text{m}$) and exceedance waves ($H \geq 1.5\text{m}$) for durations of 24 and 72 hours for HI in the Pacific coast and WA in the Sea of Japan. Triangle points

Fig. 11 Monthly variations of γ for 4 stations.

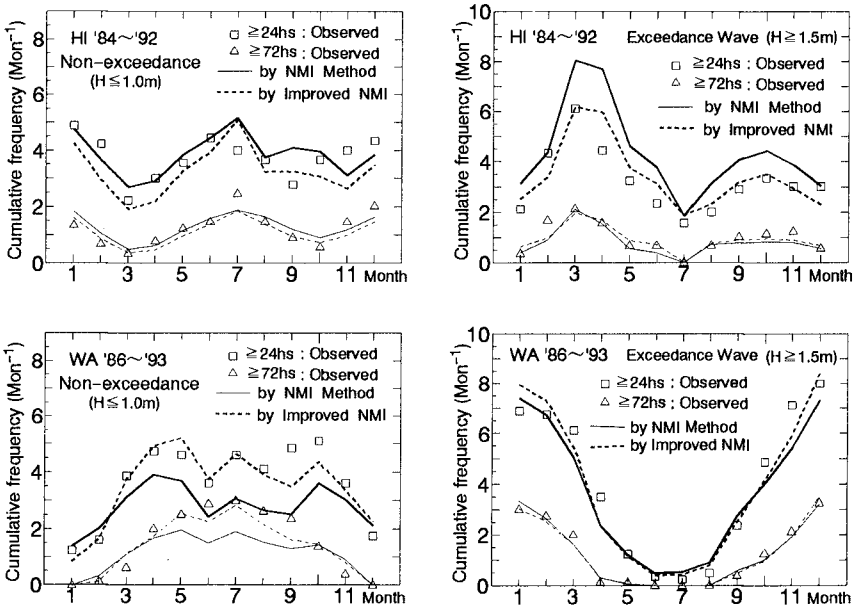

Fig.12 Estimates of wave persistence by NMI and improved NMI method in comparison with observed data at HI (upper) and WA (lower).

represent the observed values for 24 hours and square points 72 hours. Solid and dotted lines denote the estimates by NMI and improved NMI method, respectively.

From these figures it is seen that the increasing or decreasing tendencies of the estimated results are in good agreement with those of the observed values, and it may indicate the excellent feature of the NMI method in which the estimates of wave height persistence statistics are obtained from cumulative probability distributions of significant wave height $Q(\geq H_s)$ and a single parameter γ .

6. Conclusions

The NMI method was found to give reasonably good estimates, though it yielded slightly deviated result for each site. Modification like Eqs.(4) and (7) was effective. Although considerable scatters were found in evaluating the optimum NMI parameters for the different data sets, it was found from the monthly data analysis that the NMI method yielded good tendencies of variations of wave persistence statistics in comparison with the real values calculated directly from the measured wave data.

It was found contrary to our expectations that Mathiesen's model did not give any better estimates than the NMI method for the mean durations of both exceedance and non-exceedance waves. Some possible reasons were discussed. .

CHAPTER 64

PROBABILISTIC MODELING OF LONG-TERM WAVE CLIMATE

V.M. Leyden¹ and W.R. Dally²

Abstract

Utilizing eight years of wave measurements from the U.S. Army Corps of Engineers Field Research Facility (FRF), this study develops a long-term probabilistic model for the energy-based significant wave height (H_{m0}) based on the shifted gamma distribution. The method of moments is used in best-fit model parameter estimation. Shifted gamma distributions are developed for the entire eight years of H_{m0} data, as well as for the individual years in the data set. The shifted gamma distribution represents the FRF H_{m0} data for both the total and yearly data sets. Further, the distribution which represents the total, or long-term, data also effectively models the yearly data, indicating that the shifted gamma distribution is a useful engineering tool for predicting long-term wave climate.

Introduction

In order to obtain the most accurate and reliable information on ocean waves, wave climate needs to be studied over the long-term. Hogben (1990) defines long-term statistics as those which describe sea conditions over time spans of years, and it is in this definition that one discovers the problem; not many data sets exist which have time scales on this order. Isaacson and MacKenzie (1981) note in their review of long-term distributions of ocean waves that design wave estimates based on 100 years of data differ by a factor of 3 when compared to estimates considering only two successive years. Furthermore, Soares (1988) found that predictions of significant wave height varied between 9.02 and 14.11

¹Graduate Research Assistant and ²Associate Professor, Ocean Engineering Program, Florida Institute of Technology, 150 W. University Blvd., Melbourne, FL, 32901 USA.

meters when based on data sets that were one year long, whereas the significant wave height only varied between 10.49 and 12.79 meters when based on data sets which were 10 years in length. It is clear that an adequate data base is crucial to the value of any long-term wave climate study.

Although the long-term wave climate is a basic element of many coastal engineering issues, few probabilistic models for long-term statistics have been developed. Of those available, e.g., the modified exponential distribution for significant wave height presented in the Shore Protection Manual (1984), estimation of best-fit model parameters has been hampered by a lack of suitable long-term data. There are several means available for acquiring long-term wave data: visual observations, remotely sensed wave data, hindcast results, and in situ measurements. Of these, in situ measurements are regarded as the most accurate and reliable form of wave data. Because of measurement programs initiated in the early 1980's, such in situ data sets are now becoming available. For instance, Teng, Timpe, and Palao (1994) use thirteen years of buoy data from the National Data Buoy Center (NDBC) to estimate design wave heights, and Soares and Henriques (1994) use seven years of data collected from an oil platform in the North Sea to examine model parameter estimation. This study will develop generic, long-term wave climate statistical models utilizing a similar measurement program.

Description of Field Data

One of the best long-term data sets of nearshore wave climate has been collected by the U.S. Army Corps of Engineers Field Research Facility (FRF), located in Duck, North Carolina. The wave data used in this study were collected from a pressure gage located at a nominal water depth of 8 m. These time series consist of 34 minute records collected once every six hours. The sampling rate of the gages was 2 Hz (U.S. Army, 1993). Both the energy-based significant wave height, H_{m0} , and the peak wave period, T_p , are computed from the pressure gage time series and reported in monthly data summaries. H_{m0} is equal to four times the square root of the area under the wave energy spectrum, and T_p is the wave period associated with the maximum wave energy in the spectrum. The FRF data used in this study were collected from May 1987 to April 1995 - almost 11,400 entries in all.

Constructing histograms, along with finding some of the basic statistical properties of the data, provides an immediate indication of the range of the data, its most frequently occurring values, and how the data is dispersed about the typical value. A bivariate histogram of H_{m0} and T_p (Figure 1) illustrates the entire range of wave heights and periods the FRF experiences. The histograms of H_{m0} and T_p are also useful in the visualization of the wave climate at the FRF. Figures 2 and 3 show these histograms respectively.

Figure 3. Histogram of T_p Data from FRF (May 1987 - April 1995)

The Shifted Gamma Model

Past research efforts have found several probability distributions which successfully model long-term distributions of wave height. For instance, using between one and seven years of data from 18 sites around the British Isles, Burrows and Salih (1986) concluded that even though the Weibull distribution did not fit the lowermost regions of the significant wave height (H_s) histograms as well as the lognormal distribution, it provided a better overall fit. On the other hand, Soares, Lopes, and Costa (1988) took four years of waverider buoy data collected off the coast of Portugal and found that the lognormal distribution provided the best fit for H_s .

After considering several probability distributions, the present study found that the shifted gamma distribution best represented the FRF H_{mo} data set (see e.g., Benjamin & Cornell, 1970):

$$pdf(H_{mo}) = \frac{\lambda}{\Gamma(k)} [\lambda(H_{mo} - H_*)]^{k-1} e^{-\lambda(H_{mo} - H_*)} \quad H_{mo} \geq H_* \quad (1)$$

In this model H_* is a shifting parameter, λ is a scaling parameter, k is a shape parameter, and $\Gamma(k)$ is the gamma function. The method of moments was used to

determine the best-fit parameters. This method utilizes the mean (\bar{H}_{mo}), the standard deviation (σ), and the skewness (s) of the FRF H_{mo} data set to estimate the model parameters. Using this method, equations (2), (3), and (4) are solved simultaneously:

$$\bar{H}_{mo} = H_* + \frac{k}{\lambda} \quad (2)$$

$$\sigma = \frac{\sqrt{k}}{\lambda} \quad (3)$$

$$s = \frac{2}{\sqrt{k}} \quad (4)$$

One property of the shifted gamma model should be noted; i.e. if $k \leq 1$, then the shifted gamma distribution reduces to an exponential-like function, which does not represent the basic shape of the H_{mo} histogram (see Figure 2). Because the shape parameter (k) is determined strictly from the skewness of the data set [refer to equation (4)], s must be less than two. In order to overcome this problem, the H_{mo} data set was edited by removing all wave heights above 3.0 meters. As the focus of this study is on long-term wave climate, and not on extreme storm events, the removal of the largest values is not detrimental.

H_{mo} Data Editing and Statistics

Once H_{mo} values above 3.0 meters were removed from the FRF data, the edited data could be modeled successfully using the shifted gamma distribution. Table 1 presents some of the basic statistical properties of the raw data, and how these properties fared once wave heights above 3.0 meters were removed. For the entire eight years of FRF H_{mo} data (11385 observations) a total of 139 observations above 3.0 meters were trimmed. Although the mean and the standard deviation do not change significantly, the skewness undergoes the greatest change. For instance, the mean of the raw and trimmed data sets for the entire eight years are 0.87 and 0.84 meters, respectively. There is a slightly larger change in the standard deviation which drops from 0.58 meters in the raw data set to 0.49 meters in the trimmed set. The skewness undergoes the greatest change. It drops from 2.18 for the raw data to 1.52 for the trimmed data.

Comparisons between the raw and trimmed data statistics for the individual years are similar to those of the entire data set. Out of the eight years of data, the period from 1987-1988 had the fewest observations trimmed (seven observations). Although the mean and the standard deviation do not change significantly, the

skewness drops from 2.44 to 1.75. In contrast, the greatest number of observations trimmed was during 1992-1993, when 39 values were found to be above 3.0 meters. Once again, there is little change in the mean and standard deviation, whereas the skewness value drops from 1.89 to 1.40.

Table 1. Basic Statistics of Raw and Trimmed FRF H_{mo} Data

Year (s)	Raw Data Set				Trimmed Data Set				
	# of Obs.	Mean (m)	Std. dev. (m)	Skewness	# of Obs.	# Trimmed	Mean (m)	Std. dev. (m)	Skewness
1987-1995	11385	0.87	0.58	2.18	11246	139	0.84	0.49	1.52
1987-1988	1423	0.82	0.50	2.44	1416	7	0.81	0.45	1.75
1988-1989	1406	0.89	0.58	2.15	1386	20	0.85	0.48	1.33
1989-1990	1423	0.85	0.57	2.40	1410	13	0.82	0.49	1.65
1990-1991	1423	0.88	0.51	1.84	1414	9	0.86	0.47	1.28
1991-1992	1446	0.87	0.62	2.39	1421	25	0.82	0.49	1.55
1992-1993	1440	0.99	0.69	1.89	1401	39	0.92	0.55	1.40
1993-1994	1435	0.80	0.52	2.04	1425	10	0.78	0.48	1.66
1994-1995	1389	0.88	0.60	1.96	1373	16	0.84	0.53	1.50

Best-fit Model Parameters

The best-fit model parameters for the shifted gamma distribution were found using the method of moments as dictated by equations (2), (3), and (4). Table 2 illustrates the values of the shifting parameter (H_*), the shape parameter (k), and the scaling parameter (λ) for the entire eight years of FRF H_{mo} data, as well as for the yearly data sets. Table 2 also includes the maximum and minimum values of each model parameter (the bold numbers in each column), and the mean and standard deviation of the model parameters from the eight individual years of data.

The first row in Table 2 contains the values of the best-fit parameters for the entire eight years of H_{mo} data from the FRF. These values ($H_*=0.19$ m, $k=1.72$, and $\lambda=2.66$ m⁻¹) are comparable to the mean values computed from the eight individual years of data. Beginning in the second row of Table 2, the model parameters for the eight individual years of data are presented. The minimum and maximum values of H_* are 0.13 (1988-89 and 1990-91) and 0.29 meters (1987-1988), respectively. The mean value of the shifting parameter is 0.18 meters and its standard deviation is 0.06 meters. The second column contains the values for the shape parameter, k . Its minimum value occurred during the year 1987-1988 (1.31) and its maximum value occurred during 1990-1991 (2.44). The mean of the shape parameter for the eight years is 1.80 and the standard deviation is 0.40. Finally,

column three of Table 2 contains the values of the scaling parameter, λ . The minimum value for the scaling parameter is 2.49 m^{-1} , which is associated with the data from 1989-1990. The maximum value for λ is 3.33 m^{-1} (1990-1991). The mean and the standard deviation of λ from the eight individual years of data are 2.72 m^{-1} and 0.32 m^{-1} , respectively.

It is interesting to note that the maximum values for k and λ and the minimum value for H_s all occur during the year 1990-1991. For an explanation one need look no further than the skewness values for both the raw and trimmed data during this time period. In both instances, 1.84 for the raw data and 1.28 for the trimmed data, the skewness values are the lowest of all eight years. As the method of moments begins with solving equation (4), it is easy to see how the skewness of the data set can have such an impact on the rest of the model parameters.

Table 2. Best-fit Model Parameters for the Trimmed Data Sets of H_{m0}

Year(s)	H_s (m)	k	λ (m^{-1})
1987-1995	0.19	1.72	2.66
1987-1988	0.29	1.31	2.53
1988-1989	0.13	2.25	3.14
1989-1990	0.23	1.47	2.49
1990-1991	0.13	2.44	3.33
1991-1992	0.18	1.66	2.62
1992-1993	0.14	2.02	2.59
1993-1994	0.21	1.46	2.54
1994-1995	0.14	1.78	2.53
<i>Mean</i>	0.18	1.80	2.72
<i>Std. Dev.</i>	0.06	0.40	0.32

Model Comparison to Long-Term Wave Climate

Figure 5 illustrates the ability of the shifted gamma distribution to model the long-term (entire eight years) FRF H_{m0} data. In Figure 5 the circles represent the percent occurrences of the data, whereas the shifted gamma model is represented by the solid line. Although the model under-predicts the most frequently occurring wave heights (in the 0.60 meter range) by 3%, it correctly predicts that H_{m0} values in the 0.40 meter range occur 26% of the time. Overall, the shifted gamma distribution is in good agreement with the data.

Figure 4. FRF H_{m0} Model Comparison -- 1987-1995

Model Comparisons to Yearly Data Sets

Figures 5-12 show how the shifted gamma distribution compares to the FRF H_{m0} data on a yearly basis. Beginning with the year 1987-1988 (Figure 5) and ending with the year 1994-1995 (Figure 12), the shifted gamma distribution shows good agreement with the data. These figures also illustrate how the long-term shifted gamma model (the dashed line) performs when plotted on top of the yearly H_{m0} histograms. In Figures 6, 8, 9, and 12 the long-term model does as well, or better, than the model developed from only that one year of data. In three of the years (Figures 6, 8, and 12) the long-term model more accurately captures the peak of the distribution. However, there are also several cases where the long-term model fails to provide as accurate a fit as that provided by the yearly model. In

Figures 5, 7, and 11 the long-term model noticeably under-estimates the percent occurrence of the most commonly occurring wave heights. It is interesting to note, however, that these three years of data have the highest skewness values. And for two of the years, 1987-1988 (Figure 5) and 1989-1990 (Figure 7), even the yearly model failed to capture the peak percent occurrence.

Figure 10 presents the only case in which the long-term model noticeably over-predicts the most commonly occurring wave heights. This time period, (1992-1993), is unique from any other because the H_{m0} histogram lacks a well-defined peak. This year of data had the highest mean and standard deviation values, as well as the third-smallest skewness (see Table 1).

Conclusions

The problem hampering the development of long-term wave climate models, i.e. a lack of suitable data, is gradually being overcome as monitoring programs such as that from the FRF continue. Utilizing data sets such as these, best-fit model parameters can be estimated with more confidence than in the past.

Utilizing eight years of data from the FRF (May 1987 to April 1995) and the method of moments, best-fit model parameters were found for the shifted gamma distribution. This probabilistic model appears to represent the FRF H_{m0} data for the entire eight years of data, as well as on a yearly basis. Furthermore, although it sometimes fell short of capturing the peak percent occurrence, the long-term distribution modeled the yearly H_{m0} histograms to a reasonable degree. Therefore, the shifted gamma distribution should be considered when developing long-term wave climate models.

Acknowledgments

The data used in this study were provided by the Field Research Facility of the U.S. Army Engineer Waterways Experiment Station's Coastal Engineering Research Center. The authors would particularly like to thank Dr. Charles E. Long for his numerous suggestions and comments regarding the use of this data. The financial support of the Sebastian Inlet Tax District is also gratefully acknowledged.

CHAPTER 65

MONTE CARLO SIMULATION FOR NEARSHORE WAVE STATISTICS IN SOUTHERN CALIFORNIA

Chia-Chi Lu¹, Member, ASCE and R. Rea Strange III²

ABSTRACT

To develop the nearshore wave condition in Southern California, six meteorological weather patterns including extratropical cyclones of the northern hemisphere, northwest winds in the outer coastal waters, west to northwest local sea, pre-frontal local sea, tropical storm swell and extratropical cyclones of the southern hemisphere were identified and classified. Wave characteristics in deep water, corresponding to the categorized weather patterns, were computed and then transferred to the nearshore target sites via a spectral back-refraction transformation model. A Monte Carlo simulation technique was applied to generate a synoptic atlas of the nearshore wave climate in this region.

INTRODUCTION

Waves, currents and water levels are the dominant oceanographic forces that control the movement of sediment and determine, in part, the potential for coastal flood damage exposure. Waves that impinge on the shoreline perhaps more than any other oceanographic factor, determine the fate of sediment movement and the associated impacts to coastal development. An understanding of the temporal and spatial variation of waves is critical to the formulation of effective shoreline erosion management plans. Although wave hindcast and measurement data are currently available in Southern California, existing databases are sparse and lack sufficient detail of important information. For example, wave direction data, important in the understanding of sediment transport processes, are limited; and most of the hindcast wave data exclude waves generated in the southern hemisphere ocean (southerly swell). This study was therefore performed to address data gaps and to develop a practical database that can characterize the wave climate for the Orange County shoreline in Southern California.

METHODOLOGY

The technical approach taken in this study is unique and represents a significant departure from previous wave studies within Southern California. In general, the following procedures were adopted.

1. Local, regional and hemispheric meteorological weather systems which influence the wave climate within this region were identified. In this manner, the local and distant origins of ocean wave generation patterns and their recurrence frequencies were defined.
2. A state-of-art spectral transformation numerical model was applied to characterize how the offshore waves will change in height and angle of shoreline approach as they propagate into the nearshore water area.
3. A synthetic nearshore wave database was compiled by using a Monte Carlo simulation technique based on the probable sequential and combined occurrences of different meteorological events and their associated wave generation patterns.

Pattern Identification

Waves that impact the Southern California coastline, as shown in Figure 1, are generated by any one or more of the following meteorological patterns:

- I. Extratropical cyclones of the northern hemisphere (northwest to west-southwest swell);
- II. Northwest winds in the outer coastal waters (wind swell);
- III. West to northwest local sea (west sea);
- IV. Pre-frontal local sea (southeast sea);
- V. Tropical storm swell ;
- VI. Extratropical cyclones of the southern hemisphere (southerly swell).

Low pressure centers which develop along the polar front are the source of the predominant wave action along the Southern California coast during the winter half of the year. Storm swell is generated at some distance from the Southern California coastline in the North Pacific. Most commonly these storms will traverse the mid-Pacific before turning northeastward toward the Gulf of Alaska with swell decaying on the average of 2,400 kilometers to the coast of Southern California. However, under some meteorological conditions, storms can move in much closer to the coast; and on rare occasion these storms may move directly across Southern California, following either a northeast, east or southeast trajectory. In general, the modal deep water approach directions range between 275° and 285°. However, these North Pacific low pressure systems exhibit great variations from year to year such that wave approach directions and amplitudes will show a corresponding degree of variation. Years when the storm centers follow a more northerly route in the eastern Pacific will result in extremely quiet conditions in Southern California, whereas more southerly storm tracks through the mid and/or eastern Pacific will result in frequent periods of high wave conditions.

The predominant swell along the Southern California coast in spring and summer is generated by the prevailing northwest winds north and west of this area. Wave heights are usually low, less than one meter, but on occasion, with superposition of a strong surface high and an upper level trough, the northwesterlies increase, becoming very strong from north of Point Conception to San Nicolas Island. Waves traveling at a variance to the mean wind direction reach Southern California with periods on the order of 6 to 10 seconds. Moderate northwesters will produce breaker heights of one to two meters, while strong events can give two to 3 meters.

Seas generated by westerly winds can be divided into two types: 1) temperature-induced sea breezes, and 2) gradient winds. The strong sea breezes occur during the late spring and summer months, while the lightest winds are during December and January. The sea breezes usually set in during the morning and peaks in the mid-afternoon. Gradient winds are confined largely to the months of November through May with the peak in March and early April.

Pre-frontal winds blow strongly from the southeast along the coast but turn toward the south to southwest a short distance offshore. Significant wave heights are generally in the range of one to 2.5 meters. Westerly swells tend to follow the frontal passage, when southeast seas are well on the way down, but on occasion the two wave trains overlap.

Tropical cyclones form regularly along the intertropical convergence zone west of Mexico from early July to early October. On the average, about 15 of them are to be expected each year. Most of them take a westerly track, and swells generated by these storms will have little or no effect on Southern California. Some, however, take a more northerly track and swells off Southern California may reach 2 to 4 meters.

Southerly swells occur primarily between April and October and to a lesser extent the remainder of the year. Large South Pacific storm systems traversing the ocean between 40° and 60° south from Australia to South America send swells northward to the west coast of Central and North American. Great circle approach directions off Southern California range from about 215° for storms near New Zealand to 170° for South American storm system. The decay distance ranges from 7,200 to 11,200 kilometers. Swells in deep water off Southern California are generally about one meter, but breaker height may be 3 to 4 meters or more.

To better distinguish the wave conditions generated from the aforementioned meteorological patterns, each weather type was further classified according to wind speed, effective fetch, decay distance and storm duration. Table 1 tabulates the meteorological criteria for the classified categories within each generated wave pattern. The destructive storms of March 2, 1983 and January 17, 1988 are examples of the storm swells of Category 4a.

Pattern Recurrence

The meteorological characteristics, which produce various wave generation patterns, change seasonally. Four meteorological seasons were defined according to weather characteristics instead of the traditional calendar seasons. The discrete meteorological seasons have a two-month spring (April and May), a three-month summer (June to August) and fall (September to November), and a four-month winter (December to March). Observed storm swells or seas between 1974 to 1993 were reviewed from the Pacific Weather Analysis' daily logged data bank. Seasonal recurrence of the classified wave generation patterns was then derived to characterize the probability of occurrence for each classified category. Table 2 shows the resultant seasonal occurrence for each wave generation pattern. For example, the occurrence of northwest to west swells (Pattern I) has its peak frequency in winter, while observations of long-period southerly swells (Pattern VI) have a summer peak.

The possible wave approach directions generated from all six weather patterns were also evaluated from the historical data between 1974 to 1993. Wave directions with a 5-degree increment were discretized for the northwest or west storm swells (Pattern I). Table 3 lists the discretized ranges of deep water wave approach directions and their probability of occurrence for each category. Three discretized wave directions were designated for the tropical storm (Pattern V) and the southerly swell (Pattern VI). Tables 4 and 5 show the directional occurrence probability for the tropical storm and the southerly swell respectively. The prevailing deep ocean approach direction is from west (270°) for both the wind swell and west to northwest local sea, and southeast (160°) for pre-frontal local sea (southeast sea).

Deep Water Wave Characteristics

Based on the aforesaid meteorological parameters such as wind speed, effective fetch, decay distance and storm duration, the deep water wave characteristics were computed from a PWA wave generation model. The PWA hindcast method is based on the principles set forth by Pierson, Newmann, and James (1955) wherein the energy in each frequency band of the wave spectrum, propagating at group velocity with angular spreading, is generated and recombined with other frequency bands at the hindcast point to give the predicted spectrum.

The PWA model, which is proprietary, has been developed through analysis of wave data taken from several locations along the California coast. The hindcasted spectral form is quite wide during the early stages of development; but as the wind speed, fetch or duration increases the spectrum narrows, with the front face becoming steeper. The wind speed is the most critical as compared to the effect due to the fetch. The spectral area does increase as the fetch increases, and the peak energy shifts toward longer periods but at a decreasing rate. Although there is no fully developed absolute condition for this spectrum, the spectral curves flatten out to such an extent at low frequencies that maximum periods have been assigned as the criterion for the "fully developed" sea. The approximate areas where the hindcast deep water wave characteristics were performed are indicated in Figure 1.

Nearshore Wave Transformation

The wave characteristics derived from the meteorological weather patterns, described in the last section, all represent deep water environments. To determine the wave conditions within the Southern California coast, it is necessary to transform the predicted deep water wave conditions to the nearshore water area. The transformation process consists of adjusting deep water wave heights and approach directions due to the effects of island sheltering, shoaling, refraction and diffraction. In this study, a spectral back-refraction model (O'Reilly & Guza, 1991) was selected as the tool to transfer the deep water wave environments into the nearshore water area.

O'Reilly's spectral back-refraction model performs a linear spectral refraction transformation in which the transferred spectrum is established from the incident wave spectrum by back-refracting rays from the target site. The model accounts for island blocking, wave refraction, and wave shoaling. It is typically used to model waves with periods between 8 and 25 seconds. The model includes deep ocean swell directions ranging from 150 to 335 degrees. Unlike more traditional forward ray refraction methods, O'Reilly's model back-refracts wave rays from the site of interest, therefore eliminating caustics which plague forward ray tracing schemes. As a result, the spectral transformations are robust (finite solutions are always obtained), easily interpreted, and more realistic than those obtained using forward ray tracing and the assumption of unidirectional, monochromatic deep ocean waves.

For a known deep water wave condition including both energy and directional spectra, the transformation is performed by :1) decomposing the deep water energy spectrum and the deep water directional spectrum into 1-second and 1-degree increments, respectively; 2) obtaining the transformed energy at the target point for each component from the transformed and normalized coefficients; 3) assembling the transformed wave components to form an energy spectrum and a directional spectrum at the target point; and 4) determining the significant wave height, the wave period and the approach direction from the transferred spectra.

In this study, the nearshore wave conditions transformed from the hindcasted deep water wave characteristics in spectrum form were computed every three hours to describe the temporal variability of the wave condition. The significant wave height was determined from the spectrum computed every three hours; and the significant wave period and the predominant wave direction correspond to the period and the direction at the peak wave energy component. Approximately, 5,800 wave event data sets were computed and cataloged, including all classified categories and different wave approach directions for each nearshore site of interest. This wave information provides the data bank necessary for the characterization of long-term wave statistics.

Monte Carlo Simulation

A Monte Carlo simulation technique was applied to generate a synthetic practical data base to characterize the Orange County nearshore wave climate. This technique

recreates a stochastic process to solve a problem which can not be easily evaluated by a direct analytic or a standard numerical analysis procedure. In this study, a computer code was written in accordance with the probability occurrence scenarios derived from the 20-year daily recorded weather patterns, as previously described.

In addition to the individual seasonal probability distribution related to each wave pattern, the 20-year statistics of the recorded wave patterns also provide a basis for assessing the coupling (coincident events) and the likely sequential order among different wave patterns. A few principles were derived and implemented in the computer code. These are:

1. The recurrence for each weather pattern varies seasonally in accordance with the derived probabilities of occurrence.
2. The occurrence of southerly swells and tropical storms were treated independently since their meteorological characteristics are not related to the remaining weather patterns. Also, there is no intercorrelation between southerly swells and tropical storms.
3. There is a 30% chance in which the coupling between two northwest to west-southwest extratropical storm swells occurs in winter. The occurrence distribution for each storm category is listed in Table 6.
4. After a west local sea, there is a 50% chance that a wind swell follows for all seasons.
5. After a southeast local sea, there is a 30% chance that a category 4 northwest to west storm swell or a 30% chance of a west sea follows in winter.
6. A background noise is selected if no wave event occurs in each simulated day. The noise can be either a weak northwesterly swell, a light wind swell, a slight southerly swell or a sea breeze only occurring in the afternoon.

In the Monte Carlo simulation, numbers between 1 and 100 were randomly generated. The model performed the wave event selection in accordance with the sequence of the random numbers. For example, if the first random number implies a storm event is evident, the following random numbers would determine the wave pattern, intensity category and incoming direction. The model then determines if another wave pattern occurs simultaneously. After the end of all possible coincident or subsequent events which may be a few simulated days later, the model reselects a random number and repeats the same procedure. On the other hand, if the random number implies a no-storm event, the model would generate a background noise for the particular simulated day and selects a new random number the next day to proceed the simulation. The simulated daily nearshore wave environment may be composed of a single, multiple wave events or no event with a background noise only.

RESULTS

The recurrence probability of the identified weather patterns was compiled on a season-by-season basis. Therefore, the simulation can be used to statistically characterize the seasonal and annual nearshore wave environments. Figure 2 illustrates one of the simulated wave environments for a winter month at San Clemente, where a California Data Information Program (CDIP) gage station is located. For a multiple-wave-event selection, the significant wave height was computed from the superposition of all the wave energy spectra, and its associated wave period and approach direction was defined as the period and direction of the peak energy component.

In order to be statistically significant, it was necessary to perform replicate simulations so that the statistical moments such as the mean and deviation can be derived. The trial and error process was conducted to determine the required number of simulations to yield a valid record of data for one year. It was found that approximately 10 simulations were adequate to provide a statistical significance of the results. Figure 3 presents the average annual statistics of significant wave height and period at the San Clement gage station obtained from the Monte Carlo simulation compared to the average field measurements recorded over 6 years (US Army and State of California, 1984, 1985, 1986, 1987, 1992 and 1993). It is noted that no complete annual wave measurements were collected at the San Clemente gage from 1988 to 1991.

As seen in Figure 3, the majority of observed wave heights (about 88% of time) ranges from 0.4 to 1.3 meters, while an occurrence of about 73 % was estimated from the simulated results. The model overpredicts the occurrence of lowest significant wave height (16% for $H_s < 0.4$ meter). The difference may be attributed to the following reasons.

1. In the field condition, the background noise is always present. This noise would contribute additional wave energy to the total spectrum, thereby increasing the resultant significant wave height. However, in the model simulation, no background noise was introduced as long as a wave event was selected. A test simulation was conducted to incorporate the background noise on a daily basis. The resultant statistics shows the reduced occurrence of low wave events ($H_s < 0.4$ meter) and more frequent recurrence of high wave event ($H_s > 1.6$ meters). This implies that incorporated background noise combined with the selected wave patterns will overmagnify the storm events. The model result can be improved with the development of an improved background noise incorporated in the simulation.
2. The El Nino effect, which occurs every 3 to 7 years, was not implemented in the model simulation. Approximately two to three El Nino scenarios of different severities (Seymour et al, 1984) may occur over 10 simulations (10-year span). During an El Nino year, the frequency of storm events occurring in winter may increase, which would result in occurrence of more intermediate wave events ($0.4 \text{ meter} < H_s < 1.3 \text{ meters}$) and a reduction in the average percentage of occurrence for low wave events ($H_s < 0.4 \text{ meter}$).

In the statistical representation, the wave period selected only represents a peak energy component of the combined wave trains. Other components are not included in the statistical count. For example, if two wave trains with different significant periods of 11 and 15 seconds are simulated and the wave energy for the 11-second wave train is slightly higher, the statistics only count for the period of 11 seconds. The wave train with a 15-second significant wave period is as important, but is not counted in the annual statistics. Thus, comparisons of significant wave period, based solely on the peak energy period without further evaluating the combined wave trains, may be somewhat misleading. The discrepancy of annual statistics for wave period may not be as significant as that for wave height.

CONCLUSIONS

The Monte Carlo simulation method presented in this study provides an alternative to characterize a long-term (annually or seasonally) synoptic nearshore wave climate within Southern California. For each simulated daily wave environment, the influencing weather patterns originating from distant or local areas can easily be identified. Also, the spatial variation of wave climate can be evaluated as the simulation is applicable to any selected nearshore location. Further studies in better quantifying the specified background noise and including the El Nino effect are suggested.

CHAPTER 66

BOTTOM FRICTION DISSIPATION IN THE BELGIAN COASTAL REGIONS

Weimin Luo¹, Jaak Monbaliu², Jean Berlamont²

Abstract

The effect of bottom friction dissipation and of the different formulations used for this term on the wave evolution has been investigated in the Belgian coastal regions. Two eddy viscosity models for the bottom friction dissipation, the Madsen *et al.* (1988) model and Weber's (1991a) model have been implemented in the Cycle 4 version of the third generation WAM model (Günther *et al.*, 1992). The wave conditions for the area of the southern North Sea were hindcasted for the February 1993 storm. The results are compared with buoy data. It is found that the net effect of bottom friction dissipation on the significant wave height hindcast is quite big, in the order of 80% (of the wave height when the bottom friction dissipation is taken into account) along the Belgian coast. Different formulations for the bottom friction dissipation have a quite significant effect on wave evolution in storm conditions. The use of equivalent dissipation coefficients (Luo *et al.*, 1994) results in nearly identical wave hindcasts.

Introduction

Accurate knowledge of wave conditions in coastal areas is very important for the design of harbours or of coastal protection works. Very often these data are not available from measurements and one has to rely on wave models. For example, in Belgium, a wave prediction model is a very useful tool for the navigation of large sea vessels through the shallow entrance channels towards the harbours of Antwerp and Zeebrugge. In general, deep water wave hindcasts are fairly reliable. In shallower areas energy dissipation due to bottom friction can become

¹ Postdoctoral fellow, Proudman Oceanographic Lab., Birkenhead, UK.

² Professor, Lab. of Hydraulics, K.U.Leuven, de Croylaan 2, 3001 Heverlee, Belgium.

important. The Belgian coastal area is characterised by a sandy bottom and the bottom friction contributes significantly to the energy dissipation. A good representation of this source term is necessary.

In the last decades several different bottom friction dissipation formulations have been developed, including an empirical expression based on the JONSWAP experiment (Hasselmann *et al.*, 1973), two drag-law models (Hasselmann and Collins, 1968; Collins, 1972) and two eddy viscosity models (Madsen *et al.*, 1988; Weber, 1991a). These formulations have widely been used in many operational wave models. The effects of different bottom friction formulations on the energy balance were quantitatively investigated by Luo and Monbaliu (1994). They found that these formulations for the bottom friction source terms result in quite different growth curves for the total energy and the peak frequency for depth-limited wind generated waves. For a water depth of $15m$ and a wind friction velocity of $0.71m/s$ (the corresponding U_{10} equal to $16.5m/s$) a difference as big as 70% for the total energy was reported. Moreover, the required CPU time for different formulations is quite different. The empirical formulation is the simplest one and needs the least amount of computing time. The eddy viscosity model is the most complicated one, and costs the most computing time owing to the extra determination of the friction factor and the bottom friction velocity. Later on Luo *et al.* (1994) proposed the equivalent dissipation coefficients so that different bottom friction dissipation formulations produce the same or nearly the same levels for the total energy and the peak frequency for fetch-limited shallow water conditions.

In this study, the effect of different bottom friction dissipation models on wave evolution in the Belgian coastal regions is investigated. Three different models for the bottom friction dissipation, the empirical expression (Hasselmann *et al.*, 1973) and two eddy viscosity models (Madsen *et al.*, 1988; Weber, 1991a), have been implemented in the Cycle 4 version of the third generation WAM model (Günther *et al.*, 1992). Hindcasts are made for February 1993 in the Belgian coastal area as to study the effect of different bottom friction dissipation formulations on wave evolution and to test the validity of using equivalent coefficients for different formulations in operational circumstances. The results are compared with buoy data at different measurement stations.

THE WAVE MODEL

The wave model used for the present study is the Cycle 4 version of the WAM model (Günther *et al.*, 1992) with a choice for the bottom friction dissipation term. The WAM model is a third generation wave

model which solves the wave transport equation explicitly without any ad hoc assumption on the shape of the wave spectrum. It contains today's knowledge of the physics for the wave evolution of a two dimensional wave spectrum. The basic energy transport equation for a spherical latitude-longitude (ϕ, λ) co-ordinate system, in the absence of currents, can be expressed as,

$$\frac{\partial F}{\partial t} + \frac{1}{\cos\phi} \frac{\partial}{\partial\phi}(c_\phi \cos\phi F) + \frac{\partial}{\partial\lambda}(c_\lambda F) + \frac{\partial}{\partial\omega}(c_\omega F) + \frac{\partial}{\partial\theta}(c_\theta F) = S_{in} + S_{nl} + S_{ds} + S_{bf}$$

where F is the wave energy spectrum, t is the time, ϕ is the latitude, λ is the longitude, ω is the angular frequency, θ is the wave direction measured clockwise from the true north, c_ϕ , c_λ , c_ω and c_θ are the rate of change of the position and propagation direction of a wave packet travelling along a great circle path. The left hand side of the above equation represents the local rate of change of wave energy density, propagation along great circles, shifting of frequency due to time variation in depth (note that currents are not included in this study), and refraction. The right hand side represents all effects of generation and dissipation of the waves. They include wind input S_{in} , whitecapping dissipation S_{ds} , non-linear quadruplet wave-wave interactions S_{nl} and bottom friction dissipation S_{bf} . The detailed description of these source terms, except the bottom friction dissipation, can be found in Günther et al. (1992).

Models for bottom friction dissipation

The wave energy dissipation due to the bottom friction in the wave boundary layer equals the work done by the turbulent bottom stress on the free stream orbital bottom velocity. There are different models to parametrize the bottom stress. The ones implemented in this study is are an empirical expression, and some variations on the eddy viscosity model, which relates the bottom shear stress to the vertical gradient of the velocity through an eddy viscosity coefficient.

An empirical expression

The simplest form for the bottom friction dissipation was proposed by Hasselmann et al. (1973) who applied the Hasselmann and Collins (1968) theory to measure the decay of swell in the JONSWAP experiment (Hasselmann et al., 1973). It can be expressed as

$$S_{bf}(f, \theta) = -\frac{2c}{g} \frac{k}{\sinh 2kh} F(f, \theta)$$

with $S_{bf}(f, \theta)$ the bottom friction dissipation spectrum, c an empirical coefficient, g the acceleration of gravity, k the wave number, and h the

water depth. In the JONSWAP experiment, the empirical coefficient c was found to vary over two orders of magnitude, with a mean value for c of $0.038m^2s^3$. This empirical dissipation formulation with the mean value for c has been used in wave models by WAMDI (1988) and performed well.

Two eddy viscosity models

Based on the linearized form of the boundary layer equations and a simple eddy viscosity formulation of shear stress, Madsen *et al.* (1988) derived a formulation for bottom friction dissipation

$$S_{bf}(f, \theta) = -f_w u_{br} \frac{k}{\sinh 2kh} F(f, \theta)$$

with

$$u_{br}^2 = 2 \iint \frac{\omega^2}{\sinh^2 kh} F(f, \theta) df d\theta$$

where f_w is the friction factor, u_{br} is the representative near bottom velocity, and ω is the angular frequency. The friction factor f_w in the Madsen *et al.* model is a function of the bottom roughness height and parameters characterised by the wave conditions. It can be estimated using the formulation of Jonsson (1966):

$$\frac{1}{4\sqrt{f_w}} + \log_{10} \frac{1}{4\sqrt{f_w}} = m_f + \log_{10} \frac{a_{br}}{K_N}$$

where m_f is a constant. A value of -0.08 for m_f was determined experimentally by Jonsson and Carlsen (1976). The bottom roughness height K_N depends on the flow field and the sediment properties. The near-bottom excursion amplitude a_{br} is formulated as:

$$a_{br}^2 = 2 \iint \frac{1}{\sinh^2 kh} F(f, \theta) df d\theta$$

This dissipation formulation was implemented in a parametric windsea model for finite water depths by Graber and Madsen (1988), and in a third-generation model for wind waves in combined wave-current flow by Tolman (1991). Graber and Madsen (1988) incorporated the bottom dissipation using a tuned constant friction factor. Tolman (1991) reported that a constant bottom roughness height ranging between $2cm$ and $5cm$ produced a good agreement between numerical results and measurements for the nondimensional wave height and period.

With a one-layer eddy viscosity model, based on the random turbulent wave boundary layer and using perturbation theory, Weber (1991a) derived another eddy viscosity model, which results in a frequency-dependent representative bottom friction velocity.

$$S_{bf}(f, \theta) = -u_{a^*} (T_{\bar{k}}(\zeta_0) + \tilde{T}_{\bar{k}}(\zeta_0)) \frac{k}{\sinh 2kh} F(f, \theta)$$

where u_{a^*} is the wave boundary layer friction velocity and can be determined as a function of wave number, wave spectrum, bottom boundary layer thickness and bottom roughness height. $T_{\bar{k}}$ is a dimensionless function and $\tilde{T}_{\bar{k}}(\zeta_0)$ is its complex conjugate. When the bottom roughness height is given, the values for u_{a^*} , $T_{\bar{k}}$ and $\tilde{T}_{\bar{k}}(\zeta_0)$ can be worked out iteratively with an initial u_{a^*} .

This formulation was implemented in a regional third generation WAM model for the Texel storm hindcast case, and a value of $4cm$ for the bottom roughness height was selected according to the flow conditions in the southern North Sea (Weber, 1991b). Because of the better prediction of the significant wave height for that storm it was suggested that the eddy viscosity formulation with a bottom roughness height of $4cm$ is to be preferred upon the empirical JONSWAP expression with the mean value for c of $0.038 m^2 s^{-3}$.

In fact, the study of Luo and Monbaliu (1994) and Luo et al. (1994) showed that the bottom roughness height of $4cm$ in Weber's formulation is not equivalent to the mean value for c of $0.038 m^2 s^{-3}$ of the empirical JONSWAP expression in terms of the resulting total energy and peak frequency growth curve levels for an idealised fetch-limited shallow water case. In order to produce the same or nearly the same growth curves levels, a c value of $0.067 m^2 s^{-3}$ for the empirical JONSWAP formulation is equivalent to the bottom roughness height of $4cm$. A bottom roughness height of $0.69cm$ in the Weber model and a bottom roughness height of $0.35cm$ in the Madsen et al. model are equivalent to the mean value $0.038 m^2 s^{-3}$ for c of the empirical JONSWAP expression.

Model Area

The model implementation was made on two grids. In order to intercept swell generated far away, but which may travel to the Belgian coast, a coarse grid was used. A fine grid was used to cover the southern North Sea, including the Belgian coastal area, with a spatial resolution of $10km \times 10km$. This grid is nested in the coarse grid with a resolution of $50km \times 50km$ covering the whole North Sea from $48^\circ N$ to $70^\circ N$ latitude and $7^\circ W$ to $12^\circ E$ longitude. We used a stereographic projection for the grid description running the model with the Cartesian co-ordinate option. Fig. 1 shows the fine grid model bathymetry and also the indication of the two Belgian buoy stations: A2-buoy (A2B) and Westhinder (WEH). It is

clear that the water depths are quite limited and vary from less than 5m to about 47m in this area. The water depth at A2B is about 8m and at WEH it is about 25m.

Fig. 1 The bathymetry of the southern North sea and locations of two Belgian buoy stations.

Hindcast Study

One month period running from the 1st to the 28th of February 1993 is hindcasted by the WAM model. From the 19 to the 21 February, there happened a strong storm in the southern North Sea. The model wind was provided by the United Kingdom Meteorological Office (UKMO) in GRIB (GRIdded Binary) and decoded by the Management Unit of the North Sea Mathematical Models (M.U.M.M.). These winds were compared with ERS-1 satellite data and with buoy data. The comparison showed that the wind forcing used to drive the wave model is of good quality (Ovidio *et al.*, 1994).

Effect of bottom friction dissipation

In order to see the effect of the net bottom friction dissipation on the wave evolution, this term was simply switched on and off in the model. Runs were carried out, and they are denoted by J1 when the empirical JONSWAP expression ($c=0.038m^2s^{-3}$) was used as bottom

friction formulation and by NOBF for cases when no bottom friction dissipation term was used. Figures 2 (a) and (b) show the hindcasted significant wave heights from the runs J1 and NOBF and the wave buoy measurements at A2B and WEH, respectively. The maximum net effect of the bottom friction dissipation on the hindcasted H_s values is in the order of 53% (of the wave height from the J1 run) at A2B and only 12% at WEH. (a)

(b)

Fig. 2 Time series of the significant wave height from the runs J1 and NOBF and observations: (a) at A2 Buoy (A2B); (b) at Westhinder (WEH).

A2B is located in water with a depth of about $8m$, i.e. at a much shallower position than WEH where the water depth is about $25m$. At A2B, the model results agree very well with the observations when the bottom friction dissipation is included.

A global view of the net effect of the bottom friction dissipation on the significant wave height hindcast in the southern North Sea is displayed in Fig. 3 on February 21, 1993 at 12h GMT. Fig. 4 shows the prediction of the wave height from the run J1 (empirical formulation) to calculate the bottom friction dissipation in the model. It is clear that the bottom friction dissipation has to some extent an effect on the wave evolution in the whole southern North Sea. The effect is particularly strong in front of the Belgian and Dutch coast and in the south-east coastal area of the United Kingdom. Differences for the significant wave height prediction in the storm conditions can be as large as 80% (of the wave height from the J1 run) along the Belgian coast.

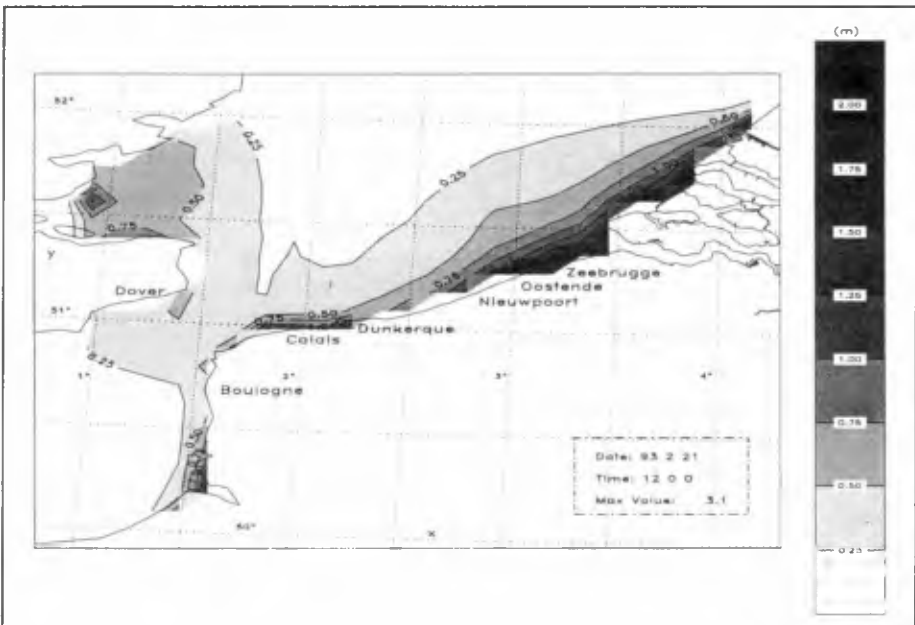

Fig. 3 The net effect of the bottom dissipation on the significant wave height hindcast at 12h GMT 21 February 1993

Effect of different formulations

Runs were also carried out with the two eddy viscosity models implemented for this study. They are denoted by M1 for the Madsen et al. (1988) model and W1 for Weber's model (1991a). The bottom roughness

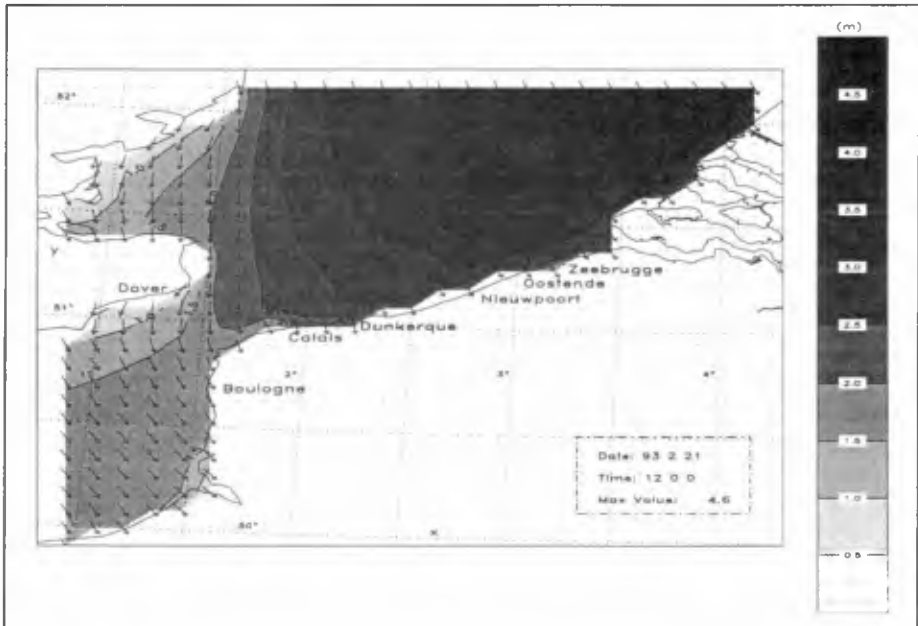

Fig. 4 The significant wave height predicted by the WAM Cycle 4 with the empirical formulation for bottom friction dissipation at 12h GMT 21 February 1993.

height in these two runs was kept the same as the original value ($K_n=4cm$) suggested by Weber (1991b) for the southern North sea areas. In Fig. 5 (a) and (b) the hindcasted results for the significant wave height from the runs J1, M1 and W1 are displayed with the measured data for stations A2B and WEH, respectively. The resultant effect on the hindcasted H_s values of using different bottom friction dissipation models with their original coefficients can be as big as 47% for station A2B and 15% for station WEH. The J1 run with the empirical formulation predicts significant wave height very close to the buoy measurement. The eddy viscosity model from Madsen et al. (1988, denoted by M1) underestimates the H_s value with about 1.5m (47% of the J1 H_s peak value in storm conditions) at A2B. The W1 run with Weber's (1991a,) model also underestimates the H_s with about 1.0m (30% of the J1 H_s peak value in storm conditions). Both eddy viscosity models with the bottom roughness height at 4cm predict too much bottom friction dissipation for this storm.

A global view at 12h GMT February 21, 1993 of the significant wave height difference between the run J1 with the empirical bottom friction dissipation formulation and the run M1 with the Madsen model is shown in Fig. 6. The maximum difference for the significant wave height

was found in front of the Belgian coast zone, in the order of $1.5m$ (about 47% of the significant wave height from the J1 run).

(a)

(b)

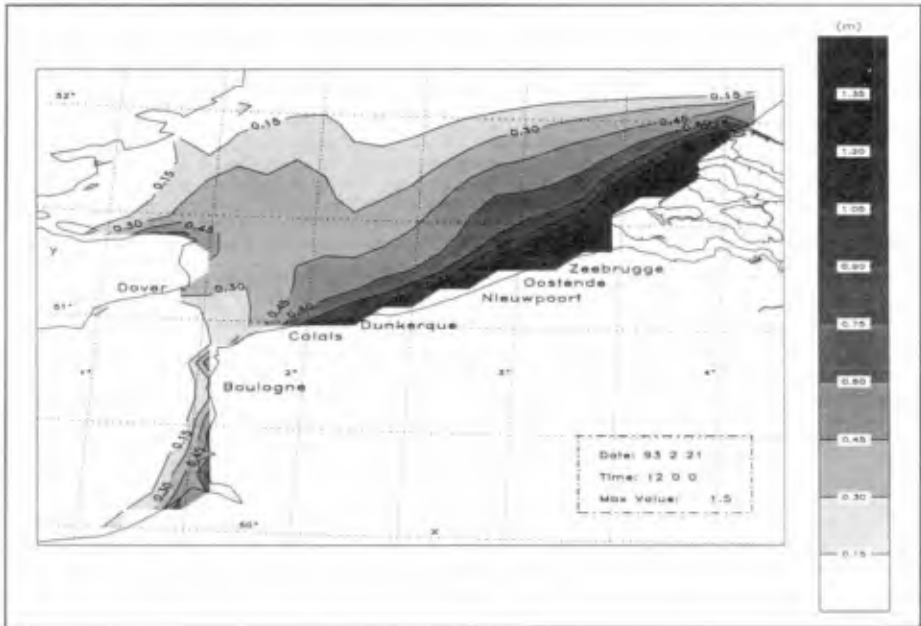

Fig. 6 The significant wave height difference between J1 and m1 runs at 12h GMT 21 February 1993.

Test of Equivalent Coefficients

As we discussed in the introduction, the study of Luo *et al.* (1994) proposed to use equivalent dissipation coefficients for different models of bottom friction dissipation in order to produce the same or nearly the same fetch-limited growth curves levels. For example, a bottom roughness height of 0.69cm in the Weber model and a bottom roughness height of 0.35cm in the Madsen *et al.* model are equivalent to the mean value of c of $0.038\text{ m}^2\text{s}^{-3}$ in the empirical JONSWAP expression. The questioned remained whether these so-called equivalent dissipation coefficients are still valid for the real circumstances. These equivalent coefficients were tested for the February 1993 storm. Different model runs were carried out with the equivalent coefficients, denoted by M2 for the Madsen model with a bottom roughness height of 0.35cm , and W2 for Weber's model with a bottom roughness height of 0.69cm .

Figures 7 (a) and (b) show time series of the significant wave height for the runs J1, M2 and W2 for the stations A2B and WEH, respectively. The obtained H_s values from the different bottom friction dissipation models with equivalent coefficients are nearly identical, and very close to the wave observations. A global view of the significant wave height difference at 12h GMT 21st of February 1993 between the

empirical formulation and the eddy viscosity Madsen et al. model but using equivalent dissipation coefficients is presented in Fig. 8. Compared with Fig. 6, it is found that the wave height difference resulting from

(a)

(b)

Fig. 7 Time series of significant wave height from three different bottom friction formulations with the equivalent dissipation coefficients for the February 1993: (a) A2B; (b) WEH.

different bottom friction formulations has been dramatically reduced (from more than $1.5m$ to only $0.2m$) along the Belgian coast .

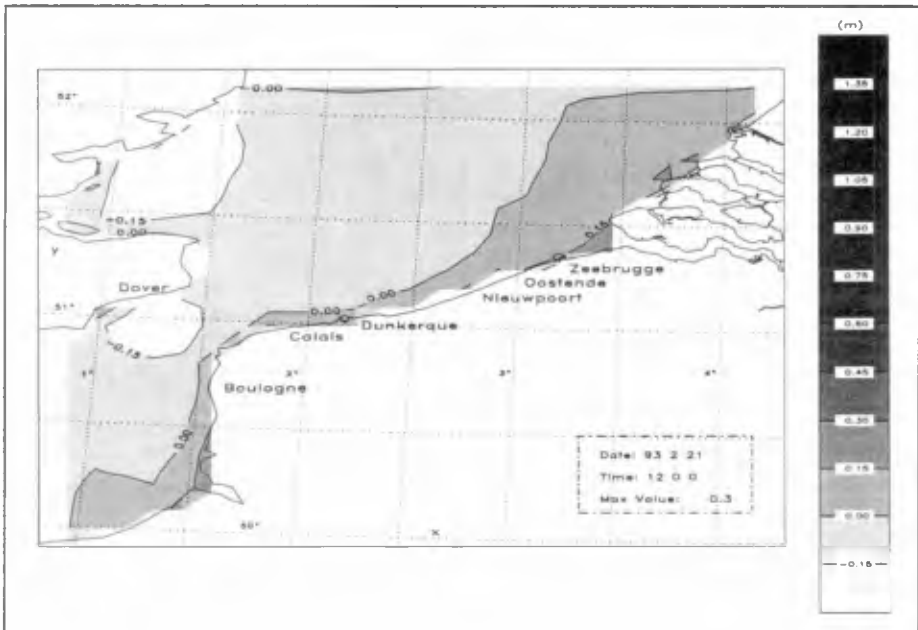

Fig. 8 The significant wave height difference between J1 and M2 runs at 12h GMT 21 February 1993.

Conclusions

A wave hindcast in the Belgian coastal region was made by using the 3G WAM Cycle 4 with three different bottom dissipation models. The results were intercompared and also compared to buoy data. It is found that the net effect of bottom friction dissipation on the significant wave height hindcast is quite big, in the order of 80% along the Belgian coast. The hindcasted wave conditions are sensitive to the use (including the choice of coefficient) of the bottom friction dissipation model, specially in storm conditions. The use of equivalent dissipation coefficients results in the same or nearly the same effect on the wave evolution and improves wave hindcast results.

CHAPTER 67

Weakly non-Gaussian model of wave height distribution for nonlinear random waves

Nobuhito MORI * and Takashi YASUDA †

ABSTRACT

The wave height distribution with Edgeworth's form of a cumulative expansion of probability density function(PDF) of surface elevation are investigated. The results show that a non-Gaussian model of wave height distribution reasonably agrees with experimental data. It is discussed that the fourth order moment(kurtosis) of water surface elevation corresponds to the first order nonlinear correction of wave heights and is related with wave grouping.

INTRODUCTION

Wave height statistics(*e.g.* wave height distribution, run length and etc) of random waves play important roles in designing coastal and ocean structures. The Rayleigh distribution is regarded as the distribution of wave heights in stochastic processes with a linear and narrow banded spectrum. Over a few decades, a considerable number of studies have been made on the validity of the Rayleigh distribution. It is commonly known that large wave heights in field do not necessarily obey the Rayleigh distribution. For example, Haring(1976) shows that large wave heights observed in storms are on the order of 10 percent less than those predicted by the Rayleigh distribution. After that, Forristall(1984), and Myrhaug and Kjeldsen(1987) also reported that occurrence probabilities of large wave heights in field are smaller than the predicted value of the Rayleigh distribution.

On the contrary, Yasuda *et al.*(1992,1994) numerically investigated that the third order nonlinear interactions have significant effects on the statistical

*Hydraulics Dept., Abiko Research Laboratory, Central Research Institute of Electric Power Industry(CRIEPI), Abiko 1646, Chiba 270-11, JAPAN (mori@criepi.denken.or.jp)

(coyasuda@cc.gifu-u.ac.jp)

properties of random wave train. That is, the third order nonlinear solution in deep water increases the occurrence probabilities of large wave heights more than the linear and second order one do. Stansburg(1993) also found the same results in his experimental work. However, there is no theoretical distribution which agrees with the data, although many studies have attempted to establish the wave height distribution without a linear or narrow banded spectrum assumption.

The Rayleigh distribution is put to practical use under the assumption that water surface elevations are regarded as independent stochastic processes, since the nonlinear wave-wave interactions are weak in deep water. Thus, the probability density function of the surface elevation had been assumed to be the Gaussian on the basis of the central-limit theorem. For the statistical point of view, the fourth order moment of the surface elevation is directly related to the third order nonlinear interaction(Longuet-Higgins 1963). It is therefore necessary to include the effects of the fourth order moment of the surface elevation for the wave height distribution to consider the influences of the third order nonlinear interaction.

In this study, a wave height theory is extended for a weakly nonlinear random waves with cumulative expansion of surface elevation including the fourth order moment and then its validity is checked with experimental data.

PDF OF WAVE HEIGHTS

Probability density function of surface elevation

According to statistical theory, the probability density function(PDF) $p^{(l)}(x)dx$ of the l -independent variables x_i $\{i \in Z\}$ (subscript i is dropped hereafter for simplicity) can be described as

$$p^{(l)}(x)dx = \sum_{r=0}^{\infty} c_r H_r(x) G(x) dx, \quad (r \in Z) \quad (1)$$

$$G(x) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{x^2}{2}\right), \quad (2)$$

where $H_r(x)$ is the Chebyshev-Hermite polynomial, $G(x)$ the Gaussian and c_r the r th order coefficient of the Gram-Charlier expansion. The convergence of the Gram-Charlier expansion is not monotonic with the order r (e.g. $c_4=O(l^{-1})$, $c_5=O(l^{-3/2})$), although the convergence of the r th order cumulant $\kappa_r^{(l)}$ is independent of l . We hence choose the Edgeworth asymptotic expansion to describe the PDF of surface elevation.

Introducing the characteristic function and collecting the terms for l , the Edgeworth expansion of type A is formally given by (e.g. Kendall and Stuart

1963)

$$p^{(l)}(x)dx = G(x) \left\{ 1 + \frac{1}{\sqrt{l}} \frac{\kappa_3}{6} H_3(x) + \frac{1}{l} \left[\frac{\kappa_4}{24} H_4(x) + \frac{\kappa_3^2}{72} H_6(x) \right] + \frac{1}{l\sqrt{l}} \left[\frac{\kappa_5}{120} H_5(x) + \frac{\kappa_3 \kappa_4}{144} H_7(x) \right] + \dots \right\} dx, \tag{3}$$

where κ_r is the r th order cumulant. The r th order cumulant has the relationship to the r th order moment μ_r :

$$\left. \begin{aligned} \kappa_1 &= 0 \\ \kappa_2 &= 1 \\ \kappa_3 &= \mu_3 \\ \kappa_4 &= \mu_4 - 3 \\ \kappa_5 &= \mu_5 - 10\mu_3 \\ \kappa_6 &= \mu_6 - 15\mu_4 - 10\mu_3^2 + 30 \\ \kappa_7 &= \mu_7 - 21\mu_2\mu_5 - 35\mu_3\mu_4 + 210\mu_2^2\mu_3 \end{aligned} \right\}. \tag{4}$$

We set the mean value μ_1 so as equal to zero and normalize all the variables by the standard deviation. Therefore, μ_3 is skewness and μ_4 is kurtosis. Each component within the bracket $[\cdot]$ of eq.(3) has monotonic convergence for l (the typical notation for l is dropped hereafter for simplicity).

It must be noted that an asymptotic expansion does not have monotonic convergence for higher order corrections, although it sometimes gives good agreement for a first few terms. Moreover, higher order moments and cumulants are influenced by sampling frequencies of data. We, therefore, use first three terms of eq.(3) to describe the PDF of the surface elevation. The influences of truncation of eq.(3) are already discussed in detail by Mori(1996). We truncate here higher than $1/l\sqrt{l}$ terms of eq.(3) following Mori(1996). This truncation gives the following relationship to the moments

$$\kappa_5 = \mu_5 - 10\mu_3 = 0, \tag{5}$$

$$\kappa_6 = \mu_6 - 15\mu_4 + 30 = 0. \tag{6}$$

The validity of these assumptions will be examined in next section.

Distribution of wave height

We assume that waves to be analyzed here are unidirectional with narrow banded spectrum and satisfy the stationarity and ergodic hypothesis. The surface elevation hence can be evaluated by the characteristic frequency $\bar{\omega}$:

$$I_c(t) = \sum_{n=1}^{\infty} a_n \cos[(\omega_n - \bar{\omega})t + \varepsilon_n] \tag{7a}$$

$$I_s(t) = \sum_{n=1}^{\infty} a_n \sin[(\omega_n - \bar{\omega})t + \varepsilon_n] \tag{7b}$$

where a_n is the amplitude of the n th mode, ω_n the angular frequency and ε_n the phase function. If ε_n is distributed uniformly and is a temporally independent variables, eq.(7) give a linear random wave field. The surface elevation $\eta(t)$ is rewritten into the amplitude of wave envelope $R(t)$ and phase angle $\theta(t)$ with I_c and I_s :

$$\eta(t) = R(t) \cos[\bar{\omega}t + \theta(t)] \quad (8a)$$

$$R(t) = \sqrt{I_c^2 + I_s^2} \quad (8b)$$

$$\theta(t) = \tan^{-1} \left[\frac{I_s(t)}{I_c(t)} \right] \quad (8c)$$

Under the assumption that the PDF of I_c and I_s are described by eq.(3) up to $1/l$ terms, I_c and I_s are independent statistical variables. Integration of $\theta(t)$ over the range from 0 to 2π results in the following PDF of wave amplitude

$$p(R) dR = \frac{1}{2\pi} \exp \left(-\frac{R^2}{2} \right) \left[1 + \sum_{i,j} \alpha_{i,j} A_{i,j}(R) \right] dR, \quad (9)$$

where $\sum_{i,j}$ is a special double summation for $i, j (i=4,6 \text{ and } j=i/2)$, $A_{i,j}(R)$ is polynomial for R (see Appendix) and $\alpha_{i,j}$ is the coefficient with μ_3 and μ_4 :

$$\left. \begin{aligned} \alpha_{4,1} &= \frac{1}{2^5}(\mu_4 - 3) \\ \alpha_{4,2} &= \frac{1}{2^{13} \times 3}(\mu_4 - 3)^2 \\ \alpha_{6,1} &= \frac{5}{2^6 \times 3^2} \mu_3^2 \\ \alpha_{6,2} &= \frac{1}{2^{13} \times 3^2} \mu_3^2 (\mu_4 - 3) \\ \alpha_{6,3} &= \frac{5}{2^{16} \times 3^4} \mu_3^4 \end{aligned} \right\} \quad (10)$$

The assumption that I_c and I_s are mutually independent is inadequate for strong nonlinear waves ($\mu_3 \geq 0.30$, see Mori 1996), but we should keep this assumption in this study.

By assuming a narrow banded spectrum for a wave field, a wave height H is regarded by two times of its amplitude A ($H=2A$). This assumption is inadequate when the vertical asymmetry of surface profile is not negligible (*i.e.* $\mu_3 \rightarrow$ large). Therefore, eq.(10) is valid for a weakly narrow banded process ($\mu_3 \ll 1$).

The assumptions of a weakly nonlinear and narrow banded spectrum give the wave height distribution as

$$p(H) dH = \frac{H}{4} \exp \left(-\frac{H^2}{8} \right) \left[1 + \sum_{i,j} \beta_{i,j} B_{i,j}(H) \right] dH, \quad (11)$$

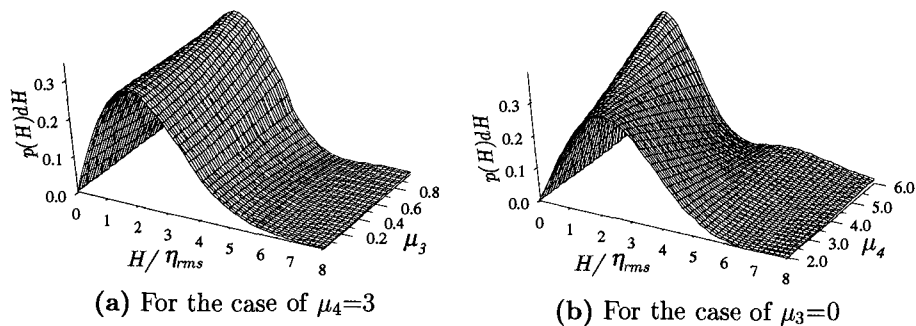

Figure 1 The variation of PDF of wave heights for the fixed value of μ_3 and μ_4 .

Figure 2 The exceedance probability of wave heights for $\mu_4=2.75$ and 3.25 with $\mu_3=0$.

where,

$$\left. \begin{aligned}
 \beta_{41} &= \frac{1}{2^9} (\mu_4 - 3) \\
 \beta_{42} &= \frac{1}{3 \times 2^{21}} (\mu_4 - 3)^2 \\
 \beta_{61} &= \frac{5}{2^{12} \times 3^2} \mu_3^2 \\
 \beta_{62} &= \frac{1}{2^{23} \times 3^2} \mu_3^2 (\mu_4 - 3) \\
 \beta_{63} &= \frac{5}{2^{28} \times 3^4} \mu_3^4
 \end{aligned} \right\}, \tag{12}$$

and $B_{i,j}(H)$ is polynomial for H (see Appendix).

The exceedance probability of wave heights is given by integrating eq.(11)

Table 1 Wave statistics of typical two cases.

Case	m	$k_p a_{1/3}$ at P1	breaking ratio
1	10	0.10	0%
2	10	0.20	10%

between $[H, \infty)$ as

$$P(H) = \exp\left(-\frac{H^2}{8}\right) \left[1 + \sum_{i,j} \beta_{i,j} E_{i,j}(H)\right], \quad (13)$$

where $E_{i,j}(H)$ is polynomial for H (see Appendix).

The first point to be noticed is that the additional terms within brackets $[\cdot]$ in eqs.(9), (11) and (13), which are related to non-Gaussian properties of the PDF of surface elevation, are equal to zero when $\mu_3=0$ and $\mu_4=3$ (*i.e.* Gaussian). Therefore eqs.(9) and (11) with $\mu_3=0$ and $\mu_4=3$ are the same the Rayleigh distribution. We shall, hence, call with distribution of this type as the Edgeworth-Rayleigh distribution. The second important point to be noted is that the first order correction to the wave amplitudes or wave heights is kurtosis ($\alpha_{4,j}$ or $\beta_{4,j}$).

Figure 1 show the variation of the PDF of the wave heights on the values of μ_3 and μ_4 . For the case of $\mu_4=3$ case, Fig.1(a), the shape of the PDF of the wave heights is not varied as increasing the value of μ_3 . However, Fig.1(b) shows that the peak of the PDF is shifted to gently as increasing of μ_4 , because μ_4 is the first order correction of the wave height distribution. Figure 2 shows the exceedance probability of the wave heights for the case of $\mu_4=2.75$ and 3.25 with $\mu_3=0$. The occurrence probability of the larger wave heights exceeds that of the Rayleigh distribution is increased when the value of μ_4 is larger than 3. We can summarize that the value of kurtosis is dominated parameter for the PDF of wave heights.

RESULTS

The laboratory experiment was conducted in the glass channel and is 65m long, 1m wide, 2m high and was filled to a depth of about 1.0m. Waves were generated by a computer-controlled piston type wave paddle. Water surface displacements were measured with twelve capacitance type wave gages. The measurements with a sampling frequency of 32Hz were performed for over 330s. No corrections were applied for filter response of the wire.

The initial spectra were given using the Wallops type spectra with band widths of $m=5, 10, 30, 60$ and 100 , and peak frequency of $f_p=1$ Hz which gives a spectral peak wavenumber $k_p=4.072\text{m}^{-1}$ and a characteristic water depth of

(a) Spatial variation of μ_3 and μ_5 (b) Spatial variation of μ_4 and μ_6

Figure 3 The spatial variations of the higher order moments of surface elevations of the case 1 and 2.

$k_p h = 3.99$, so that the waves were deep water waves. Here, h is the water depth. The number of waves were about 350-450. The maximum frequency of generated waves were 2Hz. Therefore, higher frequency components of generated waves were generated by nonlinear interaction. Initial phases of the waves were given by uniformly distributed random numbers. The initial characteristic wave steepnesses $k_p a_{1/3}$ were set about 0.1 to 0.25. Here, $a_{1/3}$ is a half of the significant wave height. Breaking waves were observed for higher waves with the steepness that the value of $k_p a_{1/3}$ is larger than 0.13. For example, the visually observed breaking ratio is about 10% for waves with the initial steepness of $k_p a_{1/3} = 0.20$ and 20% for 0.14. Consequently, waves of 24 cases were generated under the combination of the spectrum bandwidth parameter m and the wave steepness.

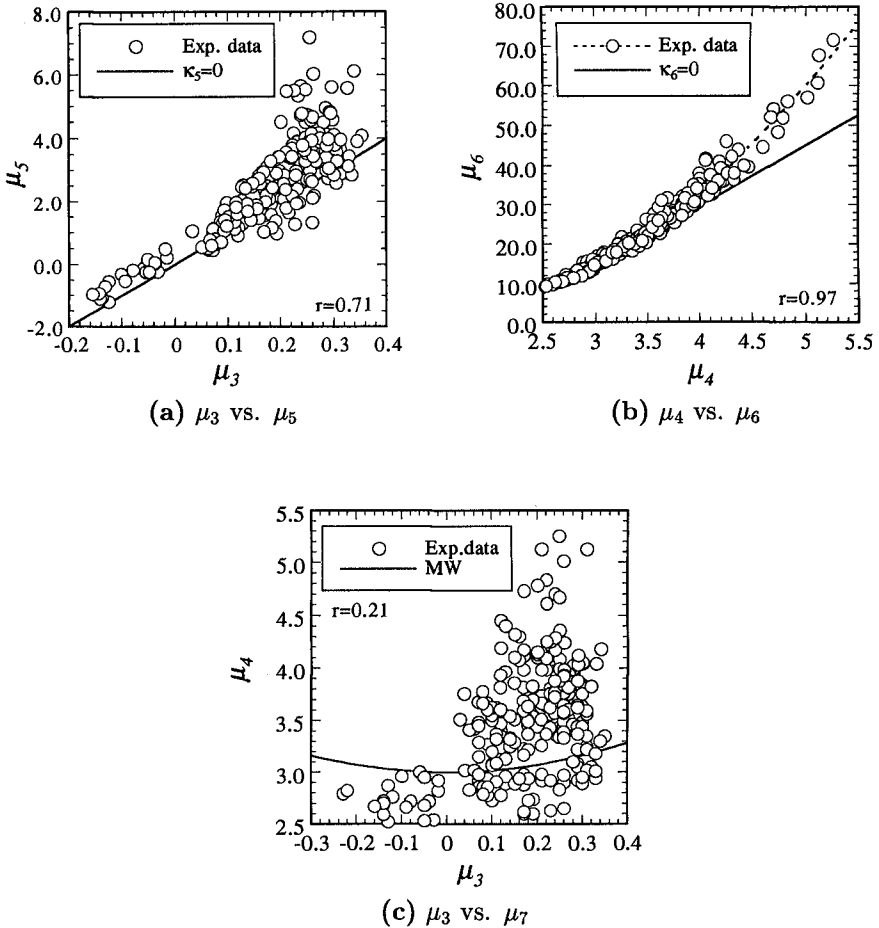

Figure 4 Relationships among the higher order moments, μ_3 , μ_4 , μ_5 , μ_6 and μ_7 .

Typical measured two cases are shown in Table 1 for breaking and non-breaking cases. The spatial variations of higher order moments for case 1 and 2 are shown in Fig.3. These show that the higher order moments are fluctuated until the location 20m distant from the wave generator(that is about 13 wave lengths of peak frequency). There are marked increase in the moments more than 20m away from the wave generator. All of the higher order moments are not equal to the Gaussian, more and less. The odd order moments μ_3 and μ_5 seem to level out 20m away from wave generator, although the even order moments μ_4 and μ_6 are still increased. The higher order moments are generally influenced

Figure 5 PDF of the surface elevation of experimental data of case 1 at location 8.

by the sampling frequency, but these trends do not depend on the sampling of data in our experiments. In addition, the spatial variations of μ_5 and μ_6 are similar to those of μ_3 and μ_4 , respectively. These indicates the non-Gaussian properties of surface elevations.

The experimental data show that the higher order moments are not constant. It should be examined the relationship between the higher order moments. The $(n+2)$ th order cumulant is related to the n th order cumulant at the lowest order correction. Hence, the higher order cumulants than the 5th one are assumed zero to formulate the Edgeworth-Rayleigh distribution:

$$\begin{aligned} \kappa_5 &= \mu_5 - 10\mu_3 = 0 \\ \kappa_6 &= \mu_6 - 15\mu_4 + 30 = 0 \end{aligned}$$

In order to check the validity of these assumptions, the relationships between μ_3 and μ_5 , μ_4 and μ_6 , and μ_3 and μ_4 are examined, respectively and are shown in Fig.4. Circles denote experimental data and solid lines in Fig.4(a) and Fig.4(b) are given by the eq.(5) and eq.(6), respectively. The correlation coefficient between μ_5 and μ_3 is 0.71, and therefore μ_5 could be regarded as a linear dependent variable on μ_3 . μ_6 is also strongly related with μ_4 (the correlation coefficient is 0.97). The experimental data show quite good agreement with eq.(6) in which the value of μ_4 is less than 4. Marthinsen and Winterstein(1992) derived the relationship between μ_3 and μ_4 from the second order kernel functions:

$$\mu_4 = 3 + \left(\frac{4}{3}\mu_3\right)^2 \tag{14}$$

The solid line in Fig.4(c) indicates eq.(14). However, there is no obvious relation between μ_3 and μ_4 from the data(the correlation coefficient is 0.21). Conse-

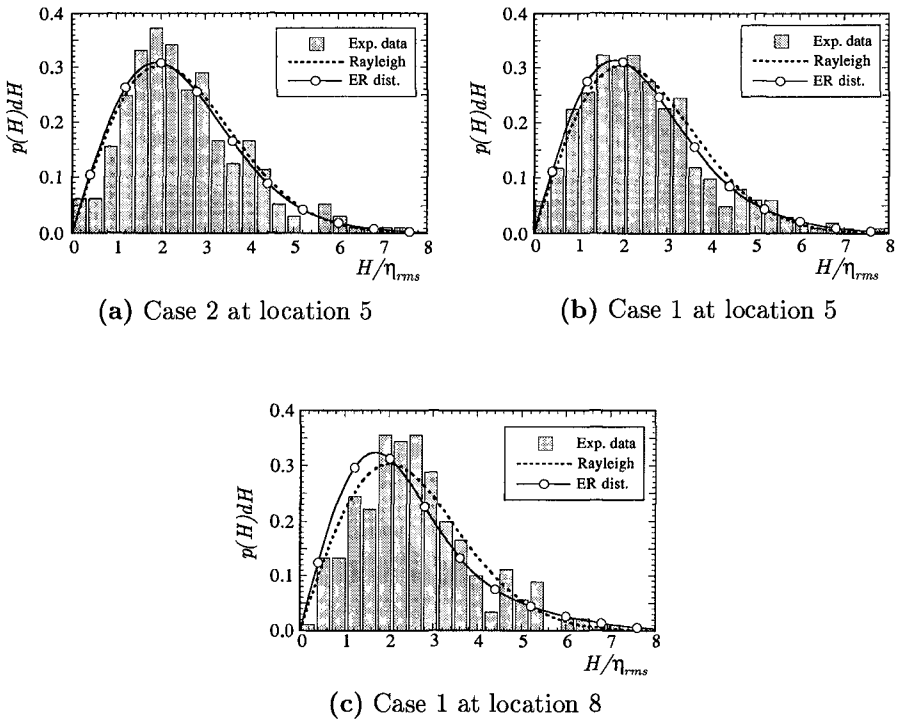

Figure 6 The PDF of wave heights at several locations.

quently, it follows from what has been said that the 5th and 6th order cumulants can be regarded as zero (*i.e.* eqs.(5) and (6) are valid), if the value of μ_3 is smaller than 0.3 and μ_4 is smaller than 4. And the value of μ_4 is independent on μ_3 .

The PDF of surface elevation of case 1 at location 8 is shown in Fig.5. The histogram is experimental data, dotted line is the Gaussian and solid line with circle is eq.(3) up to $1/l$ terms. The Edgeworth expansion shows agreement with experimental data in comparison with the Gaussian.

The PDF and exceedance probability of wave heights are shown in Figs.6 and 7, respectively. The histogram and filled circles \bullet denotes experimental data, dotted line the Rayleigh distribution and solid line the Edgeworth-Rayleigh distribution. There are no significant difference between the Rayleigh and the Edgeworth-Rayleigh distribution for the PDF of wave heights. However, the Edgeworth-Rayleigh distribution for the exceedance probability of wave heights show good agreement with the experimental data in comparison with the

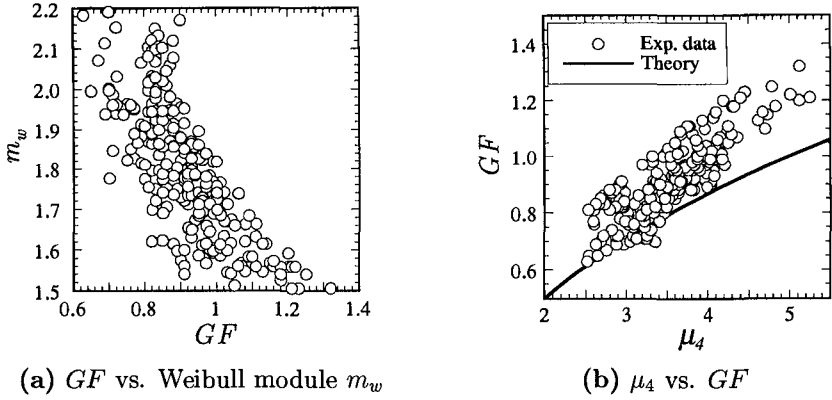

Figure 8 Relationships between μ_4 , GF and the Weibull modulus m_w , and GF and μ_4 .

Rayleigh distribution. The number of waves decrease as wave heights getting larger, so the number of waves are quite few in the range $H/\eta_{rms} \geq 5$ in Fig.7. The Edgeworth-Rayleigh distribution agrees with the experimental data, even if the number of waves are not so many. Moreover, the Edgeworth-Rayleigh distribution agrees with the experimental data for larger value of μ_4 ($\mu_4 \geq 4$), such as Fig.7(c).

RELATIONSHIP BETWEEN WAVE HEIGHT AND WAVE GROUPING

Before move to conclusion, it should be added that the relationship between the PDF of wave heights and wave grouping. Mase(1989) investigated an empirical relationship between the groupiness factor(GF) and the PDF of wave height with the Weibull modulus m_w of single parameter of the Weibull distribution.

GF is defined as

$$GF = \sqrt{\frac{1}{T_0} \int_0^{T_0} [E(t) - \bar{E}]^2 dt / \bar{E}}, \tag{15}$$

$$E(t) = \int_{-T_p}^{T_p} \eta^2(t + \tau)(1 - |\tau|/T_p)d\tau, \tag{16}$$

where $E(t)$ is SIWEH, \bar{E} a mean value of $E(t)$, T_0 an observation period and T_p the spectral peak period. If we substitute the delta function $\delta(t - \tau)$ into the numerical trigonometric filter $1 - |\tau|/T_p$ of eq.(16), we obtain the following simple relation

$$GF' = \sqrt{\mu_4 - 1}. \tag{17}$$

This means that if we do not use the numerical filter to calculate GF , there is a direct relation between GF and kurtosis μ_4 . We already know that kurtosis μ_4 is the parameter which controls the wave height distribution. That is, both the parameters the Weibull modulus and μ_4 govern the wave height distribution. Therefore, there is an obvious relation between kurtosis and GF . That is the reason why the Weibull modulus m_w governing the wave height distribution depends on GF . The relationship between GF and the Weibull modulus, and GF and μ_4 are shown in Fig.8. These relations can be summarized as

$$GF \sim \mu_4 \sim m_w. \quad (18)$$

The relationship between the Weibull modulus and GF has not a physical meaning so that we suggest to use kurtosis instead of GF to represent the wave grouping. Moreover, GF suffers from the influence of the numerical filter to obtain SIWEH. Therefore, the value of GF is influenced by two characteristics of random waves as a shape of wave height distribution and a spectrum band width. In other words, GF is insufficient as the fundamental statistical parameter to represent properties of the random wave.

CONCLUSION

A weakly non-Gaussian model of wave height distribution referred here as to the Edgeworth-Rayleigh distribution is suggested for waves with narrow banded spectra. It is found that the first order correction of the wave height distribution is equal to the fourth order moment of the surface elevation. It is also made clear that the occurrence probability of larger wave heights increases with the increasing of the value of kurtosis. The experimental data show good agreement with the Edgeworth-Rayleigh distribution within $\mu_3 \ll 1$ and $\mu_4 \leq 4$.

CHAPTER 68

An attempt at applying the chaos theory to wave forecasting

Takao Ohta¹ and Akira Kimura²

Abstract

In this paper, a prediction method based on the chaos theory is applied to wave forecasting. First, it is investigated whether a time series data of the significant wave is chaotic. The correlation integral and the Lyapunov exponent are calculated for this purpose. In the second part of the paper, the prediction for the time series of the significant wave is attempted on the basis of the chaos theory.

1. Introduction

Wave forecasting information is required to secure port and harbor works. Classifying roughly, two methods have been used for wave forecasting. One is the deterministic method using the energy balance equation. The other is the statistical method using meteorological data - atmospheric pressure and wind speed. However, the former has a problem that the meteorological knowledge, a lot of cost and time are needed. The latter requires much labor to prepare the meteorological data. Recently, a new method based on the chaos theory (deterministic nonlinear prediction method) has been developed. This methodology has been applied to the prediction of stock prices, electricity demand and water supply. An outline of the method is that ; if a time series data has chaotic characteristics, the system which generates the time series can be considered deterministic and nonlinear. The dynamical rule of the system is estimated conversely from

1 Research associate, Dept. of Social Systems Eng.,
Tottori Univ., 4-101 Koyama Minami, Tottori 680, JAPAN

2 Professor, Dept. of Social Systems Eng.,
Tottori Univ., 4-101 Koyama Minami, Tottori 680, JAPAN

the time series data. Once the hypothetical dynamical rule has been estimated, the near future of the time series is predicted using the assumed dynamical rule. Two attractive features of this method are that only time series data is needed and there is a possibility of prediction with high accuracy. In this study, it is investigated whether the obtained time series data of the significant wave height has chaotic characteristics. Furthermore the deterministic nonlinear prediction method is applied to the prediction of the significant wave height.

2. Chaotic characteristics of the obtained data

The data of the significant wave height were obtained at the Tottori, Fukui and Miyazaki port in Japan. These data are part of NOWPHAS 1991-1994. Location of the observation points is shown in Figure 1. Length and acquirement rate of the data are indicated in Table 1. Linear interpolation is used for lack of data which is less than continuous 10 times. First of all, it is necessary to verify the chaotic characteristics of the significant wave height data. The method of trajectory reconstruction by delay coordinates (Takens(1981)) is used for that purpose. A set of m-dimensional vectors X_i are made of the time series $\{x_i\}$.

$$\begin{aligned} X_1 &= \left(x_1, x_{1+r}, \dots, x_{1+(m-1)r} \right) \\ X_2 &= \left(x_2, x_{2+r}, \dots, x_{2+(m-1)r} \right) \\ &\quad \vdots \\ X_n &= \left(x_n, x_{n+r}, \dots, x_{n+(m-1)r} \right) \end{aligned} \quad (1)$$

where, r is delay time. These vectors represent points in the m-dimensional phase space and a trajectory is constructed by connecting these points. Figure 2 illustrates making of 3-dimensional vectors from a time series schematically. Figure 3 is a schematic diagram of a trajectory that is reconstructed in the 3-dimensional phase space. Two methods are proposed to investigate whether a time series is chaotic. One is based on geometric characteristic of the trajectory, and the other is related to dynamical characteristic of it. In this study, the geometric characteristic of the trajectory is examined using the correlation integral method described in 2.1. The dynamical characteristic is examined using the Lyapunov exponent described in 2.2.

2.1 Correlation integral method

If a trajectory reconstructed from a time series

Figure 1. Location of the observation points

Table 1. Length and acquirement rate of the data

point	period	number of data	acquirement rate
Tottori	Jan.'91 ~ Jul.'92 (19 months)	6868	96.8 %
Fukui	Apr.'91 ~ Apr.'94 (37 months)	13512	99.4
Miyazaki	Jan.'92 ~ Nov.'94 (35 months)	12780	98.8

data has fractal structure, there is a possibility that the time series is chaotic. Grassberger and Procaccia(1983) proposed a method to calculate fractal dimension of the trajectory by the correlation integral. The correlation integral is defined by Eq.(2).

$$C^m(\varepsilon) = \frac{1}{N^2} \sum_{i,j=1}^N H\left(\varepsilon - |X_i - X_j|\right) \quad (2)$$

where, $H(t)$ is the Heaviside function, $|X_i - X_j|$ represents distance between vector X_i and X_j . The correlation integral is calculated for variable ε respectively. If a part of plotted $(\log \varepsilon, \log C^m(\varepsilon))$ is approximately on a straight line,

Figure 2. Making of vectors from a time series

Figure 3. Reconstructed trajectory

the slope is defined as the correlation exponent $\nu(m)$. Furthermore, if the correlation exponent converges to a certain value D_c following the increase of the phase space dimension m , D_c represents the fractal dimension of the reconstructed trajectory. That is, the time series was generated by a deterministic nonlinear system, and it is estimated that the degree of freedom for this system is more than D_c . In this study, the correlation integral is calculated under the following conditions; $r=10, 20, 30$ and 40 hours, $m=5, 6, 7, 8, 9, 10, 12, 14, 16, 18, 20, 22, 24, 26, 28, 30$

and 35. Figure 4.(a), (b) and (c) illustrate the results of the correlation integral. These are the cases for the significant wave height data of Tottori, Fukui and Miyazaki respectively. Figure 5.(a),(b) and (c) show the correlation exponents which were obtained from Figure 4. In the cases of Tottori (Figure 5.(a)) and Miyazaki(Figure 5.(c)), the correlation exponent tends to converge. Therefore, there is a possibility that the significant wave height data of Tottori and Miyazaki are chaotic. In the case of Fukui(Figure 5.(b)), the tendency shown in the others is not distinct. The possibility that the data of Fukui is chaotic can not be found from this result.

2.2 Lyapunov exponent

Trajectory instability is a dynamical characteristic of chaos. It means that a distance between a point on the reconstructed trajectory and its near neighboring point increases exponentially with time development. The Lyapunov exponent is an index to represent change rate of the distance. If the Lyapunov exponent is a positive value, the distance is extended exponentially. Therefore, the trajectory is considered to be unstable. Sano and Sawada(1985) proposed a method to compute the Lyapunov exponent using a time series data. The procedure for this method is as follows. First, a point on the reconstructed trajectory is denoted with X_i , and its near neighbors X_{ki} ($i=1, \dots, M$) are looked for. Displacement vectors between X_{ki} and X_i are given as ;

$$y_i = X_{ki} - X_i \quad (3)$$

The center point X_i moves to $X_{i+\tau}$ and the points X_{ki} shift to $X_{ki+\tau}$ after the time τ . The displacement vectors z_i are as follows:

$$z_i = X_{ki+\tau} - X_{i+\tau} \quad (4)$$

If the absolute values of y_i and z_i are small sufficiently, z_i can be expressed by Eq.(5).

$$z_i = A_i y_i \quad (5)$$

The matrix A_i is given as;

$$A_i V = C$$

$$v_{kl} = \frac{1}{M} \sum_{i=1}^M y_{ik} y_{il} \quad , \quad c_{kl} = \frac{1}{M} \sum_{i=1}^M z_{ik} y_{il} \quad (6)$$

where, y_{ik} :k-th component of y_i , z_{ik} :k-th component of z_i . The matrix A_i is used for computing the Lyapunov exponent. A set of orthonormal system $\{u_i(t)\}$ ($i=1, \dots, m$) is given as an initial condition, and the matrix A_i operates on the orthonormal system. Eq.(7) represents this operation.

$$e_i(t+\tau) = A_i u_i(t) \quad (7)$$

Furthermore, $e_i(t+\tau)$ is orthonormalized by the Gram-Schmidt method (e.g., Shimada and Nagashima(1979));

$$e_i'(t+\tau) = e_i(t+\tau) - \sum_{j=1}^{i-1} \langle e_i(t+\tau), u_j(t+\tau) \rangle u_j(t+\tau) \quad (8)$$

$$u_i(t+\tau) = \frac{e_i'(t+\tau)}{|e_i'(t+\tau)|} \quad (9)$$

where, \langle, \rangle denotes the inner product. In the next step, $A_{t+\tau}$, $e_i(t+2\tau)$, $e_i'(t+2\tau)$ and $u_i(t+2\tau)$ are computed. $\{e_i'(t)\}$, which expresses a set of e_i' , is obtained by repeating this procedure. The Lyapunov exponent λ_i ($i=1, \dots, m$) is given by Eq.(10).

$$\lambda_i = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{i=0}^{N-1} \log \left| \left\{ e_i'(t) \right\} \right| \quad (10)$$

Figure 6.(a), (b) and (c) show the maximum Lyapunov exponent, which is calculated under the following conditions: delay time τ is 10, 20, 30 and 40 hours, phase space dimension m is from 5 to 15 and number of iteration N is 200. Because all of the maximum Lyapunov exponents are positive, the significant wave height data are considered to be chaotic.

3. Deterministic nonlinear prediction method

If a time series data is chaotic, the time series is considered to be generated by a deterministic nonlinear dynamical system. However, the dynamical rule of this system is unknown. It is necessary to estimate the dynamical rule conversely from the obtained time series data. In this paper, the reconstructed trajectory is divided into small sections, and a local dynamical rule is estimated for each section. The conception of Farmer and Sidorowich(1987) and the above-mentioned procedure of Sano and Sawada is applied to estimation of the local dynamical rule. In other words, the matrix A_i given by Eq.(6) is an approximation of the local dynamical rule.

(a) Tottori

(b) Fukui

(c) Miyazaki

Figure 6. Maximum Lyapunov exponent

The procedure to predict near future of a time series is as follows:

1) Take the vector which contains the latest data as X_t in Eq.(3). 2) Look for X_{k_i} ($i=1,2,\dots,M+1$), which are the close vectors to X_t . 3) Permute X_{k_i} in the order of increasing distance to X_t . Therefore, X_{k_1} is the nearest vector. 4) Set the displacement vectors $y_i = X_{k_i} - X_{k_1}$ ($i=2,\dots,M+1$) and $y_p = X_t - X_{k_1}$. 5) Obtain the displacement vectors $z_i = X_{k_{i+r}} - X_{k_{1+r}}$ ($i=2,\dots,M+1$). 6) Compute the matrix A_i by Eq.(6). 7) Calculate $z_p = A_i y_p$ and $X_{t+r} = X_{k_{1+r}} + z_p$.

The m -th component of X_{t+r} is the predicted value of the time series. In the prediction of the significant wave height, the following steps are taken furthermore; With changing M in the range of $[m+2, 2m+30]$, compute X_{t+r} for each M . From first to $(m-1)$ th (or $(m-2)$ th) component of the predicted X_{t+r} corresponds to the observed time series datum. Pick up five X_{t+r} whose sum of the square errors between the components and the observed data are small. Define the mean of m -th components as the predicted value of the significant wave height. When all X_{t+r} include negative component in the above range of M , the prediction is considered to be impossible.

4. Prediction of the significant wave height

The significant wave height is predicted by the procedure described in the section 3. The conditions under which the prediction is performed are as follows:

Tottori; The delay time r is 20 and 30 hours, the phase space dimension m is 10 and 12.
Fukui and Miyazaki; r is 10 hours and m is 10.
The prediction value is computed every 6 hours, that is, at 0,6,12 and 18 o'clock every day. The following two criteria are used to evaluate the accuracy of the prediction: Criterion I (Goto et.al.(1993));

$$\begin{cases} |H_p - H_o| \leq 0.3 (m) & (H_o \leq 1.0 (m)) \\ |H_p - H_o| / H_o \leq 0.3 & (H_o \geq 1.0 (m)) \end{cases} \quad (11)$$

where H_o is the observed significant wave height and H_p is the predicted one. The fitting rate is defined as N_r/N_t . N_r is the number of the predicted values which are in the range of Eq.(11), and N_t is the total number of the prediction.

Criterion II; Both the observed and predicted significant wave height are more or less than a set standard wave height of 1 meter.

The results of the prediction are as follows.

Table 2. Fitting rate (Tottori)

		r = 20 hours		r = 30 hours	
		m = 10	m = 12	m = 10	m = 12
Fitting rate I	Jan. '92	42.7 %	42.7 %	42.7 %	33.1 %
	Apr.	56.7	55.8	38.3	42.5
Fitting rate II	Jan. '92	71.0 %	71.0 %	70.2 %	56.5 %
	Apr.	80.0	86.7	60.8	64.2

Table 3. Fitting rate

		Tottori			Fukui			Miyazaki	
		6-hour	12-hour		6-hour	12-hour		6-hour	12-hour
Fitting rate I	Jan. '92	58.1 %	42.7 %	Jul. '93	79.8 %	66.9 %	Jan. '94	76.6 %	61.3 %
	Apr.	63.3	55.8	Oct.	70.9	48.7	Apr.	80.0	60.8
	Jul.	71.3	55.9	Jan. '94	67.7	40.7	Jul.	78.9	69.1
	-	-	-	Apr.	71.2	56.7	Oct.	79.0	61.3
Fitting rate II	Jan. '92	75.8 %	71.0 %	Jul. '93	85.5 %	80.6 %	Jan. '94	80.6 %	72.6 %
	Apr.	82.5	86.7	Oct.	83.8	72.6	Apr.	84.2	78.3
	Jul.	85.1	89.2	Jan. '94	84.7	70.2	Jul.	81.3	75.6
	-	-	-	Apr.	85.8	79.2	Oct.	85.5	79.8

Tottori: First, the 12-hour prediction for January and April 1992 was performed to compare the accuracy under the conditions of $r=20,30$ and $m=10,12$. Table 2 shows the fitting rate I and II, which are based on the criterion I and II respectively. The difference between $r=20$ and $r=30$ can be seen, however, the difference between $m=10$ and $m=12$ in the case of $r=20$ is not distinct. The 12-hour prediction for July 1992 and the 6-hour prediction for January, April and July 1992 were obtained under the conditions of $r=20$ and $m=12$. The fitting rates are shown in Table 3.

Fukui and Miyazaki: The 6-hour and 12-hour prediction was performed under the conditions of $r=10$ and $m=10$. The objects of the prediction are July, October 1993, January and April 1994 in Fukui, and January, April, July and October 1994 in Miyazaki. The data of the past 2 years was used for the prediction. The fitting rates are shown in Table 3.

Figure 7.(a),(b) and (c) illustrate a part of the results, in which the solid line is the observed value and the dotted line with closed circles is the predicted value. In the cases of the 6-hour prediction, the predicted

— ; observed, ...●... ; predicted

agree comparatively with the observed. However, time lags and fluctuations of the predicted become large in the cases of the 12-hour prediction.

5. Conclusion

In this study, the prediction method based on the chaos theory (deterministic nonlinear prediction method) was applied to the significant wave height data. The data whose length were from 19 months to 37 months were used for the prediction, and a certain of the applicability was found. However, it is necessary to improve the prediction accuracy. To increase the number of the data and to improve the estimation method of the local dynamical rule are mentioned for that purpose.

CHAPTER 69

TRANSITION OF STOCHASTIC CHARACTERISTICS OF WAVES IN THE NEARSHORE ZONE

David J. Robillard¹ and Michel K. Ochi²

Abstract

The purpose of this paper is twofold. The first is to clarify the transition of stochastic characteristics of waves; in particular, the transition from a Gaussian to non-Gaussian random process in the nearshore zone as a function of water depth and sea severity, and the second is to develop a method to estimate the non-Gaussian properties of waves at a specified water depth in the nearshore zone from knowledge of the sea severity in deep water. The probability density function applicable to non-Gaussian waves in finite water depth is applied to more than 1,000 samples of wave data obtained by the Coastal Engineering Research Center, U.S. Army, during the ARSLOE Project. From analysis of the data, the limiting water depth is defined below which wind-generated waves can no longer be considered Gaussian for a given sea severity. Furthermore, by presenting the parameters of the probability density function as a function of water depth and sea severity, it is possible to estimate the sea condition at a specified water depth in the nearshore zone from knowledge of sea severity in deep water.

Introduction

It has been known that the probability distribution of the displacement of waves in the deep ocean obeys the normal probability distribution and hence waves are considered to be a Gaussian random process. As waves propagate from deep to shallow water, however, a significant change is evident in the wave profile and this results in waves in shallow water being usually categorized as a non-Gaussian random process. It is noted, however, that transformation of wave characteristics

¹ Lieutenant, US Navy, Engineering Officer, Naval Coastal Systems Station, Panama City Beach, Florida, 32407, USA.

² Professor, Department of Coastal & Oceanographic Engineering, University of Florida, Gainesville, Florida, 32611, USA.

from a Gaussian to non-Gaussian random process may not always occur when waves propagate from deep to shallow water. If the sea severity is very mild, waves in shallow water are still a Gaussian random process. In other words, the non-Gaussian characteristics of waves in finite water depth depend on the water depth and sea severity.

One of the purposes of this study is to clarify the transition of wave characteristics from a Gaussian to a non-Gaussian random process as a function of water depth and sea severity. Another purpose is to develop a method to estimate the non-Gaussian characteristics at a specified water depth in the nearshore zone from knowledge of the sea severity in deep water, which is an extremely significant subject in practice.

Throughout the present study, the probability density function applicable to non-Gaussian waves in finite water depths is applied and analyses are carried out on more than 1,000 wave records obtained by the Coastal Engineering Research Center, U.S. Army, during the ARSLOE Project at Duck, North Carolina. The probability density function was developed based on the concept that stochastic characteristics of waves in finite water depth may be considered to be the same as the output of a nonlinear system (Ochi and Ahn 1994).

A broad range of sea conditions and water depths are examined to ensure the probability density function well represents the histograms of wave displacement data over various conditions. With the applicability verified, the probability density function is used to define criteria for the boundary where the wave field can no longer be considered Gaussian. Furthermore, analyses are carried out on parameters involved in the probability density function to present them as a function of water depth and sea severity. From the results of these analyses it is possible to estimate the sea condition, including the probability density function, at a specified water depth in the nearshore zone from knowledge of the sea severity (significant wave height) in deep water, although applicability of the results may be limited to a water depth of 25 meters where wave data were acquired and analyzed.

Probability Distribution Representing Non-Gaussian Waves

For evaluating the transformation of Gaussian to non-Gaussian characteristics of nearshore waves, the following probability density function developed based on the concept of the stochastic response of a nonlinear mechanical system (Ochi and Ahn 1994) is considered throughout the analysis in this paper:

$$f(y) = \frac{1}{\sqrt{2\pi} \sigma_*} \exp \left\{ -\frac{1}{2(\gamma a \sigma_*)^2} (1 - \gamma a \mu_* - e^{-\gamma a y})^2 - \gamma a y \right\} \quad (1)$$

where y = wave displacement from the mean, $\gamma = 12.8$ for $y \geq 0$ and 3.00 for $y < 0$.

The probability density function carries three parameters, a , μ_* and σ_* . In particular, the parameter 'a' controls the nonlinearity; the severity of nonlinear characteristics increases with increase in the magnitude of 'a'. The magnitude of 'a' becomes zero for Gaussian random waves.

It may be well to show that the above probability density function provides a good representation of the histogram of wave displacement constructed from data obtained in deep as well as in shallow water during a storm. Comparisons between the non-Gaussian probability density function given in Eq.(1) (solid line), the Gaussian distribution (broken line) and the histogram constructed from data obtained during the ARSLOE Project are shown in Figures 1(a) through 1(e). Included also in each figure is a portion of the wave data obtained at each location. The water depth, D , rms-value, σ , evaluated from data and the ratio between them, σ/D are tabulated in Table 1. The water depth is that at the time of measurement including the effect of tide as well as storm surge.

As can be seen in Figure 1(a), the histogram of wave displacement obtained at a water depth of 24.7 meters obeys the Gaussian probability distribution, while all other histograms obtained at shallower water depths deviate from the normal distribution but are well represented by the non-Gaussian probability distribution given in Eq.(1). Table 1 shows that the magnitude of σ/D increases as waves propagate from deep to shallow water, and hence the ratio σ/D may be used as a criterion indicating the limiting condition for the transformation from Gaussian to non-Gaussian random waves. Although only five examples of comparisons between the non-Gaussian distribution and histogram are shown here, about 100 comparisons for various water depths and sea severities all show excellent agreement.

Since Eq.(1) represents well the probability distribution of displacement of waves in the nearshore area, over 1,000 wave data obtained during a storm encountered at the ARSLOE Project (October 23-25, 1980) are reduced for evaluating parameters of the probability distribution function. Then, further analysis is carried out to represent these parameters as a function of water depth and sea severity.

Limiting Water Depth and Sea Severity of Gaussian Waves

The non-Gaussian property of waves in the nearshore zone depends on water depth and sea severity. Analysis of wave records obtained in shallow water shows clearly that they are still a Gaussian random process if sea severity is mild. Table 1 indicates that the transition from Gaussian to non-Gaussian waves occurs for σ/D values between 0.042 and 0.086. From analysis of about 100 samples of wave data with σ/D between 0.045 to 0.080, it is found that $\sigma/D = 0.060$ is the limiting condition below which waves can be considered as a Gaussian random process. As an example of the analysis results, Figure 2(a) shows a comparison between the Gaussian (broken line) and non-Gaussian (solid line) probability density functions of wave displacement data for $\sigma/D = 0.071$. In this case, the χ^2 -test with level of significance of 0.05 shows that the measured data cannot be considered to

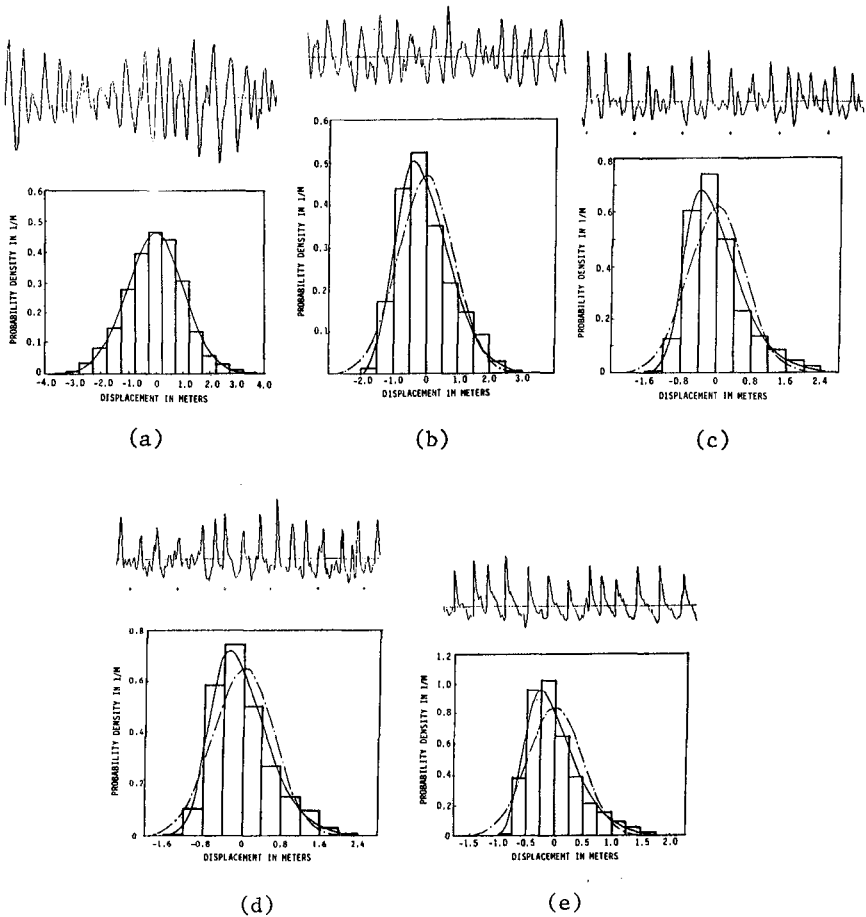

Figure 1 Comparison between probability density function and histogram of wave displacement

Table 1 Water depth and rms-value of data shown in Figure 1

WAVE DATA SHOWN IN FIG. 1	WATER DEPTH D (m)	RMS-VALUE σ (m)	σ/D
(a)	24.70	1.034	0.042
(b)	10.04	0.858	0.086
(c)	6.52	0.650	0.100
(d)	4.66	0.612	0.131
(e)	2.23	0.480	0.215

Figure 2 Comparison between Gaussian (broken line) and non-Gaussian (solid line) probability density functions of wave displacement data

Figure 3 Limiting water depth for non-Gaussian waves as a function of significant wave height

be a Gaussian random process. On the other hand, Figure 2(b) shows a comparison for $\sigma/D = 0.060$. As seen, the non-Gaussian probability distribution computed from data is virtually the normal probability distribution. It was found that all probability distributions of wave displacement obey the normal probability distribution and/or pass the χ^2 -test (using a normal distribution as the hypothesized distribution) when the ratio σ/D is less than 0.06. Assuming that waves are narrow-banded, $\sigma/D = 0.06$ is equivalent to $D/H_s = 4.17$, where $H_s =$ significant wave height.

Based on the findings presented above, Figure 3 shows the limiting water depth below which wind-generated waves are considered to be a non-Gaussian random process for a specified significant wave height. The criterion $\sigma/D = 0.06$ for the limit of Gaussian waves is given as the solid line in the figure. It is noted that the parameter 'a' of the probability density function given in Eq.(1) is zero for

Gaussian waves, which can certainly be used as another criterion for evaluating the limiting Gaussian random process. Hence, the sea severities (significant wave heights) for which the computed a-values of the density function is zero or near zero are evaluated at various water depths and plotted as the open circles in the figure. Finally, a criterion for limiting Gaussian random waves was developed from analysis using the Gram-Charlier series probability distribution with skewness $\lambda_3 = 0.2$ (Ochi and Wang 1984). This criterion is given as the dotted line in the figure.

The results obtained from the above mentioned three different analyses for evaluating limiting conditions of Gaussian waves as a function of significant wave height, H_s , and water depth show good agreements; therefore, it may be concluded that the water depth in a given sea severity for which $\sigma/D = 0.06$ (or $D = 4.17 H_s$) is the limiting depth below which waves may be considered to be a non-Gaussian random process. This criterion, however, is valid only for water depths not exceeding 25 meters where the data were acquired and analyzed.

Parameters of the probability Distribution

In this section, the functional relationship between parameters of the non-Gaussian probability density function given in Eq.(1) will be discussed and presented as a function of water depth and sea severity. Since the three parameters, a , μ_* and σ_* carry different dimensions, these parameters are expressed in dimensionless forms, $a\sigma$, μ_*/σ and σ_*/σ , respectively, where σ is the rms-value of waves at a specified location.

Figure 4 shows the functional relationship between σ_*/σ and $a\sigma$. In this figure, the relationship obtained from data at three locations (calm water depth of 1.35 m, 5.5 m and 8.8 m) are given, but data obtained at other water depths fall within the upper and lower bounds drawn in the figure. The vertical scale range is very small; from 1.00 to 1.05. Therefore, the difference between the formula given in the figure and the upper and lower bounds of data is within one per cent. That is, we can evaluate σ_*/σ as a function of $a\sigma$ within one per cent as follows:

Figure 4 Functional relationship between σ_*/σ and $a\sigma$

$$\sigma_* / \sigma = \exp\{(\alpha\sigma)^2\} \tag{2}$$

Figure 5 shows the functional relationship between μ_* / σ and $\alpha\sigma$. Again, the figure shows the results obtained at the three locations shown in Figure 5, but all data obtained at other water depths fall within the range of scatter shown in the figure. By drawing the average line, μ_* / σ can be presented as a function of $\alpha\sigma$ as follows:

$$\mu_* / \sigma = -1.55(\alpha\sigma)^{1.20} \tag{3}$$

Figure 6 shows the dimensionless parameter $\alpha\sigma$ as a function of the sea severity-water depth ratio σ/D . As seen, $\alpha\sigma$ is zero for $\sigma/D = 0.06$ as mentioned

Figure 5
Functional relationship
between μ_* / σ and $\alpha\sigma$

Figure 6
Relationship between $\alpha\sigma$
and σ/D as a function of
dimensionless water depth
 D/\bar{D}

earlier, and $a\sigma$ depends to a great extent on the water depth. In order to present the results as a function of water depth, the dimensionless water depth D/\bar{D} is used where \bar{D} is the calm water depth at each location where data were obtained. The water depth in the shallow water area, in general, increases to 1.5 (or greater) times the calm water level. Points for D/\bar{D} greater than 1.5 and σ/D greater than 0.12 in the figure are those in shallow water, on the order of less than 4 meters depth in calm water. As seen in the figure, for a specified D/\bar{D} , the value of $a\sigma$ increases rapidly for σ/D between 0.06 and 0.12 beyond which it remains constant. That is, for σ/D greater than 0.12, the parameter $a\sigma$, representing the severity of the nonlinear property of waves may be represented approximately by

$$a\sigma = 0.032 + 0.085(D/\bar{D}) \quad (4)$$

Estimation of Sea Condition in the Nearshore Zone

It may be of considerable interest to estimate the sea condition in the nearshore zone from knowledge of the sea severity (significant wave height) in the offshore area. For this, it is assumed that the sea condition remains constant in the offshore area where the water depth is greater than $4.17 H_s$; the relationship obtained in Figure 3. This water depth is denoted by D_0 in Figure 7. Next, let the variance of non-Gaussian random waves at an arbitrary location in the nearshore zone be σ^2 where the water depth is D . Figure 8 presents the sea severity-water depth ratio, σ/D , evaluated from analysis of data obtained at various locations in the nearshore zone as a function of dimensionless water depth D/D_0 . The solid circles represent high tide condition, while the open circles are for low tide. The triangular marks are indicative of the water depth during the storm being almost equal to the still water level at the various locations. By drawing the average line in the figure, the functional relationship between σ/D and D/D_0 can be obtained from the figure as

$$\sigma / D = 0.06(D / D_0)^{-0.58} \quad (5)$$

Figure 7 Sketch indicating the estimated transition of sea severity due to water depth variation in the nearshore zone

Figure 8 Relationship between σ/D and dimensionless water depth D/D_0

The two lines in Figure 8 are $\pm 5\%$ lines of the mathematical formulation which cover all data. Thus, upon estimating the water depth D at a specific location including the effect of tide and storm surge, the sea condition in the nearshore zone can be predicted by Eq.(5) from knowledge of the significant wave height in deep water. The parameters of the probability distribution of non-Gaussian waves applicable to that location can then be estimated from Eqs.(2) through (4) with information on the water depth in calm water.

As an example, Figure 9 shows the application of this approach for predicting the sea condition in the nearshore zone from knowledge of significant wave height in the offshore area, the sea condition at Duck, North Carolina at noon on October 25th, 1980 is estimated. The records show the tide was high at this time. The horizontal scale in Figure 9 is the distance from the shoreline given in logarithmic scale. The significant wave height at a distance 12 Km offshore was 4.28 meters where the water depth was 24.7 meters. It is assumed that the sea severity remains constant in areas deeper than $D_0 = 17.5$ m, which is equal to 4.17 times the significant wave height and that waves are non-Gaussian in areas shallower than D_0 . The values of σ/D are estimated at various water depths from Figure 8, and compared with measured data which are given by the square-marks in the figure. The variances, σ^2 , are then computed and compared with measured data given by the open circles. Furthermore, the dimensionless parameters $a\sigma$ are estimated at various water depths from Figure 6 (or by Eq. 4 for $\sigma/D > 0.12$) and are plotted in the figure. Good agreement between estimated and computed values from measured data is obtained in this example.

Figure 9 Comparison between estimated σ/D , σ^2 , $a\sigma$ and those computed from measured data at various locations in the nearshore zone

Conclusions

This paper presents the results of a study to clarify the transition characteristics of waves from a Gaussian to non-Gaussian random process in the nearshore zone and presents them as a function of water depth and sea severity. From analysis of more than 1,000 samples of wave data obtained by the Coastal Engineering Research Center, U.S. Army, during the ARSLOE Project, it is found that for a given sea severity a water depth of 4.17 times the significant wave height is the limiting depth for which waves may be considered to be a non-Gaussian random process. Furthermore, the parameters of the probability density function representing non-Gaussian waves are presented as a function of water depth and sea severity. By applying the results of this analysis, a method is developed to estimate the sea condition at a specified water depth in the nearshore zone from knowledge of sea severity (significant wave height) in deep water.

Acknowledgments

The authors express their appreciation to Dr. Ahn for his valuable contribution in evaluating the limiting water depth associated with non-Gaussian waves. They are also grateful to Ms. Laura Dickinson for typing the manuscript.

MONITORING AND MODELLING ON SHALLOW WATER WAVE PROPAGATIONS IN “EL SALER” BEACH

José C. Santás¹, Jose M. de la Peña², José Lozano³,
Studies Center of Harbors and Coast, CEDEX,
Ministry of Public Works, Spain⁴

ABSTRACT

Physical modelling with 3-D basins have mainly been used in relation with wind wave propagation, which input are irregular and multidirectional trains obtained from a directional system in the prototype, to test harbour structures . Very few applications are been developed to test the spectral propagation over a beach from deep waters to surf zone neither to study the relationship between spectral directional characteristic of time series obtained in prototype and in the basin. The aim of this study has been the study of the propagation of real data obtained in El Saler beach along the beach slope towards the bar and compare these results with real data, employing the 3-D basin , with the real beach profile. These data have been obtained from the Monitoring Campaign developed by CEDEX, partially sponsored by the contract MAST2, CT92-0027, G8M project, on El Saler Beach.

1.-INTRODUCTION

The general aims of the “El Saler” Project were the monitoring of the beach as well as the wind waves to study the beach evolution and the waves propagation. For that two systems to obtain wave climate data were installed at medium deep waters , 50 meters depth, and on the submerged beach, firstly located at 10 meters deep before bars, to be moved after 1 year, towards a surf position, between the bar and the swash zone of the beach.

The first work developed with the obtained information was the propagation of selected trains by mean two numerical models: a lineal one and a Boussinesq standard model, which results were compared each other. The relationship allowed between them and also taking into account the field data, were not as good as we hoped in the previous step, specially if we compare the longshore variations oh the significant wave with the field data, and also the second order peaks that appeared on the field spectra. Otherwise the relation between shoaling coefficients was so big.

Taking into account the 3-D Basin facilities, a physical model was planned to be used as a final step of this work. The aim of this paper is to show the characteristic of the physical model phase as well as its results .

2.-FIELD DATA AND SPECTRAL ASSIMILATION

The monitoring of "El Saler" beach, located in the Mediterranean spanish coast, incorporated a wide knowledge of the directional waves for no very rough conditions and the bathymetric data.

The field data acquisition survey was developed from February-93 till June-95, with 3 systems located along a perpendicular line to the coast, from 47 meters depth till 3.5, beyond the bar. Yearly bathymetric surveys have been made to study area evolution, from dune (+5 meters) to submerged beach till 10 meters deep. Special focusing was employed on three control profiles, over wich the systems were installed, with 12 surveys profiles, in front of Luis Vives Parador. An idealized profile was obtained as mean profile to get the propagation by mean the physical model as we can see later. The picture 1 shows the study area
Figure 1: Studied zone with locations of measurement systems.

Figure 2: Studied profile with the EMCM installation points

The basic equipment used into this project has been composed by :

-A **Datowell Waverider Directional buoy** (which will be called WavDir in this report) deployed in depth water (50 meters), linked to the shore station , composed by a receiver , a PC and a recording system, by RF . The buoy location has been kept watch on by the Argos System . (@Argos CLS.)

-Two **Interocean Electro-Magnetic Current-Meters**, S4ADW, instrumented with a high resolution pressure cell. These systems were located on the control profile, 0.8 meters over the bottom, in points of 8 and 3 meters deep respectively, with a special rig to sink to maintain the equipment near the bottom. These systems provided data concerning the characterization of the Waves Sea Climate in the Inshore Zone as well as near the bar , figure 2 .

The Waves Data acquisition was made attending the following items:

-Time series duration: approximately 20 minutes (wav-Dir) and 35 for S4DW,

-Sampling period of 0.78(Dir.-Wav) and 0.5 sec. (S4DW)

-Repetition period of 3 hours.

-Time series length: 1560 data points for Waverider Directional buoy and 4200 for EMCM's.

Characteristics of the Raw Data Process

The spectral process has been made with 6 blocks of 256 points and averaging the 6 spectra obtained (degrees of freedom : dof=12) for the Wav-Dir data and using 16 blocks of 128 points to obtain (dof= 32) EMCM's prototype spectra. The process allow us to obtain statistical and spectral usual results for heave (according the IAHR recommendations) as well as directional parameters for directional distribution functions.

As the EMCM Raw Data are absolute pressures and velocities in N-S direction and E-W direction, they have to be transformed to instantaneous water column height. The mean level which is eliminated in the spectral process, is taken to calculate the hydrodynamic attenuation. Also a correction taking into account non linear terms is used (proposed by Grace, 1977). Some calculations has been made in order to evaluate the effect of different possible incoming directions for waves and currents. The relative error for $u = .25$, $T_z < 2s$ and $d = 3m$ (limiting conditions in these deployments) is less that 5% .

Data sets selection and Spectral parametrization

A set of data records was chosen to fit their $S(f)$ and $G(f,\theta)$ spectral forms to parametric Jonswap Spectrum and Gaussian Distribution Functions. Four sea states were selected in order to study the propagation with the 3-D basin. The employed criteria were:

- Existence of simultaneous data in the three systems,
- Medium sea climate conditions,
- Narrow One-Peak spectral form and low directional dispersion.

A bigger number of sea states were employed for the propagations made by numerical modelling, because its ease for change initial conditions.

The parameters used to generate the waves were:

- Jonswap data : f_p , γ , H_s , σ
- Directional distribution function: Th_{Tp} , $\sigma(Th_{Tp})$ for $f=f_p$ and $f=1.5f_p$.

As the s-Misuyatsu parameter is used to generate the wave train, the relation $\sigma^2(Th_{Tp}, f_p) = 2/(s+0.5)$ was used.

3.-PHYSICAL MODEL CHARACTERISTICS

The Multidirectional Wave Tank of CEDEX, Cepyc, is 34 x 26 x 1.6 m.. The generator is endowed with 72 independent piston paddles (1.3x0.4 meters) with a total front of 28.8 meters. It is managed by modular computers controlled and connected to a VAX computer by an Ethernet network. The 3-D basin uses the GEDAP software, Hyd. Inst, NRC of Canada(3) to generate and analyze the waves. The duration of every test was 30 minutes taking 16400 data points. The method used for the generation is single summation method.

The modelled area reproduces, with a undistorted scale 1:50, the El Saler beach from coast to 30 meters depth, with an averaged profile obtained from field data. A regularization zone between the -30.0m to paddles existed. The employed measurement equipment was:

- 2 six wave-probes platforms and 2 EMCM as directional systems, located

alternatively along the test points: the perpendicular line to coast at 10,8,6,4 and 3.5 (beyond the bar) meters depth plus a platform always located at 30 m in front of the paddles system.

-Also 19+19 test points along parallel lines to coast were employed with 19 probes at same depths, figure 3.

The layout of the modelled profile is shown in the figure 4. The characteristics of the modelled sea states were specified on the Table. Figure 3 : layout of physical model

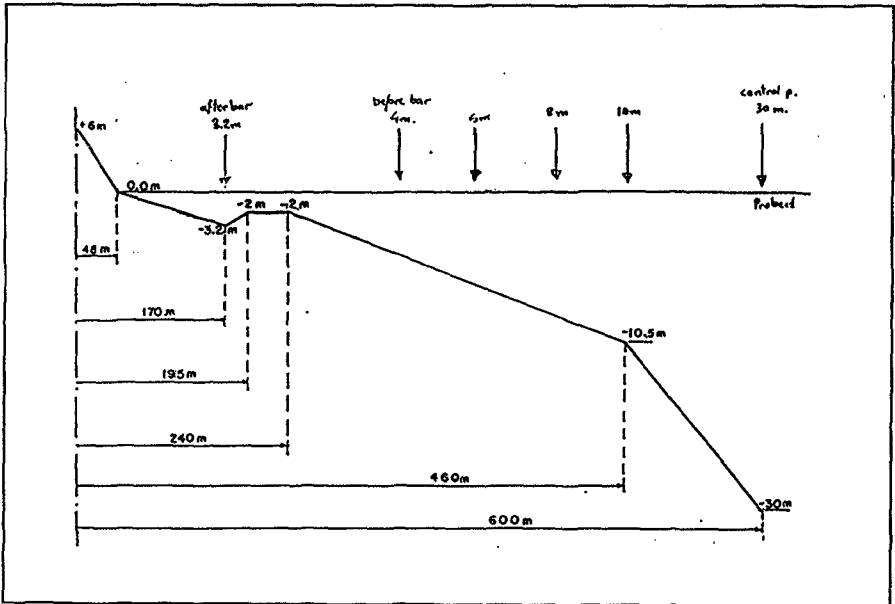

Figure 4: Profile used along the axis of the model.

TABLE I

Test number	Hm0 (50)	Hm0 (30)	Tp	γ	θ (aver)	$\sigma(\theta)$	s	α	ϕ
15	1.82	1.63	12.5	2.61	67	12	10	-3	18
17	1.40	1.32	11.1	1.86	67	13	9	-3	20
21a	1.20	0.70	7.7	1.44	68.5	21	5	-1.5	35
21b	0.52	0.47	7.7	1.44	68.5	21	5	-1.5	35

As the buoy was installed in 47 meters depth, and the deepest point of the physical model was 30, a previous lineal propagation by numerical model was employed, and the Hs(30)meters was obtained . These both data appear in the table.

The Peak period and Gamma were deduced from the fitting. The Incoming Direction θ , and its spreading were deduced from the data. The angle α is the difference between the normal to coast and θ .The angle ϕ is the propagation angle.

Figure5 : long shore variation of Hs, test 15th and 17th : Edge waves

4.-DATA OBTAINED FROM THE MODEL

The Directional distribution functions for $f=f_p$, $f=1.5 f_p$, mean direction and its spreading versus frequency were obtained. From the EMC system also the current spectra (longshore and cross shore) were taken. Only the scalar spectra were recorded for the measurement points with wavestaff

Every test was ran 6 times and the spectral characteristics were compared between them, also between the different tests, and between 3-D results and prototype. The directional spectra were obtained only along the model axis and the heave spectra for all the test points. Obtained results, statistics and spectral, have been studied to characterize wave propagation and its evolution as the depth decrease and for both sides from the axis. The more relevant items founded are:

4.1.-Significant wave height variations in parallel lines

In relation with the local variability of H_s along the measurement area, it was obtained a pattern with the H_s contour line that was compared with field data. A modulation appeared that could be produced by edge waves. The aspect of that is shown in the picture 5.

Figure 6: Wave spectra along the axis of the model: 2nd order peaks.

A modulation appeared that could be produced by edge waves. The aspect of that is shown in the picture 5.

4.2.-Peaks from the 2nd order interactions

La interaction between bands produces 2nd order peaks, as for short frequencies (Long Wave band), named as f_{-} , as in high frequencies (Short Wave band), named as f_{+} . This last peak grows up as the depth decreases, and it disappears after the breaking point, figure 6.

Figure 7

The central frequency of these 2nd order bands are approximately double and half, respectively, of the primary spectra, f_p .

The relationship between the energies of these 2nd order peaks and the first order peak, m_0 , have been calculated for the shallow waters between 8 to 4 meters depth, figure 7.

4.3.-Currents spectra

The directions X and Y have been chosen in the way that OX is the coast line and OY is normal towards sea. The spectra obtained from the central line, at 8

and 4 meters are shown in the figure 8.

The peaks of the f_+ band (short wave), only appears in the cross shore spectra. The opposite appends with the f_- , Long Wave band, that only appears in the long shore spectra. This could be seen by comparison between the same kind of spectra, V_y or V_x , in function of deep.

Figure 8 : Cross shore spectra (V_y) and Long shore spectra (V_x).

5.-CONCLUSIONS

The employed methodology reproduces quite well the evolution that has been obtained in the prototype, better than the numerical model before used (2). The test points located along the axis show the appearance of 2 second order peaks as well as for higher frequencies (double that the primary peak f_p) as for lower frequencies, long wave band, approximately at $f_p/2$. This effect was detected into the prototype.

The energy of these 2nd order peaks increases as the depth decreases. Also a modulation along the coast line is found with a length of wave function of the characteristics of the incoming wave train. This effect was not reproduced by the used numerical models (2)

The currents spectra near the bar show that the contribution of the long wave band is more important in cross shore direction, while the long shore has an important contribution of the short wave spectra.

The spectra of waves look like 'pink' noise after the bar, instead of the direction keeps incoming wave characteristics showing a few wider spreading.

DEFINITIONS OF THE USED SYMBOLS:

η : heave

(u, v) : velocity components , N-S and E-W respectively.

T_p : peak period of spectral estimation, (integrated all the directions).

H_s or H_{m0} : Significant Wave Height =4 times the squared root of m_0 ,

Th or θ : incoming direction of waves

Th_{Tp} or θ_p : Peak period band direction

$D_s(T_p)$ or $\sigma(Th_{Tp})$: Standard gaussian dispersion for the peak period band

γ, σ : Jonswap peakness parameter

$S(f, \theta)$: spectral densities for the prototype directional spectrum ,

$S(f)$: spectral densities for the scalar spectrum ; $S'(f)$: JONSWAP fitted spectrum

$G(f, \theta)$: Normalized Directional Spreading distribution for $S(f, Th)$,

dof : number of freedom degrees

d: depth

CHAPTER 71

Intercomparison of Parameter Estimation Methods in Extremal Wave Analysis

Masataka Yamaguchi¹

Abstract

Based on statistical analysis of extreme wave height data generated with a Monte-Carlo simulation technique for the prescribed parent probability distributions, a preferable method for the parameter estimation was determined for each of 8 distributions. It is also verified that a jackknife method is applicable to the correction of bias and the estimation of variance irrespective of parameter estimation method in most parent distributions, and that the information matrix methods inherent to the maximum likelihood method give generally satisfactory results in the estimation of variance of return wave height for samples of size greater than around 50.

1. Introduction

In the statistical analysis of extreme wave height data, several kinds of theoretical probability distributions and fitting methods for the parameter estimation have been employed, because the population distribution is not known a priori. Many attempts (for instance, Goda et al., 1993) have been made to find what kind of fitting method is preferable for the parameter estimation of each probability distribution to obtain a reliable estimate of return wave height and how the sampling variability could be evaluated, but the answer is still uncertain, because the class of parent distribution and the parameter condition investigated are limited.

This study uses 8 kinds of probability distributions including the Gumbel and Weibull distributions and 4

1 Prof. of Civil and Environmental Eng., Ehime Univ.
Bunkyocho 3, Matsuyama 790, Ehime Pref., Japan

kinds of parameter estimation methods. Based on the statistical analysis with use of the 4 methods for data generated by a Monte-Carlo simulation technique, in which case the parent probability distribution is taken from one of the 8 distributions, the advantage of a parameter estimation method over the other methods is investigated from the view points of bias and variance of return wave height. Also, applicability of a jackknife method to the correction of bias and the estimation of variance of return wave height, and that of information matrix methods usable in the maximum likelihood method to the estimation of variance of return wave height are discussed.

2. Parent Distributions and Estimation Methods of Parameter and Variance

2. 1 Parent distributions

The probability distributions investigated are the Gumbel, Weibull, GEV, Lognormal, Gamma, Loggamma, Hypergamma (Generalized Gamma) and Poisson-square root exponential-type maximum (SQRT) distributions. These distributions except for the Gumbel and SQRT distributions have three parameters respectively. Each probability distribution $F(x)$ is written as follows.

(a) Gumbel distribution (Greenwood et al., 1979; Goda, 1988)

$$F(x) = \exp[-\exp\{-(x-B)/A\}] ; -\infty < x < \infty \quad (1)$$

where x is the random variable, A the scale parameter and B the location parameter.

(b) Weibull distribution (Greenwood et al., 1979; Goda, 1988)

$$F(x) = 1 - \exp[-\{(x-B)/A\}^k] ; B < x < \infty \quad (2)$$

where k is the shape parameter.

(c) GEV distribution (Fisher-Tippett type II (FT-II) distribution for $k > 0$) (Hosking et al., 1985; Phien and Emma, 1989; Goda, 1990)

$$F(x) = \exp[-\{1 + (x-B)/kA\}^{-k}] ; \begin{array}{l} B - kA < x < \infty, k > 0 \\ -\infty < x < B - kA, k < 0 \end{array} \quad (3)$$

(d) 3-parameter Lognormal distribution (Takeuchi and Tsuchiya, 1988)

$$F(x) = (1/\sqrt{\pi}) \int_{-\infty}^y \exp(-y^2) dy$$

$$\begin{array}{l} y = k \cdot \log\{(x-B)/A\} ; B < x < \infty, C_S > 0 \\ y = k \cdot \log\{A/(B-x)\} ; -\infty < x < B, C_S < 0 \end{array} \quad (4)$$

where C_s is the skewness coefficient.

(e) 3-parameter Gamma distribution (Bobée, 1975; Takeuchi and Tsuchiya, 1988)

$$\begin{aligned} F(x) &= \gamma\{k, (x-B)/A\} / \Gamma(k) & ; B < x < \infty, A > 0 \\ F(x) &= 1 - \gamma\{k, (x-B)/A\} / \Gamma(k) & ; -\infty < x < B, A < 0 \end{aligned} \quad (5)$$

where $\Gamma(k)$ is the gamma function and $\gamma(k, x)$ the incomplete gamma function of the first kind defined by

$$\gamma(k, x) = \int_0^x \exp(-t) t^{k-1} dt \quad (6)$$

(f) 3-parameter Loggamma distribution (Condie, 1977)

$$\begin{aligned} F(x) &= \gamma\{k, (\log x - B)/A\} / \Gamma(k) & ; B < \log x < \infty, A > 0 \\ F(x) &= 1 - \gamma\{k, (\log x - B)/A\} / \Gamma(k) & ; -\infty < \log x < B, A < 0 \end{aligned} \quad (7)$$

(g) 3-parameter Hypergamma distribution (Suzuki, 1964)

$$\begin{aligned} F(x) &= \gamma(k, t) / \Gamma(k), \quad t = (x/A)^C & ; 0 < x < \infty, C > 0 \\ F(x) &= 1 - \gamma(k, t) / \Gamma(k) & ; 0 < x < \infty, C < 0 \end{aligned} \quad (8)$$

(h) SQRT distribution (Etoh et al., 1986)

$$F(x) = \exp\{-k(1 + \sqrt{x/A}) \exp(-\sqrt{x/A})\} ; 0 < x < \infty \quad (9)$$

This is one of the compound distributions, and k signifies yearly-averaged occurrence rate of event rather than shape property of the distribution.

2. 2 Parameter estimation methods

The parameter estimation methods used in this study are the moment method (MOM), the probability weighted moment (PWM) method and the maximum likelihood method (MLM) and the least square method (Goda, 1988, 1990) (LSM). Sample mean, unbiased variance and skewness are used in the moment method. In the parameter estimation with the moment method for the Loggamma distribution, two methods based on mean, unbiased variance and skewness of log-transformed sample data (MOM1) and cumulants of sample data (MOM2) are applied. PWM solutions are not derived in the cases of Lognormal distribution for negative skewness, Loggamma distribution, Hypergamma distribution and SQRT distribution. The parameter estimation for SQRT distribution is only derived from the maximum likelihood method.

The least square method is based on the model by Goda (1988, 1990). A set of candidate distributions is the Gumbel and Weibull distribution whose shape parameter is either of 0.75, 1.0, 1.4 or 2.0. The other set consists of the Gumbel and FT-11 type distribution whose

shape parameter is either of 2.5, 3.33, 5.0 or 10.0. A distribution with the largest correlation coefficient between the ordered data of sample and its reduced variate is selected as the best fitting distribution.

2. 3 Index of goodness of fit

The SLSC (Takasao et al., 1986) is used as an index of goodness of fit. It is defined by

$$SLSC = \left\{ \sum_{i=1}^N (x_i - s_i)^2 / N \right\}^{1/2} / |s_{0.99} - s_{0.01}| \tag{10}$$

where N is the sample size, x_i the ordered data, s_i the variate which is calculated from a theoretical probability distribution for designated probability such as 0.99 or 0.01. The Weibull plotting position formula is used as a standard formula to estimate non-exceedance probability F(x) of sample data, but in the least square method, the distribution-dependent plotting position formula is applied. The least square method eventually gives smaller SLSC than the other methods owing to its definition.

2. 4 Methods of bias correction and variance estimation

A jackknife method (Miller, 1974) is applied for bias correction and variance estimation of return wave height estimated using either method of MOM, PWM or MLM. The formulas are given by

$$H_J = N\hat{H} - (N-1)\hat{H}_*, \quad \hat{H}_* = \sum_{i=1}^N H_{*i} / N, \quad \sigma_J^2 = (N-1) \sum_{i=1}^N (H_{*i} - \hat{H}_*)^2 / N \tag{11}$$

where \hat{H} is the estimate of return wave height, H_{*i} the estimate of return wave height based on N-1 data excluding x_i , H_J the bias-corrected estimate of return wave height and σ_J^2 the jackknife estimate of variance indicated by σ_{JM}^2 for MOM, σ_{JP}^2 for PWM and σ_{JY}^2 for MLM.

In the application of the maximum likelihood method for the parameter estimation of the probability distributions except for SQRT distribution, the methods based on variance-covariance matrix of the maximum likelihood estimator (Suzuki, 1964; Phien and Emma, 1989) can be used for the asymptotic evaluation of variance of return wave height. It is defined as

$$A_{ij} = -E \left\{ \frac{\partial^2 L(X; \theta_1, \dots, \theta_r)}{\partial \theta_i \partial \theta_j} \right\} ; i, j = 1, 2, \dots, r \tag{12}$$

where E means the expected value operator, L the log-transformed maximum likelihood and θ_i the parameter of a probability distribution. A_{ij} is called the Fisher

information matrix, and if the expected value operator is dropped in eq. (12), it is called the observed information matrix. The variances estimated with both methods are indicated by σ_{FM}^2 and σ_{OM}^2 respectively.

In the case of the least square method, the standard deviation of return wave height σ_{LSM} is estimated with the empirical formula derived from numerical experiments by Goda (1988, 1990).

3. Monte-Carlo Simulation

As the inverse forms of the Gumbel, Weibull, GEV and lognormal distributions are known analytically, a sample of extreme wave height data is simulated sequentially by giving uniformly-distributed numbers between 0 and 1 generated by computer as input. In the cases of the other distributions such as the Gamma distribution, a sample of wave height is made with use of a numerical table given as the relation between equally-divided non-exceedance probability $F(x)$ and random variable x . The number of samples is 5,000 and sample size in each sampling N ranges from 10 to 1000, i.e. 10, 20, 30, 40, 50, 70, 100, 200, 500 and 1000. Value of SLSC, the parameters and the resulting 5 return wave heights $H(n)$ from 50 to 1000 years ($n=50, 100, 200, 500$ and 1000) and their variances are estimated with the above-mentioned methods from each sample. By averaging the results of 5000 simulations for each data size, mean values for SLSC, return wave height $H(n)$, jackknife-corrected return wave height $H_J(n)$, variances ($\sigma_{JM}^2, \sigma_{JP}^2, \sigma_{JY}^2, \sigma_{FM}^2, \sigma_{OM}^2$) and standard deviation σ_{LSM} , and variance of 5000 return wave height data $Var(n)$ are obtained. Then two kinds of bias $\Delta H(n)$ and $\Delta H_J(n)$ are respectively as

$$\Delta H(n) = \overline{H(n)} - H_{tr}(n), \quad \Delta H_J(n) = \overline{H_J(n)} - H_{tr}(n) \quad (13)$$

where $H_{tr}(n)$ is the true return wave height corresponding to n years, $\Delta H_J(n)$ the residual bias after jackknife correction, and ' $\bar{}$ ' means the average value. These quantities are called error statistics. Error statistics $\Delta H(n)$, $\Delta H_J(n)$, $Var^{1/2}(n)$ are normalized with use of the true return wave height $H_{tr}(n)$, and square root mean variances and mean standard deviation are divided by $Var^{1/2}(n)$. The normalized error statistics are expressed with the notation ' \sim ' and the figures are shown in the case of return period of 100 years.

4. Consideration of Results

A set of parameters is given to every parent dis-

tribution as input condition in the simulation study to find the advantage of one parameter estimation method over the other methods. Four shape parameters with the other parameters fixed are used in the simulation study to investigate the effect of shape of the distribution on the bias and variance estimated with the optimum parameter estimation method for each parent distribution.

Fig. 1 shows the relation between normalized error statistics and sample size N in the case of the Gumbel distribution, in which simulation is conducted under the condition of $A=1.39$ m and $B=4.5$ m, and the bias by the LSM given in both figures of ΔH and ΔH_j is the same one. It can be seen that bias of each, especially bias after jackknife correction by any methods is small and that the jackknife method and the information matrix methods give proper estimates of variance. Although the MLM with the jackknife correction is the optimum method for samples of size greater than about 30 from view-points of bias and variance, the PWM method is more proper from general view-points, when goodness of fit is taken into account. The LSM naturally produces the smallest SLSC, but gives greater bias and variance than the other methods. Also, the LSM yields poor estimate of standard deviation. This may be due to the fact that the empirical formula for the estimation of standard deviation is

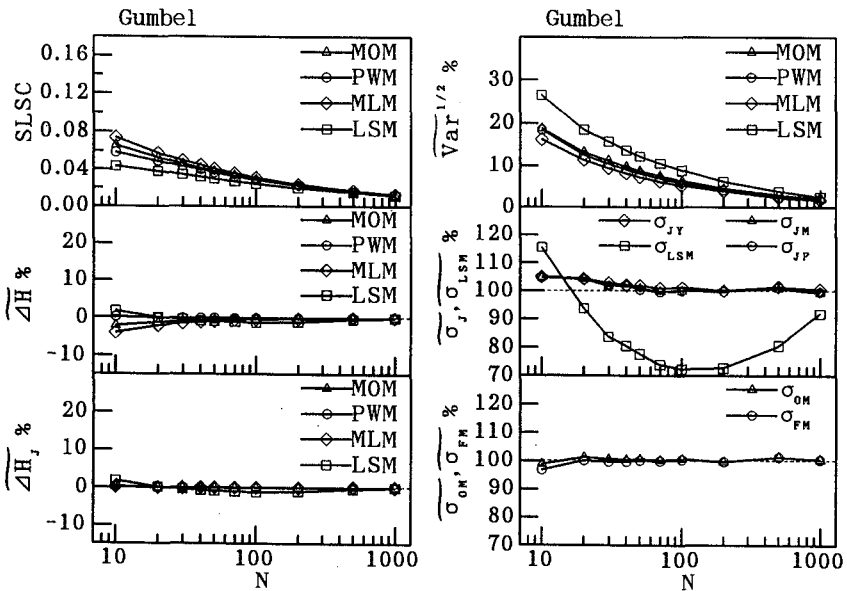

Fig. 1 Relation between error statistics and sample size (Gumbel distribution).

derived on the basis of numerical simulation for a fixed shape parameter, without taking a procedure of selecting the best fitting distribution. Similar tendencies are observed for the Weibull and FT-II type distributions.

Fig. 2 describes the relation between error statistics and sample size for the Weibull distribution. Simulation corresponding to the upper figures is conducted for the condition of $k=1.8$, $A=4.0$ m and $B=1.0$ m to find a preferable parameter estimation method, and simulations corresponding to the lower figures are made by giving either of $k=0.75, 1.0, 1.4$ or 2.0 under the fixed values of

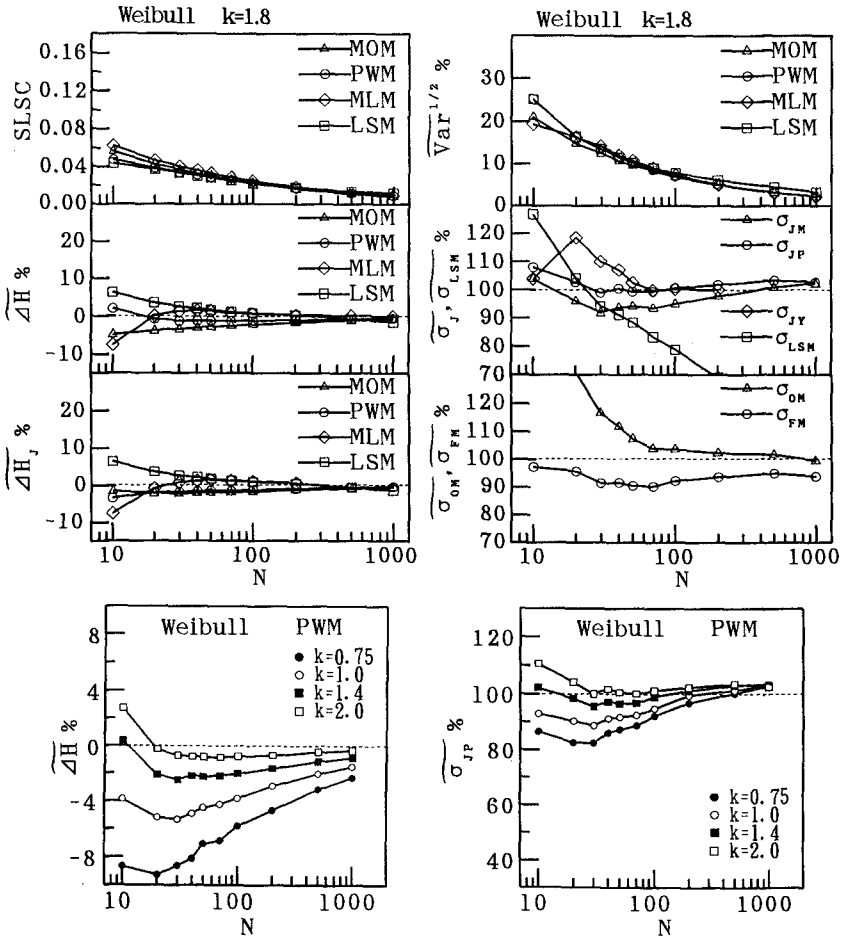

Fig. 2 Relation between error statistics and sample size (Weibull distribution).

$A=4.0$ m and $B=1.0$ m to investigate the effect of shape parameter on the error statistics. The PWM method is seen to be the optimum method from a view point of bias, although it yields a slightly larger estimate of variance than the MOM. In the PWM method, the jackknife method does not always work effectively for the bias correction, but it gives close estimate of variance. The MLM is a recommendable method in the case of sample size greater than 50 or 70. It is seen that the use of the observed information matrix method (OIMM) to the estimation of variance is possible for sample data greater than 30, if overestimation less than 10 % is allowed and that the Fisher information matrix method (FlMM) is applicable with underestimation less than 10 %. The OIMM usually gives greater estimate of variance than the FlMM. The effects of shape parameter on bias and estimate of variance are not negligible. Negative bias and degree of underestimation of variance increase with decrease of shape parameter. These reflect the widening of the Weibull distribution with decrease of shape parameter. Therefore, the application of the PWM method is preferably restricted for the case of shape parameter less than 1.0 to properly estimate return wave height and its variance.

Results for the GEV distribution are shown in Fig. 3. Conditions of simulation for finding a preferable parameter estimation method and for investigating the effect of shape parameter are $k=5.0$, $A=1.0$ m, $B=4.0$ m, and either value of $k=2.5$, 3.33, 5.0 or 10.0 for the fixed values of $A=1.0$ m and $B=4.0$ m respectively. The PWM method with the jackknife method produces excellent estimates of return wave height and its variance. Small bias is also brought about by the LSM which uses the adjusted plotting position formula, but the accuracy of estimation of variance is not so high for the reason mentioned above. The MLM with the jackknife correction gives small bias, but it does not yield good results on variance for small sample size. The information matrix methods are applicable for sample of size greater than about 50 or 70. According to the results of the lower figures, bias based on the PWM method is small except for $k=2.5$, distribution of which is widest in the investigated distributions, and the jackknife method gives fairly proper estimate of variance.

Fig. 4 illustrates the results for the Lognormal distribution. Parameter conditions in the simulation are taken as $k=3.4$, $A=8.0$ m, $B=-2.9$ m and $k=1.5$, 2.0, 2.5, 3.0, $A=3.5$ m, $B=-2.5$ m for each purpose mentioned above. The MOM is a more preferable method than the other methods from view points of bias and variance, and the jackknife method gives proper correction to bias and good

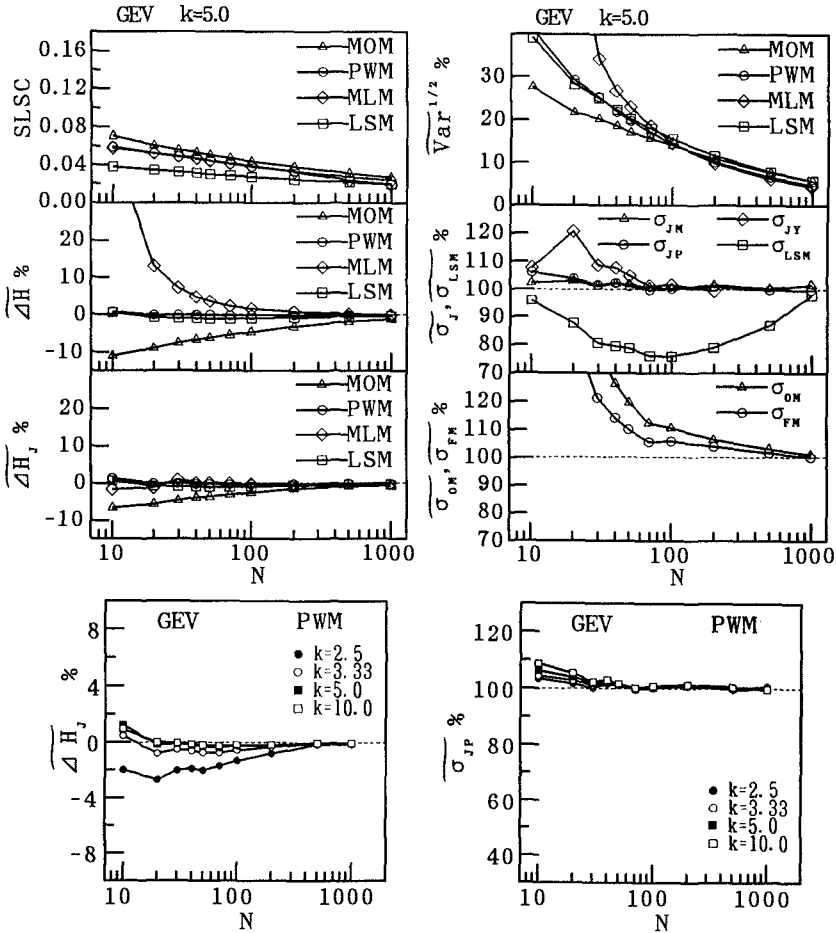

Fig. 3 Relation between error statistics and sample size (GEV distribution).

estimate of variance. Also, the MLM is a preferable method, in particular, for sample of size greater than 50 or 70. The influence of shape parameter on error statistics is seen in a diagram of bias. Even if bias-correction with the jackknife method is made, negative bias for small shape parameters is still at significant level. On the other hand, the jackknife method yields proper estimate of variance irrespective of the value of shape parameter.

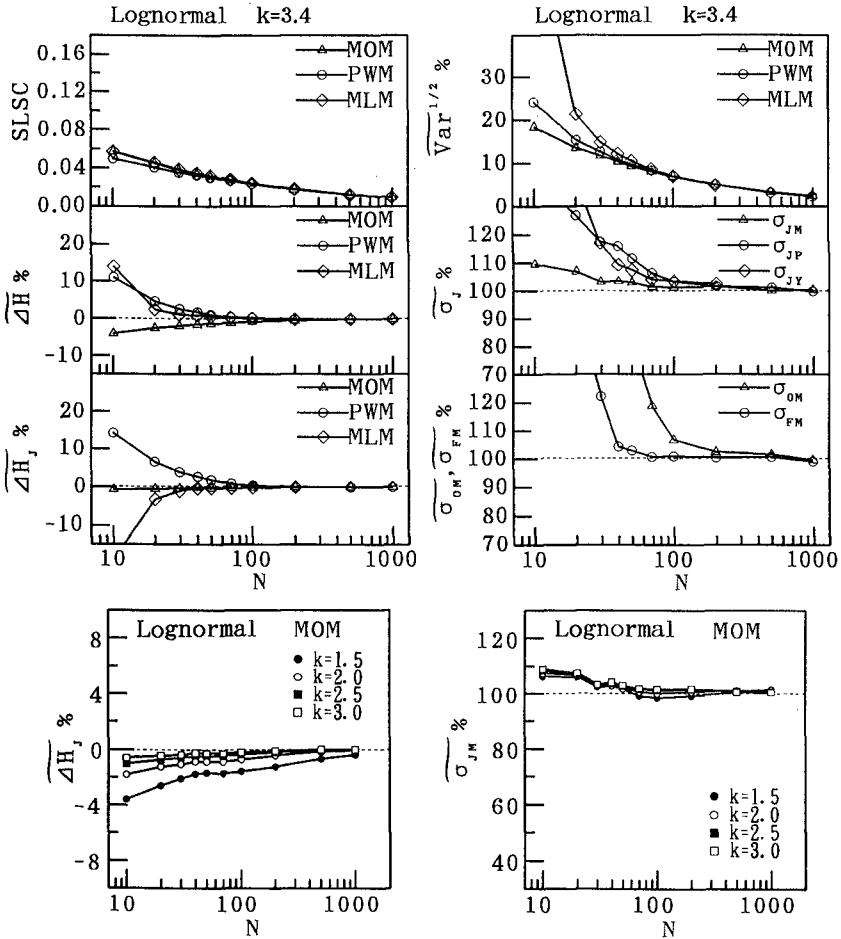

Fig. 4 Relation between error statistics and sample size (Lognormal distribution).

It can be said from similar investigation that the optimum parameter estimation method is the PWM method for the Gamma distribution, the MOM2 for the Loggamma distribution and the MOM for the Hypergamma distributions. Fig. 5 illustrates the effect of shape parameter on bias and estimate of variance in the cases of Gamma ($A=1.0$ m, $B=4.5$ m), Loggamma ($A=-0.1$ m, $B=3.5$ m) and Hypergamma ($A=0.447$ m, $C=2.0$) distributions. The shape parameters used are indicated in the corresponding figure. In the case of the Gamma distribution, even the PWM method which was judged to be the optimum method of the three methods pro-

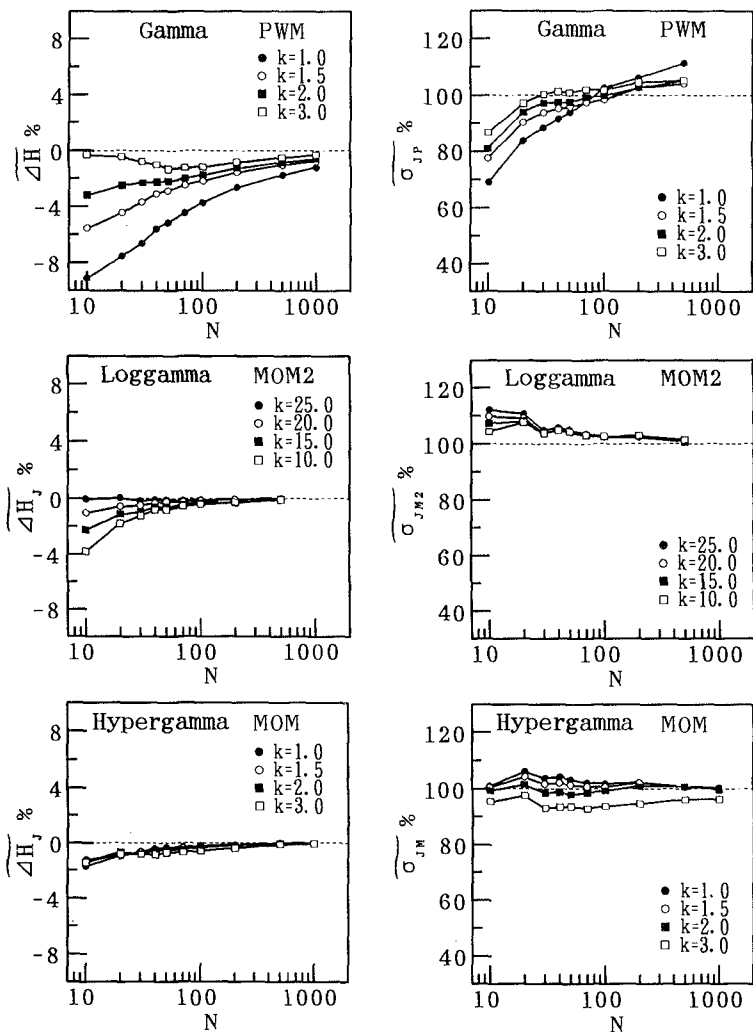

Fig. 5 Effect of shape parameter on error statistics (Gamma, Loggamma and Hypergamma distributions).

duces negative bias increasing with decrease of shape parameter, and the jackknife method does not work efficiently on the bias correction and the variance estimation. In the cases of the Loggamma and Hypergamma distribution, the jackknife method is effective for the correction to bias and the estimation of variance, although deviation from the true value slightly increases for wider distribution.

Fig. 6 Effect of shape parameter on error statistics (SQR distribution).

Finally, Fig. 6 shows the effect of shape parameter on bias and estimate of variance in the case of the SQR distribution. The scale parameter λ is fixed as $1/13$ m and the shape parameter k is either of 50, 100, 150 or 200. At present, the only method applicable to the parameter estimation is the MLM. As mentioned above, the parameter k means yearly-averaged occurrence rate of event. Change of shape parameter k in this case brings shift of a peak position of the distribution rather than variation of shape of the distribution. In the usage of the MLM, the jackknife method yields excellent correction to bias and proper estimate of variance for the given cases.

5. Conclusions

Conclusions in this study are summarized as follows.

- (1) A jackknife method is applicable to the correction of bias and the estimation of variance irrespective of parameter estimation methods in most parent probability distributions.
- (2) A preferable method to the parameter estimation in each distribution is determined as

Gumbel distribution	: PWM with jackknife correction
Weibull distribution	: PWM without jackknife correction
GEV distribution	: PWM with jackknife correction
Lognormal distribution	: MOM with jackknife correction
Gamma distribution	: PWM without jackknife correction
Loggamma distribution	: MOM2 with jackknife correction
Hypergamma distribution	: MOM with jackknife correction
SQR distribution	: MLM with jackknife correction

- (3) The LSM proposed by Goda is a preferable method from the view points of bias and goodness of fit.
- (4) The MLM with the jackknife method usually gives satisfactory estimates of return wave height and its variance for samples of size greater than about 50.
- (5) The information matrix methods are effective as variance estimators in the MLM for samples of size greater than about 50.

CHAPTER 72

INFLUENCES OF SPECTRAL SHAPES ON THE STATISTICAL PROPERTIES OF SIMULATED RANDOM WAVES

John Z. Yim¹ & M.-Y. Lai²

Abstract

Random wave fields were generated both numerically using a computer algorithm, and mechanically through a computer-controlled irregular wave generator. Statistical properties of these synthesized random waves are then compared with measured field results. It is shown that, irrespective of the methodology used, wave heights obtained from simulation always have a Rayleigh distribution, and surface elevations are approximately normally distributed, measured field data can, however, show other trend for the former with a large percentage of possibility.

Introduction

Random wave simulations provide a convenient tool for coastal engineers to study the stochastic properties associated with a wave field. Simulation can be carried out either numerically on a digital computer (Hudspeth & Borgman, 1979; Hudspeth & Chen, 1979), or physically through a computer-controlled wave generating device (Svendsen, 1985; Takayama, 1990). Tuah & Hudspeth (1982) compared the numerical methods then available, and a review was given recently by Hughes (1993). Depending upon the desired characteristics to be modeled, simulations can be carried out either in frequency (Hudspeth & Chen, 1979), or in time domain (Mo, 1993). In frequency domain, a white noise spectrum from certain pseudo-random number generator algorithm is filtered through a target spectrum. Surface elevations are then obtained by inverse Fourier transforming the simulated spectral densities.

²Graduate Student, Dept. Harbour & River Engng. National Taiwan Ocean University, 2, Bee-Ning Road, 20224 Keelung, Taiwan Rep. China.

For laboratory experiments, a (nonlinear) transfer function connecting the actual strokes of the wave generating device and simulated results must be further implemented.

Although not stated explicitly, it is often assumed that waves thus generated have all the characteristics that are in close agreement with those of actual wave fields (Kimura, 1981; Sobey, 1992). Deterministic properties obtained through analyzing simulated surface elevations are then used to verify theoretical predictions. Kimura (1981), for example, used a two-dimensional Weibull distribution to model the joint distribution of wave heights and periods of mechanically generated random waves. He found that the so-called shape parameter for the marginal distribution of wave heights has a value close to 2. Sobey (1992) studied the distributions of zero-crossing wave heights and periods of numerically simulated random wave fields, and concluded that, wave heights "*differ little from Rayleigh distribution.*" It should be noted that since Rayleigh distribution is a special case of the Weibull distribution with a shape parameter equals to 2, the findings of these two researchers, therefore, all indicate to the same fact that, simulated random waves have heights that are Rayleigh distributed.

It is well known that Longuet-Higgins (1952) derived the Rayleigh model based upon the assumptions of narrow-banded wave fields and normality of the surface fluctuations. Even though this model was often shown to overpredict larger wave heights (Chakrabarti & Cooley, 1977), most researchers, however, do find it rather satisfactory (Dattatri et al., 1979).

For the majority of studies concerning random wave simulations, a theoretical and/or empirical spectrum is often used as target spectrum. Spectra carrying the names such as Bretschneider-Mitsuyasu, Pierson-Moskowitz [P-M], or JONSWAP are the most frequently used ones. Among these spectra, the first two are often considered to represent fully developed seas and can be categorically termed as broad-banded, while the JONSWAP spectral shape is designated for growing wind-seas, and is thus narrow-banded.

Even if simulated random wave fields may have spectral shapes that have close resemblance with targets, it would be justifiable to ask whether other deterministic properties of the simulated wave fields, such as the probability distributions of wave heights and periods, would also bear the same affinity with reality. This assumption can be questioned when one considers that measured spectra are sometimes wider and flatter, and sometimes more energetic and narrower than theoretical predictions. Under these circumstances, it is not clear how close the deterministic statistical properties obtained from simulated random waves would match those of measured ones. Direct comparisons with field data are, as far as the authors are aware of, rather limited. This problem is addressed here in some detail.

In the following, the remaining of this paper is further divided into three parts. In section II a short description of the methodologies applied will be given. Section III presents some of the experimental results, and with a discussion in section IV we conclude this paper.

The methodology

Waves were also generated mechanically in a large wave flume of the Department of Harbour and River Engineering in National Taiwan Ocean University. The wave flume has a dimension of $100 \times 3.0 \times 3.0$ (length \times width \times height, in meters). Two series of experiments were conducted. For the first series of experiments only five wave gauges were installed. As the results of these experiments were not quite satisfactory, a second series of experiments with eight wave gauges was carried out. Variations of surface elevations along the flume were measured by capacitance wave gauges. Locations of the measuring stations are: 3.0, 12, 22, 32, and 42 meters for the first series of experiment, and 3.0, 12.0, 32.0, 42.0, 71.5, 73.4, 75.0, and 76.1 meters for the second series, away from the piston wave generator. Figure 1 shows the experimental setups for the first series of experiments.

Fig. 1 Schematic representation of wave generation facilities.

Throughout the experiments, water depth was kept constant at 1.5 meter. As target spectrum, the theoretical five-parameter JONSWAP spectrum is used. Experimental conditions were varied by changing values of the parameters of the target spectrum. A recording time of 330 seconds (5.5 minutes) was used for all experiments so that statistical equilibrium in the wave flume was always achieved. Surface elevations measured by wave gauges and the amplified analog signals were then digitized by an A/D converter of type TEAC DR-F1. The sampling frequency is 50 Hz, so that each data set contains a total of 16,500 sampling points. Table 1 summarizes all the experimental conditions used.

During spectral analyses, wave records were further divided into segments, each containing 1024 data points. The degrees of freedom for the spectral density es-

timates are 32, with a frequency resolution equal to 0.048828. A total of 71 for the first, and 66 for the second, series of experiments were conducted.

Field data were recorded with a pressure gauge in a two hour interval from October 1991 to October 1993 in northern Taiwan. The measuring station is located 800 m away from coastline where the mean water depth is 16 m. Total length of the data is 10 minutes with a sampling rate of 2.0 Hz. The field records were first divided into segments each containing 256 points. A cosine squared taper function was used to eliminate the discontinuities at the beginning and end of each record. The FFT calculated spectral densities were then smoothed with a Hanning window. The degrees of freedom and the frequency resolution are, 24 and 0.0078, respectively.

Numerical simulations were carried out using the two algorithms originally proposed by Tuah & Hudspeth (1982), with an extra term representing nonlinear correction as given by Duncan & Drake (1995). As target spectra, both measured and theoretical spectra were used. Every target spectrum was simulated 205 times and all the parameters obtained were averaged to account for statistical variability. All analyses were carried out on an IBM 586 compatible personal computer.

Traditional zero-crossing methods were applied for all "wave records." Characteristics of numerical simulations are compared with those obtained from measurements, either from laboratory, or field. Since the program for generating measured spectra in wave flume still needs some adjustments, only field spectra with shapes that can be fitted into the standard JONSWAP form were used for comparison. Probability distributions of wave heights, and surface elevations from all these three sources were compared with each other. Three models, namely, the Rayleigh,

the Gaussian, and the two-parameter Weibull, were used to test the distribution of wave heights. Surface elevations were fitted using a Gaussian and a Gram-Charlier series expansion.

The results

Fig. 2 Comparison of measured and simulated spectral densities: _____ measured; ----- NSA simulated and DSA simulated. Field data taken at 17.00, on February 4, 1992.

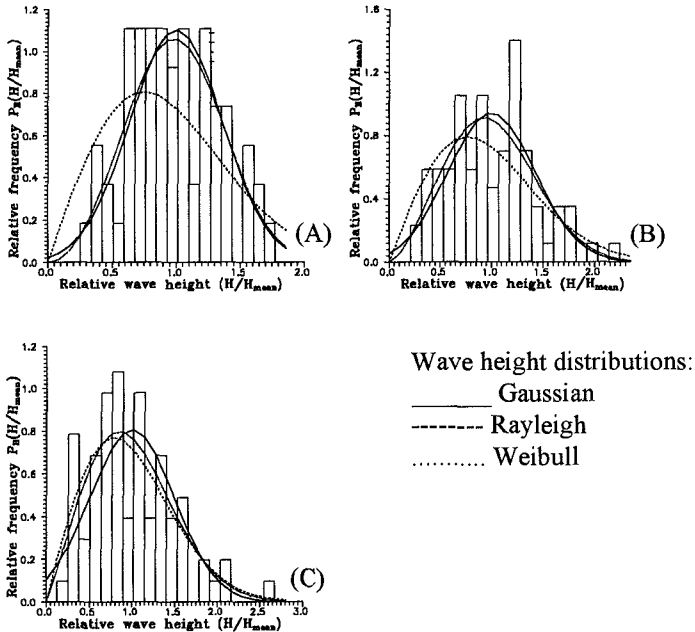

Fig. 3 Wave height distributions from measured (Fig. 3A), NSA simulated (Fig. 3B) and DSA simulated (Fig. 3C). Actual data source same as Fig. 2.

Even though spectral densities of target spectra can be modelled rather satisfactorily through the present algorithms, deterministic properties of a wave field can not be reproduced truthfully. Figure 3 compares measured wave height distribution with the 100th numerically simulated results. It should be mentioned that this choice is purely arbitrary. Three curves, representing, respectively, the Gaussian, the Rayleigh, and the Weibull distributions, were also plotted along with the histograms for comparison. As can be seen, simulated wave heights have distributions that are very close to the theoretical Rayleigh (Figs. 3B & 3C), whereas that of measured results can be approximated with Gaussian or the Weibull distribution (Fig. 3A), either one can fit the data better than the Rayleigh.

Distributions of measured and simulated surface elevations were plotted in Figure 4 for comparison. Also shown in the figure are the theoretical curves representing, respectively, normal distributions (solid lines) and the Edgeworth's form of the type A Gram-Charlier series (dotted lines). As can be seen from Figure 4, all surface elevations have probability distributions that are approximately Gaussian. Except causing small deviations from normality (Figs. 4B & 4C), nonlinear correction does not seem to a profound influence on the simulated results. In the following, since results concerning distributions of surface elevations are rather similar for all the cases studied, figures concerning this topic will not be presented for space reasons.

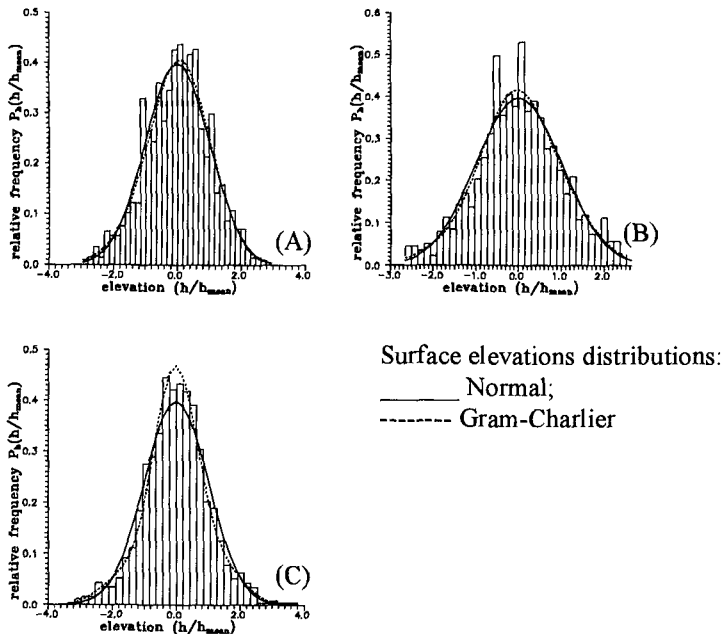

Fig. 4 Comparison of measured and simulated probability distributions for surface elevations. Original data source same as Figure 2.

As mentioned before, experiments were conducted by varying the parameters of the typical five-parameter JONSWAP spectrum. Figure 5 shows the development of the spectra along the wave flume for the first four measuring stations. Conditions used for this example is: peak frequency $f_p = 0.5$ Hz, peak enhancement factor $\gamma = 1.0$, with all other parameters equal to the standard JONSWAP spectrum. Nondimensionalized theoretical spectra are also shown in every figure for comparison. It is seen that, except for the irregularities occurred at approximately 0.75 Hz, the target spectra are reproduced quite satisfactorily.

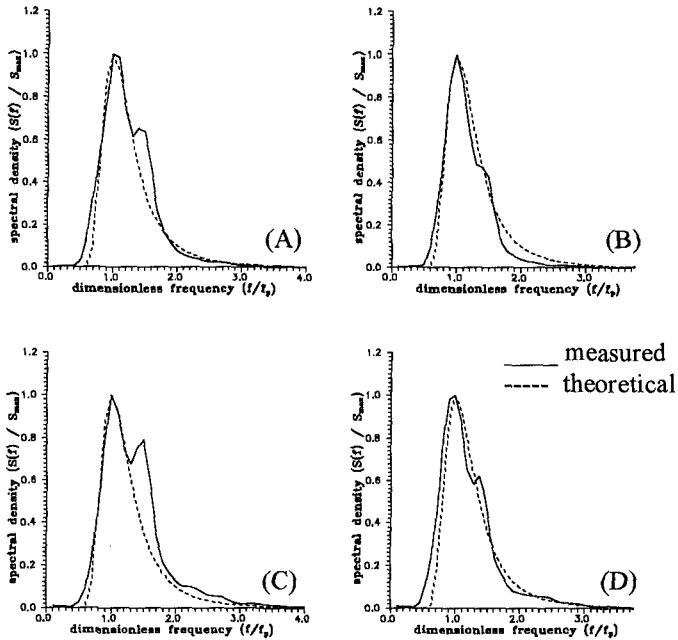

Fig. 5 Measured and theoretical spectra. Experimental conditions: $f_p = 0.5$ Hz, peak enhancement factor $\gamma = 1.0$.

Figure 6 shows the distributions of wave heights along the wave flume. As is seen from this figure, all the three models used seem can be used quite satisfactorily. In fact, judging from the χ^2 goodness-of-fit test results (Table 2), no definite conclusion can be drawn as which one of the models applied is more appropriate for this case. As can be seen from Table 2, based upon the χ^2 test results, the Gaussian model should sometimes be rejected. However, the numbers of misfits are too small to be conclusive.

Results shown in Figure 6 are not inconsistent with theoretical predictions. As is well known, Longuet-Higgins (1952) derived the Rayleigh distribution for wave heights based upon the assumptions of narrow-bandedness and Gaussianity of the

surface elevations. With $\gamma = 1$ of the JONSWAP spectrum, the case shown in Figures 5 & 6 represents, however, Pierson-Moskowitz spectrum for a fully-developed wind-sea. A fully-developed wave field has energies more widely spread over low- and high-frequency component waves, as compared with the case for growing sea. Wave heights for a typical P-M spectrum should, therefore, differ from those for JONSWAP.

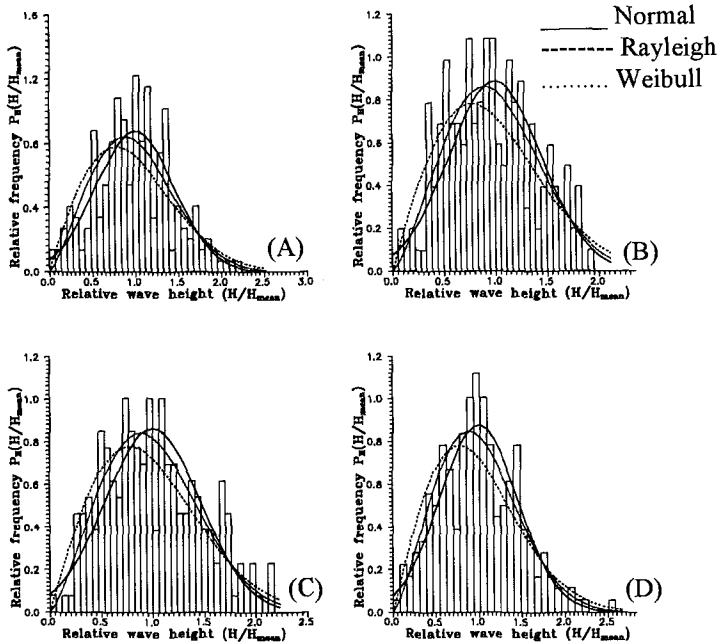

Fig. 6 Distributions of wave heights for the first four stations along the wave flume. Experimental conditions same as Fig. 5.

Table 2 shows values of the χ^2 goodness-of-fit test results for the second series of experiments. For every peak frequency considered, there are occasions where the χ^2 test results of the fitted normal distribution are too large for the theoretical values of the χ^2 distribution based on a 90% confidence interval. This is called misfit here in this paper and the total count of misfits for every peak frequency is shown in the square parentheses in the table. Since for the other two models, namely Rayleigh and Weibull distributions, no misfits occurred, it seems that the normal distribution is probably not a good model for simulated wave heights in a wave flume. However, it seems worth mentioning that the maximum count of misfits is limited to 3, for peak frequency $f_p = 1.0$ Hz at station 3. Considering the total number of experiments for this series, namely 66, it seems also safe to say that this model can not be totally rejected as well. It should, however, be remembered that among other available tests, the χ^2 goodness-of-fit test is not a very stringent one and perhaps other tests should be used before any definite conclusion can be drawn.

Table 2 Statistical properties of χ^2 goodness-of-fit test results for wave height distributions. Figures shown are mean values, figures in the parentheses represent standard deviations, and figures in the square parentheses are number of misfits, i.e., the model should be rejected.

frequency (f_p) [Hz]		0.5	0.8	1.0

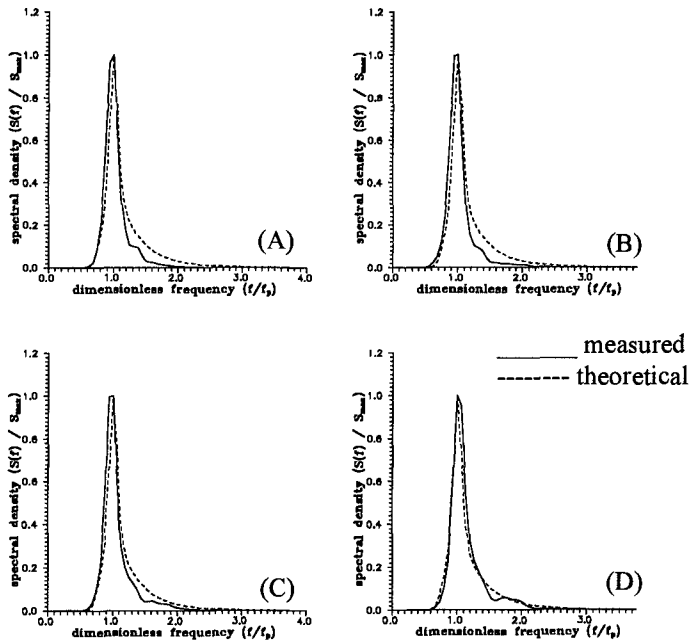

Fig. 7 Development of spectral densities of simulated JONSWAP spectrum along the wave flume. Experimental conditions: $f_p = 0.8$ Hz, $\gamma = 3.3$. Figs. (A)-(D): Measuring stations 1-4.

For the case with narrower band width, Figure 7 shows measured spectra along the flume. It is seen that high frequency components are missing at the first three stations, as compared with theoretical predictions. Whether this will affect the deterministic properties of simulated wave fields is not known at present, but is believed to be small. This is because wave heights from other experiments (not shown here) all have probability distributions that are not markedly different to those shown in Fig. 8. Wave heights for this experiments are rather scattered. Judging by eye examination, strictly speaking, all of the three models applied are not suitable for describing the probability distribution of wave heights in the flume. However, based upon the χ^2 test results, none of these models can also be rejected. It should be stressed that, wave heights shown in this figure are rather special, because in analyzing our experimental results, it is found that wave heights are mostly Rayleigh distributed. This fact is also reflected in Table 2, where all the χ^2 test results of the Rayleigh distribution are smaller than those for the other two models.

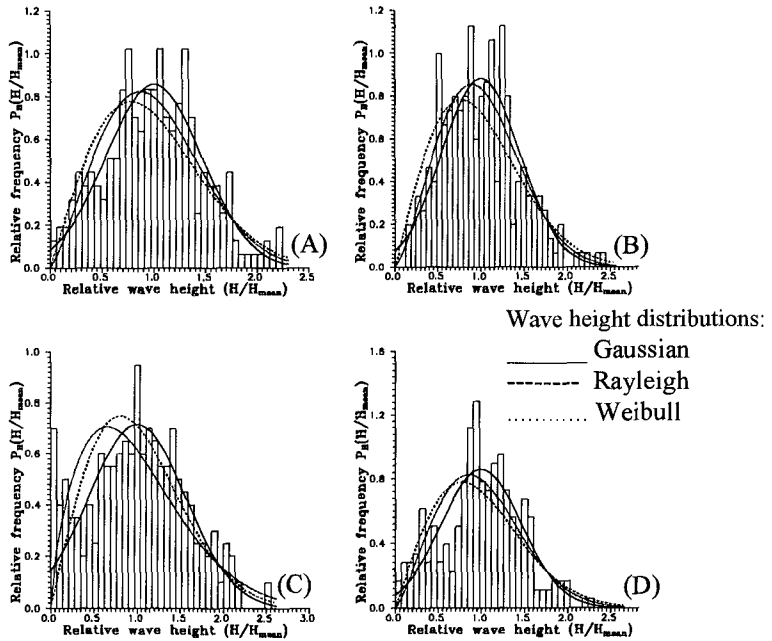

Fig. 8 Distributions of wave heights along the flume. Experimental conditions same as Fig. 7.

Discussions and Conclusions

When the energy of a random wave field is concentrated within a few components (narrow-bandedness), and when the phases of these waves are randomly distributed, then as shown by Longuet-Higgins (1952), wave heights should have a

Rayleigh distribution. Almost all (linear) random wave simulation techniques presently available, utilize these two basic assumptions. Even though a (nonlinear) transfer function is involved in wave flume experiments, present study indicates that the results have little difference as compared with numerical simulations.

In the experiments the JONSWAP spectrum is used. This can be written as:

$$S(f) = \frac{\alpha g^2}{(2\pi)^4 f^5} \exp\left[-\frac{5}{4}\left(\frac{f}{f_p}\right)^{-4}\right] \gamma^a \quad \dots (1)$$

where

f_p = the peak frequency;

α = the "Phillips constant" with a mean value of 0.0081;

γ = the peak enhancement factor, having a mean value of 3.3; with

$$a = \exp\left[-\frac{(f - f_p)^2}{2 \sigma^2 f_p^2}\right] \quad \dots (2)$$

and

$$\sigma = \begin{cases} \sigma_a = 0.07 & \text{for } f \leq f_p \\ \sigma_b = 0.09 & \text{for } f > f_p \end{cases} \quad \dots (3)$$

where the parameters σ_a and σ_b denote deviations from the peak frequency to, respectively, the left and right side of the corresponding Pierson-Moskowitz (P-M) spectrum. As can be seen from Eq. (1), the P-M spectrum is recovered with the peak enhancement factor $\gamma = 1$. It is generally believed that the JONSWAP spectrum represents the case of active wave generation by wind, where energies are concentrated; and the P-M spectrum represents fully developed wind-sea, where energies of the wave field are spread more or less widely over frequency bands.

During second series of the physical experiments, three values, $\gamma = 1.0, 3.3,$ and $7.0,$ of the peak enhancement factor were chosen. It is considered that in this way the results should cover all the possible conditions encountered in the reality, i.e., from extremely narrow- to broad-bandedness. Effects of spectral width on wave height distribution have been studied theoretically by Longuet-Higgins (1980), and experimentally by Larsen (1981). They all concluded that spectral width affects the distribution more profoundly than nonlinearity. Our present results indicate, however, no noticeable effects can be found in simulated random wave fields, at least with the present algorithms.

Simulations were also carried out numerically using spectra from measured field data. The results indicate that, irrespective of the underlying target spectral shapes, wave heights obtained from synthesized wave records always have a distribution that is better to be approximated by a Rayleigh than the other two models used. With the inclusion of a term representing nonlinearity in the algorithms, it is found that only the probability distributions of surface elevations is slightly improved, whereas wave heights may still have distributions that deviate largely from reality. In conclusion, it is plausible to say, even though simulated waves may have spectral densities similar to that of the targets, this does not necessarily mean that other characteristics of the wave field are also successfully modelled automatically. Possible modifications of the applied methodologies are needed and are presently under study.

CHAPTER 73

SECOND-ORDER INTERACTION BETWEEN RANDOM WAVE AND SUBMERGED OBSTACLE

Akinori Yoshida¹, Keisuke Murakami,²
Masaru Yamashiro³, Haruyuki Kojima⁴

Abstract

A numerical method to solve the second-order interaction between a multi-component random wave and a submerged obstacle is presented by using Stokes' wave expansion and Green's second identity. The wave is unidirectional random wave, but nonlinear interaction up to the second-order is strictly considered. Laboratory experiments with several multicomponent random waves for several different wave powers are conducted. The transmitted wave spectra obtained both in the experiment and in the numerical calculation are compared. The effects of wave breaking on the obstacle to the transmitted wave spectra are also investigated.

Introduction

When propagating waves encounter a submerged obstacle, comparably large amplitude of higher order waves (free waves) could be generated because of the abruptly decreased water depth and nonlinear free-surface boundary condition. This free wave generation is called near-resonant interaction (e.g., Bryand, 1973). Several numerical method applicable to solve this nonlinear wave-structure interaction have been presented: for example, Massel(1983) solved the second-order interaction for a submerged step using the method of matched eigenfunction expansions; Ohyama and Nadaoka (1992) investigated nonlinear interaction for a submerged dike using time domain boundary integral

equation method; Kojima et al.(1994) clarified the second-order interaction for a submerged horizontal plate using the collocation method of matched eigenfunction expansions; Yoshida. et al.(1994) solved the second-order interaction between bichromatic wave and submerged structure using a frequency domain boundary integral equation method.

These solutions however deal mostly with interaction of a single frequency component wave. Since in real sea state waves generally consist of a multicomponent wave of different frequency, second-order interactions between different frequency components also occur, and lower and higher harmonics at the difference and the sum frequencies of the primary component waves are generated. The knowledge of this energy transfer between frequencies caused by nonlinear wave-structure interactions seems to be lacking.

Main aim of this study is to obtain a theoretical method to solve interaction problems between a random wave train of arbitrary spectrum and a submerged obstacle in relatively deep water depth. The wave is an unidirectional random wave, but nonlinear interaction up to the second-order is strictly considered. A solution to a multicomponent random wave is first derived using frequency domain boundary integral equation method, then Laboratory experiments with several multicomponent random waves are conducted as well as numerical calculations. Transmitted wave spectra obtained in the experiment are compared to those obtained with the present method. The effect of wave breaking on the obstacle to the free-wave generation is also investigated.

Theoretical Formulation

Basic assumptions and free surface boundary condition

As shown in figure-1, a N component random wave is incident on a submerged obstacle from the positive x -direction. The water depth h is constant, and the angular frequency of each component wave is designated with σ_p , ($p = 1, \dots, N$). Fluid motion is assumed to be incompressible, inviscid wave motion, and the velocity potential $\Phi(x, z, t)$ exists. We consider the waves are Stokes' waves, and the velocity potential $\Phi(x, z, t)$, water surface variation $\zeta(x, t)$, Bernoulli's constant $Q(t)$ can be expanded with small parameter $\epsilon (= k\zeta_0)$ as follows:

$$\Phi(x, z, t) = \frac{g\zeta_0}{\sigma} \left\{ \epsilon\varphi^{(1)}(x, z, t) + \epsilon^2\varphi^{(2)}(x, z, t) + \dots \right\} \quad (1)$$

$$\zeta(x, t) = \zeta_0 \left\{ \zeta^{(1)}(x, t) + \epsilon\zeta^{(2)}(x, t) + \dots \right\} \quad (2)$$

$$Q(t) = g\zeta_0 \left\{ Q^{(1)}(t) + \epsilon Q^{(2)}(t) + \dots \right\} \quad (3)$$

in which k , σ , ζ_0 mean the wave number, the angular frequency and the wave amplitude, respectively, of a characteristic wave in the multicomponent random wave.

Figure 1: Definition sketch

From Stokes' wave theory, the free surface boundary condition for the second-order velocity potential $\varphi^{(2)}$ can be expressed in terms of the first-order velocity potential $\varphi^{(1)}$ as (e.g. Newman,1977)

$$\frac{\partial\varphi^{(2)}}{\partial z} + \frac{1}{g} \frac{\partial^2\varphi^{(2)}}{\partial t^2} = -\frac{1}{k\sigma} \frac{\partial}{\partial t} \left\{ \left(\frac{\partial\varphi^{(1)}}{\partial x} \right)^2 + \left(\frac{\partial\varphi^{(1)}}{\partial z} \right)^2 \right\} - \frac{1}{kg\sigma} \frac{\partial\varphi^{(1)}}{\partial t} \frac{\partial}{\partial z} \left\{ \frac{\partial^2\varphi^{(1)}}{\partial t^2} + g \frac{\partial\varphi^{(1)}}{\partial z} \right\} + \frac{\sigma}{g} \frac{\partial Q^{(2)}(t)}{\partial t} \tag{4}$$

The first-order velocity potential $\varphi^{(1)}(x, z, t)$ can be expressed as

$$\varphi^{(1)}(x, z, t) = Re \left[\sum_{p=1}^N \phi_p(x, z) e^{i\sigma_p t} \right] \tag{5}$$

where $\phi_p(x, z)$ is a non-dimensional complex function.

Substituting equation (5) into equation (4), we have

$$\frac{\partial\varphi^{(2)}}{\partial z} + \frac{1}{g} \frac{\partial^2\varphi^{(2)}}{\partial t^2} - \frac{\sigma}{g} \frac{\partial Q^{(2)}}{\partial t} = Re \left[\sum_{p=1}^N \left\{ \Omega_{pp}(x) e^{i\sigma_p t} + \Pi_{pp}(x) \right\} + \sum_{p=1}^N \sum_{q=p+1}^N \left\{ \Omega_{pq}(x) e^{i\sigma_{pq} t} + \bar{\Omega}_{pq}(x) e^{i\bar{\sigma}_{pq} t} \right\} \right] \tag{6}$$

where $\Omega_{pp}(x)$, $\Omega_{pq}(x)$, $\bar{\Omega}_{pq}(x)$ and $\Pi_{pp}(x)$ are given by

$$\Omega_{pp}(x) = -\frac{i}{2k} \left[\frac{\sigma_{pp}}{\sigma} \left\{ \left(\frac{\partial\phi_p}{\partial x} \right)^2 + \left(\frac{\partial\phi_p}{\partial z} \right)^2 \right\} + \frac{\sigma_p}{\sigma} \phi_p \left\{ \frac{\sigma_p^2}{g} \frac{\partial\phi_p}{\partial z} - \frac{\partial^2\phi_p}{\partial z^2} \right\} \right]_{z=0} \tag{7}$$

$$\Omega_{pq}(x) = -\frac{i}{2k} \left[2 \frac{\sigma_{pq}}{\sigma} \left\{ \frac{\partial \phi_p}{\partial x} \frac{\partial \phi_q}{\partial x} + \frac{\partial \phi_p}{\partial z} \frac{\partial \phi_q}{\partial z} \right\} + \frac{\sigma_p}{\sigma} \phi_p \left\{ \frac{\sigma_q^2}{g} \frac{\partial \phi_q}{\partial z} - \frac{\partial^2 \phi_q}{\partial z^2} \right\} + \frac{\sigma_q}{\sigma} \phi_q \left\{ \frac{\sigma_p^2}{g} \frac{\partial \phi_p}{\partial z} - \frac{\partial^2 \phi_p}{\partial z^2} \right\} \right]_{z=0} \quad (8)$$

$$\bar{\Omega}_{pq}(x) = -\frac{i}{2k} \left[2 \frac{\bar{\sigma}_{pq}}{\sigma} \left\{ \frac{\partial \phi_p}{\partial x} \frac{\partial \bar{\phi}_q}{\partial x} + \frac{\partial \phi_p}{\partial z} \frac{\partial \bar{\phi}_q}{\partial z} \right\} + \frac{\sigma_p}{\sigma} \phi_p \left\{ \frac{\sigma_q^2}{g} \frac{\partial \bar{\phi}_q}{\partial z} - \frac{\partial^2 \bar{\phi}_q}{\partial z^2} \right\} - \frac{\sigma_q}{\sigma} \bar{\phi}_q \left\{ \frac{\sigma_p^2}{g} \frac{\partial \phi_p}{\partial z} - \frac{\partial^2 \phi_p}{\partial z^2} \right\} \right]_{z=0} \quad (9)$$

$$\Pi_{pp}(x) = -\frac{i}{2k} \left[\frac{\sigma_p}{\sigma} \phi_p \left\{ \frac{\sigma_p^2}{g} \frac{\partial \bar{\phi}_p}{\partial z} - \frac{\partial^2 \bar{\phi}_p}{\partial z^2} \right\} \right]_{z=0} \quad (10)$$

in which $\bar{\phi}_q, \partial \bar{\phi}_p / \partial z, \dots$ mean complex conjugate of $\phi_q, \partial \phi_p / \partial z, \dots$, and $\sigma_{pp}, \sigma_{pq}, \bar{\sigma}_{pq}$ mean angular frequencies defined by $\sigma_{pp} = 2\sigma_p, \sigma_{pq} = \sigma_p + \sigma_q, \bar{\sigma}_{pq} = \sigma_p - \sigma_q$

Equation (6) implies the second-order potential $\varphi^{(2)}$ takes the form as

$$\varphi^{(2)}(x, z, t) = Re \left[\sum_{p=1}^N \left\{ \phi_{0pp}^{(2)}(x, z) + \phi_{pp}^{(2)}(x, z) e^{i\sigma_{pp}t} \right\} + \sum_{p=1}^N \sum_{q=p+1}^N \left\{ \phi_{pq}^{(2)}(x, z) e^{i\sigma_{pq}t} + \phi_{pq*}^{(2)}(x, z) e^{i\bar{\sigma}_{pq}t} \right\} \right] \quad (11)$$

where $\phi_{0pp}^{(2)}(x, z), \phi_{pp}^{(2)}(x, z), \dots$ are non-dimensional complex functions; the stationary component $\phi_{0pp}^{(2)}(x, z)$ does not contribute to the estimation of the second-order water surface variation and the pressure of the fluid motion, thus it will be neglected in the theoretical formulation from now on.

Then from equation (11) and equation (6), the free surface boundary conditions for $\phi_{pp}^{(2)}, \phi_{pq}^{(2)}$ and $\phi_{pq*}^{(2)}$ are obtained, for example, for $\phi_{pp}^{(2)}$ as

$$\frac{\partial \phi_{pp}^{(2)}}{\partial z} - \frac{\sigma_{pp}^2}{g} \phi_{pp}^{(2)} = \Omega_{pp}(x) \quad (12)$$

Exact solutions in the open regions (1) and (2)

The first-order potential functions ϕ_p in the open region (1) and (2) are found in any textbook and they can be expressed as:

$$\phi_p(x, z) = \begin{cases} \{ a_p e^{ik_p x} + A_p e^{-ik_p x} \} Z(k_p, z) & \text{(region(1))} \\ \{ B_p e^{ik_p x} \} Z(k_p, z) & \text{(region(2))} \end{cases} \quad (13)$$

in which $Z(k_p, z) = \cosh k_p(z + h) / \cosh k_p h$ and k_p is the wave number given by the dispersion equation, $\sigma_p^2/g = k_p \tanh k_p h$.

The complex coefficient a_p denotes the wave amplitude and phase of each component of the incident wave, with angular frequency σ_p ; the complex coefficients A_p and B_p , the wave amplitude and phase of each component of the reflected and transmitted waves, respectively.

Substitution of the first-order potential into equations (7), (8) and (9) yields

$$\Omega_{pp}(x) = \begin{cases} -i\beta_1 \{ a_p^2 e^{ik_{pp}x} + A_p^2 e^{-ik_{pp}x} \} - i\beta_2 a_p A_p & \text{(region(1))} \\ -i\beta_1 B_p e^{ik_{pp}x} & \text{(region(2))} \end{cases} \tag{14}$$

$$\Omega_{pq}(x) = \begin{cases} -i\beta_3 \{ a_p a_q e^{ik_{pq}x} + A_p A_q e^{-ik_{pq}x} \} \\ \quad -i\beta_4 \{ a_p A_q e^{i\bar{k}_{pq}x} + a_q A_p e^{-i\bar{k}_{pq}x} \} & \text{(region(1))} \\ -i\beta_3 B_p B_q e^{ik_{pq}x} & \text{(region(2))} \end{cases} \tag{15}$$

$$\bar{\Omega}_{pq}(x) = \begin{cases} -i\beta_5 \{ a_p \bar{a}_q e^{i\bar{k}_{pq}x} + A_p \bar{A}_q e^{-i\bar{k}_{pq}x} \} \\ \quad -i\beta_6 \{ a_p \bar{A}_q e^{ik_{pq}x} + \bar{a}_q A_p e^{-ik_{pq}x} \} & \text{(region(1))} \\ -i\beta_5 B_p \bar{B}_q e^{i\bar{k}_{pq}x} & \text{(region(2))} \end{cases} \tag{16}$$

in which $k_{pp} = k_p + k_p$, $k_{pq} = k_p + k_q$, $\bar{k}_{pq} = |k_p - k_q|$, $\Gamma_p = \sigma_p^2/g$ and β_1, β_2, \dots are

$$\left. \begin{aligned} \beta_1 &= \frac{3}{2k} \frac{\sigma_p}{\sigma} \{ \Gamma_p^2 - k_p^2 \}, & \beta_2 &= \frac{1}{k} \frac{\sigma_p}{\sigma} \{ 3\Gamma_p^2 + k_p^2 \} \\ \beta_3 &= \frac{1}{2k} \left[2 \frac{\sigma_{pq}}{\sigma} \{ \Gamma_p \Gamma_q - k_p k_q \} + \frac{\sigma_p}{\sigma} \{ \Gamma_q^2 - k_q^2 \} + \frac{\sigma_q}{\sigma} \{ \Gamma_p^2 - k_p^2 \} \right] \\ \beta_4 &= \frac{1}{2k} \left[2 \frac{\sigma_{pq}}{\sigma} \{ \Gamma_p \Gamma_q + k_p k_q \} + \frac{\sigma_p}{\sigma} \{ \Gamma_q^2 - k_q^2 \} + \frac{\sigma_q}{\sigma} \{ \Gamma_p^2 - k_p^2 \} \right] \\ \beta_5 &= \frac{1}{2k} \left[2 \frac{\bar{\sigma}_{pq}}{\sigma} \{ \Gamma_p \Gamma_q + k_p k_q \} + \frac{\sigma_p}{\sigma} \{ \Gamma_q^2 - k_q^2 \} - \frac{\sigma_q}{\sigma} \{ \Gamma_p^2 - k_p^2 \} \right] \\ \beta_6 &= \frac{1}{2k} \left[2 \frac{\bar{\sigma}_{pq}}{\sigma} \{ \Gamma_p \Gamma_q - k_p k_q \} + \frac{\sigma_p}{\sigma} \{ \Gamma_q^2 - k_q^2 \} - \frac{\sigma_q}{\sigma} \{ \Gamma_p^2 - k_p^2 \} \right] \end{aligned} \right\}$$

Now we can derive a general solution of the second-order potential function in the open region (1) and (2). The equations, for example, governing $\phi_{pp}^{(2)}$ can be given by

$$\frac{\partial^2 \phi_{pp}^{(2)}}{\partial x^2} + \frac{\partial^2 \phi_{pp}^{(2)}}{\partial z^2} = 0 \quad (-h \leq z \leq 0) \tag{17}$$

$$\frac{\partial \phi_{pp}^{(2)}}{\partial z} = 0 \quad (z = -h) \tag{18}$$

$$\frac{\partial \phi_{pp}^{(2)}}{\partial z} - \frac{\sigma_{pp}^2}{g} \phi_{pp}^{(2)} = -i\beta_1 \left\{ a_p^2 e^{ik_{pp}x} + A_p^2 e^{-ik_{pp}x} \right\} - i\beta_2 a_p A_p \quad (z = 0) \tag{19}$$

The general solution $\phi_{pp}^{(2)}$ can be obtained by the sum of a homogeneous solution which satisfies homogeneous surface boundary condition given by replacing the right-hand side of equation (19) by zero and a special solution which satisfies equation (19), and it can be obtained, after some calculations, as

$$\left. \begin{aligned} \phi_{pp}^{(2)}(x, z) = & A_{pp}^{(2)} Z(k_{pp}^{(2)}, z) e^{-ik_{pp}^{(2)}x} + i b_{s1} a_p A_p \\ & + i a_{s1} \left\{ a_p^2 e^{ik_{pp}x} + A_p^2 e^{-ik_{pp}x} \right\} Z(k_{pp}, z) \end{aligned} \right\} \tag{20}$$

and similarly $\phi_{pq}^{(2)}$ and $\phi_{pq*}^{(2)}$ are also obtained as:

$$\left. \begin{aligned} \phi_{pq}^{(2)}(x, z) = & A_{pq}^{(2)} Z(k_{pq}^{(2)}, z) e^{-ik_{pq}^{(2)}x} \\ & + i c_{s1} \left\{ a_p a_q e^{ik_{pq}x} + A_p A_q e^{-ik_{pq}x} \right\} Z(k_{pq}, z) \\ & + i d_{s1} \left\{ a_p A_q e^{i\bar{k}_{pq}x} + A_p a_q e^{-i\bar{k}_{pq}x} \right\} Z(\bar{k}_{pq}, z) \end{aligned} \right\} \tag{21}$$

$$\left. \begin{aligned} \phi_{pq*}^{(2)}(x, z) = & A_{pq*}^{(2)} Z(k_{pq*}^{(2)}, z) e^{-ik_{pq*}^{(2)}x} \\ & + i d_{s2} \left\{ a_p \bar{a}_q e^{i\bar{k}_{pq}x} + A_p \bar{A}_q e^{-i\bar{k}_{pq}x} \right\} Z(\bar{k}_{pq}, z) \\ & + i c_{s2} \left\{ a_p \bar{A}_q e^{ik_{pq}x} + A_p \bar{a}_q e^{-ik_{pq}x} \right\} Z(k_{pq}, z) \end{aligned} \right\} \tag{22}$$

in which $k_{pp}^{(2)}$, $k_{pq}^{(2)}$ and $k_{pq*}^{(2)}$ are the wave numbers given by the dispersion equations to angular frequencies, σ_{pp} , σ_{pq} and $\bar{\sigma}_{pq}$, respectively. The coefficients a_{s1} , b_{s1} , \dots are

$$\left. \begin{aligned} a_{s1} = & \frac{-\beta_1}{k_{pp} \tanh k_{pp} h - \Gamma_{pp}}, & b_{s1} = & \frac{\beta_2}{\Gamma_{pp}} \\ c_{s1} = & \frac{-\beta_3}{k_{pq} \tanh k_{pq} h - \Gamma_{pq}}, & c_{s2} = & \frac{-\beta_6}{k_{pq} \tanh k_{pq} h - \bar{\Gamma}_{pq}} \\ d_{s1} = & \frac{-\beta_4}{\bar{k}_{pq} \tanh \bar{k}_{pq} h - \Gamma_{pq}}, & d_{s2} = & \frac{-\beta_5}{\bar{k}_{pq} \tanh \bar{k}_{pq} h - \bar{\Gamma}_{pq}} \end{aligned} \right\}$$

where $\Gamma_{pp} = \sigma_{pp}^2/g$, $\Gamma_{pq} = \sigma_{pq}^2/g$, $\bar{\Gamma}_{pq} = \bar{\sigma}_{pq}^2/g$.

The general solutions, $\phi_{pp}^{(2)}$, $\phi_{pq}^{(2)}$ and $\phi_{pq*}^{(2)}$ in the transmitted wave region (2) are also obtained as follows:

$$\phi_{pp}^{(2)}(x, z) = B_{pp}^{(2)} Z(k_{pp}^{(2)}, z) e^{ik_{pp}^{(2)}x} + ia_{s1} \left\{ B_p^2 e^{ik_{pp}x} \right\} Z(k_{pp}, z) \tag{23}$$

$$\phi_{pq}^{(2)}(x, z) = B_{pq}^{(2)} Z(k_{pq}^{(2)}, z) e^{ik_{pq}^{(2)}x} + ic_{s1} \left\{ B_p B_q e^{ik_{pq}x} \right\} Z(k_{pq}, z) \tag{24}$$

$$\phi_{pq*}^{(2)}(x, z) = B_{pq*}^{(2)} Z(k_{pq*}^{(2)}, z) e^{ik_{pq*}^{(2)}x} + id_{s2} \left\{ B_p \bar{B}_q e^{i\bar{k}_{pq}x} \right\} Z(\bar{k}_{pq}, z) \tag{25}$$

Green's second identity and linear equations

Potential theory shows harmonic function in a closed domain, $\phi(X)$, which is a solution of Laplace equation, can be expressed with Green's second identity

$$\phi(X) = \frac{1}{\alpha} \int_D \left\{ \phi(X_b) \frac{\partial}{\partial \nu} G(r) - G(r) \frac{\partial}{\partial \nu} \phi(X_b) \right\} ds \tag{26}$$

where $G(r) = \log r + \log r^*$, and r is the length between an arbitrary point $X = (x, z)$ in the domain and a point $X_b = (x_b, z_b)$ on the boundary, r^* is the length between the point X and its mirror image X_b^* with respect to the uniform bottom boundary. α is defined to take π when X is on the boundary, and to take 2π when X is inside the boundary. ν denotes outward normal to the boundary of the region (0), and the direction of the integral is taken counterclockwise along the boundary $D (= S_1 + S_2 + S_3 + S_4)$.

By dividing the boundary D into N number of small elements, ΔS_j ($j = 1, 2, \dots, N$), and by assuming that the potential ϕ is uniform on each element, the integral equation (26) can be discretized as

$$\left. \begin{aligned} \sum_{j=1}^N \left\{ (\bar{E}_{ij} - \delta_{ij}) \phi(j) - E_{ij} \frac{\partial \phi(j)}{\partial \nu} \right\} = 0 \\ (i = 1, 2, \dots, N) \end{aligned} \right\} \tag{27}$$

where

$$\left. \begin{aligned} E_{ij} &= \frac{1}{\alpha} \int_{\Delta S_j} G(r_{ij}) ds, & \bar{E}_{ij} &= \frac{1}{\alpha} \int_{\Delta S_j} \frac{\partial G(r_{ij})}{\partial \nu} ds \\ r_{ij} &= \sqrt{(x_j - x_i)^2 + (z_j - z_i)^2}, & r_{ij}^* &= \sqrt{(x_j - x_i)^2 + (z_j + 2h + z_i)^2} \end{aligned} \right\} \tag{28}$$

Substituting all the boundary conditions along the closed region (0) into equation (27), we have a set of linear equations, for the second-order as well as the first-order problems, in terms of the velocity potentials on the boundary elements and unknown coefficients $A_p, B_p, A_{pp}, B_{pp}, \dots$. The boundary conditions on the imaginary boundaries are given through the exact solutions

for $\phi_{pp}^{(2)}$, $\phi_{pq}^{(2)}$, $\phi_{pq*}^{(2)}$ in the open regions (1) and (2). Thus we solve at first the linear interaction problem (e.g., Yeoung,1975) for every component wave of angular frequency σ_p , then for every combination of the first-order solutions with frequency components σ_p and σ_q , the linear equations for the second-order potentials $\phi_{pp}^{(2)}$, $\phi_{pq}^{(2)}$, $\phi_{pq*}^{(2)}$ are solved, respectively.

Energy flux correction

The solutions have to be corrected to balance wave energy fluxes between the incident, reflected and transmitted waves, because in perturbation analysis up to the second-order the balance of wave energy flux is satisfied in the first-order; the generated second-order free waves produce excessive wave energy. The effect of this excessive energy may be negligible for a single incident wave, but for multicomponent incident wave the number of generated free waves increases in proportion to the square of the number of the incident wave components, and numerical results may become unrealistic.

To correct the numerical results so as to satisfy the conservation of the incident wave energy flux, the incident wave energy flux F_I , the reflected wave energy flux F_R and the transmitted wave energy flux F_T are calculated with numerical results of the first-order and the second-order potentials; F_R and F_T include in them the excessive wave energy flux of the generated free-waves, and thus F_I is always less than $F_R + F_T$. The correction factor β is defined as $\sqrt{F_I/(F_R + F_T)}$, and all the reflected and the transmitted wave components are multiplied by β . The effects of this energy flux correction are verified by comparing the corrected numerical results against the experimental results.

Numerical and Experimental Results

Laboratory experiments were conducted with a submerged structure as shown in figure-1 with $B/h=2.0$, $q=0.3$, $R/h=0.7$, and the water depth $h=0.37m$. Multicomponent random waves used in the experiment are shown in Table-1. For each multicomponent random wave, ten different phase combinations were used, and the results were averaged. The wave amplitudes of the component waves were set approximately the same, and for each multicomponent random wave, several different wave amplitudes ranging from small amplitude to large amplitude that intense wave breaking occurs on the structure were used to investigate the effects of wave breaking on the generation of the second-order free waves. In addition to the above multicomponent random waves, twenty component random wave, modeled from Bretschneider-Mitsuyasu spectra, was also used.

The wave tank is 0.3m wide, 0.5m deep and 28m long, and it is equipped at one end with a random wave generator having a function of wave absorption, and at the other end with a wave absorber. The reflection coefficients of the

wave absorber were measured for several frequencies ranging $kh=0.5 \sim kh=3.0$, and they are around 0.05 for waves kh greater than 1.0 (frequency 0.7_{Hz}). Thus the lowest frequency in the multicomponent random waves was chosen to be greater than $kh=1.0$ to minimize the contamination by the reflected waves from the wave absorber.

Before setting the model of the submerged obstacle in the wave tank, every multicomponent random wave was generated and it was measured by capacity-type wave gauges with sampling interval 10_{Hz} for the number of sampled data 8192, and from the data the incident wave spectra were obtained using First-Fourier-Transform(FFT). Then setting the model structure midway of the wave tank, transmitted waves were measured 3.0m behind the center of the structure, and the transmitted wave spectra were also calculated by FFT. The wave spectra for ten different phase combinations were averaged for every multicomponent random wave.

Table 1: Frequencies of multicomponent random waves

In the numerical calculations, the location of the right-hand side and the left-hand side imaginary boundaries are taken both $6h$ apart from the center of the obstacle. The length of the boundary element is taken $0.05h$ for all the elements. Incident wave amplitudes of component waves in the numerical calculation were obtained by integrating the power spectra of the incident multicomponent random waves in the experiment. The phases of the component waves are given by generating random number numerically, and thus the numerical calculation were also carried out for ten phase combinations as in the experiment for every multicomponent random wave. Water surface variations at the same location where transmitted waves were measured in the experiment were computed and their wave spectra were also obtained by using FFT with the same sampling interval and data length as in the experiment.

Figure-2 shows power spectra of the transmitted wave $S_T(f)$ for two component incident wave. \bar{S} means component averaged power of the incident wave,

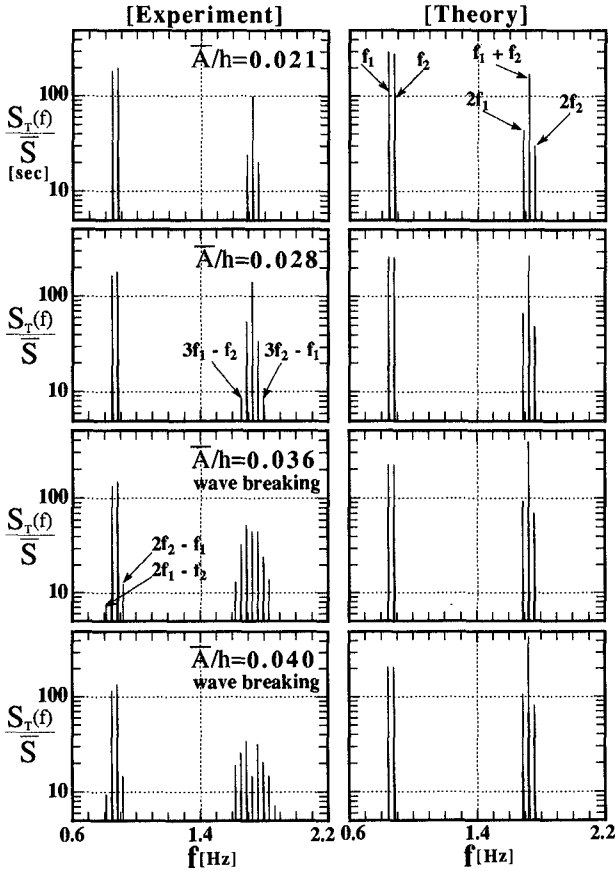

Figure 2: Comparison of the numerical results against the experimental results in terms of transmitted wave spectra $S_T(f)$ for two component wave ($f_1 = 0.772_{Hz}$, $f_2 = 0.809_{Hz}$); \bar{S} is component averaged power of incident wave: from the top, figures show spectral change resulting from increase of incident wave amplitude.

which is given by dividing the power of the incident wave by its number of component. \bar{A} means wave amplitude which has the same power as \bar{S} . Since the amplitudes of the component wave in a multicomponent random wave were made almost the same each other, \bar{A} is approximately the same as the amplitude of the component wave in the experiment. In the figure-2, when the averaged wave amplitude \bar{A}/h is 0.036 and 0.040, wave breakings occur on the structure, and especially when $\bar{A}/h = 0.040$ the wave breaking is very intense. The power of the second-order difference frequency waves and the power of the higher order waves generated around the third-order sum frequencies are negli-

Figure 3: Comparison of the numerical results against the experimental results in terms of transmitted wave spectra $S_T(f)$ for five component incident wave: $\bar{A}/h = 0.015$.

gibly small compared to the powers of the second-order sum frequency waves, and thus results are shown for the first-order frequency and the second-order sum frequency ranges.

It can be seen that as \bar{A} increases more higher order waves are observed around the second-order sum frequencies, though their powers are very small, even before wave breaking occurs. Once wave breaking occurs on the obstacle, more power is transformed to higher order waves around the incident wave frequencies (f_1, f_2) as well as around the second-order sum frequencies, and the power of the second-order sum frequency components ($2f_1, f_1 + f_2, 2f_2$) decrease drastically. On the contrary in the numerical results, the amplitudes of the second-order sum frequency waves increase unrealistically even after wave breaking occurs.

The figure-3 shows the comparison for five component wave. The averaged wave amplitude \bar{A}/h is 0.015 and wave breaking occurs on the obstacle intermittently. Since the energy dissipation caused by vortices and wave breaking are not considered in the present method, the numerical results gives smaller power spectra, but it can be however said that the numerical calculation gives good estimation for the spectral structure of the transmitted waves.

In order to compare the numerical results against the experimental ones more quantitatively, the power along the incident wave frequency range $S_T^{(1)}$ and the power of the second-order sum frequency range $S_T^{(2)}$ were obtained by integrating the transmitted wave spectra as illustrated in figure-3. The square root of their ratios to the power of the incident wave spectra, $\sqrt{S_T^{(1)}/S_I}$ and $\sqrt{S_T^{(2)}/S_I}$, are computed and they are shown in figure-4 for five and ten component waves. The broken lines in the figures show the numerical results without energy flux correction. The numerical results always underestimate the exper-

Figure 4: Comparison of the numerical results against the experimental results in terms of power $S_T^{(1)}$ obtained by integrating transmitted wave spectra along the first-order frequency range and Power $S_T^{(2)}$ for the second-order sum frequency range, which are normalized by power of incident wave S_I : ● ○ experimental results, — numerical results with energy flux correction, - - - numerical result without energy flux correction.

imental results even before wave breaking occurs, due to the energy dissipation by vortices caused around the structure, and thus the numerical results gradually deviate from the experimental results as the incident wave amplitude increases. Once however wave breaking begins to occur on the structure, even it is not so intense, numerical results for the second-order waves largely underestimate the experimental results. It however should be noted that the power of the first-order frequency range $\sqrt{S_T^{(1)}/S_I}$ well estimated by the present method even after wave breaking occurs. This may imply that the energy lost by wave breaking is approximately equal to the energy which should have been transferred to the second-order free-waves in potential theory.

To show more clearly the effect of wave breaking, the ratios of $\sqrt{S_T^{(2)}/S_T^{(1)}}$ are calculated and the results are shown in figure-5. These show that the present method can well estimate the rate of wave energy transferred to the generated second-order waves as far as no wave breaking occurs on the structure.

Figure-6 shows transmitted wave spectra for twenty component incident wave, modeled of Bretschneider-Mitsuyasu spectra with significant wave height $H_{1/3} = 4.0cm$ ($H/h = 0.11$) and significant wave period $T_{1/3} = 1.25sec$ ($kh = 1.16$). No wave breaking observed in this case. Because of the energy dissipation due to vortices around the structure the numerical results underestimate the experimental ones, but overall structure of the transmitted wave spectra is well estimated.

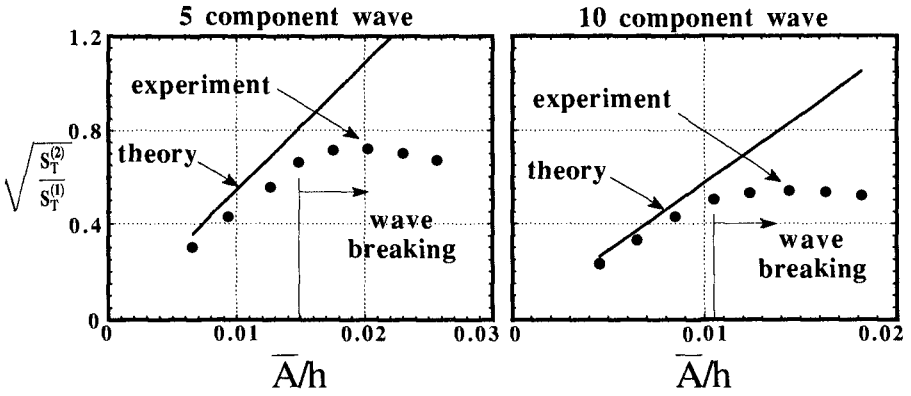

Figure 5: Comparison of the numerical results against the experimental results in terms of ratio $\sqrt{S_T^{(2)}/S_T^{(1)}}$: ——— numerical results, ● experimental results.

Figure 6: Comparison of the numerical results against the experimental results in terms of transmitted wave spectra for incident random wave modeled from Bretschneider-Mitsuyasu spectra ($H_{1/3} = 4\text{cm}$, $T_{1/3} = 1.25\text{sec}$); low frequency side ($f < 0.7\text{Hz}$) and high frequency side ($f > 1.1\text{Hz}$) are cut off in the incident wave to avoid contamination by reflected waves from wave absorber and to avoid overlap of incident wave and generated second-order sum frequency waves.

Conclusions

A numerical method to solve the second-order interactions between multicomponent random wave and submerged obstacle is presented. Numerical results give good estimation of the transformation of the incident wave spec-

tra, caused by the second-order wave structure interactions, as long as no wave breaking occurs on the obstacle. Once however wave breaking occurs (even if it is not so intense), the generation of the second-order free waves is greatly suppressed, and numerical results largely underestimate the experimental results. The energy flux correction of the numerical results is particularly effective, even after wave breaking occurs, for accurate estimation of the first-order transmitted waves.

CHAPTER 74

A uniform mild-slope model for waves over varying bottom

Libang Zhang¹ and Billy L. Edge²

Abstract

A time-dependent mild-slope equation is derived, based on the formal derivation of Smith & Sprinks (1975), from which the higher-order dispersion relation for waves over uneven bottom is obtained. If only linear dispersion is used for steady waves, the equation (2.12) of Chamberlain & Porter (1995), referred as the modified mild-slope equation (MMSE), is recovered from this equation. To the leading-order solution, it is found that the modified curvature terms of the MMSE have significant effects, while the slope square terms are negligible in accordance with mild-slope assumption. Therefore, retaining all the modified curvature terms neglected in the MSE, the uniform model is developed.

A numerical model using the finite element method (FEM) is developed to predict wave scattering by a varying bottom. In general, the uniform model can predict salient features of waves over various sea beds, such as sinusoidal beds and man-made bars. For sinusoidal beds, the results of the uniform model are in closer agreement with the experimental data than other established models. For man-made bars, the results of both the MMSE and uniform model are in closer agreement with the experimental data than the results of Kirby (1986). An important result of the FEM model is application to transformation of waves over arbitrarily-varying bathymetry.

Introduction

Surface wave scattering by rippled seabeds has been studied by many researchers during the past decade. Rippled seabed are used to represent both regular and irregular ocean bottoms. Davies & Heathershaw (1984) provided solutions to the linear problem and verified their solutions experimentally. Mei (1985) concentrated his studies on the process close to the Bragg resonance condition. Dalrymple & Kirby (1986) studied a single sinusoidal bed for both resonant and non-resonant cases, using a boundary integral equation method. The step-approximation model (Guazzelli et al. 1992), or the successive-application matrix (O'Hare & Davies 1993), in which the bed is divided into a series of very small horizontal shelves, was also developed to model the wave scattering by the rippled bed. Edge & Zhang (1996) first predicted random wave scattering by berms using P-M spectrum.

Alternative methods related to the mild-slope equation (MSE), such as the modified mild-slope equation (MMSE), have been investigated extensively since it was derived by Berkhoff (1972) and Smith & Sprinks (1975). Kirby (1986) developed the equations to predict wave propagation over rapidly varying to-

pography, which is based on the concept of expanding the rapidly varying component on a very mild-slope bottom. Massel (1993) extended the mild-slope equation by using a Galerkin-eigenfunction method. Recently, Chamberlain & Porter (1995) presented several modified versions of the MSE (or MMSE) by using both variational and Galerkin methods.

Kirby's model (1986) is limited to a rapidly-varying topography. The deficiency of the Kirby's model in prediction of the higher- and sub-harmonic resonance peaks was found by Guazzelli et al. (1992) and O'Hare & Davies (1993). Two of Chamberlain & Porter's models, i.e. Eqs.(3.2) and (3.3) of Chamberlain & Porter (1995), were shown to be ineffective in predicting some resonance peaks (see Fig.3 of Chamberlain & Porter, 1995). In other words, these models break down at some frequencies, similar to the MSE's breaking down as described by Kirby (1986). It means that the approximations of these models are not uniform, but are frequency-dependent. Therefore, to overcome the deficiency of the models mentioned above, the uniform model is developed to predict wave scattering by both slowly-varying and rapidly-varying components of beds uniformly.

The first part of this paper presents the three-dimensional wave model based on Green's identity method for general topography. Secondly, the paper presents a numerical implementation for the finite element method (FEM). Thirdly, the uniform model is verified and the results for sinusoidal beds are given. Finally, numerical results of the uniform models for waves over the man-made bars are presented and compared with the experimental data and other numerical solutions.

Governing equations for general topography

For a small-amplitude wave with angular frequency ω , it is assumed that the flow is incompressible and irrotational and that the pressure is constant at the free surface. The rectilinear coordinates (x, y, z) are fixed in space and $z=0$ is located at the calm water level. The wave potential $\Phi(x, y, z)$ satisfies the equations:

$$\nabla^2 \Phi + \Phi_{zz} = 0, \quad (-h \leq z \leq 0), \quad (1)$$

$$\Phi_{tt} + g\Phi_z = 0, \quad \text{at } z = 0, \quad (2)$$

Since the sea bottom is fixed at $z = -h(x, y)$, the normal velocity vanishes; this implies

$$\Phi_z + \nabla h \cdot \nabla \Phi = 0, \quad \text{at } z = -h, \quad (3)$$

where ∇ denotes the horizontal gradient operator, i.e. $\nabla = \{\partial/\partial x, \partial/\partial y\}$.

By utilizing the Green's identity method, Equations (1)-(3) can be combined to obtain the time-dependent equation governing the velocity potential $\phi(x, y)$ and the wave number $k(x, y)$:

$$\phi_{tt} - \nabla \cdot (CC_g \nabla \phi) + (\omega^2 - k^2 CC_g) \phi - gF\phi = 0 \quad (4)$$

where

$$\omega^2 = gk \tanh kh, \quad (5)$$

is leading-order dispersion relation, and

$$F = \alpha_1(\nabla h \cdot \nabla h)k + \alpha_2 \nabla^2 h + \alpha_3 \nabla k \cdot \nabla h/k + \alpha_4 \nabla^2 k/k^2 + \alpha_5(\nabla k \cdot \nabla k)/k^3. \quad (6)$$

$C(x, y) = \omega/k$ and $C_g(x, y) = \partial\omega/\partial k$ are the wave celerity and the group velocity, respectively. The dimensionless parameters of α_i ($i = 1, 5$) become

$$\alpha_1 = -\sigma(1 - \sigma^2)(1 - \sigma q) \quad (7)$$

$$\alpha_2 = -\sigma q(1 - \sigma^2)/2 \quad (8)$$

$$\alpha_3 = q(1 - \sigma^2)(2q\sigma^2 - 5\sigma/2 - q/2) \quad (9)$$

$$\alpha_4 = q(1 - \sigma^2)(1 - 2\sigma q)/4 - \sigma/4 \quad (10)$$

$$\alpha_5 = q(1 - \sigma^2)(4\sigma^2 q^2 - 4q^2/3 - 2\sigma q - 1)/4 + \sigma/4 \quad (11)$$

Throughout this paper, the notations $q = kh$, $Q = k(z+h)$, and $\sigma = \tanh kh$ are used for convenience. The detailed derivation of Eq.(4) is given in the Appendix.

Higher-order dispersion relation

The time-dependent MMSE can be further decomposed into the real and imaginary parts, which are corresponding to the dispersion relation and wave action conservation, respectively. Let

$$\phi = Ae^{i\theta}$$

where A is the potential amplitude and θ is the phase and is defined by

$$\nabla\theta = \hat{k} \quad \theta_t = -\hat{\omega}$$

Separating the time-dependent equation into real and imaginary parts, the higher-order dispersion relation is obtained:

$$\hat{\omega}^2 = \omega^2 + CC_g(\hat{k}^2 - k^2) + \frac{A_{tt}}{A} - CC_g \frac{\nabla^2 A}{A} - \frac{\nabla(CC_g) \cdot \nabla A}{A} - gF, \quad (12)$$

where ω is defined in Eq.(5). If the frequency is fixed and temporal variation of amplitude is not considered, the effective wave number for the MMSE is

$$\hat{k}^2 = k^2 + \frac{\nabla^2 A}{A} + \frac{\nabla(CC_g) \cdot \nabla A}{CC_g A} + \frac{gF}{CC_g}. \quad (13)$$

Discarding the last terms, the effective wave number for the MSE (Liu, 1990, p35)

$$\hat{k}^2 = k^2 + \frac{\nabla^2 A}{A} + \frac{\nabla(CC_g) \cdot \nabla A}{CC_g A} \quad (14)$$

is recovered. It is clear that the last terms in general MMSE will directly affect the wave phase prediction if they are comparable with the original terms in the MSE.

Correspondence to previous models

For the monochromatic and steady waves, the general MMSE becomes:

$$\nabla \cdot (CC_g \nabla \phi) + k^2 CC_g \phi + gF\phi = 0 \tag{15}$$

by using

$$\phi_{tt} = -\phi\omega^2. \tag{16}$$

The relations of the wavenumber slope and curvature with those of bottom, can be obtained from $\nabla\omega = 0$, i.e.

$$\frac{\nabla k}{k} = \beta_1 \frac{\nabla h}{h}, \tag{17}$$

and

$$\frac{\nabla^2 k}{k} = \beta_1 \frac{\nabla^2 h}{h} + \beta_2 \frac{(\nabla h \cdot \nabla h)}{h^2}, \tag{18}$$

where

$$\beta_1 = -q(1 - \sigma^2)/\gamma, \tag{19}$$

$$\beta_2 = 2q^2(1 - \sigma^2)(\gamma - \alpha_1)/\gamma^3, \tag{20}$$

$$\gamma = \sigma + q(1 - \sigma^2). \tag{21}$$

Thus the MMSE in specific case reads

$$\nabla \cdot (CC_g \nabla \phi) + k^2 CC_g \phi + g [f_c \nabla^2 h + k f_s (\nabla h \cdot \nabla h)] \phi = 0 \tag{22}$$

where

$$f_c(kh) = \alpha_2 + \alpha_4 \beta_1 / q, \tag{23}$$

$$f_s(kh) = \alpha_1 + \alpha_3 \beta_1 / q + \alpha_4 \beta_2 / q^2 + \alpha_5 \beta_1^2 / q^2. \tag{24}$$

Using the notations of Massel(1993) and Chamberlain & Porter(1995), the following relations are found:

$$R_{00}^1 = 2qf_s, \quad R_{00}^2 = 2q\sigma f_c, \tag{25}$$

$$u_1 = f_c, \quad u_2 = kf_s. \tag{26}$$

Therefore, both Equation (34) of Massel(1993) and Equation (2.12) of Chamberlain & Porter(1995) can be recovered from Eq.(4). Obviously, Eq.(4) for the MMSE is more general. The plots of R_{00}^1 and R_{00}^2 have been done for checking with Massel (1993).

However, if the water depth is constant but k is still arbitrary due to the variation of wave amplitude, the general equation is reduced to:

$$\phi_{tt} - \nabla \cdot (CC_g \nabla \phi) + (\omega^2 - k^2 CC_g) \phi - g \{ \alpha_4 \nabla^2 k / k^2 + \alpha_5 (\nabla k \cdot \nabla k) / k^3 \} \phi = 0 \tag{27}$$

In this case the equations of Massel(1993) and Chamberlain & Porter(1995) fail to consider the variation of wavenumber k . Obviously, the equation (4) in this paper is more general.

Uniform model equation

To exam errors induced by omitting the last terms, which consist of either curvature or slope terms, we compare the ratio of modified terms to the original term of the conventional MSE by using Eqs.(17), (18) and

$$CC_g = g\gamma/(2k), \tag{28}$$

i.e.

$$\frac{gF\phi}{k^2CC_g\phi} = R_c \frac{\nabla^2 h}{k} + R_s(\nabla h \cdot \nabla h) \tag{29}$$

where

$$R_c(kh) = 2(\alpha_2 + \alpha_4\beta_1/q)/\gamma, \tag{30}$$

and

$$R_s(kh) = 2(\alpha_1 + \alpha_3\beta_1/q + \alpha_4\beta_2/q^2 + \alpha_5\beta_1^2/q^2)/\gamma, \tag{31}$$

are functions of only kh . The plots of R_c and R_s are presented in Fig. 1. It is found that approximately $max|R_c, R_s| < 0.2$ in Fig. 1. Nevertheless, from Eq.(29) it is clear that the relative errors still depend on both

$$\frac{\nabla^2 h}{k}, \quad \text{and} \quad (\nabla h \cdot \nabla h).$$

It is well known that the MSE was derived by neglecting all the modified terms based on the assumption that

$$\frac{\nabla h}{kh} \ll 1.$$

In the following we will show that the slope square terms are negligible, but the mild-slope assumption does not mean that the terms proportional to bottom curvature (i. e. $\nabla^2 h$) can also be neglected. For example, Massel (1993, p109) mentioned an example that the curvature terms are quite significant even for small mean bottom slope for a sinusoidal bed:

$$|\nabla h| = 0.1\pi \approx 0.3 \quad |\nabla^2 h| = 0.2\pi^2 \approx 2.$$

Instead of using $|\nabla^2 h|$, dimensionless $|\nabla^2 h|/k$ is used in this paper. It can be proved that the slope square terms are higher order than the curvature terms, if the ratio of bed wave number to surface wave number is of unity order. For simplicity, let the sinusoidal bed be defined by

$$h(x) = h_0 - b\sin Kx, \tag{32}$$

where h_0 is mean depth, K is bed wave number, and b is bed amplitude. It is easily found that

$$\frac{|\nabla^2 h|}{k} = \frac{K}{k} |\nabla h|$$

for sinusoidal bed case. It indicates that curvature terms depend not only on bed slope but also the ratio of bed wave number to surface wave number. Since

the modified terms are omitted in the MSE, the errors induced by the MSE will be significant in the lower frequency ranges.

Moreover, the ratio of slope square terms to curvature terms in Eq.(22) can be found from Eq.(32):

$$\frac{f_s k(\nabla h \cdot \nabla h)}{f_c \nabla^2 h} = \frac{f_s}{f_c}(kb) \cot Kx = O(kb) \tag{33}$$

From Eqs.(23) and (24) it is seen that the ratio of f_s to f_c is of $O(1)$. It means that the magnitude of Eq.(33) depends on surface wave number k and bottom amplitude b . Generally, kb is small value, except for very high frequency waves. Thus based on this ratio of Eq.(33), it is clear that slope square terms are only comparable to curvature terms for very large k , i.e. in the very high frequency ranges. According to Guazzelli et al. (1992), the high-frequency waves are hardly scattered by bottom undulation. Therefore, if the mild-slope assumption

$$\frac{\nabla h}{kh} \ll 1,$$

is applied, only slope square terms can be omitted, i.e.

$$\nabla \cdot (CC_g \nabla \phi) + k^2 CC_g \phi + gf_c \nabla^2 h \phi = 0 \tag{34}$$

The conventional mild-slope equation (MSE)

$$\nabla \cdot (CC_g \nabla \phi) + k^2 CC_g \phi = 0 \tag{35}$$

is recovered, if the modified term (last term) in Eq.(34) is neglected. Since the magnitude of neglected terms (curvature terms) is depend on the ratio of bed wave number to surface wave number (K/k), the error induced by the MSE is frequency-dependent.

On the other hand, Kirby's equation (1986) is originally derived for a rapidly-varying bottom. For the fixed bottom, the surface wave number k should be smaller than bed wave number K . It means that the solutions of Kirby's model are also frequency-dependent, which have been confirmed by other numerical methods and experimental data. The error of the model based on Eq.(34) is more uniform over a large frequency range than other models, thus it is called uniform mild-slope model.

Finite element method based on a weak form

For simplicity, we limit the remaining parts to the problem of two dimensional wave problems. For steady waves, the MMSE reads:

$$(CC_g \phi_x)_x + p\phi = 0 \tag{36}$$

where

$$p = k^2 CC_g + gF \tag{37}$$

The boundary conditions for a patch of rippled beds are

$$\phi_x = -ik(\phi - 2\phi_I) \quad (x_1 \leq 0) \tag{38}$$

$$\phi_x = ik\phi \quad (x_2 \geq L) \tag{39}$$

where $\phi_I = e^{ikx}$ is the incident wave of unit amplitude, x_1 and x_2 represent the upwave and downwave limits of the computational grid, and L is the length of computation domain. These boundary conditions have been given previously by Kirby (1986).

Considering potential applications in the three dimensional wave, a FEM model is developed for general topography. It seems that the numerical model in Chamberlain & Porter (1995) is suitable for periodic topography. The FEM model has advantages in the three dimensional problems with complex geometries, where it is desirable to use irregular meshes.

Multiplying the entire left hand side of equation (36) with a weight function w , and integrating over the domain $(0,L)$ gives the weighted-residual statement:

$$\int_0^L \{(CC_g\phi_x)_x + p\phi\}w dx = 0 \tag{40}$$

Mathematically, the above equation is a statement that the numerical error is needed to be zero in the weighted-integral sense. The trading of differentiability from ϕ to w provides the weak form

$$\int_0^L (CC_g\phi_x w_x - p\phi w) dx - [CC_g w \phi_x] \Big|_0^L = 0 \tag{41}$$

The trading of differentiability from ϕ to w can only be performed if it leads to boundary terms that are physically meaningful. The choice of the approximation ϕ for weight function gives the boundary terms $CC_g(\phi)_x\phi$, which has physical meaning of energy flux through a section. It is easy to find that the primary variable and the secondary variable are ϕ and $(\phi)_x$ respectively. Thus $[\phi_x] \Big|_0^L$ is the natural boundary condition. Using the notations of Reddy (1993), we have

$$B(w, \phi) - l(w) = 0$$

where

$$B(w, \phi) = \int_0^L (\phi_x w_x - p\phi w) dx - [ikCC_g w \phi_x] \Big|_0^L,$$

and

$$l(w) = -[2ikCC_g w \phi_I] \Big|_{x=0}$$

are bilinear and linear forms, respectively. For a typical element, ϕ is approximated by

$$\phi = \sum_{j=1}^4 \phi_j N_j$$

where N_j are cubic shape functions and ϕ_j are unknowns at the nodes. The water depth $h(x)$, slope and curvature of both h and k at each element in the FEM scheme can readily be evaluated as

$$h = \sum_{j=1}^4 h_j N_j, \quad k = \sum_{j=1}^4 k_j N_j$$

$$h_x = \sum_{j=1}^4 h_j \frac{\partial N_j}{\partial x}, \quad k_x = \sum_{j=1}^4 k_j \frac{\partial N_j}{\partial x}$$

$$h_{xx} = \sum_{j=1}^4 h_j \frac{\partial^2 N_j}{\partial x^2}, \quad \text{and} \quad k_{xx} = \sum_{j=1}^4 k_j \frac{\partial^2 N_j}{\partial x^2}.$$

The FEM schemes based on weak forms for the MSE, EMSE and UMSE are similar but much more simple. Bubnov-Galerkin method is adopted, thus the solution shape functions are used as weighting function.

It is worthy to note that most FEM models for water wave problems are established based on the functional formulation. For example, the hybrid element method of Mei (1983) and the modified hybrid element method of Zhang (1991,1996) are all based on variation of a functional. As noted in Reddy (1993), not all differential equations admit the functional formulation, and in order for the functional to exist, the bilinear form must be symmetric in its arguments. Since the weak form statement is equivalent to the differential equation and the specified natural boundary condition of the problem, the weak form FEM is used in this paper. Substituting the assumed approximate solution into the weak form (42), and following the procedure in Reddy (1993), the FEM is developed. Considering the fact that the coefficients of the FEM are high order functions of space, cubic shape functions are used here.

Verification of numerical model

In this section, the numerical solutions for sinusoidal beds and man-made bars are presented in *Figs.2 ~ 4*, and compared with experimental data.

For the case of the bottom having only one sinusoidal component, there are two resonant peaks of reflection coefficients, which were shown numerically by Dalrymple & Kirby (1986) by solving the 2-D Laplace equation. Later it was confirmed by Davies et al. (1989) and O'Hare & Davies (1993). Consider the case of sinusoidal bed $n = 2$, $b/h_0 = 0.32$, where h_0 is mean water depth, b is amplitude of bed undulation, and n is the number of sinusoidal bars. The numerical results of the MMSE, uniform and Kirby's model are presented in *Fig.2*, respectively, to compare with experimental data of Davies & Heathershaw (1984).

In *Fig.2*, it is seen that Kirby's model does not predict the second resonance peaks, while results of MMSE and uniform models are in good agreement with experimental data. Also it noted that the uniform model predicts the second peak better than the MMSE model.

Consider now the case of a doubly-sinusoidal bed (chosen here to be of equal amplitude b). The inclusion of a more rapid component makes the

bottom slope relatively larger, so the difference between the uniform model and the model of Chamberlain & Porter (1995) becomes significant. As indicated in *Fig.3*, Chamberlain & Porter (1995) overpredict reflection coefficients at higher-harmonic resonant peaks, if compared with experimental data (Guazzelli et al. 1992).

Numerical solutions and experimental results for the artificial bar field (Kirby & Anton 1990) are also studied. The bar field is periodic over intervals of width L , and can be conveniently represented by the Fourier series. The man-made bars have many sinusoidal components (Kirby & Anton 1990), some of which have shorter wavelengths than the surface wavelength, not belonging to rapidly-varying case. Since Kirby's model is valid only for rapidly-varying components, the slowly-varying components are not properly modeled. Therefore the overall reflections predicted by Kirby's model have larger discrepancy with experimental data than these predicted by the uniform model and MMSE as indicated in *Fig.4*.

The convergence of the numerical model is confirmed by checking the energy relation $R^2 + T^2 = 1$, where R and T are reflection and transmission coefficients, respectively. The maximum error is less than 10^{-5} .

Conclusions

To overcome the limitations of Kirby's model, the uniform model for wave transformation over an arbitrary-varying topography has been developed. Several cases of sinusoidal bed configuration have been studied and presented to confirm the numerical models. Based on the comparison between the numerical results and experimental data, it is clear that Kirby's method is frequency-dependent.

For sinusoidal beds, the numerical results of the MMSE, uniform and Kirby's model are all in good agreement with the experimental data of Davies & Heathershaw (1984), except at the second resonance peak ($2k/K \sim 2$), the uniform model predicts a reflection coefficient closer to the laboratory data than the other numerical results. For man-made bar case, it is shown that both the MMSE and uniform model give excellent comparison with experiments. Since Kirby's equation is originally derived for a rapidly-varying bottom, it becomes less accurate as ripple-bed undulations become slower (i.e. $2k/K$ becomes larger). The uniform model is capable of modeling not only the slowly-varying components but also rapidly-varying of sea beds.

The success of the uniform model in model tests and better agreement with experimental data than other models, suggest that the uniform model is more efficient and accurate tool for the prediction of wave transformation over general sea bed. An important result of the uniform model is application to reflection of wave energy from offshore bars and dredged material dump sites. In addition, the uniform wave model can be extended to further the work of Kirby (1984).

Appendix: Derivation of the time-dependent wave equation

The depth-integrated wave equation for monochromatic, linear waves propagating over ripple beds may be formulated following the Green's identity method of Smith & Sprinks (1975). The solution to Equation (1)-(3) may be expressed as

$$\Phi(x, y, z, t) = f(q, Q)\phi(x, y, t) + (\text{non-propagating modes}) \quad (\text{A1})$$

where

$$f = \cosh Q / \cosh q \quad (\text{A2})$$

is a function of z , k , and h . The propagation of waves is associated with only the propagating mode, thus extracting this mode component and applying Green's identity to f and Φ :

$$\int_{-h}^0 (f\Phi_{zz} - \Phi f_{zz}) dz = [f\Phi_z - \Phi f_z]_{-h}^0$$

or

$$\int_{-h}^0 (f\nabla^2\Phi + \Phi f_{zz}) dz = -[f\Phi_z - \Phi f_z]_{-h}^0 \quad (\text{A3})$$

Using (A1) and (A2)

$$\begin{aligned} f_{zz} &= k^2 f \\ \nabla\Phi &= f\nabla\phi + \phi\nabla f \\ \nabla^2\Phi &= f\nabla^2\phi + 2\nabla\phi \cdot \nabla f + \phi\nabla^2 f \\ \Phi_z|_{z=-h} &= -\nabla h \cdot (f\nabla\phi + \phi\nabla f) \end{aligned} \quad (\text{A4})$$

Inserting (A4) into (A3)

$$\int_{-h}^0 (\phi k^2 f^2 + \nabla^2\phi f^2 + 2f\nabla\phi \cdot \nabla f + \phi f\nabla^2 f) dz = (\phi_{tt} + \omega^2\phi)/g|_{z=0} + \Phi_z f|_{z=-h} \quad (\text{A5})$$

Based on (A2), every term in (A5) is evaluated using the following

$$\nabla f = f_h \nabla h + f_k \nabla k$$

$$\nabla^2 f = f_{hh}(\nabla h \cdot \nabla h) + f_h \nabla^2 h + 2f_{hk} \nabla h \cdot \nabla k + f_k \nabla^2 k + f_{kk}(\nabla k \cdot \nabla k)$$

where $f_h = \frac{\partial f}{\partial h}$, $f_k = \frac{\partial f}{\partial k}$, $f_{hh} = \frac{\partial^2 f}{\partial h^2}$, $f_{hk} = \frac{\partial^2 f}{\partial h \partial k}$, $f_{kk} = \frac{\partial^2 f}{\partial k^2}$, and derived in the following:

$$\begin{aligned} f_h &= k(\sinh Q - \sigma \cosh Q) / \cosh q \\ f_k &= (Q \sinh Q - q\sigma \cosh Q) / (k \cosh q) \\ f_{hh} &= 2\sigma k^2(\sigma \cosh Q - \sinh Q) / \cosh q \\ f_{kk} &= \{Q^2 \cosh Q - 2\sigma q Q \sinh Q - q^2(1 - 2\sigma^2) \cosh Q\} / (k^2 \cosh q) \\ f_{hk} &= \{(2q\sigma^2 - \sigma - q) \cosh Q + (1 - q\sigma) \sinh Q + Q \cosh Q - Q\sigma \sinh Q\} / \cosh q \end{aligned} \quad (\text{A6})$$

Applying Leibniz's rule,

$$\int_{-h}^0 (\nabla^2 \phi f^2 + 2f \nabla \phi \cdot \nabla f) dz + f^2 \nabla h \cdot \nabla \phi|_{z=-h} = \nabla \cdot (CC_g \nabla \phi) / g \quad (A7)$$

Using the following integrations

$$g \int_{-h}^0 k^2 \phi f^2 dz = k^2 CC_g \phi$$

$$2k \int_{-h}^0 \sinh Q \cosh Q dz = \sigma^2 / (1 - \sigma^2)$$

$$4k \int_{-h}^0 Q \sinh Q \cosh Q dz = \{q(1 + \sigma^2) - \sigma\} / (1 - \sigma^2)$$

$$4k \int_{-h}^0 Q \cosh Q \cosh Q dz = \{q^2(1 - \sigma^2) + 2q\sigma - \sigma^2\} / (1 - \sigma^2)$$

$$4k \int_{-h}^0 Q^2 \cosh Q \cosh Q dz = \{2q^3(1 - \sigma^2) + 2q^2\sigma - q(1 + \sigma^2) + \sigma\} / (1 - \sigma^2)$$

and substituting (A6) and (A7) into (A5), finally the time-dependent Eq.(4) is obtained.

It may be worth remarking that the terms in (A5) involving

$$f_k = \frac{\partial f}{\partial k}, \quad f_{hk} = \frac{\partial^2 f}{\partial h \partial k}, \quad f_{kk} = \frac{\partial^2 f}{\partial k^2},$$

were mistakenly omitted by Smith & Sprinks (1975). Furthermore, Smith & Sprinks (1975) obtained the conversional mild-slope equation (MSE) by neglecting all the so-called 'forcing' terms, which are assumed to be of higher order. The validity of this assumption of higher order about the forcing terms must, however, be questioned. In the absence of current, similar treatment was made by Kirby (1984) (see Eq.17 of Kirby, 1984).

CHAPTER 75

Bragg Reflection of Shallow-Water Waves on a Sloping Beach

Yong-Sik Cho¹ · Jong-In Lee² · Jong-Kyu Lee³

Abstract

In this study a set of governing equations describing the evolution of modulated shallow-water waves over a sinusoidally varying topography on a sloping beach is derived. The governing equations include the nonlinear interactions among different wave components as well as the shoaling effect over a slowly varying topography. It has been shown that the incident waves could be resonantly reflected by the interaction with the rippled seabed under the Bragg reflection condition. The magnitude of the resonantly reflected wave is almost equal to those of the incident and the transmitted waves.

1. Introduction

Water waves, approaching the coastline from deep water, undergo many physical phenomena caused by combined effects of bottom topographical variations, interference with man-made structures and nonlinear interactions among different wave components. One fascinating but challenging feature among these phenomena is so called the Bragg reflection occurring when the wave number of incident wave is a half of that of the sinusoidally varying topography. The Bragg reflection is believed to play an important role in the formation of submerged offshore sandbars frequently observed in Danish coast, the Great Lakes, Japanese coast and many other open coasts. In general, typical offshore multiple sandbars exist on beaches milder than 5 per 1000 and the number of sandbars varies 3 to 17 with a spacing of 10 m to 480 m between two adjacent bars (Mei and Liu, 1993).

¹Assistant Professor, Dept. of Civil Engineering, Sejong University, Seoul, 143-747, KOREA

²Research Assistant, ³Professor, Dept. of Civil Engineering, Hanyang University, Seoul, 133-791, KOREA

A lot of experimental and theoretical investigations have been performed to explain the possible formation mechanism of these sandbars as well as the effects of offshore sandbars on the change of the coastal morphology and the wave characteristics (Davies and Heathershaw, 1984; Mei, 1985; Yoon and Liu, 1987; Hara and Mei, 1987; Kirby and Vengayil, 1988; Liu and Cho, 1993). Through the laboratory experiment Carter et al. (1973) found that the formation of offshore sandbars is probably triggered by mass transport velocity near the seabed under partially reflected waves. They also pointed out that the incipient reflection coefficient for the sandbar formation is about 0.414. According to Mei and Liu (1993), a special bottom topography can reflect a significant amount of wave energy, and therefore can protect the beach from the possible erosion and deposit, that is, the strong reflection of incident waves could be the cause and the effect of offshore multiple sandbars.

Yoon and Liu (1987) investigated the near resonant reflection of periodic waves in shallow water over a sinusoidally varying topography. Since they were interested in near resonant reflection, only self-product terms of propagating wave components were considered. In this paper, we extend Yoon and Liu's study to examine the effects of the cross-product terms of oppositely propagating wave components and the number of seabed ripples. Thus, Yoon and Liu's study can be viewed as a limiting case of the present study. We also investigate the effect of a sloping beach on the reflection. Since the domain is fixed in shallow water, the Boussinesq equations are adequate to describe wave fields. The resonant reflection of incident periodic waves from a sinusoidally varying seabed laid on a sloping beach will be examined by solving a set of coupled nonlinear, ordinary differential equations. The effects of nonlinear interactions among different harmonics will also be examined for different numbers of seabed ripples.

In the following section, a set of governing equations describing modulation of shallow-water waves is first derived. These governing equations include effects of nonlinearity, dispersion, shoaling and interactions among different wave components. In section 3, two coupled ordinary differential equations are derived to describe evolution of water waves over a slowly varying topography. Numerical examples are given in section 4. Finally, concluding remarks are made in section 5.

2. Modulation Equations

By using a_0' as the characteristic wave amplitude, h_0' as the water depth and k' as the wave number, we introduce the following nondimensional variables:

$$\begin{aligned} (x, y) &= k'(x', y'), & z &= \frac{z'}{h_0'}, & h &= \frac{h'}{h_0'}, \\ t &= k' \sqrt{gh_0'} t', & \zeta &= \frac{\zeta'}{a_0'}, & \mathbf{u} &= \frac{h_0'}{a_0' (gh_0')^{1/2}} \mathbf{u}'. \end{aligned} \quad (1)$$

Figure 1. Definition sketch of the seabed and incident waves.

in which ζ' represents the free surface displacement and \mathbf{u}' does the depth-averaged horizontal velocity vector. We also introduce following two parameters:

$$\varepsilon = \frac{a_0'}{h_0'}, \quad \mu^2 = (k' h_0')^2 \quad (2)$$

in which ε and μ^2 represent the nonlinearity and the frequency dispersion, respectively. In the Boussinesq equations, orders of magnitude of both parameters are assumed to be equal and small enough. Using nondimensional variables the Boussinesq equations can be written in the following form (Yoon and Liu, 1987; Liu and Cho, 1993):

$$\frac{\partial \zeta}{\partial t} + \nabla \cdot [(h + \varepsilon \zeta) \mathbf{u}] = 0, \quad (3)$$

$$\frac{\partial \mathbf{u}}{\partial t} + \varepsilon \mathbf{u} \cdot \nabla \mathbf{u} + \nabla \zeta = \mu^2 \left\{ \frac{1}{2} h \frac{\partial}{\partial t} \nabla [\nabla \cdot (h \mathbf{u})] - \frac{1}{6} h^2 \frac{\partial}{\partial t} \nabla (\nabla \cdot \mathbf{u}) \right\}. \quad (4)$$

It is noted that equation (3) is an exact expression, while equation (4) is truncated at the order of $O(\varepsilon^2, \varepsilon \mu^2, \mu^4)$.

To investigate resonant reflection and shoaling of incident waves over a slowly varying topography the water depth is defined as (see figure 1):

$$h(x, y) = \bar{h}(x, y) + \hat{h}(x, y) \quad (5)$$

in which

$$\bar{h}(x, y) \sim O(1), \quad \hat{h}(x, y) \sim O(\mu^2) \quad (6)$$

and

$$|\nabla \bar{h}| \sim O(\mu^2), \quad |\nabla \hat{h}| \sim O(\mu^2). \quad (7)$$

Following Yoon and Liu (1987) the free surface displacement and the velocity can be expressed in Fourier series. That is,

$$\zeta(x, y, t) = \frac{1}{2} \sum_n \zeta_n(x, y) e^{-int}, \tag{8}$$

$$u(x, y, t) = \frac{1}{2} \sum_n U_n(x, y) e^{-int} \tag{9}$$

in which a periodic motion in time has been assumed and $n=0, \pm 1, \pm 2, \dots$. In equations (8) and (9), ζ_{-n} and U_{-n} are the complex conjugates of ζ_n and U_n , respectively. For simplicity, the symbols of $O(\varepsilon)$ and $O(\varepsilon^2)$ will be used to represent $O(\varepsilon, \mu^2)$ and $O(\varepsilon^2, \varepsilon\mu^2, \mu^4)$, respectively throughout the study.

By substituting equations (5)-(9) into equations (3) and (4), the following continuity and momentum equations are obtained for the n th Fourier components:

$$-in\zeta_n + \nabla \cdot (h U_n) + \frac{1}{2} \varepsilon \sum_s \nabla \cdot (\zeta_s U_{n-s}) = 0, \tag{10}$$

$$\begin{aligned} -in U_n + \frac{1}{2} \varepsilon \sum_s U_s \cdot \nabla U_{n-s} + \nabla \zeta_n \\ = -\frac{1}{3} in\mu^2 \bar{h}^2 \nabla (\nabla \cdot U_n) = O(\varepsilon^2), \end{aligned} \tag{11}$$

in which $s=0, \pm 1, \pm 2, \dots$. The leading order terms of equations (10) and (11) give

$$\zeta_n = -\frac{i}{n} \bar{h} \nabla \cdot U_n + O(\varepsilon), \tag{12}$$

$$U_n = -\frac{i}{n} \nabla \zeta_n + O(\varepsilon) \tag{13}$$

for $n \neq 0$ and

$$U_0 = -\frac{\varepsilon}{2\bar{h}} \sum_s \zeta_s U_{-s} + O(\varepsilon^2), \tag{14}$$

$$\zeta_0 = -\frac{1}{4} \varepsilon \sum_s U_s \cdot U_{-s} + O(\varepsilon^2) \tag{15}$$

for $n=0$. Equations (14) and (15) represent steady components which have no contribution to other harmonics up to $O(\varepsilon)$. Thus, the steady components are excluded in this study. By eliminating the velocity vector from equations (10) and (11) and using equations (5), (12) and (13), we can obtain the following combined equation:

$$\begin{aligned} n^2 \zeta_n + \nabla \cdot (h \nabla \zeta_n) - \varepsilon \frac{\bar{h}}{2} \sum_{s \neq 0, n} \frac{1}{s(n-s)} \nabla \cdot [(\nabla \zeta_s \cdot \nabla) \nabla \zeta_{n-s}] \\ + \frac{1}{3} \mu^2 \bar{h}^3 \nabla^4 \zeta_n + \varepsilon \frac{n}{2} \sum_{s \neq 0, n} \frac{1}{n-s} \nabla \cdot (\zeta_s \nabla \zeta_{n-s}) = O(\varepsilon^2). \end{aligned} \tag{16}$$

The leading orders of equation (16) yield

$$\nabla^2 \zeta_n = -\frac{n^2}{\bar{h}} \zeta_n. \tag{17}$$

By substituting equation (17) into equation (16), we also obtain

$$\begin{aligned} & \bar{h} \nabla^2 \zeta_n + \nabla(\bar{h} + \hat{h}) \cdot \nabla \zeta_n + n^2 \left[1 - \frac{\hat{h}}{h} - \frac{1}{3} \mu^2 \bar{h} n^2 \right] \zeta_n \\ &= \varepsilon \sum_{s \neq 0, n} \left\{ \frac{\bar{h}}{2s(n-s)} \nabla \cdot [(\nabla \zeta_s \cdot \nabla) \nabla \zeta_{n-s}] - \frac{n}{2(n-s)} \nabla \cdot (\zeta_s \nabla \zeta_{n-s}) \right\} \end{aligned} \quad (18)$$

where $|\partial \zeta / \partial y|^2 \sim O(\varepsilon, \mu^2)$ has been assumed.

3. Evolution Equations

In this section we derive a set of coupled ordinary differential equations to describe evolution of waves over a slowly varying topography. After omitting y -direction components equation (18) can be rewritten as:

$$\begin{aligned} & \bar{h} \frac{d^2 \zeta_n}{dx^2} + \frac{d\bar{h}}{dx} \frac{d\zeta_n}{dx} + n^2 \left(1 - \frac{\hat{h}}{h} + \frac{1}{3} \mu^2 \bar{h} n^2 \right) \zeta_n \\ &= \frac{\varepsilon}{2\bar{h}} \sum_{s \neq 0, n} (n^2 - s^2) \zeta_s \zeta_{n-s} - \frac{\varepsilon}{2} \sum_{s \neq 0, n} \frac{n+s}{n-s} \frac{d\zeta_s}{dx} \frac{d\zeta_{n-s}}{dx} + O(\varepsilon^2). \end{aligned} \quad (19)$$

The homogeneous leading order of equation (19) is the long wave equation and implies that wave components propagate both in $+x$ and $-x$ directions. Thus, the wave field can be split into the right- and the left-going components as (Liu and Cho, 1993):

$$\zeta_n = \zeta_n^+ + \zeta_n^- \quad (20)$$

where ζ_n^+ and ζ_n^- represent the right- and the left-going wave components, respectively. Then, the following coupled relationships can be obtained (Liu and Cho, 1993):

$$\frac{d\zeta_n^+}{dx} = \frac{in}{h} \zeta_n^+ + F_n, \quad \frac{d\zeta_n^-}{dx} = -\frac{in}{h} \zeta_n^- - F_n \quad (21)$$

in which F_n is an unknown coupling term. By substituting equations (20) and (21) into equation (19) and after lengthy algebra, the coupling term F_n is determined as:

$$\begin{aligned} F_n = & -\frac{1}{2\bar{h}} \left(\frac{1}{2} \frac{d\bar{h}}{dx} + \frac{d\hat{h}}{dx} \right) (\zeta_n^+ - \zeta_n^-) + \frac{in}{2h} \left(-\frac{\hat{h}}{h} + \frac{1}{3} \mu^2 n^2 \bar{h} \right) (\zeta_n^+ + \zeta_n^-) \\ & - \frac{i\varepsilon}{4h\bar{h}} \sum_{s \neq 0, n} (n+s) \left[(\zeta_s^+ \zeta_{n-s}^+ + \zeta_s^- \zeta_{n-s}^-) + \frac{n-2s}{n} (\zeta_s^- \zeta_{n-s}^+ + \zeta_s^+ \zeta_{n-s}^-) \right]. \end{aligned} \quad (22)$$

By assuming a periodic motion in space the wave components can be expressed as:

$$\zeta_n^+ = A_n(x) e^{in\theta}, \quad \zeta_n^- = B_n(x) e^{-in\theta} \quad (23)$$

in which $A_n(x)$ and $B_n(x)$ are complex amplitude functions for the right- and the left-going waves, respectively and the following definition is used:

$$\theta = \int \frac{dx}{h}$$

Substituting equations (22) and (23) into equation (21), a set of coupled nonlinear ordinary differential equations can be obtained:

$$\begin{aligned}
& \frac{dA_n}{dx} + \left[\frac{in\tilde{h}}{2h\sqrt{h}} + \frac{1}{4} \frac{d}{dx} (\ln \bar{h}) + \frac{1}{2h} \frac{d\tilde{h}}{dx} - \frac{i}{6} \mu^2 n^3 \sqrt{\bar{h}} \right] A_n \\
& - \left[-\frac{in\tilde{h}}{2h\sqrt{h}} + \frac{1}{4} \frac{d}{dx} (\ln \bar{h}) + \frac{1}{2h} \frac{d\tilde{h}}{dx} + \frac{i}{6} \mu^2 n^3 \sqrt{\bar{h}} \right] B_n e^{-2in\theta} \\
& = \text{NLT}_r + O(\varepsilon^2)
\end{aligned} \tag{24a}$$

where

$$\begin{aligned}
\text{NLT}_r = & -\frac{i\varepsilon}{4h\sqrt{h}} \sum_{s \neq 0, n} (n+s) \left[(A_s A_{n-s} + \frac{n-2s}{n} B_s A_{n-s} e^{-2is\theta}) \right] \\
& - \frac{i\varepsilon}{4h\sqrt{h}} \left[\sum_{s \neq 0, n} (n+s) (B_s B_{n-s} + \frac{n-2s}{n} A_s B_{n-s} e^{2is\theta}) \right] e^{-2in\theta}
\end{aligned}$$

for right-going waves,

$$\begin{aligned}
& \frac{dB_n}{dx} + \left[-\frac{in\tilde{h}}{2h\sqrt{h}} + \frac{1}{4} \frac{d}{dx} (\ln \bar{h}) + \frac{1}{2h} \frac{d\tilde{h}}{dx} + \frac{i}{6} \mu^2 n^3 \sqrt{\bar{h}} \right] B_n \\
& - \left[\frac{in\tilde{h}}{2h\sqrt{h}} + \frac{1}{4} \frac{d}{dx} (\ln \bar{h}) + \frac{1}{2h} \frac{d\tilde{h}}{dx} - \frac{i}{6} \mu^2 n^3 \sqrt{\bar{h}} \right] A_n e^{2in\theta} \\
& = \text{NLT}_l + O(\varepsilon^2)
\end{aligned} \tag{24b}$$

where

$$\begin{aligned}
\text{NLT}_l = & \frac{i\varepsilon}{4h\sqrt{h}} \sum_{s \neq 0, n} (n+s) \left[(B_s B_{n-s} + \frac{n-2s}{n} A_s B_{n-s} e^{2is\theta}) \right] \\
& + \frac{i\varepsilon}{4h\sqrt{h}} \left[\sum_{s \neq 0, n} (n+s) (A_s A_{n-s} + \frac{n-2s}{n} B_s A_{n-s} e^{-2is\theta}) \right] e^{2in\theta}
\end{aligned}$$

for left-going waves. Equations (24a) and (24b) are evolution equations for waves propagating over a slowly varying topography.

In summary, equations (24a) and (24b) are the governing equations for shallow-water waves forced by self- and cross-product wave components. In equation (24) the terms multiplied by the exponential function and $d\tilde{h}/dx$ are mathematically fast varying, whereas the other terms are slowly varying. The effects of the fast varying terms are generally insignificant, while they are significant if a phase is properly matched. Therefore, the present study is more general than Yoon and Liu's (1987) in which all fast varying terms are ignored. The role of fast varying terms will be discussed in detail in the following section. After solving equation (24) the free surface profile of wave can be recovered as

$$\zeta(x, t) = \frac{1}{2} \sum_n [A_n e^{in\theta} + B_n e^{-in\theta}] e^{-int}. \tag{25}$$

The corresponding velocity up to the leading order can also be obtained by substituting equation (25) into equations (9) and (13).

4. Numerical Example

An iterative scheme is employed to solve coupled equations (24a) and

(24b) with prescribed initial conditions of A_n . In the iterative scheme the transmitted wave field is first solved without considering the reflected wave field. The reflected wave field is then estimated with the calculated transmitted wave. The transmitted wave field is finally updated with the newly obtained reflected wave field. The procedure is repeated until the converged solutions are obtained. More detailed description of the iterative scheme and the convergence condition are given in Liu and Cho (1993).

Now we examine the resonant reflection of incident periodic waves over a finite length of the rippled seabed. Although the shoaling effect is included in equation (25), we first focus on the Bragg reflection. Then, the shoaling effect over a sloping beach will also be examined later. In this study the nondimensional water depth is given as:

$$\begin{aligned} h &= 1 - Sx, & x \leq 0, \quad x \geq L \\ h &= 1 - Sx - \rho \sin(\delta x), & 0 \leq x \leq L \end{aligned} \quad (26)$$

in which ρ is the amplitude, S is the beach slope and δ is the wave number of the sinusoidally varying seabed. As mentioned in section 2, the orders of magnitudes of ρ and δ are $O(\mu^2)$ and $O(1)$, respectively. Figure 1 briefly illustrates the bottom topography consisting of sinusoidal ripples and a sloping beach as defined in equation (26).

In the first numerical example, we investigate the Bragg reflection of a train of cnoidal waves over a sinusoidally varying topography. Following Yoon and Liu (1987), the initial conditions for incident cnoidal waves are given as:

$$A_1 = 0.8923, \quad A_2 = 0.4198, \quad A_3 = 0.1568, \quad A_4 = 0.0522, \quad A_5 = 0.0163.$$

The number of harmonics is fixed at 5 throughout the study. Figure 2 shows the free surface profile of a train of cnoidal waves obtained by using 5 harmonics given above.

Figure 2. Free surface profile of the incident cnoidal waves at $t=0$.

Figure 3. Reflected amplitude $|B_1|$ of cnoidal wave for $n = 5, \epsilon = 0.0881, \mu^2 = 0.1067, \rho = 0.15$.

To examine the effect of ripples on the reflection we calculate the reflected waves for three different numbers of ripples, that is, $m = 6, 8$ and 10 with m being the number of sinusoidal ripples. The reflection becomes stronger as the number of ripples increases as shown in figure 3. Therefore, the strongest reflection occurs when $m = 10$. We briefly explain the mathematics involved in the Bragg reflection. From equation (26)

$$\begin{aligned} \frac{d\tilde{h}}{dx} &= \frac{d\tilde{h}}{dx} = -\rho\delta \cos(\delta x) \\ &= -\rho\delta \frac{e^{i\delta x} + e^{-i\delta x}}{2} \end{aligned} \tag{27}$$

By substituting equation (27) into equation (24b) the third term in the second parenthesis becomes

$$\begin{aligned} &\frac{1}{2\tilde{h}} \frac{d\tilde{h}}{dx} e^{2in\theta} \\ &= -\frac{\rho\delta}{4} [e^{i(\delta+2n)x} + e^{i(-\delta+2n)x}] \end{aligned} \tag{28}$$

We can see that the second term of equation (28) becomes the unity if $\delta = 2n$. The second term of equation (28) varies slowly, whereas the first term does fast. Since the first harmonic dominates the incident wave system (Yoon and Liu, 1987), the forcing term of equation (24b) becomes largest

when $\delta=2$, that is, the wave number of the ripple is twice that of the first harmonic of incident wave. As plotted in figure 3, the maximum reflection occurs at $\delta \approx 2$. The reflection coefficient is greater than 0.414 even for $m=6$.

The reflected waves for the first and the second harmonics are plotted with $L=6\pi$ and $L=10\pi$ in figures 4 and 5, respectively. The amplitude of the seabed ripple is fixed as $\rho=0.1$ for both cases. The reflected waves without considering fast varying terms are slightly larger than those with considering fast varying terms. As stated previously, the magnitude of the first harmonic component is much larger than that of the second harmonic component. The difference between without considering and with considering fast varying terms is not surprising but appreciable. The beach slope is not considered both in figures 4 and 5.

In figure 6, the reflected waves for the first harmonic are plotted for $L=10\pi$ and $\rho=0.1$ with three different nonlinear effects. The strength of reflection is rapidly decreasing as the nonlinearity increases. This is because wave energy transfers more actively as the nonlinearity increases. That is, more wave energy transfers to higher harmonic components. The peak is also moving leftward as the nonlinearity increases.

Figure 4. Reflected amplitudes of cnoidal wave for $L=6\pi$, $S=0.0$, $\epsilon=0.10$, $\mu^2=0.1067$, $\rho=0.10$.

Figure 5. Reflected amplitudes of cnoidal wave for $L=10\pi$, $S=0.0$, $\epsilon=0.10$, $\mu^2=0.1067$, $\rho=0.10$.

Figure 6. Effects of nonlinearity for $L=10\pi$, $S=0.0$, $\mu^2=0.1067$, $\rho=0.10$.

Finally, the first harmonic components of reflected waves are plotted in figures 7 and 8 for $L=6\pi$ and $L=10\pi$ with two different beach slopes, $S=0$ and $S=0.005$. The amplitude of the seabed ripple is also fixed as $\rho=0.1$. The magnitudes of reflected waves remain almost the same in figures 7 and 8, respectively. This is because the beach slope $S=0.005$ is too mild to affect to the magnitude of the reflected wave. As discussed in section 2, the order of magnitude of a beach slope is assumed to be $O(\mu^2)$ in this study. However, the slope used in figures 7 and 8 is 0.005 much smaller than $O(\mu^2)$. The peak moves slightly leftward as the beach slope increases.

5. Concluding Remarks

In this study a set of governing equations is derived from the Boussinesq equations to examine the evolution of periodic waves over a sinusoidally varying topography laid on a sloping beach. The derived governing equations are used to study the evolution of cnoidal waves over a slowly varying topography. It has been shown that reflected waves can be resonantly amplified under the Bragg reflection condition..

Figure 7. Comparison of reflected amplitudes for $L=6\pi$, $\varepsilon=0.075$, $\mu^2=0.10$, $\rho=0.10$.

Figure 8. Comparison of reflected amplitudes for $L=10\pi$, $\varepsilon=0.075$, $\mu^2=0.10$, $\rho=0.10$.

In very shallow water the nonlinear effect may dominate the entire wave system. Especially, just before the breaking point waves might be highly nonlinear. Furthermore, the bottom friction becomes increasingly important as the water depth decreases. An extension with inclusion of highly nonlinear terms and the bottom friction is now progressing. The result will be reported in future.

CHAPTER 76

Reflection Analysis with Separation of Cross Modes

John Grønbech*, Thomas Jensen** and Henning Andersen**

Abstract

During physical model tests in a wave flume an accurate determination of the incident waves is crucial. Normally, the determination of the incident waves is conducted by a traditional reflection analysis and in this case the influence of any cross modes is ignored. The present paper concerns the advantage of including the possible presence of cross modal activity in the reflection analysis when determining the incident waves. It is shown both analytically and numerically how the cross modes affect the results of a traditional reflection analysis, and that ignoring cross modal activity can lead to an inaccurate determination of the incident waves. A new method is introduced where the cross modes are separated in the reflection analysis. This method requires at least three wave probes while a traditional reflection analyses only requires two wave probes. The applicability of the method is verified both numerically and by physical flume tests at the Hydraulic Laboratory of Aalborg University, Denmark. In both cases the new method seems to give very good results.

1 Introduction

One of the most important tasks in physical model studies is the determination of incident waves. The determination of the incident waves is often carried out using some kind of reflection analysis capable of separating the incident and reflected wave components mathematically.

* Department of Civil Engineering, Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark.

** Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

Goda and Suzuki (1976) presented a method capable of separating the incident and reflected waves on the basis of wave measurements at two known positions on a line parallel to the direction of wave propagation. Mansard and Funke (1980) improved this method by applying three wave gauges instead of only two. This enabled an optimization of the determination of the incident and reflected waves by the use of a least squares technique. Zelt and Skjelbreia (1992) improved this optimization procedure further by applying an arbitrary number of wave probes.

However, all these commonly used methods of reflection analysis are based on the assumption that the waves measured in the flume are composed of only two wave components; The incident and reflected components. If the measured waves contain other components, for instance cross modes, which is a well-known phenomenon in flume tests, the reflection analysis can produce inaccurate results.

In this paper, a new method of reflection analysis is presented. This method, which also uses an arbitrary number of wave probes, assumes that the measured waves are composed of three components; The usual incident and reflected wave components *and* a component representing any cross modal activity present in the wave flume. Before presenting the new method of reflection analysis, the influence of cross modes on the results of a traditional reflection analysis is addressed. This is done using the method of Zelt and Skjelbreia (1992).

2 Influence of Cross Modal Activity

The presence of cross modal activity affects the composite wave field measured in the flume. Depending on the phase differences between the cross modes and the longitudinal waves, the ordinary wave heights measured at each wave probe either increase or decrease. In case of regular waves, the influence of the cross modes is verified analytically by decomposing the measured Fourier coefficients into a primary term representing the longitudinal waves and secondary term representing the cross modes. The analytical approach is supported by numerical simulations using the method of Zelt and Skjelbreia (1992) with 5 wave probes on simulated time series with and without cross modes. In case of irregular waves, the influence of cross modes is investigated by comparing the incident and reflected wave spectra with and without cross modes contained in the simulated time series.

2.1 Analytical Verification of the Influence of Cross Modes

To investigate the influence of cross modes in traditional methods of reflection analysis analytically, the method of Zelt and Skjelbreia (1992) has been used. The method is explained very briefly in the following.

Using standard Fourier analysis techniques the surface elevation (η_p) measured at wave probe p (see Figure 1) can be expressed as:

$$\eta_p(t) = \sum_{n=0}^{N-1} A_{n,p} e^{i\omega_n t} \quad ; \quad A_{n,p} = a_{n,p} - ib_{n,p} \tag{1}$$

where $a_{n,p}$ and $b_{n,p}$ are the Fourier coefficients corresponding to frequency component n and wave probe p . ω_n is the n th cyclic frequency. Assuming linear wave theory, no frequency modulation due to the reflection process, and a composite wave field composed of incident waves and reflected waves only, the theoretical surface elevation at wave probe p (see Figure 1) can be written as:

$$\eta(x_p, t) = \sum_{n=0}^{N-1} (a_{I,n} e^{-ik_n x_p} + a_{R,n} e^{ik_n x_p}) e^{i\omega_n t} \tag{2}$$

where $a_{I,n}$ and $a_{R,n}$ are complex numbers containing the Fourier coefficients of the n th frequency component of the incident waves and reflected waves. k_n is the wave number of the n th frequency component and x_p is the position of wave probe p .

Figure 1 - Measuring composite wave fields at P wave probes.

Combining Equations (1) and (2) a complex equation for each wave probe p and frequency component n is obtained:

$$A_{n,p} = a_{I,n} e^{-ik_n x_p} + a_{R,n} e^{ik_n x_p} \tag{3}$$

The unknowns of this equation ($a_{I,n}$ and $a_{R,n}$) are the same for each wave probe. If only two wave probes are applied, Equation (3) is solved exactly but singularities at certain frequencies will occur (Goda and Suzuki, 1976). If more than two wave probes are applied the overdetermined system of equations is solved by introducing an error $\epsilon_{n,p}$ to the decomposed wave field:

$$\varepsilon_{n,p} = a_{L,n} e^{-ik_n x_p} + a_{R,n} e^{ik_n x_p} - A_{n,p} \tag{4}$$

$a_{L,n}$, and $a_{R,n}$ are then determined by minimizing a weighted sum of the squares of the error $\varepsilon_{n,p}$ (for details please refer to Zelt and Skjelbreia, 1992). The explicit solution is given by:

$$a_{L,n} = \left[S_n \sum_{p=1}^P W_{n,p} A_{n,p} e^{i\Delta\phi_{n,p}} - \sum_{p=1}^P W_{n,p} A_{n,p} e^{-i\Delta\phi_{n,p}} \sum_{p=1}^P W_{n,p} e^{2i\Delta\phi_{n,p}} \right] \frac{e^{i\phi_{n,1}}}{D_n} \tag{5}$$

$$a_{R,n} = \left[S_n \sum_{p=1}^P W_{n,p} A_{n,p} e^{-i\Delta\phi_{n,p}} - \sum_{p=1}^P W_{n,p} A_{n,p} e^{i\Delta\phi_{n,p}} \sum_{p=1}^P W_{n,p} e^{-2i\Delta\phi_{n,p}} \right] \frac{e^{-i\phi_{n,1}}}{D_n} \tag{6}$$

where:

$$S_n = \sum_{p=1}^P W_{n,p} \quad ; \quad \Delta\phi_{n,p} = \phi_{n,p} - \phi_{n,1} = k_n (x_p - x_1) \tag{7}$$

$$D_n = S_n^2 - \sum_{p=1}^P W_{n,p} e^{2i\Delta\phi_{n,p}} \sum_{q=1}^P W_{n,q} e^{-2i\Delta\phi_{n,q}} \tag{8}$$

$W_{n,p}$ is a weight coefficient determined for each wave probe and frequency component as introduced by Zelt and Skjelbreia (1992).

If cross modes are present in the flume their influence can be investigated by decomposing the measured Fourier coefficients ($A_{n,p}$) into one part representing the longitudinal waves ($A_{L,n,p}$) and one part representing the cross modes ($A_{C,n}$), which is independent of the probe number.

$$A_{n,p} = A_{L,n,p} + A_{C,n} \tag{9}$$

Equations (5) and (6) can now be rewritten as:

$$a_{L,n} = a_{L,L,n} + A_{C,n} B_n \tag{10}$$

$$a_{R,n} = a_{L,R,n} + A_{C,n} B_n^* \tag{11}$$

where:

$$B_n = \left[S_n \sum_{p=1}^P W_{n,p} e^{i\Delta\phi_{n,p}} - \sum_{p=1}^P W_{n,p} e^{-i\Delta\phi_{n,p}} \sum_{p=1}^P W_{n,p} e^{2i\Delta\phi_{n,p}} \right] \frac{e^{i\phi_{n,1}}}{D_n} \tag{12}$$

and B_n^* is the complex conjugate of B_n , $a_{L,L,n}$ and $a_{L,R,n}$ in Equation (10) and (11)

represent the solution without cross modes, whereas the last terms represent the cross mode contribution, consisting of one part representing the Fourier coefficients ($A_{c,n}$) and one pure geometrical part depending on the probe spacings (B_n and B_n^*).

The influence of the cross modes is not determined by the amplitude only, also the phase of the cross modes affects the incident and reflected Fourier coefficients as it appears from Equations (10) and (11). Due to the fact that B_n appears as the complex conjugate in Equation (11) the presence of cross modes does not affect the determination of the incident and reflected waves equally. Essentially, this means that no constant ratio of the deviations between the estimated incident and reflected wave heights and their true values exists. Furthermore, it is seen that depending on the amount of reflection, the relative deviation of the reflected amplitudes is larger than the relative deviation of the incident amplitudes.

2.2 Numerical Verification of the Influence of Cross Modes

To investigate the influence of cross modes numerically, the cross modal activity has been introduced to the longitudinal wave train by adding a secondary wave train propagating perpendicular to the ordinary direction of wave propagation. This secondary wave train is assumed to have similar spectral properties as the primary wave train but with a different phase spectrum. For regular waves the amount of cross modes in the simulated wave trains is denoted by the ratio of the amplitudes of the cross modes to the amplitude of the incident waves. For irregular waves a JONSWAP spectrum was synthesized and the ratio of the significant cross mode wave height ($H_{m0,c}$) to the incident significant wave height ($H_{m0,i}$) has been used to describe the amount of cross modal activity.

It is of course possible that natural cross modal activity would possess different spectral distributions with the spectral density concentrated at the natural frequencies of the flume. However, it seems reasonable to investigate the case where the noise in each spectral band is proportional to the energy in this band. This was also used by Mansard and Funke (1987).

Analytically, it was shown that the influence of cross modes is affected by the phase of the cross modes, but the significance of the influence has not been shown. For regular waves the influence is illustrated by varying the phase from 0 to 2π . In Figure 2, the relative deviation between the calculated wave height and the simulated wave height is shown as a function of the phase difference between the cross mode and the incident wave ($\Phi_c - \Phi_i$). A positive deviation corresponds to an overestimation of the incident or reflected wave height (H_i and H_R).

The relative deviations shown in Figure 2 are calculated on the basis of 10% and 20% cross modes. The simulated incident wave height is $H_i=0.5$ m, the period is $T=1.86$ s and the reflection coefficient is $C_r=0.25$. The phase of the incident

waves is zero, essentially meaning that the phases in Figure 2 correspond to the phase of the cross mode. However, from Equations (10) and (11) it is seen that the phase of the reflected waves also affects the results. This is also seen in Figure 2 since a constant ratio of -0.25 between the deviations of the incident and reflected wave heights exists when shifting the phase difference approximately $\pi/10$ between the two curves. Of course, the absolute value of this ratio corresponds to the ratio between the theoretical reflected and the incident wave heights.

Figure 2 - Dependency of phase difference ($\Phi_C - \Phi_I$). $H_I=0.50$ m, $H_R=0.125$ m.

It appears from Figure 2 that the relative deviations are strongly dependent on the phase of the cross mode (Φ_C), the phase of the incident wave (Φ_I), and the phase of the reflected wave (Φ_R). For 10% cross modes, the relative deviation of the reflected wave height varies from zero to approximately 25%, whereas the relative deviation of the incident wave height does not exceed 7%.

Equations (10) and (11) explain the fact that the deviation in the determination of the incident and reflected waves is in almost opposite phase because of the appearance of B_n as the complex conjugate in Equation (11). If the deviations should be in exactly opposite phases, it can be seen from Equations (10) and (11) that the cross mode contribution must be zero.

As experienced through the analysis with regular waves, the appearance of cross modes do affect the individual frequency components, which is also seen for irregular waves in Figures 3 and 4, where 25 % cross modes have been introduced. Again, the cross modes affect the determination of the reflected spectrum more significantly than the determination of incident spectrum. However, the deviations are small and they can be reduced by further smoothing of the of the wave spectra.

Thus, the sensitivity to cross modes for irregular waves must be evaluated in terms of the applied smoothing of the spectra. Keeping in mind that the wave heights of the incident and reflected waves are determined as H_{m0} -values, the deviations in Figure 3 do not represent the real picture of the deviations, which is seen from the listed parameters in Figure 3. In case of regular waves it was seen from Figure 2 that if the incident wave height was overestimated, the reflected wave heights was underestimated for most phase differences. For irregular waves the deviations will be the mean value of the curves shown in Figure 2.

**Figure 3 - The influence of cross modes on irregular waves. $DOF=64$.
 Bandwidth=0.156 Hz.**

It is seen from Figure 2* that for irregular waves the incident wave height is underestimated in general (mean value < 0), whereas the reflected wave height is overestimated (mean value > 0). This is also seen from the irregular test shown in Figure 3.

As regards the reflection coefficient spectrum (Figure 4), the presence of cross modes causes a relative deviation of approximately 30% in the vicinity of the peak frequency, that is, a 30% overestimation of the reflection coefficient at the peak frequency. However, as it appears from Figure 4, the reflection coefficient is both overestimated and underestimated (depending on the frequency), which obviously can be reduced by further smoothing of the spectra.

* However, this implies that the cross mode phases, the phases of the incident waves and the phases of the reflected waves are independent and uniformly distributed between 0 and 2π . Normally, this assumption is not fulfilled for "real" waves. For instance, the phases of the incident and the reflected waves are correlated.

Figure 4 - The influence of cross modes on irregular waves. $DOF=64$.
Bandwidth=0.156 Hz.

3 Reflection Analysis with Cross Mode Separation

It has been shown above that the presence of cross modes can cause inaccurate estimations of the incident and reflected waves when using traditional reflection analysis methods. In this section a new method of reflection analysis will be presented, capable of taking the cross modal activity into account and thereby improving the estimation of the incident and reflected waves. First, the mathematical formulation of the reflection analysis with separation of cross modes is developed. Secondly, results from reflection analysis with separation of cross modes based on simulated data are presented. Finally, the result of a flume test carried out at the Hydraulics Laboratory of Aalborg University, Denmark is presented.

3.1 Mathematical Formulation

The cross modes are characterized by an oscillating signal which is the same at all probe locations. Obviously, this implies that the probes are placed on a straight line in the direction of wave propagation. Expanding Equation (2) the new composite wave field at wave probe p can be written as:

$$\eta(x_p, t) = \sum_{n=0}^{N-1} (a_{I,n} e^{-i\phi_{n,p}} + a_{R,n} e^{i\phi_{n,p}} + a_{C,n}) e^{i\omega_n t} \quad (13)$$

where $a_{C,n}$ is the Fourier coefficients of the cross modes.

The measured wave field is still given by Equation (1) and equating the coefficients in Equations (1) and (13) yields:

$$A_{n,p} = a_{I,n} e^{-i\phi_{n,p}} + a_{R,n} e^{i\phi_{n,p}} + a_{C,n} \quad ; \quad p = 1, 2, \dots, P \quad (14)$$

A complex equation for each wave probe with three unknowns (as opposed to two unknowns in Equation (3)), which are the same for all wave probes for each frequency has now been obtained. Therefore, an exact solution to Equation (14) requires at least three wave probes. However, using only three wave probes will cause singularities at certain frequencies, similar to those for two wave probes in the traditional methods (Andersen et al., 1995). For more than three wave probes, Equation (14) is solved by a least squares minimization procedure similar to the one described in Section 2.1 (please refer to Andersen et al. (1995) for further details). The solution is given implicitly by Equation (15).

$$\begin{aligned} a_{I,n} \sum_{p=1}^P W_{n,p} e^{-2i\phi_{n,p}} + a_{R,n} S_n + a_{C,n} \sum_{p=1}^P W_{n,p} e^{-i\phi_{n,p}} &= \sum_{p=1}^P W_{n,p} A_{n,p} e^{-i\phi_{n,p}} \\ a_{I,n} S_n + a_{R,n} \sum_{p=1}^P W_{n,p} e^{2i\phi_{n,p}} + a_{C,n} \sum_{p=1}^P W_{n,p} e^{i\phi_{n,p}} &= \sum_{p=1}^P W_{n,p} A_{n,p} e^{i\phi_{n,p}} \\ a_{I,n} \sum_{p=1}^P W_{n,p} e^{-i\phi_{n,p}} + a_{R,n} \sum_{p=1}^P W_{n,p} e^{i\phi_{n,p}} + a_{C,n} S_n &= \sum_{p=1}^P W_{n,p} A_{n,p} \end{aligned} \quad (15)$$

The explicit solution for the three complex unknowns has not been derived. Because the unknowns are complex numbers, Equation (15) is solved as six linear equations with six unknowns using standard procedures. In the present study the weight function ($W_{n,p}$) introduced by Zelt and Skjelbreia (1992) has been set equal to one (see Andersen et al., 1995).

3.2 Results

In the following the results of reflection analysis with cross mode separation are shown. These results are presented in terms of spectra and wave heights for a simulated irregular composite wave field. The composite wave field is based on the same geometry and spectral characteristics as used in Section 2. Again $H_{m0,I} = 0.50$ m, and $C_r = 0.50$ for all frequencies and finally 25 % cross modes have been added to the signal i.e., $H_{m0,C} = 0.125$ m. The peak period is 1.86 s.

In Figure 5 the incident, the reflected and the cross mode spectra are shown. It is seen that the calculated wave heights correspond to the target parameters within acceptable accuracy.

Figure 5 - Incident, reflected and cross mode spectra. Irregular waves. $DOF=64$, $bandwidth=0.156$ Hz.

Figure 6 - Spectra with and without cross mode separation. $DOF=64$, $bandwidth=0.156$ Hz.

In Figure 6 the spectra from the reflection analysis with cross mode separation and the spectra from the analysis without cross mode separation are shown. It is seen that the incident spectrum determined with cross mode separation has larger spectral densities than the spectrum determined without cross mode separation. Particularly near the peak this is significant. This is also seen from the wave heights where the former corresponds to the simulated while the latter is 3.5 % too small. Regarding the reflected spectra the opposite is seen and the deviations are more significant, since the wave height from the analysis without cross mode separation is 8.8 % too large. These contrasts were explained in connection to Figures 2 and 3. The difference between the two spectra would be even larger if less smoothing of the wave spectra was applied. Therefore, in the case of the presence of cross modal activity the separation of cross modes is important when determining the incident wave train by inverse Fourier transformation because too much smoothing should be avoided. The deviations between the two incident spectra and the two reflected spectra are of course also seen on the reflection coefficient spectra in Figure 7.

Figure 7 - Reflection coefficient spectra with and without cross mode separation.
DOF=64, bandwidth=0.156 Hz.

In Figure 8, the results of a flume test carried out in the Hydraulics Laboratory at Aalborg University, Denmark are shown. The irregular waves had a peak period of 1.00 s, corresponding to the 2nd natural frequency of the flume. It appears that the cross mode spectrum has a significant peak at the 2nd natural frequency of the flume ($f=1.00$ Hz). The two minor peaks (at $f=1.44$ Hz and $f=2.28$ Hz) correspond to the 4th and the 10th eigenmode, respectively. The deviation between the incident and reflected significant wave heights determined with and without cross mode separation is about 2 % in the present case.

Figure 8 - Incident, reflected and cross mode spectra from flume test with irregular waves. $DOF=128$ and $bandwidth=0.31$ Hz for the incident and reflected spectra. $DOF=32$ and $bandwidth=0.078$ Hz for the cross mode spectrum.

4 Conclusions

It has been shown that if the waves measured during a flume test contain cross modal activity, it can lead to an inaccurate determination of the incident and reflected waves if ordinary methods of reflection analysis are applied. For regular waves it was shown that an error of 7 % can occur in the estimation of the incident wave height for 10 % cross modes. It was also found that the error on the reflected wave height was generally higher than the error on the incident wave height. For irregular described by their H_{m0} -value only, the error is of course smaller due to averaging.

To obtain a better estimation of the incident and reflected waves in case of cross modal activity in the flume, a new method was developed. Instead of only assuming a composite wave field composed of the incident and reflected wave components, the new method assumes that the composite wave field also contains a cross mode component. Whereas the traditional methods of reflection analysis requires at least two wave probes in order to separate the incident and reflected wave components, the new method requires at least three wave probes. To avoid singularities and to obtain more reliable solutions it is however recommended to use a least 5 wave probes.

The performance of the new reflection analysis with cross mode separation was tested both numerically and physically. It was shown that the method is capable of

separating the cross mode spectrum and thereby obtain a more accurate determination of the incident and reflected waves.

Acknowledgements

This study was carried out as a part of the authors MSc. Thesis at Aalborg University, Denmark. The use of laboratory equipment and the many useful discussions with staff at the Hydraulics Laboratory at Aalborg University are gratefully acknowledged.

CHAPTER 77

Wave Runup on Beaches

John P. Ahrens¹ and William N. Seelig²

Abstract

Runup on beaches is an important topic in coastal engineering because it defines the upper limit of direct wave influence on land. It is also a phenomenon that has proved very difficult to analyze and characterize in a quantitative manner. The reason for this difficulty is the more general problem of understanding the response of beaches to waves. This paper develops formulas to estimate the approximate upper limit of wave runup on sand and gravel beaches. The relationship between these formulas and recent progress in quantifying beach profile response to waves and the morphodynamics of beaches is discussed. It was found that estimates of wave runup on sand beaches could be improved if sediment sizes in both swash zone and surf zone are known.

Introduction

This paper develops equations to predict the approximate upper limit of wave runup on sand and gravel beaches and shows the connection between runup and beach morphology. Runup on beaches is an important topic in coastal engineering because it defines the limit of direct wave influence on land. Specifically, these concerns relate to beach and dune erosion and coastal flooding.

2) Engineer; Naval Facilities Engineering Command NFESC ECDDET, Washington Navy Yard, Washington DC 20374-5063

Background and Approach

A logical starting point for the analysis of wave runup is Hunt's (1959) formula, i.e.\

$$R/H = C[\tan\theta/\sqrt{(H/L_o)}] = C\xi \quad \text{Eq. 1}$$

where R is the vertical limit of wave uprush above the still water level, H is the incident wave height, L_o is the deep water wave length, $\tan\theta$ is the tangent of the slope of the structure or beach, C is a dimensionless coefficient, ξ is the Iribarron Number (Battjes 1974) and R/H is referred to as relative runup. Hunt found that Eq.1 worked very well for monochromatic breaking wave conditions on plane, smooth slopes. Subsequent research has confirmed the usefulness of Eq.1 for irregular wave conditions and rough slopes (van der Meer and Stam 1992).

Eq. 1 presents some problems for use with beaches. It is not clear if the submerged beach slope that the wave is propagating over or the beach face slope should be used in Eq. 1. The submerged slope presents the additional problem of being dynamic and not being plane, even in an approximate way. To circumvent the problem, beach slope can be treated as a dependent variable and Eq. 1 can be rewritten as:

$$R_2/\sqrt{(H_{so}L_o)} = f(X_1, X_2, \text{etc.}) \quad \text{Eq. 2}$$

where R_2 is the elevation above the still water level exceeded by two percent of the runups and H_{so} is the deep water significant wave height. The left hand side of Eq. 2 is referred to as the runup intensity and the equation indicates that it is a function of one or possibly more variables that act approximately as surrogates for beach slope. Recent research, including this study, suggests some possible simple variables for predicting beach slope, they are:

$$N_o = H_{so}/wT \text{ -----> beach face slope, Kriebel, et al. (1991), and}$$

$$F_o = w/\sqrt{(gH_{so})} \text{ -----> beach slope in surf zone, Dean (1991) and appendix,}$$

where T is a characteristic wave period, g is the acceleration of gravity and w is the sediment fall velocity. H_{so}/wT is a fall speed parameter sometimes referred to as the Dean Number and $w/\sqrt{(gH_{so})}$ is a surf zone Froude-type number, Kraus, et. al (1991). Equations developed in this study are formulated in terms of deep water wave conditions because of the wider range of applicability and utility for users.

The approach sketched out above converges with findings from a very extensive study of beach profiles and beach evolution that show erosion/accretion profiles, bar size, bar depth, and bar movement are all

functions of wave steepness and the fall speed parameter, Larson and Kraus (1989, 1992). There is also convergence with research on beach morphology by Wright and Short (1984). Wright et al. (1985) shows that reflective beaches are associated with small values of the fall speed parameter, dissipative beaches are associated with large values and beaches with a variety of bar and trough configurations are associated with intermediate values. Wright also notes that runup is high on reflective beaches and low on dissipative beaches.

Sources of Data

Data on the height of the berm crest of gravel beaches was collected in the laboratory by van Hijum and Pilarczyk (1982) and Ward and Ahrens (1992). The primary source of the two percent runup was Nielsen and Hanslow (1991), collected on six sand beaches in New South Wales, Australia. Additional two percent runup data was collected on the sand beach at the Field Research Facility of the Corps of Engineers at Duck, North Carolina, Holman (1986) and Douglass (1990).

Analysis and Development of Equations

Swash Zone Fall Speed Parameter

Fig. 1 shows the runup intensity versus fall speed parameter calculated using the fall speed for sediment in the swash zone. The data shown is from the two laboratory studies of gravel beaches, van Hijum and Pilarczyk (1982) and Ward and Ahrens (1992), and the six sand beaches in New South Wales, Nielsen and Hanslow (1991). From a morphological perspective the gravel beaches can be regarded as adsorbitive beaches and the sand beaches fall into the reflective, dissipative, or intermediate categories of Wright and Short (1984). For the gravel beaches the two percent runup has been assumed to be equal to the berm crest height. This assumption is supported by laboratory and field research of Powell (1988), who found the berm crest formed after 3000 waves was overtopped by less than 3% of the waves, with a mean probability of being overtopped of 0.015 ± 0.011 . A data trend curve is shown which is given by the equation

$$R_2/\sqrt{H_{s0}L_0} = 0.27\exp[-0.26(H_{s0}/d)]/(1.0+6.3\exp[-5.6/N_0]) \quad \text{Eq. 3}$$

where, d , is the depth of water at the toe of the gravel beach. The trend curve in Fig. 1 does not fit the gravel beach data well, i.e. $N_0 < 1$, because the figure does not account for the influence of relative wave height which is assumed to be zero, i.e. $H_{s0}/d = 0$, for plotting in Fig. 1.

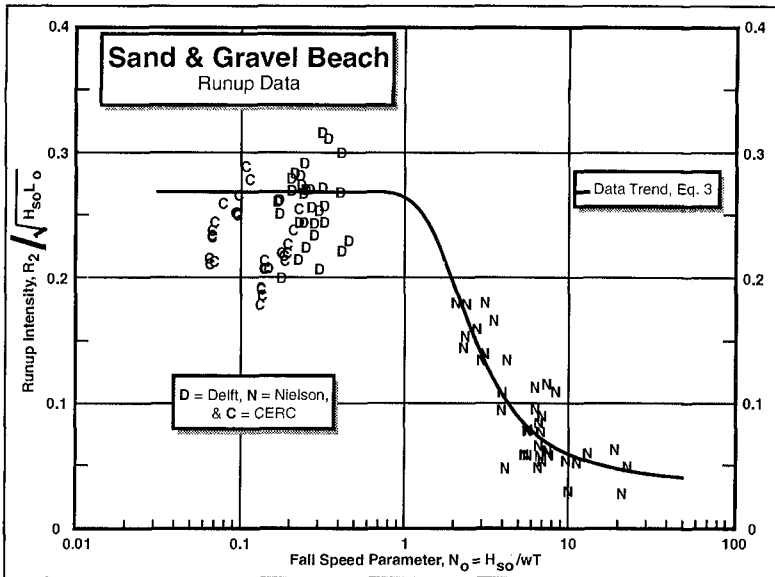

Fig. 1 Runup intensity as a function of the swash zone fall speed parameter, for three studies.

Fig. 2 shows the runup intensity versus the relative wave height for just the gravel beach data. The figure shows that runup intensity decreases as relative wave height increases. This trend is interpreted as being due to the truncation of the wave height distribution in shallow water; it is the larger waves which build and maintain the berm crest. Eq. 3 follows this trend reasonably well, which is more pronounced for CERC data, Ward and Ahrens (1992), because of the relatively shallow water at the toe of the gravel beach in that study as compared to the Delft data, van Hijum and Pilarczyk (1982).

Eq. 3 approaches a limit of 0.27 for runup intensity on gravel beaches which appears logical from Fig. 2, albeit there is considerable data scatter. For dissipative beaches the limiting value of Eq. 3 for runup intensity is 0.037 which seems reasonable from Fig. 1 and is consistent with a limiting value of 0.035 found by Yamamoto, et al. (1994). The analysis based on the swash zone fall speed parameter and relative wave height worked moderately well, but has at least two limitations for sand beaches: 1.) It is not clear what is the meaning of the water depth, d , (possibly the depth over a bar ?) and 2.) The lack of information about the surf zone. In order to predict runup on a sand beach in terms of deep water wave conditions, clearly some information about what is going on between the two locations is required.

Fig. 2 Runup intensity as a function of relative wave height, for gravel beaches.

Surf Zone Froude Number

At the beginning of this study the authors did not know the sediment characteristics in the surf zone of the New South Wales beaches, Nielsen and Hanslow (1991). After receiving this information (Nielsen 1996) the authors realized that information about the surf zone was probably more important for predicting sand beach runup than swash zone data. The gravel beach studies (van Hijum and Pilarczyk 1982, Ward and Ahrens 1992) were collected in the laboratory with fixed beds offshore so no surf zone analysis was conducted with this data.

The surf zone Froude Number, F_o , addresses limitations noted in the above section in using the swash zone fall speed parameter to predict wave runup on sand beaches. Fig. 3 shows there is a surprisingly strong linear relationship between runup intensity and F_o on sand beaches, Nielsen and Hanslow (1991). Regression analysis was used to quantify the data trend shown in Fig. 3, i.e.,

$$R_2 / \sqrt{(H_{s0} L_0)} = 11.6 [w_{sr} / \sqrt{(g H_{s0})}] = 11.6 F_o \quad \text{Eq. 4}$$

As shown in the appendix F_o is proportional to the submerged beach slope in the surf zone. An attempt was made to use the information given in Nielsen and Hanslow to classify beaches using categories proposed by Wright and Short (1984) and shown by symbols in Fig. 3.

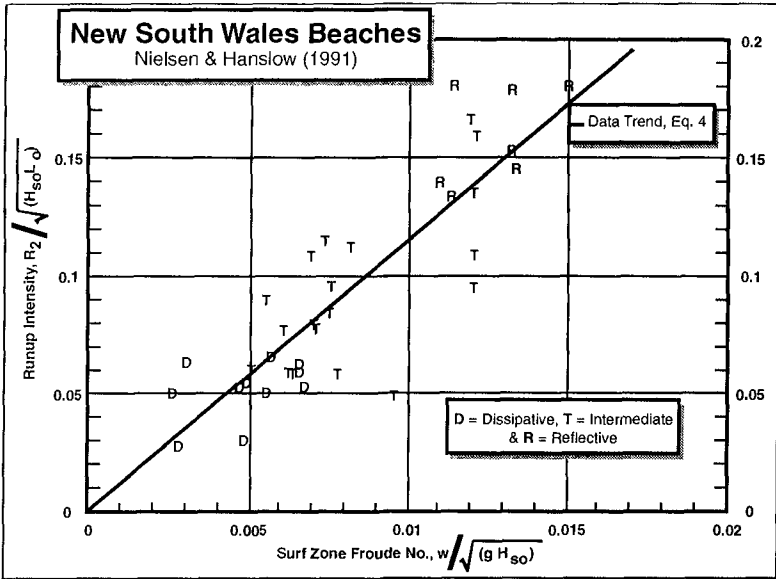

Fig. 3 Runup intensity as a function of surf zone Froude Number, for sand beaches in New South Wales.

Beach Diversity Correction

In examining the New South Wales data (Nielsen and Hanslow 1991) it was observed that there was a tendency for runup intensity to increase with increasing diversity in the sediment sizes on the beach profile. Beach diversity is defined as the ratio of median sediment size in the swash zone, d_{sw} , to median size in the surf zone, d_{sr} . Typically this ratio is greater than one and for the New South Wales beaches it was in the range, $1.0 \leq d_{sw}/d_{sr} \leq 1.6$.

Considering the influence of the surf zone Froude No. and beach diversity on runup intensity, regression analysis was used to help develop the following prediction equation for sand beaches:

$$R_2/\sqrt{(H_{s0}L_0)} = 10.4\sqrt{(d_{sw}/d_{sr})}[w_{sr}/\sqrt{(gH_{s0})}] \tag{Eq. 5}$$

The right hand side of Eq. 5 can be thought of as the $C[\tan\theta]$ terms in Hunt's Eq., Eq. 1, in the sense of a compound slope approach to predicting beach runup. Median diameter of the swash zone is used in Eq. 5 rather than fall speed of the sediment because beach permeability is so strongly dependent on sediment size. Permeability and wave conditions are the most important variables influencing the slope of the beach face. Therefore, the form of Eq. 5 helps identify the physical processes influencing runup even though it may seem anomalous to use sediment size and fall speed in the same equation. Eq. 5 explains 77.3 %

of the variance in the dependent variable compared to 74.6 % for Eq. 4.

For wave runup the value of a prediction method can best be judged by how well it predicts the dimensional runup rather than a dimensionless runup parameter. Fig. 4 shows the predicted two percent runup using Eq. 5 versus the observed two percent runup. Eq. 5 explains about 80% of the variance in the data.

Fig. 4 Predicted two percent runup versus the observed two percent runup for sand beaches in New South Wales.

Thought Experiment

It is useful to use a thought experiment approach to illustrate the implications of Eq. 5. Imagine two beaches both having fine sand in the surf zone but one also having fine sand in the swash zone, i.e. a uniform beach, and the other having coarse sand in the swash zone, i.e. a diverse beach. Consider the response of the two beaches to both mild and storm wave conditions. For the same wave conditions the runup intensity is always greater on the beach with coarse sand in the swash zone. In going from mild to storm wave conditions runup intensity decreases on both beaches because the slope of the surf zone gets flatter or the surf zone gets wider. Interestingly, the difference in runup intensity between the two beaches is less during storm conditions because the increased width of the surf zone has made runup intensity less sensitive to conditions on the beach face, see thought experiment sketch, Fig. 5. The effects noted in the experiment seem consistent with current understanding of runup on beaches.

Fig. 5 Thought experiment figure to illustrate implications of runup equation, Eq. 5.

Duck 1982 Data

During the initial stages of the analysis the runup data from the beach at Duck, N.C. seemed to be anomalously high (Holman 1986 and Douglass 1990). However, after seeing the influence of sediment diversity the Duck data looked more logical. The beach at Duck has sediment with a median diameter of about 0.75mm in the swash zone and about 0.20mm in the surf zone (Mason et al. 1984) for a diversity ratio of 3.75, much higher than any of the New South Wales beaches.

Fig. 6 shows the predicted two percent runup versus the observed two percent runup for the data collected on the beach at Duck, N.C. Some data has been omitted to eliminate bimodal spectra using the approach of Resio (1987). Eq. 5 explains about 51% of the variance in the data.

There is relatively high alongshore variability in runup on the beach at Duck. This is what would be expected based on the morphological categorization of Wright and Short (1984) which puts the beach in intermediated categories that are dominated by a variety of offshore bars and troughs. Normally some of these features are three dimensional. There is one particularly long subset of data from Duck that shows runup variability along 500m of beach for storm wave conditions. For 13 stations the mean two percent runup was 2.163m with

a standard deviation of 0.215m or a mean percent deviation of about 10%. Conditions were unusual for an East Coast storm with $H_{s0} = 2.51\text{m}$ and $T_p = 12.2\text{sec}$. Eq. 5 gives a predicted $R_2 = 2.26\text{m}$ which is somewhat higher than the observed mean value of the two percent runup but well within one standard deviation of the mean.

Fig. 6 Predicted two percent runup versus the observed two percent runup for the sand beach at Duck, N.C.

Surf Zone Fall Speed Parameter and Morphological Connection

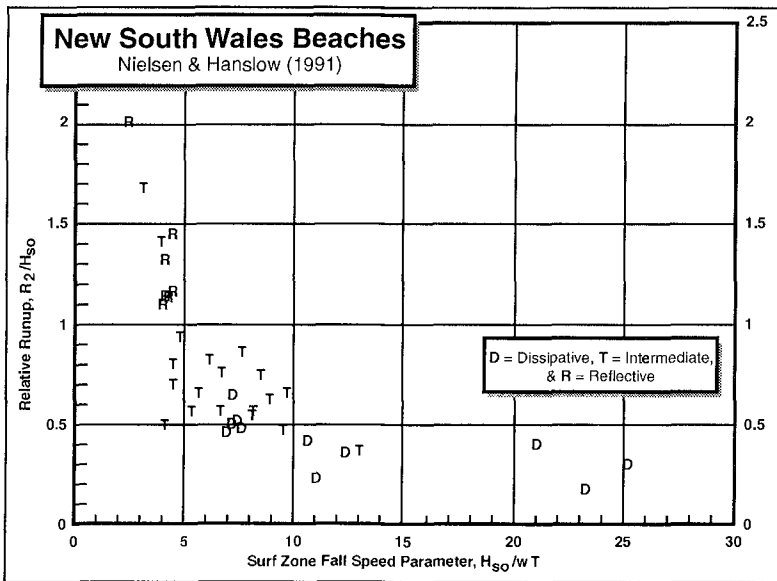

Surprisingly, Eq. 5 can be rewritten in a form which helps suggest the processes involved and using the surf zone fall speed parameter provides a connection to beach morphology, i.e.

$$\begin{aligned}
 R_2/H_{s0} &= C[\tan\theta]/\sqrt{(H_{s0}/L_0)} \\
 &= 10.4\sqrt{(d_{sw}/d_{sr})}[w_{sr}\sqrt{(gH_{s0})}]/\sqrt{(H_{s0}/L_0)} \\
 &\quad \begin{array}{c} <-----> <-----> <-----> \\ \text{swash} & \text{surf} & \text{deep-water} \end{array} \\
 &= \{10.4/\sqrt{(2\pi)}\}\sqrt{(d_{sw}/d_{sr})}/N_0 = 4.1\sqrt{(d_{sw}/d_{sr})}/N_0
 \end{aligned}
 \tag{Eq. 6}$$

The fall speed parameter, N_o , used in the final line of Eq. 6 is similar to the parameter used by Wright and Short (1984) to categorize the morphology of beaches. The difference between the parameters is that Wright and Short used the breaker height while the deep water significant height is used in this study.

Eq. 6 also provides a link to the beach profile study of Kraus, et al. (1991) who found that erosional or accretionary profiles could be predicted using $w_{sr}/\sqrt{(gH_{s0})}$ and H_{s0}/L_0 . Since these two variables can be used to form a surrogate for the surf similarity parameter or Iribarron No., i.e. $\xi \approx 3.4 [w_{sr}/\sqrt{(gH_{s0})}] / \sqrt{(H_{s0}/L_0)} = 1.3/N_o$, they should be able to predict breaker characteristics near the shoreline.

In Fig. 7 the relative runup is shown as a function of the surf zone fall speed parameter, as suggested by Eq. 6. Data points are shown in Fig. 7 using letters to distinguish morphopological conditions of dissipative, reflective, or intermediate beaches as defined by Wright and Short (1984). The figure shows that both relative runup and beach morphology are strongly correlated to the surf zone fall velocity parameter.

Surf Beat and Edge Waves

A variety of oscillations are present in the surf zone at periods greater than the period of incident wind waves. These long waves tend to modulate the conspicuous runup oscillations occurring at approximately the period of wind waves. Trapped edge waves at periods twice the incident wind waves are responsible for cusp formations on reflective beaches, Guza and Inman (1975). As morphological conditions change from reflective to dissipative beaches there is a corresponding attenuation of trapped edge waves and amplification of surf beat. Surf beat periods typically are in the range of one to three minutes.

Summary, Conclusions and Recommendations

Starting with Hunt's (1959) equation and replacing the beach slope with functional relationships, which provide an equivalent compound slope that includes both the slope of the beach in the surf zone and the slope of the beach face, produces an equation, Eq. 6, to calculate the approximate upper limit of runup on a beach. Eq. 6 makes reasonably good estimates of runup for a variety of beach and wave conditions and helps to show the connection between beach morphology and wave runup.

It was found that when estimating runup in terms of deep water wave conditions that the slope of the beach in the surf zone or the width of the surf zone, was generally more important than the slope of the beach face. In Eq.6 the beach face or swash zone characteristics are treated as a correction to the basic runup equation, Eq. 4. This correction is important when there is a big difference between the sediment size in the surf and swash zone.

This research shows that studies of beach morphology and beach runup should be coordinated. Data requirements include, but are not limited to: knowledge of the sediment size across the beach profile, reliable estimates of deep water wave conditions, the three dimensional characteristics of the submerged beach, and the alongshore variation in runup. In addition, a time history of beach states and wave characteristics as discussed by Wright et al. (1985) would almost certainly help make better estimates of beach runup.

Appendix: Slope of Beach in Surf Zone

A standard beach equilibrium profile is given by:

$$h = Ax^{2/3} \text{ or } x = (h/A)^{3/2}, \quad \text{Dean (1991)}$$

therefore the tangent of the submerged slope from the still water line out to some depth, h , is given by $\tan\theta = h/x = A^{3/2}/\sqrt[3]{h}$,

and since $A = 2.25(w_f^2/g)^{1/3}$, good in the range $1.0 \leq w_f \leq 10$ cm/sec. and temperatures around 20°C, Kriebel, Kraus & Larson (1991), then

$$\tan\theta = 3.375w_f/\sqrt[3]{gh},$$

and if h is set equal to H_{s0} as suggested for biplaner slopes or composite slope analysis, de Waal and van der Meer (1992), then

$$\tan\theta = 3.375w_f/\sqrt[3]{gH_{s0}} = 3.375F_o.$$

CHAPTER 78

FIELD STUDY ON WAVE RUN-UP ON SEADYKES

Joachim Grüne ¹

Abstract

This paper deals with a comprehensive field research program on wave run-up, which is ongoing at different locations at the landside borders of the wadden sea (tidal flats) and the tidal estuaries of the German Bight since 1991. The field measurement equipment is described and an overview about first results is given.

Introduction

Due to the increasing of storm surges and the supposed long-term rising of water levels at the coastlines of the North Sea, for safety analysis of existing dykes in field a more exact knowledge is needed on wave run-up and overtopping process, especially with respect to non-uniform dyke cross-sections and to real sea state conditions. Air entrainment and wave climate characteristics under real sea state conditions play an important role on wave run-up process. Thus boundary effects and scale effects have to be minimized by using field data or large scale laboratory test data.

Field measuring program and equipment

The ongoing research program is focussed on the influence not only of real sea state wave climate but also of complex non-uniform dyke cross-sections on wave run-up. The investigations have been doing for recent years at four different locations at the coast of Dithmarschen and at the Elbe river estuary (Fig. 1) in cooperation with the Regional State Board for Water Management (ALW Heide, supervision Dipl.-Ing. J. Gärtner) of the State of Schleswig-Holstein. At two locations (Heringsand and Stinteck) the measurements have started in 1991,

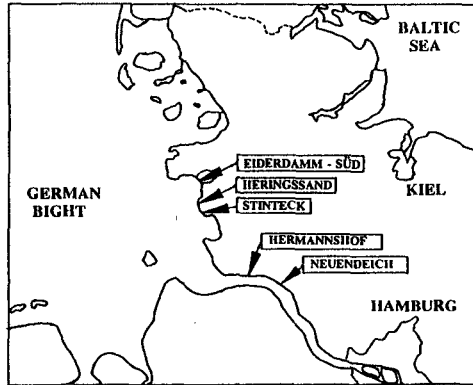

Fig. 1 Measuring locations at German Bight

at the two other locations in 1993. At another location (Eiderdamm-Süd) measurements already had been done during previous programs (Grüne, 1982).

Each of these locations represents one specific type with respect as well to different characteristics of morphologic boundary conditions, which generally occur in wadden seas and estuaries as to different existing non-uniform types of dyke cross-sections. Fig. 2 shows a scheme of the installed sensors at each location. The incoming wave climate has been measuring with a pressure cell for evaluation of surface elevation and with a two-component velocity meter for evaluation of the wave approach direction at the outermost seawards position. At two locations additional pressure cells were installed between the outermost position and the dyke. The wave run-up has been measured with a 70-step gauge. The aim of the program is to generalize all the measured relations between wave climate (in dependence of the morphologic boundary conditions) and wave run-up (in dependence of dyke cross-sections). The generalized results shall be used for safety analysis with extrapolated storm surge level conditions.

At the locations Heringsand and Stinteck (Fig. 3) occur a distinct wadden sea wave climate. At Heringsand location there are less wave energy parts dissipating from the closedby tidal gully compared to Stinteck. Furthermore at Heringsand the wave climate in front of the dyke is strongly influenced by the wave damping effect of the higher green foreland, which has a mean level of NN + 2.0 m and a width of roughly 500 m.

Fig. 2 Scheme of installed sensors at each location.

Fig. 3 Measuring locations Heringsand and Stinteck

The cross-section of the dyke at Heringsand is plotted in Fig. 4. Due to the relatively less intensive wave climate the dyke surface is covered totally with grass on clay and has a relatively gentle slope of roughly 1:10 in the lower part. In all cross-sections in Fig. 4 the dotted lines give the geodetic reference level (Normalnull). The upper waterlevels are the highest ones ever been recorded (HHThw), the lower ones are the Mean High Tide levels (MThw) and the water levels between HHThw and MThw are the highest ones, used for measurements within this program till today. The supports of the installed run-up step gauges (which are described in detail by Grüne, 1982) are marked with a solid line parallel on the dyke surface. The 70 steps of the gauge have different distances between each other in dependence of the slope. But all steps are calibrated in such way, that the signal is linear to the vertical component of the watertongue running up and down on dyke surface.

Fig. 4 Cross - sections of the dykes used for field measurements

The Mean High Tide level MThw at Heringsand lies roughly 0.5 m below the green foreland. Wave climate at Heringsand is measuring at three positions: 1040 m, 470 m and 50 m in front of the dykefoot. The vertical distances of the 70 run-up steps at Heringsand vary from 5 cm on the lower gentle slope to 12 cm on the higher steeper slope.

The dyke at Stinteck location has a berm made with natural stones, which are placed irregular (marked in Fig. 4 with a dotted line under the dyke surface). The top of the berm partly is covered with smooth artificial concrete stones and is used as a working road (marked with a solid line under the surface). This area also has an inner slope partly, which creates an extended water basin for water levels around the berm top level. The dyke surface above this area is covered with grass. The wave climate is measuring 700 m and 50 m in front of the dykefoot. The run-up steps have vertical distances from 4 cm on the lower gentle slope to 12 cm on the higher steeper slope. An impression of waves acting on the dyke at Stinteck is given in Fig. 7. The photo was taken during a stormsurge with a water level roughly 2.0 m above Mean High Tide, where all waves break on top of the berm.

The wave climate at the locations Hermannshof (Fig. 5) and Neuendeich (Fig. 6) are influenced as well by the deepwater conditions in the Elbe river estuary as by the restricted depths due to flats in front of the dykes. But these flats only have a width of roughly 200 meters at Hermannshof and of roughly 400 meters at Neuendeich, respectively.

The berm of the dyke at Hermannshof (Fig. 4) is covered in the same way as at Stinteck with stones up to the top, but the top of the berm is smaller and has an outer slope, which is covered with asphalt concrete. The grass covered surface above the berm has a nearly uniform slope. Wave climate at Hermannshof only is measuring 50 m in front of the dyke. The vertical distances of the 70 run-up steps vary from 5 cm at the lower levels up to 9 cm at the higher levels.

Fig. 5 Measuring location Hermannshof

Fig. 6 Measuring location Neuendeich

Fig. 7 Waves acting on the dyke at Stintek location during a storm surge

The dyke profile at Neuendeich (Fig. 4) has an extended berm. The outer steep berm slope is covered with artificial smooth concrete stones (in Fig. 4 marked with a solid line under surface). The surface on the berm and on the higher steep slope is covered with grass. Wave climate is measuring also only at the positions 50 m in front of the dykefoot. The run-up steps have vertical distances between 3 cm on the lower gentle slopes and 11 cm on the higher steeper slope.

At all locations the sensors are connected by cables with a computer-controlled recording system in a shelter box at the backside of the dykes. Data recording is starting automatically in dependance of desired storm surge waterlevels (usually 1.5 m above MThw).

Data analysing

The wave parameters of the surface elevation were evaluated from the recorded pressure signals. Linear theory was used for transformation, modified with correctionfactors. These factors depend on relative depth of sensor and were found from laboratory and field experiments. Analysis has been done in time domain (modified Zerodowncrossing method) and in frequency domain.

Analyzing run-up records from field can be rather complicate, because characteristics of run-up signals may be strongly influenced by two main effects:

- Firstly by the physical breaking process on gentle slopes and on berms.
- Secondly by the kind of gauge with a relatively long distance on the slope between the steps for gentle slopes.

The first effect can be demonstrated in Fig. 8, where in the lefthand plot a short time history is given as an example of synchronous signals of waves and run - ups, recorded at Stinteck location. One won't find any direct linkage between both signals, as one may expect it from the literature according to small scale model tests with regular or irregular PM-spectra waves on uniform steep slopes. This effect comes out clearly, if one look on the cross-section in Fig. 4 with the extremely broad berm and on Fig. 7, where one can see the waves breaking in front of or on the berm, which create reduced and longperioded run-ups after passing the distance to the upper dyke surface. Furthermore the run-downs mostly stay above stillwaterlevel, which is a typical result of gentle slopes.

With other boundary conditions the run-up records may have other characteristics. Such an example from Neuendeich location is given in the righthand plot of Fig. 8 with same time scale as in lefthand plot. Due to a very high water level for these data the waves break mainly at the higher steep slope. Thus these run-ups are neighter affected by breaking of waves before they reach the dyke surface nor by breaking on gentle slopes. In the timeexpanded part of the righthand plot the different linkage behaviour between the run-up signals from these both locations comes out evident.

Fig. 8 Time histories of synchronously measured waves and run-ups

The second effect, mentioned before is caused by the kind of gauge. A step gauge on gentle slopes necessarily has long distances between the single steps. Together with longperioded and damped run-ups thus leads to signals, which are shown schematically in Fig. 9. Such signals may be processed with step identification and smoothing modes.

Fig. 9
Scheme of signals
from a step gauge

Furthermore a definition mode far from the zerocrossing mode is necessary, due to the fact, that the run-down mostly stay above stillwaterlevel. An overview about the definitions and analysing modes used in this paper for the run-ups R_u , run-downs R_d (R_{dR} is used) and periods T_R is given in Fig. 10. The mode for separating single run-up events from a sequence is shown schematically in Fig. 11. Separated run-ups were analyzed, if the relation a/b don't exceed the threshold value G within a certain time window. The used treshold value is in the order of magnitude of 10 to 20. As conclusion it must be stated that run-up records from field measurements have to be analysed very carefully and seriously.

Fig. 10 Definition of run-up and run-down parameters

Fig. 11 Mode for separating of single run-up events

First results

Data were recorded during strong wind and storm surge conditions. A part of the data were measured at the different locations during same storm surge events. A comparison of the first data from all different types of cross-sections show distinct differences, which are both influenced by the different wave climates and by the different shapes of cross-sections. Due to restricted space in this paper only an overview of some first results can be given. More detailed results will be published in following papers.

The maximum run-up and run-down values, measured at all four locations, are shown in Fig. 12. The values are added on the stillwaterlevel *SWL* and are plotted versus the stillwaterlevel *SWL*, which is referred to geodetic level Normal Null. The full line represents the stillwaterlevel, the dotted line shows the geodetic level of the lowest step of the run-up gauge. Obvious are the small run-down values (except for higher waterlevels at Neuendeich), mostly around the stillwaterlevel, which is caused by the gentle slopes mainly, as already mentioned before.

In Fig. 13 the run-ups R_{98u} and run-down R_{98d} are related to significant waveheights $H_{1/3}$ and are again plotted versus the stillwaterlevel *SWL*. No run-up data are presented for Hermannshof location, because a part of those were measured without recording wave climate due to sensor defects. The data from Heringssand and Neuendeich have a trend of higher values for smaller waterdepths. This is contrary to that, which could be expected, but has simple reasons, which will be explained later.

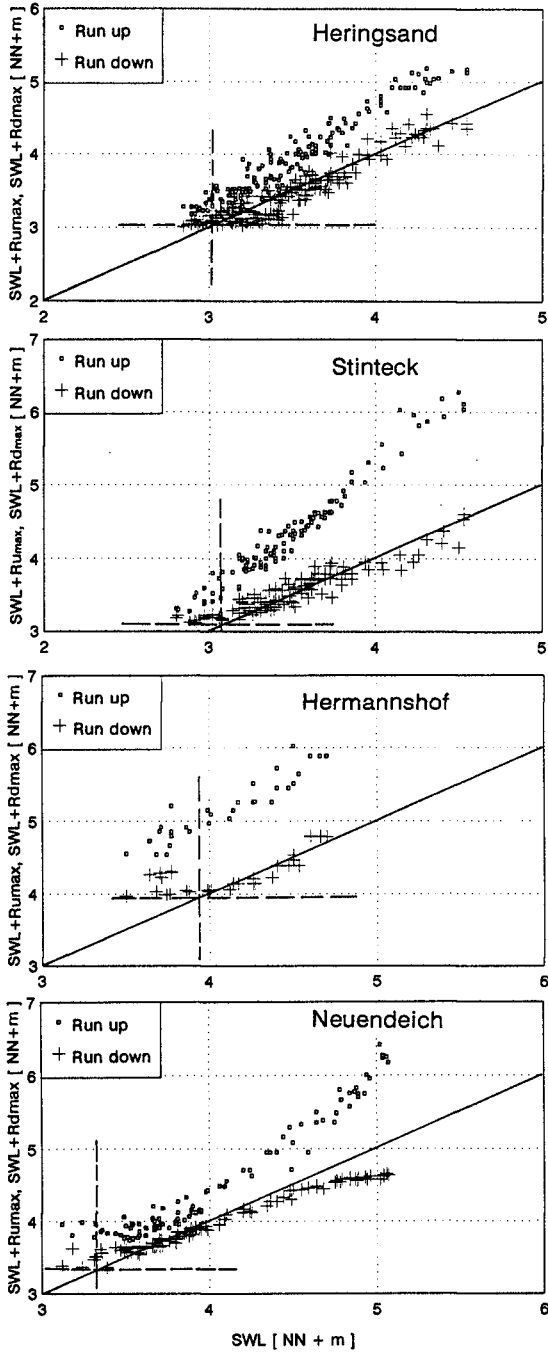

Fig. 12 Maximum run-up and run-down levels versus stillwaterlevels

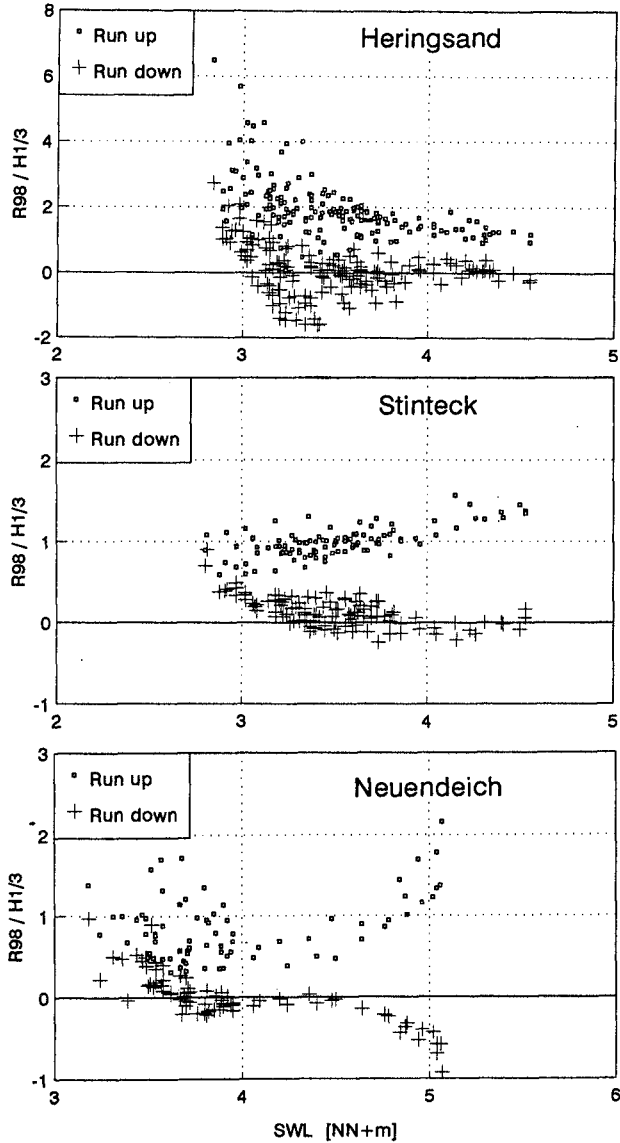

Fig. 13 $R_{98} / H_{1/3}$ versus stillwaterlevel SWL

Similar confusions come out from Fig. 14, where the relations between the mean wave periods T_{Hm} and the mean run-up periods T_{Rm} are plotted versus the stillwaterlevel SWL . Considerable differences are obvious between the different locations. Whereas at Heringsand location with higher stillwaterlevels above $NN + 4.0$ m only 20% of the waves create a run-up, at Stinteck there are 40% and at Neuendeich up to 100% of the waves, which create a run-up.

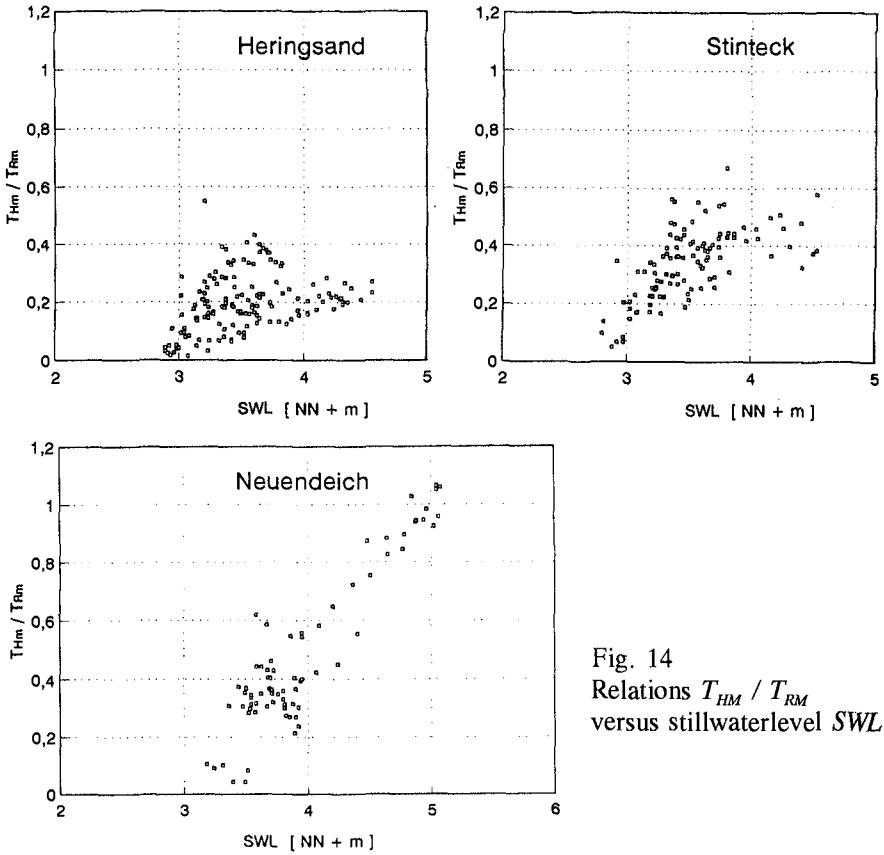

Fig. 14
Relations T_{HM} / T_{RM}
versus stillwaterlevel SWL

Other results with confusing different trends for the different locations occur for other parameters and relations, as shown in Fig. 15, where all data $R_{98} / H_{1/3}$ are plotted versus the breakerindices ξ . But all these trends can be explained by the different boundary conditions at the different locations. The boundary conditions also are changing in dependence of the stillwaterlevel SWL . One example is the occurrence of relatively high values $R_{98} / H_{1/3}$ up to 6 at Heringsand (upper plot in Fig. 15). From detailed analysis it was found, that the relative higher run-ups are created by longperioded parts of the surface elevations, which are eliminated for wave analysis, but have amplitudes up to roughly 0.3 m.

Another example can be demonstrated by the results, found for Neuendeich location and plotted in the lower parts of Figs. 13 and 15. In both plots one can distinguish the data into two groups, each with a more or less distinct trend. In Fig. 16 the appertaining mean waterdepths on the berm $d_{BE} / H_{1/3}$ (related to $H_{1/3}$) of these data are plotted versus stillwater level SWL and breakerindex ξ , respectively. From this figure and comparison with Figs. 13 and 15 the separation comes

Fig. 15 $R_{98} / H_{1/3}$ versus breakerindex ξ

Fig. 16 $d_{BE} / H_{1/3}$ versus SWL (lefthand) and breakerindex ξ (righthand)

Fig. 17 $R_{98} / H_{1/3}$ versus $d_{BE} / H_{1/3}$

out clearly: one group with waterlevels below and one group with such above mean berm level. It can be stated that $R_{98} / H_{1/3}$ increase with increasing distance $d_{BE} / H_{1/3}$ as well for SWL below as for SWL above the mean berm level, which is shown distinctly in Fig. 17. The data in this plot confirm the well-known effect, that run-up reduction is most effective for waterlevels around the berm level.

Conclusion

Analyzing of run-up measured in field and on complex cross-sections can be complicate, therefore the analysis has to be done very carefully and seriously. All the different influences have to be separated and quantified in detail.

CHAPTER 79

WAVE RUN-UP ON REVETMENTS WITH COMPOSITE SLOPES

Zeya Wang¹ and Joachim Grüne²

Abstract

The paper deals with wave run-up on revetments and seadykes with composite slopes. The presented data were obtained from large scale laboratory tests with different wave climate characteristics in the " Large Wave Channel " (GWK) at Hannover, Germany. The results are discussed with respect to slope angle transformation mode to be used in the well-known HUNT-formula.

Introduction

Safety analysis of existing coastal protection works becomes again more important due to the world wide increasing of storm surges and the supposed long-term rising of water levels at the coastlines. Within such a safety analysis wave run-up and overtopping is the most important load factor.

Previous investigations on wave run-up have shown different results using different verifications of formulae to fit the boundary conditions with complex cross-sections and with real sea state wave conditions. Thus a research program has been established, which is focussed on the effects of non-uniform cross-sections and of real sea state wave characteristics. A part of this research program deals with cross-sections, which are composed from different uniform slopes. Results from investigations on run-up with such composed cross-sections are presented in the following.

¹ M.-Ing., Researcher,

² Dipl.-Ing., Senior researcher, Operation Manager of Joint Central Institution " Coastal Research Center (FZK) " of University Hannover and of Technical University Braunschweig, GWK, Merkurstrasse 11, 30419 Hannover, Germany

The most convenient formula for calculating wave run-up on gentle smooth slopes like seadykes and revetments normally have, is the well-known one derived by HUNT (1959). Although originally derived for regular waves on a uniform slope the tendency of the HUNT-formula also agrees quite well with irregular data.

Usually the HUNT-formula is written in dependence of the breakerindex ξ in the following form:

$$R / H = C_{\xi} \cdot \xi, \quad \text{with} \quad \xi = \frac{\tan \alpha}{\sqrt{\frac{2\pi H}{g \cdot T^2}}}$$

and with R = run-up
 C = coefficient
 H = waveheight
 T = wave period
 α = slope angle ($\tan \alpha = 1 : N$, with N = slope value)

For using this formula in a savety analysis of dykes and revetments in field this general form has to be verified as well with respect to the irregular waveheight and wave period parameters of the real sea state conditions (see BATTJES, 1974) as with respect to the non-uniformly sloped seadyke cross-sections, which mostly occur in prototype. These verifications lead to different values C_{ξ} in dependence of used irregular wave parameters and/or the mode of slope angle α transformation for non-uniform cross-sections. In a lot of previous papers such verifications of the HUNT-formula have been reported, among them a few with data from field and/or from large scale laboratory tests. For example are those from GRÜNE (1982), FÜHRBÖTER et. al. (1989), SPARBOOM et. al. (1990), v. d. MEER & STAM (1992), d. WAAL & v. d. MEER (1992), WANG & GRÜNE (1995). The results shown in this paper will be discussed mainly with respect to the mode of slope angle transformation for composed slopes.

Only a few suggestions exist for slope angle α transformation approaches for slopes of composed cross-sections. SAVILLE (1958) proposed an equivalent gradient method, where the equivalent slope is defined by the linear interpolation between the breakerpoint and the maximum wave run-up on the non-uniform slope. But this mode is not necessarily representative for all types of non-uniform slopes, the method was not tested by SAVILLE (1958) with measurements on convex slopes. Some field data for composite slopes (1:4 and 1:6) have been reported by GRÜNE (1982), who found that the influence of slopes occur roughly in the range between $1.0 H_{1/3}$ below and $2.0 H_{1/3}$ above stillwaterlevel. A similar suggestion for an average slope was given by d. WAAL & v. d. MEER (1992) with a linear interpolation between the points $1.0 H_{1/3}$ below and $1.0 H_{1/3}$ above stillwaterlevel on the dyke surface.

Test equipment

The data, presented in this paper, are from large scale laboratory tests, which have been done in the Large Wave Channel (GWK) at Hannover (GRÜNE & FÜHRBÖTER, 1976). The GWK is a facility of the recently founded Coastal Research Center "Forschungszentrum Küste (FZK)", which is a joint institution both of the University Hannover and the Technical University Braunschweig.

The cross-sections of the revetment used for the tests in the GWK are shown in Fig. 1. It has a sand core and is covered with asphalt-concrete. The composed slope consist of two different uniform slopes: a slope of 1:6 in the upper part and a slope of 1:3 in the lower part. The lower slope 1:3 was varied twice: for one testseries the slope junction level of both uniform slopes was 3.3 m above bottom, for the other testseries the slope junction level was 4.5 m above bottom.

Wave run-up was measured with a run-up step gauge (GRÜNE, 1982), which was installed on the upper slope 1:6 for the testseries with the slope junction level 3.3 m above bottom and on both slopes for the other testseries. The steps of the run-up gauge had vertical distances of 6.5 cm on the slope 1:6. The waves in front of the revetment were measured with some wire gauges. The wire gauges had roughly constant distances between each other and reflexion effects had been minimized by using the data of four of these gauges. The analog signals from waves gauges and run-up step gauge were continuously digitized with 100 Hz and stored by the main processing computer.

Fig. 1 : Cross-section of the revetment used for large scale tests in the GWK

All tests were conducted with two different water levels (4.0 m and 5.0 m above bottom), this results in altogether four different testseries with respect to the vertical distance D_c between still water level SWL and slope junction level ($D_c = 1.7$ m, 0.7 m, 0.5 m and - 0.5 m). Three different types of wave characteristics were generated: Regular waves, PM - spectra (narrow banded) and field spectra (wide banded). The generated field spectra had been measured in front of similar dyke cross-sections at the german coast during high storm surges. For each testseries roughly 15 single tests with each of these three different wave climate types were run. Fig. 2 gives an impression of wave acting on the revetment during a large scale test in the GWK.

Fig. 2 : Wave action on the revetment during a test in the GWK

Results

The results presented in this paper will be focussed on the approach of slope angle transformation with respect to HUNT-formula. All data are referred to the mean period T_m from the time domain analysis. In a previous report on the results from the tests with the berm (WANG, GRÜNE, 1995), it was demonstrated, that the correlation using T_m is quite better than using the peak period T_p . This is due to the fact, that the estimation of a peak period from the spectral density distribution of real sea state shallow water waves is of problematic nature and can create confusion.

The first results to be discussed are from the testseries with regular waves, where the still water level *SWL* was 1.7 m above, 0.5 m above and 0.5 m below the junction level of the two slopes ($D_c = +1.7$ m, $+0.5$ m, and -0.5 m).

The measured run-up data R_{98} are related to the mean regular wave height and are plotted in Fig. 4 versus the breakerindex ξ , which is related to three different slopes separately (slopes of upper part of 1:6, lower part of 1:3 and average slope $1:N_{av}$). The average slope N_{av} has been evaluated according to the mode, given by d. WAAL & v. d. MEER (1992), and is defined in Fig. 3 (left hand). It is clear that due to the mode the data for N_{av} with $D_c = +1.7$ m (waterdepth of 1.7 m above junction level) are identical with those of the upper slope 1:6. This means, that the lower slope 1:3 has more or less no influence.

It must be remarked, that the average slope approach by de WAAL and v. d. MEER was evaluated for irregular waves, but there is no functional difference for regular waves. On the other hand, because the HUNT formula was originally evaluated from regular wave run-up data, thus fundamental trends may be demonstrated firstly with regular wave run-up data.

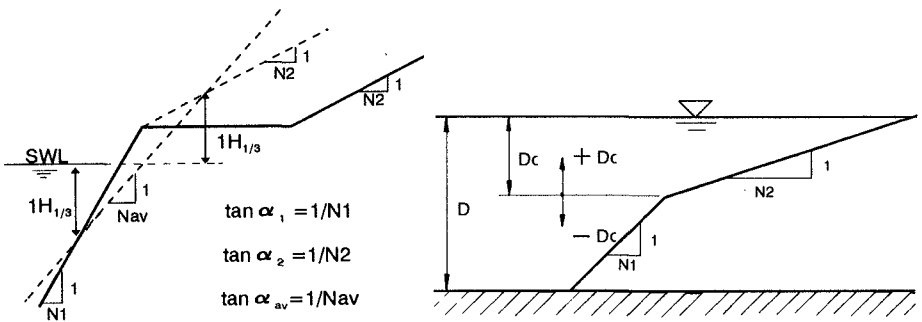

Fig. 3 : Definition of average slope N_{av} by de WAAL and v. d. MEER (left hand) and Definition of slope junction D_c (right hand)

In the middle plot of Fig. 4 the data with $D_c = +0.5$ m (SWL only 0.5 m above the junction level) show similar trends and only small differences between the average slope N_{av} related data and those for the uniform upper slope 1:6, which means, that the lower slope 1:3 has only a small influence. Greater differences occur for the data with $D_c = -0.5$ m (SWL 0.5 m below the junction level). The average slope data agree much more to the 1:3 slope, but they all are far away from a linear dependence with identical gradients.

A new mode for slope angle transformation of two composed uniform slopes is based on the rather old approach, derived by DROGOSZ-WAWRZY尼亚K (1965) as follows with the definitions shown in Fig. 3 (right hand):

$$\frac{1}{N} = \frac{1}{N_1} + 2 \cdot \frac{D_c}{L_o} * \left(\frac{1}{N_2} - \frac{1}{N_1} \right)$$

This formula was modified by the authors in the following manner: the original factor $2 * D_c / L_o$, which is a function of position of junction level D_c and

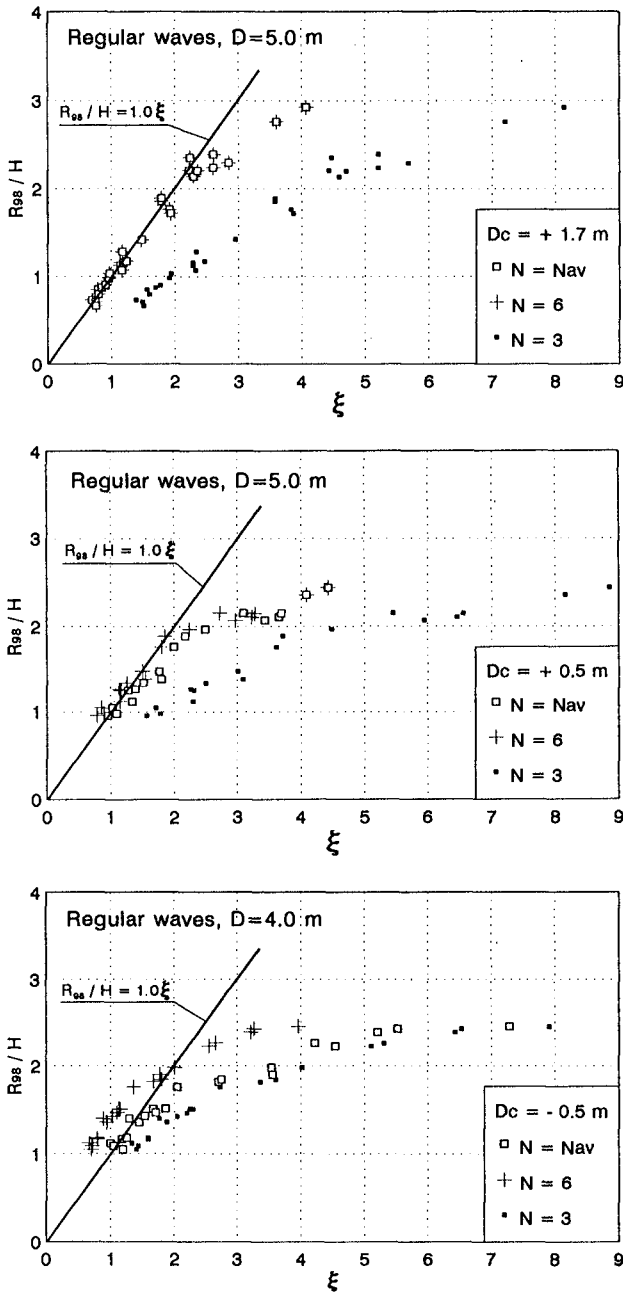

Fig. 4 : R_{98}/H versus breakerindex ξ for tests with regular waves

wavelength L_o , has been extended, so that the new factor is a function of the dyke geometry in terms of the depth related position of junction level D_c / D and the deepwater wave steepness H / L_o or the wave period, respectively. Compared to the average slope approach of d. WAAL and v. d. MEER, this slope approach has been extended by the wave period:

$$2 * \frac{D_c}{L_o} \Rightarrow f \left(\frac{D_c}{D}, \frac{H}{L_o} \right)$$

Thus the modified formula is written:

$$\frac{1}{N_{su}} = \frac{1}{N_2} + f \left(\frac{D_c}{D}, \frac{H}{L_o} \right) * \left(\frac{1}{N_1} - \frac{1}{N_2} \right)$$

with the following factors
for regular wave climate:

$$f \left(\frac{D_c}{D}, \frac{H}{L_o} \right) = \left(\frac{1}{2} - \frac{D_c}{D} \right) * \left(7 * \left(\frac{H}{L_o} \right)^{0.1} - 4.43 - \frac{D_c}{D} \right)$$

for irregular wave climate:

$$f \left(\frac{D_c}{D}, \frac{H_{1/3}}{L_o} \right) = 2 * e^{-\frac{D_c}{D}} * \left(3 * \left(\frac{H_{1/3}}{L_o} \right)^{0.2} - 1 \right)$$

with D_c = distance between stillwaterlevel and junction level
 D = waterdepth
 H = waveheight
 L_o = deepwater wave length = $g * T_m^2 / 2\pi$

The high accuracy of this slope angle transformation may be demonstrated in the best way by the plots in Fig. 5, where the results for waveheight related run-up data are plotted versus the deepwater steepnesses H / L_o for the testseries with regular waves and $D_c = +0.5$ m (upper plot) and $D_c = -0.5$ m (lower plot). The full line in Fig. 5 represents the HUNT-formula, using the new approach for slope angle transformation with $1:N = 1:N_{su}$. It is obvious, that the differences to the measured values are rather small. The two dotted straight lines, marked with $N = 3$ and $N = 6$, represents the original HUNT-formula, using one of the uniform slopes $N = 3$ or $N = 6$ respectively. If one of these slope angle approaches would be correct, all measured data should fit one of these dotted lines. The irregular dotted line, marked with $N = N_{av}$, which lies between the two others straight ones, represents the HUNT-formula, using the average slope N_{av} according to de WAAL & v. d. MEER. Whereas the agreement for higher wave steepnesses is quite well, there are considerable differences for lower steepnesses.

The accuracy of the new slope angle transformation also comes out clearly in Fig. 6, where the measured data are plotted versus the breakerindex ξ . The upper plot again is for the data with $D_c = +0.5$ m and the lower plot for the data with $D_c = -0.5$ m. It must be stated, that the measured data agree quite well with

Fig. 5 : R_{98} / H versus steepness H / L_0 for tests with regular waves

the HUNT-formula with the new mode of slope angle transformation, especially no range with a constant value has to be defined as it is necessary with previous slope angle transformation modes.

Similar relations were found for the data from the testseries with PM-spectra and field spectra, using the slope angle transformation mode $N = N_{su}$ in the HUNT-formula. The measured run-up data $R_{98} / H_{1/3}$ from the testseries with PM-spectra are plotted versus the significant waveheight related deepwater steepnesses $H_{1/3} / L_0$ in Fig. 7 for the testseries with $D_c = +0.5 \text{ m}$ and with $D_c = -0.5 \text{ m}$. The notations for N are the same as used in Fig. 5.

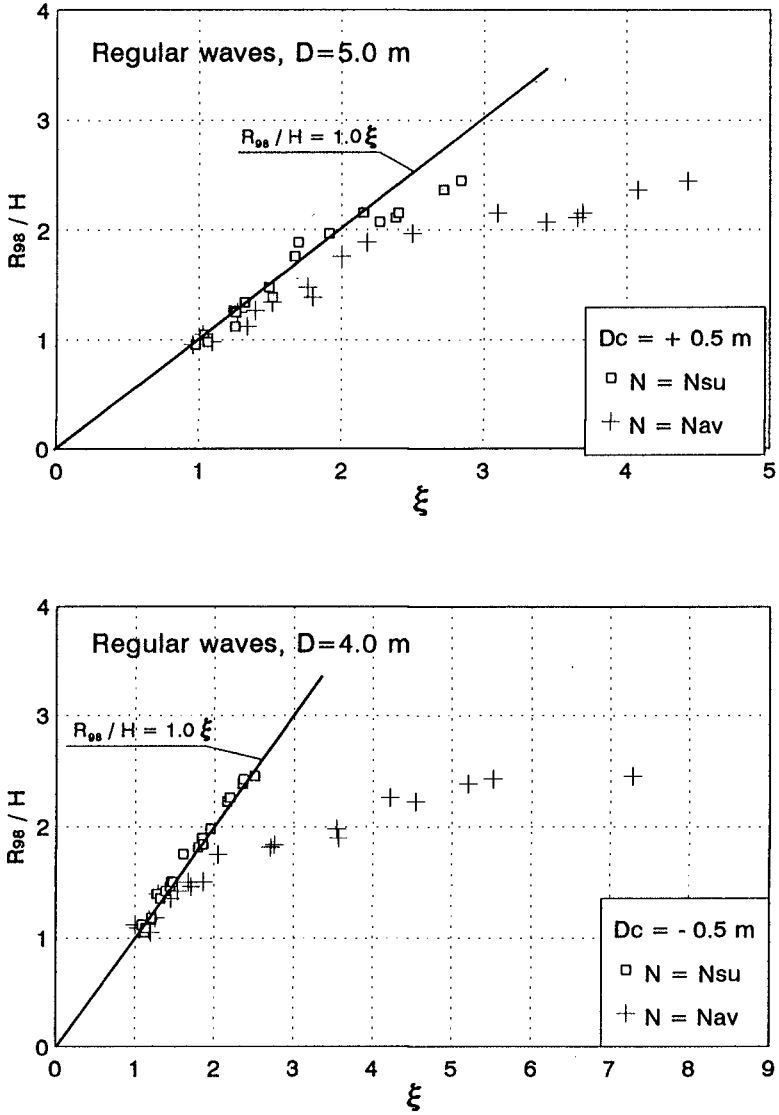

Fig. 6 : R_{98} / H versus breakerindex ξ for tests with regular waves

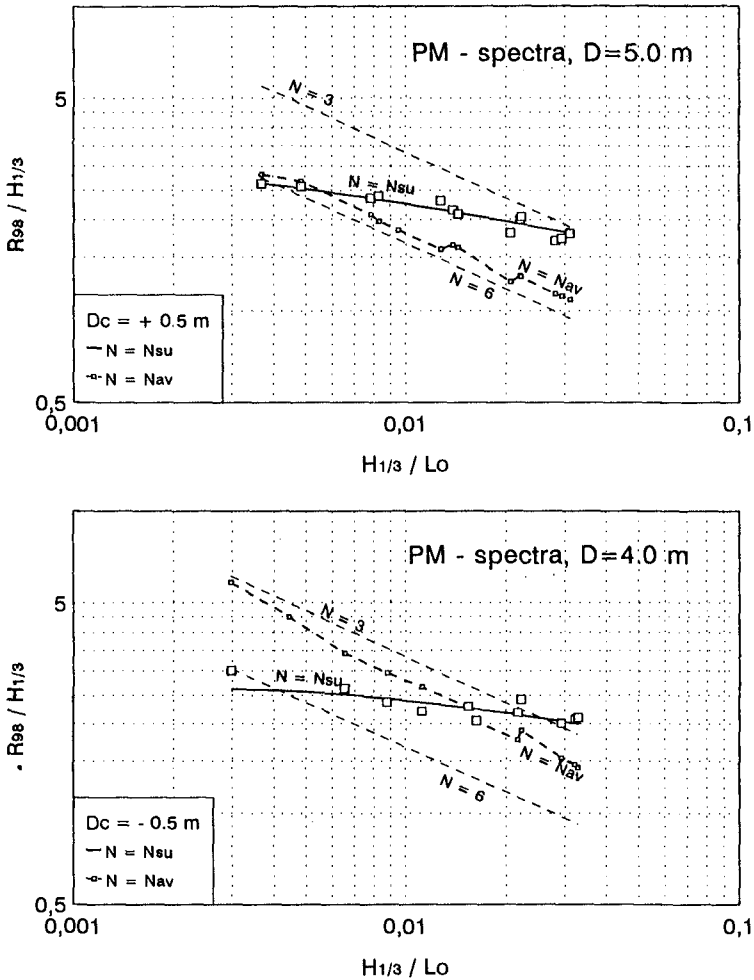

Fig. 7 : $R_{98} / H_{1/3}$ versus steepness $H_{1/3} / L_0$ for tests with PM-spectra

The data from the testseries with field spectra in Fig. 8 indicate similar relations, but they have a much smaller range of deepwater steepnesses, which is normal for a wadden sea wave climate.

The same data from Fig. 7 and 8 are plotted versus the breakerindex ξ in Fig. 9 (PM-spectra) and 10 (field spectra), respectively. As well as for tests with regular waves the linear correlation of the test data with irregular waves is much stronger (PM- and field spectra), using the new slope approach $N = N_{su}$, in comparison with using the average slope approach. The field spectra in Fig. 10 data scatter a little bit more, but without any distinct trend.

Fig. 8 : $R_{98} / H_{1/3}$ versus steepness $H_{1/3} / L_0$ for tests with field-spectra

Conclusion

The HUNT-formula has been verified with respect to slope angle transformation. Data from large scale laboratory tests with regular waves and irregular waves (PM-spectra and field spectra) were used. The wave run-up data on revetments with composite slopes are well presented with the HUNT-formula, using a new slope angle transformation, which takes not only the depth related position of junction point D_c / D but also the wave steepnesses H / L_0 into account.

CHAPTER 80

Landward Transport of Spray Generated from a Wave Absorbing Sea Wall

Misao Hashida¹, Nobuhiro Matsunaga² and Isao Irie³

Abstract

A landward transport process of spray generated from a wave absorbing sea wall under a strong wind has been investigated experimentally. Near the wall, the concentration of spray decays exponentially both in the leeward direction and in the upward direction. The profiles are determined by the equilibrium between the advection of spray and the sedimentation. The characteristic quantities on the profiles have been related to the experimental parameters.

1. Introduction

Extending from August to October every year, Japan often suffers severe damages due to typhoons. In winter, a strong seasonal wind from the northwest blows against coastal areas fronting the Japan Sea. Moreover, Japanese coastal line is exposed to the danger of tsunami disasters because Japanese Archipelago is one of the world's most seismologically active areas. Therefore, most of Japanese coastal engineers and researchers have devoted their energies to the prevention against the coastal disasters due to big waves, storm surges, tsunamis and so on. Various types of wave absorbing works have been developed to protect the coastal areas and have made remarkable achievements.

1 Professor, Dept. of Civil Engineering, Nippon Bunri University, Oita 870-03, Japan.

2 Associate Professor, Dept. of Earth System Science and Technology, Kyushu University, Kasuga 816, Japan.

3 Professor, Dept. of Civil Engineering, Kyushu University, Fukuoka 812, Japan.

Wave absorbing sea wall construction is one of them. In a storm, however, a wave absorbing sea wall generates a large amount of spray in compensation for the effective dissipation of wave energy. If it is transported landward, salt damages are given to the agricultural products or the infrastructural system in the coastal zone. Recently, the human life zone is expanding rapidly in the seaward direction. It also requires that the generation of sea water spray should be reduced from the standpoint of the preservation of atmospheric environments. Several studies have been already made on the generation of water spray and the transport of sea-salt particles. Hayami & Toba (1958) and Toba (1959) observed the generation of spray in the bursting process of air bubbles floating on the water surface, and concluded that the process is essential as a source of sea-salt particles in the atmosphere. Toba & Tanaka (1963) and Toba (1965 a, b) measured sea-salt particles in the atmosphere and demonstrated a good agreement to be seen between the observed results and the theoretical ones. Matsunaga et al (1994) investigated a transport process of spray generated from breaking waves by using a wave tank equipped with a wind tunnel. They showed that a large amount of spray is separated from the crests of breaking waves and the concentration of spray decreases exponentially in the vertical direction.

However, no studies have been made on the generation of spray from coastal structures in a storm and its landward transport process. In this study, how spray occurring from a wave absorbing sea wall is transported landward has been investigated experimentally.

2. Experimental methods

Experiments were carried out by using a wave tank, which is equipped with an inhalation-type wind tunnel (see figure 1). The tank

was 32 m long, 0.6 m wide and 1.30 m high. A wave absorbing sea wall, which is constructed at Beppu Port in Oita Prefecture, Japan, was used as a model. Figure 2 shows its cross-section and dimensions. The sea wall is covered with randomly piled 4 t-Tetrapod blocks. The gradient of the wall surface was 1 : 1.5. In the experiments, the scale of the wall was reduced to 1/16. The mean water depth was set at 0.34 m. The crown height h_c was 0.18 m. As a model of land, a 11 m

solid bed was attached horizontally to the back of the wall model. Five tests were made by varying wave parameters and wind velocity (see table 1). Two types of regular waves were made by a wavemaker. Their periods T were 1.38 s and 1.20 s. The wave heights in deep water H_0 were 14.3 cm and 11.7 cm. The wave parameters L_0 and C_0 are the wavelength and the wave velocity in deep water, respectively. U_0 is the cross-sectionally averaged wind velocity above the water surface and U_m is the one above the horizontal bed. The values of U_0 were varied from 9.43 to 15.1 m/s. The coordinate axes x and z were taken leeward and vertically upward from the back of the wall model, respectively. Water spray was captured by using cylindrical containers filled with cotton. They were 3.0 cm in diameter and 5.0 cm in depth. The vertical profiles of spray quantity were obtained by setting the containers at 5.0 cm vertical intervals. The measurements were made at 1.0 m horizontal intervals in the range of $x=0$ m to 11 m. The descriptions about the characteristic quantities l , $C(0, 0)$ and w_0/U_m shown in table 1 will be given in the next section.

3. Results and discussion

Figures 3 (a) to (e) show how the vertical profiles of spray concentration C vary in the leeward direction. The values of C are calculated from $C = q / \rho U_m$, where q is the mass of spray transported per unit area and time, and ρ the density of water. The concentration decreases exponentially with the increase of z and approaches to a constant value. As spray is transported in the leeward direction, the concentration decreases rapidly near the bed surface and the vertical profiles become uniform. It means that relatively large spray distributing at the back of the sea wall precipitates rapidly during the advection. On the other hand, very small spray remains to be suspended in a region far away from the wall. Therefore, the equilibrium between the advection of spray and the sedimentation may be essential near the wall and the advection-diffusion equilibrium may determine the concentration profiles far away from the wall. A typical profile of spray concentration is drawn schematically in figure 4, and the characteristic quantities are defined. The spray concentration at $z=0$, i.e., $C(x, 0)$, is estimated by extrapolating from the data in the exponentially decaying region. The characteristic length scale l is defined as a height at which the spray concentration takes the value of $C(x, 0)/e$. C^* is defined as a spray concentration at a large value of z and z^* is the height where C becomes nearly equal to C^* . It is unsuitable to examine experimentally the spray concentration in the

advection-diffusion equilibrium region because the concentration depends strongly on the height of the wind tunnel. Therefore, the characteristic quantities of C^* and z^* are not discussed here. In the advection-sedimentation equilibrium region, the equation of the spray concentration is given by

$$U_m \frac{\partial C}{\partial x} - w_o \frac{\partial C}{\partial z} = 0. \tag{1}$$

Here, it is assumed that the distribution of the spray concentration is steady and the settling velocity of spray w_o is constant. By assuming

$$C(x, z) = C(x, 0) \exp\left(-\frac{z}{l}\right), \tag{2}$$

we obtain

$$C(x, 0) = C(0, 0) \exp\left(-\frac{w_o}{U_m} \frac{x}{l}\right) \tag{3}$$

The values of $C(x, 0)$ and l can be estimated by fitting equation (2) to the experimental data shown in figures 3 (a) to (e). In figures 5 (a) to (e), the data are normalized by using the obtained values. The data plotted above the solid lines are relatively uniform in the vertical direction and belong to the advection-diffusion equilibrium region. It is seen that the exponentially decaying region becomes narrow as the increase of x .

Figure 6 shows the dependence of l on x . Though some variation is seen, it is very small in comparison with the 11 m horizontal advection. Therefore, the values averaged in the leeward direction \bar{l} are given in table 1. The values of \bar{l} / h_c are plotted against U_m / C_0 in figure 7. The values of \bar{l} are approximately given by $0.35 h_c$.
