CHAPTER 235

MECHANISM AND CALCULATION OF SAND DUNE EROSION BY STORMS

Ryuichiro Nishi¹ and Nicholas C. Kraus²

ABSTRACT: Dunes constitute a central element in shore-protection designs aimed at preventing inundation and erosion of the upland by storms. In the present study, the dune-erosion mechanism is investigated through field observations of the performance of sand dunes under storm action in Japan and in the United States. The observations are quantified by analysis of three test series carried out in the SUPERTANK project. The SUPERTANK data set includes tests on erosion of an uncompacted and a compacted near-vertical dune by random waves. The SBEACH numerical model of dune erosion and profile change is modified to erode dunes by the force of incident waves. This sediment can then supply the profile change model that demands offshore movement of sand in response to the occurrence of storm waves and elevated water level. The simulations show good agreement with the erosion measured at SUPERTANK for the uncompacted and the compacted dunes.

INTRODUCTION

Dune design is a central element in shore-protection projects aimed at preventing inundation and erosion of the upland by storms. In the United States and some other countries, the performance of protective dunes is often estimated with the Kriebel and Dean (1985) model or the Larson and Kraus (1989) (SBEACH) model of storm-induced beach erosion. These models operate under the assumption that erosion of the beach and dune complex is controlled by the demand for sand in the surf zone to satisfy establishment of an equilibrium profile under the impressed storm water level and waves. The demand, or, cross-shore sediment transport capacity, is estimated from the difference in wave energy dissipation between the existing profile and an assumed equilibrium profile shape. Conceptually, in such a demand-and-supply model (demand model), if a dune exists on an equilibrium beach profile for a given storm condition, little dune erosion is expected to occur. Clearly, however, a dune will erode if it is subjected to violent wave action almost independently of the equilibrium profile dynamics occurring offshore. Resolution of this problem is discussed here.

 2. Research Physical Scientist, US Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, Mississippi 39180-6199, USA.

In the present study, the dune-erosion mechanism is investigated through field observations of the performance of sand dunes under storm action in Japan and the United States. These observations are quantified by analysis of test series from the SUPERTANK Data-Collection Project (Kraus et al. 1992, Kraus and Smith 1995, Smith and Kraus 1996). The data set includes two tests involving erosion by random waves of 0.8-m high, nearly vertical dunes composed of 0.23-mm median-diameter sand. One test involved an uncompacted dune (SUPERTANK Test ST_50) and the other a compacted dune (ST_60). Complete time series of the water-surface elevation are available from the offshore to the face of the dune, although only breaking waves were employed here to compute the impact parameter and related volume of dune erosion.

Dune erosion is calculated as a function of a wave-force parameter (Sunamura 1977, Fisher and Overton 1984). Material eroded from the dune is supplied to the nearshore where profile change is calculated through equilibrium-profile concepts. Therefore, we call the methodology a *supply-and-demand* dune erosion and profile change model. This paper describes different mechanisms of dune erosion and the new supply-and-demand model. The model is then tested to simulate dune erosion measured at SUPERTANK.

MECHANISM OF SAND DUNE EROSION BY STORMS

In this paper, we consider dune erosion produced by impact forces of waves incident nearly normal to the shore, a cross-shore transport process that is assumed to be two dimensional. This assumption is supported by the uniform dune recession commonly observed after large storms along kilometers of shore despite longshore variations in coastal structures and offshore bathymetry. However, we note the possibility of the action of shearing forces exerted on dunes by waves and associated currents passing tangentially to the shore. Such a situation occurs by waves generated by ships passing dunes in narrow channels. Shearing erosion is not considered further here.

Field Observations

Sunamura (1992) has described basal erosion and mass movement (failure or erosion) of cliffs on rocky coasts as four types: falls, topples, slides, and flows. In the present study, the authors have documented three types of erosion mechanisms of sand dunes by wave impacts during storms or strong wave action. The cross-shore dune-erosion mechanisms, schematized in Fig. 1, are classified as (a) layer separation, including layer separation and overturning, (b) notching and slumping, and (c) sliding and flowing.

Layer separation. Layer separation typically occurs if a near-vertical dune face is subjected to wave impact. Over the duration of a certain number of impacts, a vertical fault line (crack) develops, and this outer layer gradually separates (typically 30 to 50 cm thick) from the landward portion of the dune. As it separates, the outer layer detaches from the main body of the dune, becomes unstable, and either collapses suddenly (Fig. 1a) or tilts forward and overturns (Fig. 1a').

Notching and slumping. Severe notching tends to occur if a dune slope is nearly vertical, permeated by roots, highly compacted, or composed of rocks such as a rocky cliff. Notching is limited to the elevation of wave attack and, after the notch is cut sufficiently deep into the base of the dune, the overlying sand column collapses. (Some notching may also occur during layer separation, but it is not the dominant factor in the collapse of the separated layer.) The material from the collapsed dune face is deposited in front of the new dune face.

The width of sand deposition at the foot of the dune face is less than that of layer separation, which involves the overturning and sliding of a layer.

Sliding and flowing. Sliding and flowing occur on uncompacted gently sloping dunes that have a face slope close to the angle of repose of the sediments forming them. In this situation, modest wave impact at the base of the dune or even pelting by rain or exposure to strong wind can cause a thin layer of sand to run down the slope. It is expected that this mode of dune erosion does not cause severe dune recession in a short period of time; however, this mechanism tends to steepen the dune face and a resultant steeper dune slope will probably trigger layer separation or notching and slumping under storm conditions.

Fig. 1. Dune erosion mechanisms by cross-shore processes.

SUPERTANK Dune-Erosion Tests

The erosion mechanism was quantified by using profile response measurements made at the SUPERTANK project. The particular tests analyzed here concern profile steepening and dune erosion. These test series involved random wave incident to a near-equilibrium profile, and to uncompacted (loose sand) and compacted near-vertically faced dunes. Complete time series of the water surface elevation are available from the offshore to the dune face (Smith and Kraus 1995); however, in this study, as a preliminary and less computationally intensive step, only wave-related quantities calculated at the breaker line were used.

The three SUPERTANK tests discussed in the present study were ST_10 (erosion of an equilibrium profile), ST_50 (uncompacted dune), and ST_60 (compacted dune). The waves were run in bursts of 10-40 min, and conditions were sometimes changed between bursts, for which representative waves are as follows:

<u>Test Number</u>	<u>Significant Wave</u>	<u>Peak Spectral</u>
	<u>Height, m</u>	<u>Period, sec</u>
ST_10	0.8	3.0
ST_50	0.5 - 0.8	6.0 - 3.0
ST_60	0.5 - 0.7	6.0 - 3.0

Erosion above a near-equilibrium profile. For SUPERTANK Test ST_10, random waves and monochromatic waves were generated to act on an initial idealized sub-aqueous equilibrium beach profile. Evolution of the beach profile is shown in Fig. 2. Four series of slope steepening (scarping) events occurred in the test. The profile in the swash zone steepened and maintained a constant angle at the second through fourth wave-burst events, while the upper beach face receded. The slope of the upper beach face is $\tan\beta \approx 0.89$, slightly less than that of a one-to-one slope (45 deg) typically specified in the Kriebel and Dean (1985) model. The slope of the upper beach face appears to exert control on the speed and volume of upper beach erosion.

Fig. 3 shows the process of profile steepening and scarp generation at the first and second wave-burst events of the erosion processes shown in Fig. 2. The beach-face slope steepened, and the swash waves carried the sediment offshore while lowering the beach face. Once the slope of the upper beach face approached the angle of failure (avalanching), the upper portion of beach face collapsed and the sediment was deposited in front of the scarp. Thereafter, successive swash waves transported the sediment seaward that was supplied from the upper beach face. As the beach face was lowered by erosive swash waves, swash uprush intensely impacted the steep beach face, again causing avalanching. These erosion processes in the swash zone continued until the upper beach face was no longer vulnerable to swash waves. This test series demonstrates that the upper beach face behind a sub-aqueous near-equilibrium beach profile can be eroded by swash wave activity until it also achieves equilibrium with the water level and swash.

Dune erosion tests. Two dune-erosion tests were conducted at SUPERTANK, one for a dune formed of sand without compaction (ST_50) and the other for an artificially compacted dune (ST_60). The dune was compacted by applying a pavement vibrator for approximately 2 hr. Both dunes were subjected to short-period high waves. The water level was lower at the beginning of the tests and higher at the end of the tests (Kraus and Smith 1995, Smith and Kraus 1996). In the dune-erosion tests, the dune face tended to recede in parallel to itself, as shown in Fig. 4. Video records made during SUPERTANK indicate both the uncompacted and compacted dunes eroded primarily by layer separation. In all situations observed in the field and at SUPERTANK, dune faces tended to recede in parallel to themselves.

This coherent behavior of dune evolution illustrates the consistency and reproducibility of the dune-erosion mechanism. The sediment supply from the dune to the swash zone by either the layer-separation or notching-and-slumping erosion mechanisms was injected virtually instantaneously (order of one wave period) when a wave or backwash swept the eroded sediment toward the swash zone.

Fig. 2. Profile change on a near-equilibrium beach (ST_10).

Fig. 3. Beach face steepening and scarp generation (ST_10).

Fig. 4. Erosion of uncompacted (ST_50) and compacted (ST_60) dunes.

The volume of erosion of the compacted dune was less than that of the uncompacted dune, despite the slope of the compacted dune being steeper than that of the uncompacted dune during the erosion, as shown in Fig. 4. Compaction altered the strength of the dune and the volume of eroded material, thickness of layer separation, and angle of slope failure. It is clear that a compaction coefficient should be introduced in future studies of profile evolution.

DUNE EROSION MODEL

A numerical model of dune erosion was developed in the present study that simulates the impact force of individual waves on the dune face. Research conducted at Tuskuba University, Japan, for cliff erosion (see Sunamura 1977, 1992) and at North Carolina State University for sand dunes (see Fisher and Overton 1984, Fisher et al. 1986, and Overton et al. 1994) has advanced this approach. The impact-force and dune-erosion model was incorporated as a sub-model of SBEACH (Larson and Kraus 1989, Nishi et al. 1991) and employs the wave model of SBEACH supplemented by a swash model that includes bore velocity and height to estimate the impact parameter. The total model consists of a wave transformation model, cross-shore sediment transport model in the surf zone, and a sediment supply model from the dune.

In SBEACH, wave transformation in the surf zone is computed based on the Dally et al. (1985) model. For describing random wave incidence, it was assumed that the heights of individual waves follow a Rayleigh distribution and the wave period for an individual wave corresponds to an average wave period. The wave height of individual waves was computed by a Monte Carlo method (Larson and Kraus 1991).

Profile Zonation

Because the model computes the sediment transport in the surf zone and sediment supply and transport from the dune by different mechanisms, the beach and dune systems were divided into three zones as the (a) dune, (b) swash zone, and (c) surf zone (Fig. 5). This profile zonation modifies that of the original SBEACH model at the dune. The maximum runup or swash elevation Z_r is defined as a function of the surf-similarity parameter as given by Eq. (1) (Larson and Kraus 1989)

$$\frac{Z_r}{H_o} = 1.47 \left(\frac{\tan \beta}{\sqrt{H_o / L_o}} \right)^{0.79} \quad (1)$$

where H_o = deep-water wave height, and L_o = deep-water wavelength by linear-wave theory.

Fig. 5. Schematic diagram of dune and beach system.

Calculation of Sediment Supply from Dune

As storm waves approach the beach, bores impact the dune face and cause erosion. Thus, the volume of dune erosion during a storm or by waves that reach the dune face during times of elevated water level should be related to the force of wave impact. Sunamura (1977) parameterized this impact wave force by the incident wave height in study of rocky cliff erosion. A strong correlation between wave impact force and sand dune erosion was found by Fisher et al. (1986) for artificially constructed sand dunes in the field and by Overton et al. (1994), who obtained a correlation between the force of impacting waves and volume of dune erosion for the compacted dune at SUPERTANK.

The wave-force impact parameter is derived heuristically by considering the situation shown in Fig. 6 and the rate of change of wave momentum. The mass m of water per unit length of crest in a bore of height H and length L moving in shallow water of average depth h over the length of the wave is given by

$$m \approx \frac{1}{2} \rho_w HL = \frac{1}{2} \rho_w HT \sqrt{gh} \quad (2)$$

where ρ_w = density of water, T = wave period, g = gravitational acceleration, and $(gh)^{1/2}$ is the celerity of the wave. The wave impact force per unit length of dune is estimated by multiplying the mass m by the deceleration $(gh)^{1/2}/T$ resulting from the wave striking the dune and stopping in the time interval of the wave period T . This derivation suggests consideration of a cumulative wave-force impact parameter I defined by

$$I \equiv \rho_w gh H \frac{\Delta t}{T} \quad (3)$$

where Δt is the time interval or duration over which the waves impact, and the ratio $\Delta t/T$ is the number of waves. The ratio $\Delta t/T$ can be easily modified to describe random waves by summing the contributions of the individual waves of different height, period, and speed. The impact parameter has the dimensions of Newtons per unit wave crest or dune width.

Fig. 6. Schematic diagram for the wave impact parameter.

For dimensional homogeneity it is convenient to work with the weight per unit width alongshore of the eroded material $W_E = \rho_s (1 - p) g V_E$, where ρ_s = density of the sand comprising the dune, p is the porosity of the sand (0.4 for uncompacted sand, 0.2 estimated for the compacted sand dune), and V_E is the volume of material eroded from the dune. The density and, therefore, the porosity, of the uncompacted and compacted dunes should be different.

Analysis of the data computed from the average of the impact forces indicated a linear relationship as shown in Fig. 7 and resulted in the empirical equation for the weight per unit width $(W_E)_U$

$$(W_E)_U = 0.81(I - I_{crit}) \quad (4)$$

for the uncompacted dune, and the weight $(W_E)_C$

$$(W_E)_C = 0.50(I - I_{crit}) \quad (5)$$

for the compacted dune. In the above, the critical wave impact parameter for inception of erosion I_{crit} is set to zero at the present time because of uncertainty in its value.

These equations and Fig. 7 show that waves with the same impact parameter erode a compacted dune less than a uncompacted or unconsolidated dune. An engineering lesson from this result indicates that greater erosion protection would be gained through construction of dunes by wetting the sand for consolidation and compacting them with vibrating compactors, rollers, and other heavy equipment. The above result was obtained from a limited number of tests available from the SUPERTANK project, and further verification needs to be done to refine the result.

Fig. 7. Impact parameters for uncompacted and compacted dunes at SUPERTANK.

NUMERICAL MODEL OF DUNE EROSION

From the above discussion, the volume of sand eroded from a dune can be calculated as a function of time through knowledge of the incident waves and the wave-force impact parameter. Thus, the amount of sand supplied to the profile by the dune is known. As the next step, an assumption must be made as to how the sediment enters the swash zone or surf zone where other transporting mechanisms are operating. Here, it is assumed that sediment is introduced to the swash zone at a uniform rate within each time step of the model according to the supply available from the dune at that time step. A typical calculation time step in the model is 1 min, and the grid cell size on the foreshore is 0.1 m. Uniform distribution of sediment supply agrees with visual observations made at SUPERTANK and inferences from field observations, and it is also reasonable in a time-average sense. The structure of the numerical model does not preclude a more detailed description of the sediment-supply procedure to the swash zone and can be modified as understanding improves.

Dune Erosion Model (Supply)

We found above that a dune face recedes with a certain angle in accordance with the amount of compaction. Nearly vertical dune faces produced by erosion during storms are commonly observed in the field, in particular for well-established dunes presumably compacted by natural settling and wetting. In the SUPERTANK project, the angles of the dune face were approximately 68 deg for the uncompacted dune and 87 deg for the artificially compacted dune, as shown in Fig. 8. The irregularity in dune-face angle through time for the compacted dune may have been caused by uneven compaction close to the initial dune face. In the model simulations described below, it is assumed that the slope of the dune face is 68 or 87 deg depending on the amount of compaction.

Fig. 8. Angle of dune face for uncompacted and compacted dunes at SUPERTANK.

As determined from the SUPERTANK data, the volume of dune erosion can be estimated by the duration and intensity of wave impact, which yields an eroded volume ΔV_E per unit longshore width of dune. A corresponding recession distance can be computed by assuming the dune face retreats a certain distance and at a certain angle to a baseline. The baseline is a vertical datum located at the toe of the dune. In the model, the volume of sand eroded from the dune is distributed uniformly as a thickness Δh_s over a distance X_s , which is taken to be an effective distance of the swash zone extending from the toe of the dune at the present time step to some depth defining the seaward limit of the swash zone, arbitrarily set to 0.3 m or a comparable value (Larson and Kraus 1989). Then we have

$$\Delta h_s = \frac{\Delta V_E}{X_s} \quad (6)$$

for the thickness of the sand layer.

Profile Change Model (Demand)

In the SBEACH model, sediment demand or the potential transport rate in the surf zone is calculated based on the dissipation of wave energy flux originally derived by Dean (1977) and implemented by Kriebel and Dean (1985) in dune-erosion modeling. In the surf zone, SBEACH computes the cross-shore sediment transport rate as

$$q = K \left(D - D_{eq} + \frac{\varepsilon}{K} \frac{\partial h}{\partial x} \right) \quad (7)$$

where K = empirical transport rate coefficient, ε = empirical coefficient controlling the strength of the slope-dependent transport rate term, and the energy dissipation per unit water volume D is

$$D = \frac{1}{h} \frac{\partial F}{\partial x} \quad (8)$$

in which F is the wave-energy flux. The dissipation for a profile in equilibrium with the existing waves and water level D_{eq} is given by (Dean 1977)

$$D_{eq} = \frac{5}{24} \rho_w g^{3/2} \left(\frac{H_b}{h_b} \right)^2 A^{3/2} \quad (9)$$

where A is an empirical "shape" parameter related to the form of the equilibrium profile and the grain size of the beach (Moore 1982).

In SBEACH, the transport rate in the surf zone as given by Eq. (7) is only calculated if $D > D_{eq} - \varepsilon/K \partial h/\partial x$, and the transport direction as onshore or offshore is determined by a separate function (Kraus et al. 1991). As originally developed (Larson and Kraus 1989), SBEACH calculates cross-shore transport rates in four zones, with a linear rate employed in the swash zone and a magnitude as determined by matching with Eq. (7) at the swash zone and surf zone interface. Material moved from the dune to the swash zone by the supply dune-erosion model is then moved offshore by the swash and surf zone transport.

Numerical Simulation of Dune Erosion at SUPERTANK

A numerical simulation was conducted to calculate dune erosion for Test ST_60 (compacted dune). The empirical dune-erosion predictor incorporated in the model was developed based on the SUPERTANK data and impact parameter, as described above. Therefore, the simulation is not a verification of the model; rather, it demonstrates the validity of the numerical scheme and behavior of the supply-and-demand procedure that connects the dune to the profile.

Fig. 9 shows the profile change simulated by applying the (standard) demand model, which can be compared to the profile change simulated by applying the supply-and-demand model, Fig. 10. The demand model underestimates the dune erosion for which the compacted dune is located on a beach profile in near equilibrium with the impressed waves.

We note in this paragraph independent contemporaneous work involving SUPERTANK Tests ST_10, ST_50, and ST_60. Wise et al. (1996) report comparisons of SUPERTANK measurements (and field measurements) and calculations performed with the most recent version of SBEACH operated by the US Army Engineer Waterways Experiment Station (WES), for which default calibration parameters (K and ϵ) were specified (the calibration parameters were not optimized for the individual tests). The most recent WES version of SBEACH incorporates sophisticated random-wave and cross-shore sediment transport models not applied in the version used in the present study. The WES version is still a demand model. For equilibrium Test ST_10, erosion of the foreshore was obtained by Wise et al. for random waves with the new WES version of SBEACH. For the dune erosion tests, the WES version well reproduced erosion of the uncompacted dune (ST_50) and overpredicted dune erosion for the compacted dune (ST_60). Wise et al. comment that "The difference in model predictions between the two dune cases might be expected due to greater erosion resistance associated with the compacted sediment which is not accounted for in SBEACH." This comment was verified in the present work.

CONCLUDING DISCUSSION

Three types of dune erosion mechanisms were identified through field observations as: (a) layer separation, (b) notching and slumping, and (c) sliding and flowing. The layer-separation mechanism was quantified by analysis of the SUPERTANK dune erosion tests by which the eroded volume could be related to the cumulative wave impact force. The degree of compaction was found to be a significant parameter that decreases the potential for dunes to erode. Therefore, an economic benefit might be gained by compacting artificially placed dunes to improve their performance as shore protection. The supply-and-demand model developed can simulate dune erosion and beach profile change based on representations of the hydrodynamics and sediment transport acting in each region and provides, in principle, a more accurate representation than existing demand models, especially in applications where the beach profile is approximately in equilibrium with the impressed storm waves and water level. The present study suggests ways through which geotechnical considerations might be incorporated in dune erosion modeling to both account for compaction and introduce supply and demand considerations.

CHAPTER 236

SIMULATION OF COASTAL PROFILE DEVELOPMENT USING A BOUSSINESQ WAVE MODEL

K.A. Rakha¹, R. Deigaard², P.A. Madsen¹, I. Brøker³, and J.K. Rønberg³

ABSTRACT

A phase-resolving wave transformation module is combined with an intra-wave sediment transport module to calculate the on/offshore sediment transport rates. The wave module is based on the Boussinesq equations extended into the surf zone. The vertical variation of the instantaneous currents and concentrations are calculated. The net sediment transport rates are calculated, and the equation for conservation of sediment is solved to predict the beach profile evolution. The results of the present paper showed that the undertow contribution to the sediment transport rates dominated only at local areas even for eroding beaches, suggesting that other contributions should not be neglected.

1. INTRODUCTION

The study of beach profile evolution includes a large range of time and space scales. Process based morphology models (Roelvink and Brøker, 1993) usually include some averaging of the different space and time scales. This averaging is applied to either the hydrodynamic or the sediment transport calculations or both. The sediment transport calculations used in most of the present morphology models are based on phase-averaged calculations of the sediment concentrations or on the 'energetics approach'. Although models based on the energetics approach account for the intra-wave sediment transport rates, the intra-wave variation of the eddy viscosities and sediment concentrations are not calculated. Such models may be classified as semi-intra-wave sediment transport models. The model developed by Fredsøe et al. (1985) represents an example of a detailed intra-wave model for the sediment concentrations. Watanabe (1994) combined a wave model based on the Boussinesq equations with a semi-intra-wave sediment transport model. Such a model neglects a large part of the information provided by the wave module, and will require some approximations for irregular waves. The model described by Brøker et al. (1991) combines a detailed intra-wave sediment transport module with a phase-averaged wave module, where a wave theory is required to describe the intra-wave water motion. The extension of such a model to irregular waves will also require some approximations. In the present study a phase-resolving wave module is combined with a detailed intra-wave sediment transport module to study in more detail the process of sediment transport and morphological evolution.

2. MODEL DESCRIPTION

The morphological calculations are performed by updating the beach profile over the morphological time step Δt_{\max} . For each morphological update the simulations are performed by four modules; a wave module, a hydrodynamic module, a sediment transport module and a bathymetry updating module.

2.1 Wave Module

The wave module simulates the wave conditions across the beach profile by a phase-resolving model based on the Boussinesq equations, with improved linear dispersion characteristics as explained in Madsen et al. (1991), and Madsen and Sørensen (1992). The effect of wave breaking is included by using the surface roller concept (Schäffer et al., 1993). Figure (1A) shows a sketch of the assumed velocity field under a wave with a surface roller. An extra term is included in the momentum equation to represent the momentum flux due to the rollers. This term extracts energy from the wave motion. Breaking is initiated when the local water surface slope exceeds the initial value of ϕ_b . The roller is defined as the water above the tangent slope $\tan(\phi)$. Initially ϕ is equal to ϕ_b for each roller, which then decreases exponentially to ϕ_o , and breaking is assumed to cease when the maximum of the local slope becomes less than $\tan(\phi)$. The resulting roller thickness δ is finally multiplied by the roller shape factor f_δ to compensate for the simple method of separating the roller from the rest of the flow.

The calculation proceeds into the swash zone using the slot-technique (Madsen et al. 1994), by extending the computational domain into an artificial permeable beach. Near the moving shoreline the water surface will intersect with the sea bed and continue into the porous beach. The instantaneous position of the shoreline is simply determined by this intersection.

2.2 Hydrodynamic Module

The hydrodynamic module consists of two parts, an oscillatory boundary layer model (Figure, 1B) and an undertow model (Figure, 1C). The boundary layer model calculates the vertical velocity distribution for the oscillatory wave motion u_o inside the boundary layer. The undertow model determines the vertical distribution of the mean undertow \bar{U}_o .

2.2.1 Boundary Layer Calculations

The oscillatory flow near the bottom is modelled by the momentum integral method developed by Fredsoe (1984). The shear stress is assumed to be zero at the top of the boundary layer, and the velocity distribution u inside the boundary layer is assumed to follow a logarithmic distribution. The boundary layer thickness is assumed to develop from zero at every zero-crossing of u_o outside the boundary layer. The values of the shear velocity U and the boundary layer thickness ζ are calculated for each time step. The streaming in the boundary layer and the wave asymmetry causes the time averaged bed shear stress to deviate from zero. To obtain this mean shear stress a constant drift velocity V_{st} is added to the near bed orbital velocity. The magnitude of V_{st} is found by iteration requiring that the time averaged bed shear stress in the boundary layer model is equal to the shear stress determined by the streaming.

2.2.2 Eddy Viscosity Calculations

The eddy viscosities are calculated by assuming that the total kinetic energy can be determined as the sum of three contributions (Brøker et al., 1991),

$$\epsilon = \sqrt{\epsilon_w^2 + \epsilon_b^2 + \epsilon_U^2} \quad (1)$$

where, ϵ_w , ϵ_b , and ϵ_U are the eddy viscosities due to the bottom boundary layer, wave breaking, and the undertow, respectively. The eddy viscosity ϵ_w is calculated based on the variables calculated in

the boundary layer, assuming a parabolic distribution inside the bottom boundary layer (Fredsøe et al., 1985). The eddy viscosity ϵ_v is calculated from the undertow velocity profile using a simple mixing length formulation. The eddy viscosity ϵ_b is calculated from the turbulent kinetic energy induced by wave breaking calculated from a one-equation turbulence model (Deigaard et al. 1991). The instantaneous production of turbulence due to wave breaking is calculated from the following equation proposed by Deigaard (1989),

$$P_r = \alpha_p Diss = \alpha_p \rho g c \delta \tan \phi_o \quad (2)$$

where, Diss is the instantaneous energy dissipation due to wave breaking, and α_p is the fraction of the energy that is not dissipated immediately in the shear layer beneath the roller. α_p is assumed to be 0.33 as suggested by Deigaard et al. (1991). The production of turbulence is assumed to have a parabolic distribution over a distance of half the wave height ($H/2$) below the mean water depth as shown in Figure (2).

2.2.3 Undertow Calculation

The undertow is calculated by the following approximate equation,

$$\frac{\partial U_c}{\partial y} = \frac{1}{\rho \epsilon} \bar{\tau} \quad (3)$$

where an overbar denotes time averaging over a single wave. The time averaged shear stress distribution is assumed to vary linearly over the water depth as shown in Figure (2). The shear stress at the surface (mean water level, MWL) is calculated from the following formula,

$$\bar{\tau}_s = \frac{Diss}{c} \quad (4)$$

Eqn. (3) is solved with the no slip condition imposed at the bed, and the condition that the total flux compensates the wave drift (determined from the Boussinesq model) and the velocity V_{st} determined by the boundary layer model.

2.3 Sediment Transport Module

2.3.1 Bed Load and Sediment Concentrations

The instantaneous near bed concentration C_b is calculated from the formulation suggested by Zyserman and Fredsøe (1994). The value of C_b depends on the instantaneous value of the Shield's parameter. The instantaneous bed load q_b is calculated using the formulation by Engelund and Fredsøe (1976).

Neglecting the convective terms, the distribution of the sediment concentration C can be calculated from the diffusion equation,

$$\frac{\partial C}{\partial t} = w_f \frac{\partial C}{\partial y} + \frac{\partial}{\partial y} \left(\epsilon_s \frac{\partial C}{\partial y} \right) \quad (5)$$

where, ϵ_s is the sediment diffusion coefficient assumed to be the same as the flow eddy viscosity ϵ , and w_f is the fall velocity. Eqn. (5) is solved with the boundary conditions $C = C_b$ at the bed ($y = 2D_{50}$), and zero sediment flux through the water surface.

Figure (1): The elements of the hydrodynamic module; A- The wave description. B- The oscillatory current. C- The undertow.

Figure (2): Vertical distribution of production of turbulence and shear stresses due to wave breaking.

2.3.2 Lagrangian Drift

For an Eulerian calculation a contribution due to the Lagrangian drift should be added as an approximation for the wave drift of suspended sediment (Brøker et al., 1991). This approximation is required because the convective terms were not included in the calculations for the sediment concentrations. The Lagrangian drift velocity U_l results from the fact that the water particles do not follow a closed path, but a net forward displacement exists. As an approximation it is assumed that the sediment on average follows the fluid motion. The drift current for each wave is calculated from,

$$U_l = \frac{1}{c} \left(\overline{u^2} - (\bar{u})^2 \right) \quad (6)$$

where an overbar again denotes time averaging over a single wave.

2.3.3 Total Sediment Transport Rates

The total instantaneous sediment transport rates are obtained from,

$$q'_s = q_b + q_{sw} + q_{su} + q_{sl} \quad (7)$$

where the sediment transport rates due to the oscillatory motion q_{sw} are evaluated by integrating uC over the water depth. The contributions due to the undertow q_{su} and the Lagrangian drift q_l are evaluated by integrating $U_c C$ and $U_l C$ over the water depth respectively. The swash zone was included in an approximate manner by assuming that q'_s varies linearly from the last grid point to the location of the water line for each time step. Time averaging of q'_s over the time series provides the time averaged sediment transport rates q_s . Figure (3) shows the instantaneous sediment transport rates calculated for a regular and irregular wave of the same deep water rms wave height for Test 1c explained later. As shown in Figure (3) the time variation of the sediment transport rates under an irregular wave are quite different from a "representative" regular wave.

2.4 MORPHOLOGY MODULE

The bathymetry is updated by solving the conservation of sediment equation,

$$\frac{\partial Z_b}{\partial t} = -\frac{1}{(1-n)} \frac{\partial q_s}{\partial x} \quad (8)$$

where Z_b is the bed level, and n is the porosity of the sediment assumed to be 0.4. A Forward in Time Central in Space (FTCS) finite difference scheme was used to solve Eqn. (8), with an additional diffusive term for the numerical stability (Abbott and Basco, 1989). The resulting finite difference equation would correspond to the following differential equation,

$$\frac{\partial Z_b}{\partial t} + \frac{1}{(1-n)} \frac{\partial q_s}{\partial Z_b} \frac{\partial Z_b}{\partial x} = K \frac{\partial^2 Z_b}{\partial x^2} \quad (9)$$

where, K is a diffusion coefficient assumed to be proportional to q_s ,

$$K = \epsilon_s |q_s| \quad (10)$$

which is similar to the additional gravitational term included by De Vriend et al. (1993) and

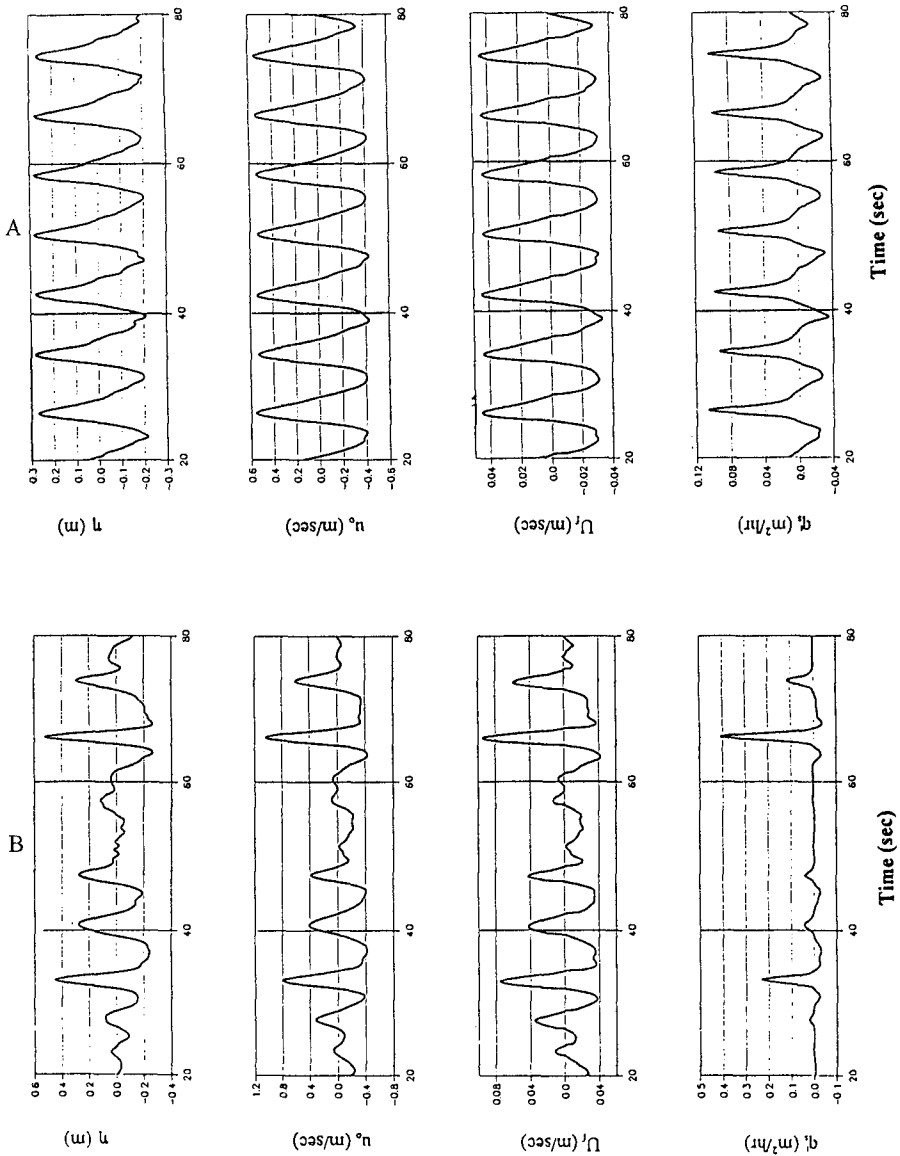

Figure (3): A- Time series of η , u_o , U_r , and q_o of Test 1c (regular wave).
 B- Time series of η , u_o , U_r , and q_o of Test 1c (irregular wave).

Horikawa (1988). ϵ_s is an empirical coefficient. The following constraint on the morphological time step Δt must be satisfied (Abbott and Basco, 1989),

$$D_{cr} \leq \frac{1}{2} ; D_{cr} = \frac{K\Delta t}{\Delta x^2} \tag{11}$$

where, Δx is the spatial grid spacing. In the present study two time steps are used; the first is called the inner time step Δt_i and the second the outer time step Δt_{max} . The maximum value of Δt_i is chosen to satisfy Eqn. (11). Eqn. (8) is solved over the duration Δt_{max} with the values of q assumed constant (Horikawa, 1988, and Rakha and Kamphuis, 1996). The value of Δt_{max} was specified to the model together with a criterion limiting the maximum change in bed level to 10% of the deep water average wave height (Rakha et al., 1996). A modified Lax-Scheme (Abbott, 1979) with no inner times steps was also tested.

Figure (4) shows a long term simulation for a highly erosive beach with a specified outer time step $\Delta t_{max} = 0.2$ hr. The actual time step was less than 0.1 hr resulting in nearly 80 wave field updates. As shown in Figure (4) the bars tended to move offshore with the depth over their crests increasing with time. Onshore of the previous bar, new bars also developed with time.

Figure (4): Long term morphology simulation for a regular wave.

3. MODEL VALIDATION

3.1 LIP 11D Delta Flume Tests

The Delta Flume '93 tests were performed at the Delft Hydraulics large-scale wave flume. These tests were supported by the "Large Installations Plan" (LIP) of the European Union. The main purpose of the tests was to provide high quality data to validate/calibrate numerical beach profile models. The details of the tests performed can be found in Arcilla et al. (1993) and Roelvink and Reniers (1995). Two tests (Tests 1b and 1c) were selected for the model verification. Test 1b represents a highly erosive wave condition, and Test 1c a strongly accretive wave condition. Table (1) provides a summary of the test conditions used in this paper.

Table (1): Summary of Test Conditions.

Test	H_{m0} (m)	T_p (sec)	D_{s0} (mm)	Type
LIP 11D: Test 1c	0.60	8.0	0.2	Irregular
LIP 11D: Test 1b	1.40	5.0	0.2	Irregular
Shimizu et al. (1985): Test 3-2	1.05	6.0	0.27	Regular

The prediction of the characteristic wave height H_{m0} variation over the initial bathymetry for Tests 1c and 1b is shown in Figures (5) and (6) respectively. The Boussinesq model predicted the wave heights well for both Tests. It appears that the wave heights are slightly overpredicted inside the surf zone for Test 1c (Figure, 5). The results obtained using a phase-averaged wave model based on the Battjes and Janssen (1978) model are also shown in both figures, which shows that such a model provides a good estimate for H_{m0} .

Figures (7) and (8) show the time-averaged undertow for Tests 1c and 1b. At some locations measurements were performed twice at different hours of the test. Figures (7) and (8) show that the undertow is predicted well for most sections. The undertow however is overpredicted just before the bar ($x = 138$) for Test 1c and underpredicted in the trough of the bar ($x = 145$) for both Tests 1b and 1c.

The predicted on/offshore sediment transport rates for Test 1c are shown in Figure (5). Very good results are obtained outside the surf zone showing that the calculation of the sediment transport rates due to the oscillatory current is well predicted. Over the bar, the overestimation of the undertow (Figure, 8) results in the underestimation of the onshore sediment transport rates. Good predictions of the sediment transport rates for Test 1b are also shown in Figure (6), where the model follows the measured sediment transport rates well. The onshore sediment transport rates are overestimated inside the trough of the bar ($x = 145$) due to the underestimation of the undertow as explained earlier (Figure, 8). The use of the Boussinesq model provided much better results than the use of a phase-averaged wave model (Figures, 5 & 6). Linear wave theory was used with the rms wave height assumed to be the representative wave for the phase-averaged wave model calculations.

Figure (9) shows a decomposition of the time averaged sediment transport rates into three of the four calculated components. The three contributions plotted are the Lagrangian drift, the integral of uC , and the contribution due to the undertow. The bed load was not included since it gives only a small contribution for these tests. From Figure (9) it can be seen that for Test 1c just before the bar where some of the waves start breaking, the undertow contribution increases rapidly. The measurements suggest that the drop in the sediment transport rates is delayed and occurs on the top of the bar. Figure (9) shows that for eroding beaches (Test 1b) the contributions due to the oscillatory current and the Lagrangian drift are important. The undertow contribution dominates only at the locations where a high percentage of waves are breaking.

Figure (5): Model results for H_{mo} and q_s of Test 1c (LIP 11D).

Figure (6): Model results for H_{mo} and q_s of Test Ib (LIP IID).

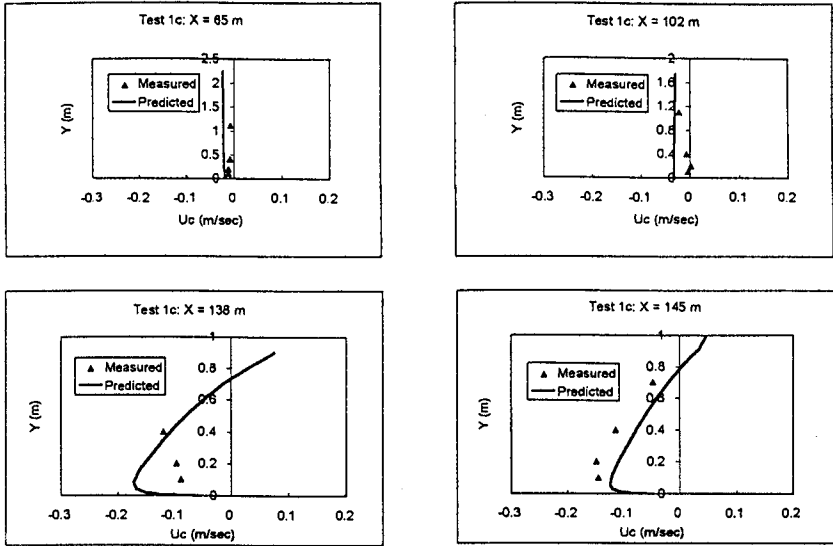

Figure (7): Model results for Undertow of Test 1c (LIP 11D).

Figure (9): Sediment transport rate contributions for Tests 1c and 1b (LIP 11D).

Figure (10): Model results for Test 3-2 (Shimizu et al., 1985).

3.2 Validation of Morphology Model

Figure (10) shows the morphology model predictions for Test 3-2 of Shimizu et al. (1985) with the test conditions provided in Table (1). Good results were obtained for the bar formation as shown in Figure (10) although the numerical model underpredicted the bar development due to the underprediction of the sediment transport rates outside the surf zone. Figure (10) shows that the Boussinesq model underpredicts the shoaling of the waves outside the surf zone. This underprediction of the wave shoaling could be responsible for the underprediction of the sediment transport rates. As shown in Figure (10) the modified Lax-scheme and the FTCS scheme with $\epsilon_s = 0.2$ gave similar results. A sensitivity analysis on the effect of using a value of $\epsilon_s = 2.0$ (as suggested by Watanabe, 1994) showed that the model was not sensitive to the value of ϵ_s for this case.

CONCLUSIONS

A phase-resolving wave transformation module was combined with an intra-wave sediment transport module to predict the on/offshore sediment transport rates and the resulting beach evolution. The roller geometry was used to determine the instantaneous production of turbulence and a mean shear stress at the water surface. The instantaneous sediment transport rates due to the oscillatory wave induced currents (bed load and suspended load), the undertow, and the Lagrangian drift were calculated.

The present model was verified against a few test conditions. The model predicted the undertow and the sediment transport rates well for both erosive and accretive conditions. The onshore sediment transport rates for accretive beaches were underpredicted before the bar due to the overprediction of the undertow, and the underprediction of wave shoaling.

The results of the present paper showed that even for eroding beaches the undertow contribution to the sediment transport rates dominated only at local areas, suggesting that other contributions should not be neglected for eroding beaches.

ACKNOWLEDGMENT

The Danish National Research Foundation financed the first and third authors and the Danish Technical Research Council under the program 'Marin Teknik' financed the fourth author, their support is greatly appreciated. The assistance of Ole Sørensen with the Boussinesq model is also appreciated. Dano Roelvink (Delft Hydraulics) helped in providing the data for the LIP experiments.

CHAPTER 237

Cross-shore Sediment Transport and Beach Deformation Model

Rattanapitikon Winyu ¹

Tomoya Shibayama ²

Abstract

Based on a large amount of published laboratory results, reliable model is developed for computing beach profiles under regular wave actions. The sediment transport is separated into suspended load and bed load. The suspended load is computed as the product of the time-averaged suspended concentration and the time-averaged velocity. The bed load is developed following the similar step as Watanabe (1983) but the applied area is different. The wave model of Dally et al. (1985) is modified and used to compute wave height transformation. The beach profile change is computed from the conservation of sediment mass. The beach deformation model is verified with small scale and large scale experiments. Reasonably good agreement is obtained between measured and computed beach profiles.

I. Introduction

In the previous research works, most of the models were developed based on data with the limited experimental conditions. Therefore their validity is limited according to the range of experimental conditions which were employed in the calibration or examination. The evidence is that there are so many models exist. At this moment, the experimental results obtained by many researchers have been accumulated and a large number of experimental results have become available. It is a good time to develop a model based on the large amount and wide range of experimental results. The present model is developed based on 1138 data sets of 24 sources of published experimental results covering both small and large scale experiments, as shown in table 1.

where $c(z)$ is the time-averaged sediment concentration, $u(z)$ is the time-averaged fluid velocity, H is the wave height, $h(x,t)$ is the beach profile, A is the cross section area of surface roller, h_{ot} is the still water depth at transition point, SE is the small scale experiment, and LE is the large scale experiment.

1.1 Governing equation

The cross-shore change in local water depth, h , can be calculated by solving the conservation of sediment mass as the following

$$\frac{\partial h}{\partial t} = \frac{1}{(1-\Lambda)} \frac{\partial q_t}{\partial x} \dots\dots\dots (1)$$

where t is the time, x is the horizontal coordinate in cross-shore direction, Λ is the porosity, and q_t is the total transport rate per unit width.

The sediment transport rate is usually expressed as

$$q_t = \int_{-s}^h c(z)u(z) dz \dots\dots\dots (2)$$

where δ is the level above which there is no effective movement of sand particles, z is the vertical coordinate measured upward from the bed, $c(z)$ is the time-averaged sediment concentration, and $u(z)$ is the time-averaged fluid velocity.

In order to compute the transport rate, q_s , the sediment concentration and fluid velocity should be known first. The sediment concentration profile was described in Shibayama and Rattanapitikon (1993). The following sections will describe about velocity profile, sediment transport, wave model, and beach deformation model, respectively.

II. Time-Averaged Velocity Profiles

Following Okayasu et al. (1988, pp. 93-94), the vertical distribution of time-averaged velocity profile is calculated based on the assumption of eddy viscosity model. By considering time-averaged values, the eddy viscosity model can be expressed as

$$\tau = \rho \nu_t \frac{\partial u}{\partial z} \dots\dots\dots (3)$$

where τ is the time averaged shear stress, ρ is the fluid density, ν_t is the time-averaged eddy viscosity coefficient, u is the time-averaged velocity, and z is the upward vertical coordinate from the bed.

To solve the eddy viscosity model, one boundary condition of velocity should be given and the expression of τ / ν_t should also be known. In this study, the vertical-averaged value of velocity, u_m , is used as the boundary condition for Eq. 3 and will be described in the following subsection.

2.1 Vertically averaged velocity

Using the concept of Svendsen (1984), the vertically averaged velocity, from bed to wave trough, u_m , consists of two components. One is caused by the wave motion, u_w , and the other is caused by the surface roller, u_r .

$$u_m = u_w + u_r \dots\dots\dots (4)$$

Various formulas for computing u_w and u_r have been suggested by the previous researchers. From the previous studies, of Duncan (1981), Svendsen (1984), Stive and Wind (1986), Deigaard et al. (1991), and Fredsoe and Deigaard (1992), we can conclude that there are three formulas for computing u_w and three formulas for computing u_r (see in table 2).

Table 2. Formulas for computing u_m and u_r

	Formula 1	Formula 2	Formula 3
u_w	$\frac{B_o \sigma H^2 \coth(kh)}{h}$	$\frac{B_o c_w H^2}{h^2}$	$\frac{c_w H}{h}$
u_r	$\frac{H^3}{(0.7Th^2)}$	$\frac{0.9H^2}{(Th)}$	$\frac{0.1c_w H}{h}$

where $B_o = (1/T) \int_0^T (\xi/H) dt$, c_w is the phase velocity, H is the wave height, h is the mean water depth, T is the wave period, and ξ is the water surface elevation measured from mean water level.

The general form of u_m may be written as

$$u_m = au_w + bu_r \dots\dots\dots (5)$$

where a and b are the constants.

The proper combination of u_w and u_r and the constants a, b can be found from multi-regression analysis with the observed u_m .

After the regression analysis and include the effect of transition zone, the final equation for computing u_m can be written as

$$u_m = 0.77 \frac{B_o \sigma H^2 \coth(kh)}{h} + b_1 0.1 \frac{c_w H}{h} \dots\dots\dots (6)$$

where b_1 is the constant and expressed as

$$b_1 = \begin{cases} 0 & \text{offshore zone} \\ (1/\sqrt{H} - 1/\sqrt{H_b}) / (1/\sqrt{H_t} - 1/\sqrt{H_b}) & \text{transition zone} \\ 1 & \text{inner zone} \end{cases}$$

where H_b and H_t is the wave height at breaking point and transition point.

Example of examination results of u_m along the cross-shore direction are shown in Fig. 1.

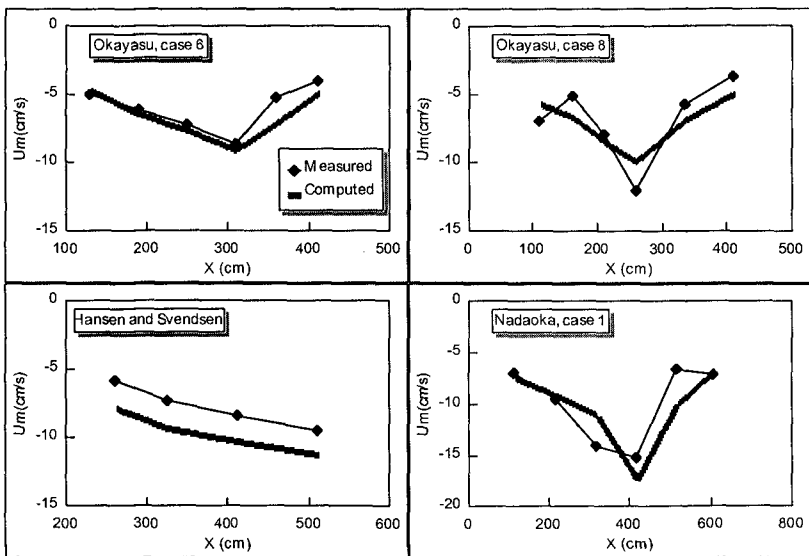

Figure 1. Example of cross-shore variations of measured and computed vertical averaged velocity, u_m .

2.2 Vertical distribution of shear stress and eddy viscosity coefficient

Based on dimensional analysis, Okayasu (1989, pp. 93-94) proposed a formulas for computing τ / ν_t as follows

$$\frac{\tau}{\nu_t} = \rho^{1/3} D_B^{1/3} \left[\frac{k_3}{d_t} + \frac{k_4}{z} \right] \dots\dots\dots (7)$$

where k_3 and k_4 are the constants, d_t is the water depth at wave trough, and D_B is the energy dissipation. From the bore model (Thornton and Guza, 1983),

$$D_B = \frac{\rho g H^3}{47h} \dots\dots\dots (8)$$

By inserting Eq. 7 into Eq. 3 and then, after an integration of Eq. 3 and use u_m as the boundary condition, the analytical solution of u can be expressed as

$$u = \rho^{1/3} D_B^{1/3} \left[k_3 \left(\frac{z}{d_t} - \frac{1}{2} \right) + k_4 \left(\ln \frac{z}{d_t} - 1 \right) \right] + u_m \dots\dots\dots (9)$$

As mentioned in previous research works, the energy dissipation process at the breaking point is not in the same manner as in the inner zone (e.g., Okayasu, 1989). To incorporate this process, Eq. 9 may be written as follows

$$u = k_5 \rho^{1/3} D_B^{1/3} \left[k_3 \left(\frac{z}{d_t} - \frac{1}{2} \right) + k_4 \left(\ln \frac{z}{d_t} - 1 \right) \right] + u_m \dots\dots\dots (10)$$

where k_5 is the constant and equal to 1 at the inner zone.

From the multi-regression analysis and assume linear distribution of energy dissipation in the transition zone, Eq. 10 become

$$u = b_2 \rho^{1/3} D_B^{1/3} \left[b_3 \left(\frac{z}{d_t} - \frac{1}{2} \right) - 0.22 \left(\ln \frac{z}{d_t} - 1 \right) \right] + u_m \dots\dots\dots (11)$$

where b_2 and b_3 are the constants and expressed as,

$$b_2 = \begin{cases} 0.3 + 0.7(x_b - x) / (x_b - x_t) & \text{transition zone} \\ 1.0 & \text{inner zone} \end{cases}$$

$$b_3 = \begin{cases} (x_b - x) / (x_b - x_t) & \text{transition zone} \\ 1.0 & \text{inner zone} \end{cases}$$

where x is the position in cross-shore direction, x_b is the position at the breaking point, and x_t is the position of the transition point.

The comparison between measured u and computed u from Eq. 11, using measured u_m , are shown in Fig. 2. From Fig. 2 we can judge that the form of τ / ν_t in Eq. 7 are accurate enough to be used for computing the velocity profiles. Examples of measured and computed velocity are shown in Fig. 3.

2.3 Formula verification

The prototype scale experiment of Kajima et al. (1983) is used to examine the validity of present formula. By using the same formula as that used for small scale wave flume (Eq. 11), Fig. 4 shows examples of verification results in the term of averaged velocity of each section along the cross-shore direction.

Figure 2. Comparison between measured and computed u (using measured u_m).

Figure 3. Comparison between measured and computed velocity profiles (laboratory data from Okayasu et al., 1988, case 6).

Figure 4. Example of verification results in term of averaged velocity along the cross-shore direction (laboratory data from Kajima et al., 1983).

III. Sediment Transport Rate

The sediment transport rate is separated into bed load and suspended load. The suspended load is expressed as the product of sediment concentration and fluid velocity. The bed load formula is derived in the similar procedure as Watanabe (1983) but the assumption on the time level and region of application are not the same. After calibrate the coefficient of bed load, the total load can be written as

$$q_t = \int_{\delta_s}^{d_s} c(z)u(z) dz + 2.0(\psi - \psi_c)\sqrt{\psi} w_s d \quad \dots\dots\dots (12)$$

where ψ is the Shields parameter, ψ_c is the critical Shields parameter, w_s is the falling velocity, and δ_s is the bottom boundary layer which computed from Jonsson (1966) formula.

The comparison of computed suspended load, bed load and total load and the measured total load are shown in Fig. 5. It should be note that the separated equation for computing transport direction is not necessary in the present model. The transport direction is depended on the combination of bed load and suspended load. In the present model, bed load is the dominant transport for accretion beach (on-shore directed transport), and suspended load is the dominant transport for erosion beach (off-shore directed transport). These transport directions correspond well with the measured total load transport as shown in Fig. 5.

Figure 5. Comparisons between measured and computed sediment transport (laboratory data from Kajima et al., 1983, case 2.2, and 4.3).

IV. Wave Model

For computing beach transformation, the wave model should be kept as simple as possible because of the frequent updating of wave field for accounting the variability of mean water surface and the change of bottom profiles. In the present study, wave height transformation in cross-shore direction will be computed from the energy flux conservation.

$$\frac{\partial Ec_g}{\partial x} = -D_B \dots\dots\dots (13)$$

where E is the wave energy density, c_g is the group velocity, and D_B is the energy dissipation rate which is zero outside the surf zone.

4.1 Energy dissipation rate

Widely used formulas for computing energy dissipation rate are Bore model and Dally et al. (1985) model. The Bore model is shown in Eq. 8, and Dally model is

$$D_B = \frac{0.15c_g \rho g}{8h} [H^2 - (\Gamma h)^2] \dots\dots\dots (14)$$

The advantage of Dally model is that it is able to reproduce the pause (or stop breaking) in the wave breaking process at a finite wave height on a horizontal bed or in the recovery zone while the Bore model gives a continuous dissipation due to wave breaking. However, for the condition when waves continuously break both two models give nearly the same result of energy dissipation rates (for example see Fig. 6). Based on the above considerations, Dally model is selected for calculation in the present research.

The published experimental results of wave height transformation inside the surf zone have been collected to test the ability of Dally model as shown in the first column of table 3. Total 9 sources of published experimental results, covering 331 data sets, are used in this section. The experiments cover wide range of wave and bottom topography conditions, including both small scale and large scale wave flume experiments. Most of the experiments were performed under fixed bed conditions, except data of Kajima et al. (1983) and Shibayama and Horikawa (1985) which were performed under movable bed conditions.

The verification results are presented in term of error function, ER , as used by Dally et al. (1985), which is defined as

$$ER = 100 \sqrt{\frac{\sum_{i=1}^{tn} (H_{ci} - H_{mi})^2}{\sum_{i=1}^{tn} H_{mi}^2}} \dots\dots\dots (15)$$

where i is the wave height number, H_{ci} is the computed wave height of number i , H_{mi} is the measured wave height of number i , and tn is the total number of measured wave height. Small value of ER expresses a good prediction.

The verification results of Dally model are shown in the third column of table 3. From the third column of table 3, we can see that Dally model gives quite good estimation of wave height inside the surf zone.

Although, Dally model gives good estimation to the experimental results, it still has some error. We may be able to improve Dally model.

Considering Dally model, the measured Γ can be computed from the measured wave height and water depth by using the following formula (rewriting Eq. 14).

$$\Gamma = \frac{1}{h} \sqrt{H^2 - \frac{\partial(Ec_g)}{\partial x} \frac{8h}{0.15c_g \rho g}} \dots\dots\dots (16)$$

The right hand side term of Eq. 16, RS , can be computed if we have the profile of wave height transformation. If we plot RS with any wave parameters, it will show a horizontal line (since Γ is constant).

Fig. 7 shows the relation between RS and the various dimensionless parameters, i.e., h/L_o , h/L , h/\sqrt{LH} . From Fig. 7 we can see that the parameter Γ is not a constant. Comparison among Fig. 7a-7c, the relation between Γ and h/\sqrt{LH} , in Fig. 7c, shows more consistent results than the others. A formula for parameter Γ , from Fig. 7c, can be expressed as

$$\Gamma = \exp\left[-0.36 - 1.25 \frac{h}{\sqrt{LH}}\right] \dots\dots\dots (17)$$

The next question is how much difference of computed wave height is resulted when we compare the results calculated by using constant Γ and calculated by using Γ from Eq. 17. Table 3 shows the error function, ER , when wave height is computed from Dally model by using either constant Γ or Γ from Eq. 17.

From table 3 we can see that the computed results show not much difference, but for most cases the results of computed wave height are improved. The selection of any type of model depends on each researcher. In the present study, the better estimation formula (Eq. 17) will be used.

Table 3. Verification results in term of error function parameter, ER .

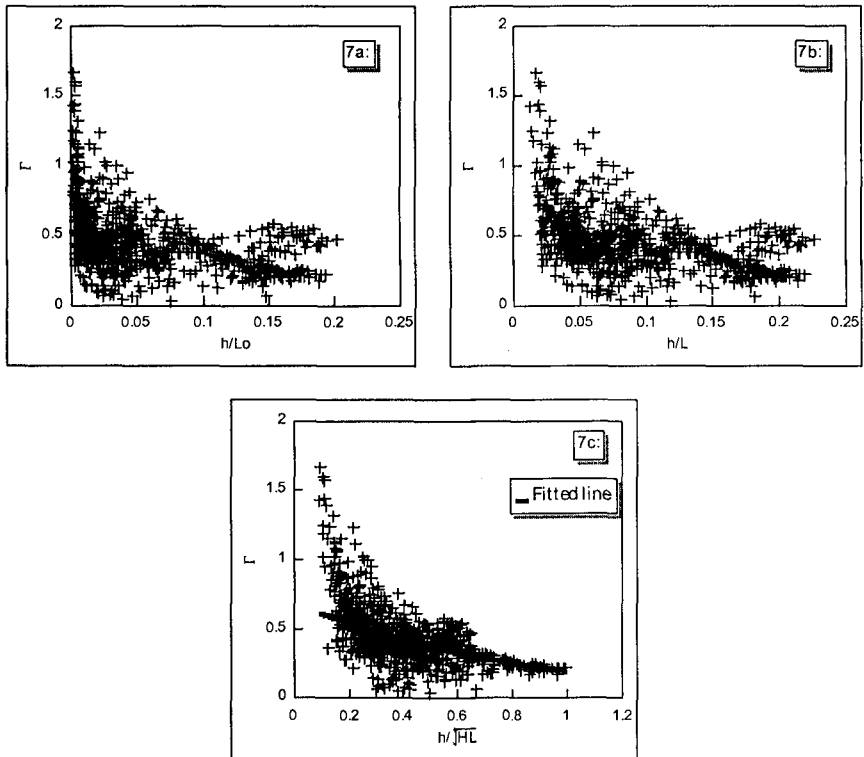

Figure 7. Relations between Γ and a: h/L_0 , b: h/L , c: h/\sqrt{LH} (laboratory data from Kajima et al., 1983).

V. Beach Deformation Model

Wave model is used to compute wave transformation from offshore boundary to shoreline boundary. From the computed wave height, sediment transport rate can be computed. Then new beach profile can be computed from the mass conservation equation (Eq. 1). The new beach profile will feed-back into the wave model and causes wave height changes. This yields the loop of dynamic beach deformation and the beach profile at any desired time can be computed.

The shoreward boundary is defined at the wave runup height. Following Larson and Kraus (1989, pp. 170-172), the sediment transport inside the swash zone is assumed to decrease linearly from the end of surf zone to zero at the runup limit. If the local beach slope exceeded the repose angle, avalanching concept will be used.

5.1 Model verification

A number of simulations are performed in order to examine the capability of the present model. All coefficients in the model are kept to be constant for all cases in the verification. Model results are compared with laboratory data of small scale experiment of Shibayama and Horikawa (1985) and large scale experiment of Kajima et al. (1983) and Kraus and Larson (1988).

The verification is performed for all cases, total 45 cases. The verification of these independent data sources and wide range of experiment conditions are expected to clearly demonstrate the accuracy, and stability of present model. The main input data of the model is the incident wave dimensions and initial beach profile. The model was run on workstations (HP 9000 series 700 computers); the total CPU time for simulation about 1000 hr (45 cases) is about 6 min. Examples of examination results are shown in Figs. 8-10. The examination results of all cases, including four profiles per case, are shown in Rattanapitikon (1995, pp. 173-196). Interesting points of the comparison results are described as follows

1. The global shapes of measured profiles are generally well predicted by the model. The predicted profiles are smoother than the measured ones. Small fluctuation of measured profiles can not be predicted by the present model (see Kajima, case 3.1 and Kraus, case 510 in Fig. 8).
2. The agreements of predicted beach profiles of the prototype scale are better than those of small scale wave flume. The fluctuation of measured beach profiles in small scale experiment are more than the prototype scale experiment and the present model can not predict those fluctuations.
3. The model is able to simulate a breaker bar of either the growth of breaker bar (see case 5.2 in Fig. 10) or the reduction of breaker bar (see case 1.2 in Fig. 9).

VI. Conclusions

Cross-shore beach deformation model is developed based on a large amount of published laboratory results. The model contains description of time-averaged concentration profile, velocity profile, sediment transport, wave height, and beach deformation. The validity of model is confirmed by small scale and large scale experiments. The main merit of this model is that it requires very short CPU time and the results are reasonably well.

Acknowledgment

The authors wish to express their gratitude to Prof. Yoshimi Goda of the Yokohama National University for his comments and fruitful discussions.

CHAPTER 238

Experimental Study on Sediment Transport in Surf and Swash Zones Using Large Wave Flume

Takao Shimizu¹, Masaaki Ikeno²

Abstract

In the present study, experiments were conducted using CRIEPI's Large Wave Flume (205m long, 3.4m wide and 6m deep) to investigate cross-shore hydrodynamics, sediment transport and beach change processes. On the experiments, suspended sediment transport in the surf and swash zones was directly measured under the condition of random waves. Moreover, the long wave effect to sediment transport was also investigated.

Introduction

Suspended sediment transport rate must be evaluated accurately to predict beach change, especially in a calm basin behind an artificial island, because suspended sediment in a surf zone is transported into the calm basin by circulating nearshore current. Recently, it was mentioned that low frequency component in a wave group influences remarkably suspended sediment transport(Sato et al.;1993). Sediment transport rate in a swash zone has to be estimated correctly to expect shoreline change, because erosion and accretion in a swash zone causes shoreline change directly. Ogawa et al.(1981) and Katori(1983) observed sediment transport in a swash zone by using sand traps.

In this study, large scale experiments on beach profile changes due to irregular waves were performed in the Large Wave Flume. Suspended sediment transport and sediment transport rate in a swash zone were measured directly. Effects of irregularity of waves on a sediment transport and influences of low frequency component in a wave group were discussed.

Experimental method

Uniform slopes of sand were piled up in the Large Wave Flume(Kajima et al; 1982) as shown in Fig.1. The bottom of offshore side 90m length of the flume is 1/15 slope. Horizontal coordinate X was defined as an seaward distance from the onshore side end of the flume. An origin of a vertical coordinate Z was defined on a still water level. Still water depth was 4m in cases of 1/10 and 1/20 slope of sand and 3.2m in a case of 1/50 slope of sand. A toe of the sand slope of 1/50 was cut

-
- 1) Research Fellow, Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-city, Chiba 270-11, JAPAN.
 - 2) Senior Research Engineer, Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-city, Chiba 270-11, JAPAN.

off by a 1/10 slope, because the still water level can't be smaller than 3.2m for wave generating and the sand volume was limited.

A measuring vehicle that runs on the flume onshore-offshore was used for measurement in a surf zone. The measuring vehicle is equipped with a capacitance type wave gauge(W) and an installing arm going up and down just beside each other. Two sets of an electromagnetic current meter(C), an optical turbidity meter(T) and a pumping tube(P) for water sampling were assembled to the installing arm. Vertical distance between two sets is 40cm. Water sample including suspended sediment was sucked up by an engine pump, and a volume of sampled water was measured by a water counter. Between the pump and the counter, the suspended sediment was filtered out by a 97μ mesh plankton net and weighed. Median diameter of the sand was 1mm, and the grain size distributed from 0.2mm to 1.3mm as shown in Figure 2. Output of turbidity meter was calibrated individually by the time averaged sediment concentration based on the water sampling data. A wheel type sand surface profiler was loaded on a trolley dragged by the measuring vehicle. The profiler can trace the beach profile under the still water and in the air continuously, accurately and speedy.

In some cases, sediment transport due to uprush and sediment transport due to downrush of individual waves were measured respectively by sand traps(S) in a swash zone. The sand traps are original hand made with metal frame and 97μ mesh plankton net as shown in Photo 1. A mouth of the trap is 5cm wide and 20cm high. The length of the trap is 1m. Fifty traps were prepared and numbered. Two footings was built up in a swash zone, and sediment transport was trapped by three persons on the footings as shown in Photo 2. Right one of this side in the photo is trapping sediment transport due to downrush pressing the under edge of the mouth of the trap against the sand surface. Right one of back side is taking a trap away from the one of this side and going to stack it in a bucket. Left one is preparing the next trap. Trappings of sediment transport due to uprush were continued for fifty waves, and after the collection of trapped sand, sediment transport due to fifty downrushes were trapped. A trapping of sediment transport due to uprush was started when a front edge of an uprush reached the trapping point, and was finished when the water started to flow down. But if the front edge of the next uprush reached the trapping point before the water started to flow down, the trap was changed quickly to the next trap. A trapping of sediment transport due to downrush

Figure 1. Arrangement of experiments

was started when the water started to flow down, and was finished when the front edge of the next uprush reached the trapping point or the down flow of the water sank into the sand. A wave gauge and a current meter was set up just beside the sand trapping. Bottom end of the wave gauge was stuck in a sand. Head of the current meter was set 1 or 2cm above the sand surface. The wave gauge on the measuring vehicle was set 8m offshore the trapping point. Outputs of wave gauges and a current meter were recorded in a memory of a personal computer and on a chart of linear-corder with trap numbers called by the trapper.

Irregular waves were generated by piston type wave generator. The wave train was repeated every hundred waves. Sampling of outputs of a wave gauge, current meters, turbidity meters and sampling water were continued for one hundred waves at every measuring points in a surf zone. Trappings of sediment transport in a swash zone was performed in the first half of the wave train and in the second half separately. In some cases, the free long wave generated at the paddle of the wave generator was canceled by the method after Ikeno et al.(1996).

Experimental cases and conditions

Table 1 shows experimental cases and conditions. In the case L1, sand slope " $\tan\beta$ " was 1/20 and regular waves were generated. Offshore wave height " H_o " was 1m and wave period " T_o " was 5s. In the case L2, irregular waves were generated using JONSWAP spectrum. Significant wave height and significant wave period was same to the case L1. Sharpness parameter " γ " is 1 according to the wind wave condition. Conditions of the case L3 were same to the case L2 except for the sharpness parameter is 7 according to the swell condition. In the case L4, free long wave cancel method was adopted to the condition of the case L2, but the significant wave height had to be reduced to 0.6m because the stroke of the paddle of wave generator is limited up to 2.1m. Conditions of the case L5 were same to the case L3 except for the sand slope and the wave was steeper than the case L3. Condition of the case L6 was same to the case L5 except for the free long wave was canceled. Conditions of the case L7 was same to the case L3 except for the sand slope and the wave was more gentle than the case L3.

Experimental results

Figure 3 shows the initial beach profiles of each cases as dotted lines and final profiles as solid lines. Profile changes of the cases L1, L2 and L3 are bar and berm system. Profile change pattern is decided by significant wave characteristics, not by sharpness of spectrum or irregularity. Profile change due to swell is more rapid than due to wind waves of the same significant wave characteristics. Profile changes of the cases L5 and L6 are typical erosional pattern with remarkably developed bar. Profile change in the case L7 is accretional pattern with sediment transport from offshore zone to surf zone.

Figure 4 shows fluctuation of suspended sand concentration "c" due to wave motion near the breaking point in the cases L1 and L6 together with horizontal velocity "u" and water surface elevation " η ". Suspension of sediment due to regular wave motion takes place at the phase when the horizontal velocity changes from onshore to offshore. Sediment is suspended due to irregular wave motion at the phase when horizontal velocity changes not only from onshore to offshore, but also from offshore to onshore.

Figure 5 to 8 show vertical distributions of suspended sediment transport flux in the cases. The graph at the top is cross-shore distribution of significant wave height and beach profiles. The graphs in the second row are vertical distributions of time averaged suspended sediment concentration. The graphs in the third row are vertical distributions of time averaged horizontal velocity. The graphs at the bottom is vertical distributions of time averaged product of suspended sediment concentration and horizontal velocity namely suspended sediment transport flux. In the cases L5 and L6, suspended sediment concentrations are higher than the other cases. In the almost cases, suspended sediment transport fluxes near the bottom are directed offshore, even in the accretional case L7.

Figure 9 shows low and high frequency components of suspended sediment transport flux in the cases L5 and L6. In the case L6 where the free long wave is canceled, long wave components of suspended sediment transport fluxes are directed offshore when the sort wave components are directed onshore. In the case L5, the above mentioned property is not clear.

Figure 10 shows synchronized data observed at the point A in a swash zone and at the point B in a surf zone of the case L5. The graph at the top of four is volume of sand per unit width trapped at the point A. Length of right side of each triangle is trapped volume. Left vertex points to the starting moment of trapping. Right

Figure 3. Beach profile change

vertices point to the finishing moment of trapping. For convenience' sake, sediment transport due to uprush and downrush are shown in one graph. The second graph is horizontal velocity 1 or 2cm above the sand surface at the point A. The curve is interrupted in the middle of downrush, because the head of current meter is exposed in the air. The third and the bottom graphs are water surface elevation at the points A and B. The waves corresponding to each other are connected by dotted lines. Number of waves reduces by half propagating from the point A to B. Waves in a swash zone are apt to be grouped and uprush velocity due to the first wave of the group is strong and uprush sediment transport is remarkable under the action of the first wave. Crest level of the last wave of the group in a swash zone is highest and downrush velocity due to the last wave is strong and the downrush sediment transport due to the last wave is striking and drags on.

Table 2 shows the uprush and downrush data of individual waves in a surf zone of the case L5. "H" is crest height measured from the trough just before the crest. "h" is water depth under the trough. "Uu" is horizontal velocity under the crest. Positive data is onshore velocity. Three data are negative, because the bottom velocity remains offshore when the front of the next uprush reached the trapping point. "Qu" is trapped volume of sediment transport due to uprush par unit width. "Ud" is trapped volume of sediment transport due to downrush par unit width. Total volume of Qu is 65.7 litter par meter and total volume of Qd is -84.4 litter par meter. Net volume of sediment transport during one hundred waves is -18.7 litter par meter. It is converted to the net sediment transport rate $-6.2 \times 10^{-5} \text{ m}^3/\text{m/s}$.

Figure 11 shows sand transport rate counted back from profile change in the case L5. The net sediment transport rate at the trapping point $-6.3 \times 10^{-5} \text{ m}^3/\text{m/s}$ is read

Figure 14. Φ' due to individual uprush and $\Psi'(H+h)/D_{50}$

due to individual uprush and nondimensional bottom friction Ψ' . Relationship between Φ' and Ψ' is bad, because uprushing bore involves suspended sediment according to not only bottom friction but also thickness of the bore.

Figure 14 shows relationship between nondimensional sediment transport rate Φ' due to individual uprush and product of nondimensional bottom friction Ψ' and nondimensional thickness of the front bore of uprush. Sediment transport rate due to uprush is modeled by following equation;

$$\Phi' = 1.38 \times 10^{-5} \{ \Psi' (H+h)/D \}^{1.43} \quad (4)$$

Conclusions

- ① Beach profile change due to swells is more rapidly than that due to wind waves.
- ② Around the breaking point, there is the case that low frequency component of suspended sediment transport due to long waves is offshore, and high frequency one is onshore.
- ③ The number of waves decreases immediately in the swash zone, because a downrush prevents runoff of the next wave in trough phases of long wave.
- ④ Waves in a swash zone are apt to be grouped and uprushing bottom flow due to the first wave of the group is strong. Hence, uprush sediment transport is remarkable under the action of the first wave.
- ⑤ Crest level of the last wave of the group in the swash zone is highest and downrush bottom flow due to the last wave is strong. So, downrush sediment transport due to the last wave is striking and drags on.
- ⑥ Sediment transport rate due to uprush and downrush in a swash zone was modeled relating to bottom friction and thickness of uprushing bore.

CHAPTER 239

The Influence of Long Waves on Macrotidal Beach Morphology

David J. Simmonds¹, Tim J. O'Hare² & David A. Huntley³

Abstract

The aim of the following paper is to demonstrate that standing long waves can generate intertidal morphological features in a dissipative macrotidal setting. In this environment the tidal excursion can exceed the length scales associated with long waves. This extends the work of Simmonds et al (1995) in which it was shown that monochromatic long waves could generate sediment convergence patterns that bore a good similarity to observed topographic features, namely ridges and runnels from a field site on the Belgian coast. The simulation is modified to include a band of long waves and it is found that a good correspondence with real topography can still be achieved on a tidally averaged basis by allowing for a degree of uncertainty in the breaking criterion. It is also argued why the observed scales are more likely to correspond with the shorter end of the long wave spectrum. The simulation helps to shed light on the conditions in which such features are known to form.

Introduction

This paper examines the question “can a spectrum of long waves be capable of creating intertidal bedforms on a macrotidal beach?”

Despite the abundance of macrotidal coastlines Short (1991) has been led to remark that the “study of macro-tidal beaches has lagged considerably” in relation to the published material on micro- and meso-tidal coasts. Whilst numerical modellers are beginning to recognise the importance of long wave processes in the modeling of coastal morphology (Roelvink & Broker, 1993) very few of these models, even though applied to macrotidal coastal regions, appear to consider the further complication of a tidally modulated boundary. Although the concept of an equilibrium cross-shore profile is useful in a microtidal setting, the interpretation of equilibrium profile is questionable in the macrotidal setting when considered with

¹ Res. Fellow, School Civil Eng., Univ. Plymouth, Palace Court, Plymouth, UK PL1 2DE

³ Reader, Inst. Marine Studies, Univ. Plymouth, Drake Circus, Plymouth, UK PL4 8AA

respect to timescales of the order of days, even when tidally averaged quantities are considered. The cross shore tidal excursion on a dissipative macrotidal beach is measured in hundreds of meters and is further modulated by the Spring-Neap cycle. The boundary is neither steady nor varying by the same amount from day to day. It seems more appropriate to speak of a dynamic equilibrium whereby the profile is constantly adjusting from minute to minute within limits determined by the tidal level and variations in the wave climate.

Standing long wave motion at the shoreline is often associated with the formation of submerged bars (Short, 1991, Sallenger & Holman, 1987) and support for this has been provided by field observations (e.g. Bauer & Greenwood, 1990). But what of the intertidal bedforms such as the bar-like features, referred to as ridges and runnels, that are evident on some macrotidal coastlines?

Wright et al (1982) suggested that macrotidal beach profiles are due to the combination of swash, surf and deeper water processes that operate over different regions of the beach face for different periods of time. It was also suggested that some wave-lain features may survive swash & surf zone excursion in low energy conditions — but that in high energy conditions any bedforms are erased by the more energetic processes.

These studies have been predominantly based on high energy exposed shorelines. In the European context, many dissipative macrotidal shorelines are to be found sheltering in fetch limited environments well away from the continental shelf breaks. In these situations, more subtle, lower energy mechanisms might be more evident.

It is tempting to suggest that standing long waves might be somehow responsible for the development of intertidal features such as ridges and runnels as the length scales of both are comparable. In addition it is widely recognised by field workers that long wave energy is present, to some degree, on all shorelines. In the simplest analysis, topographic features are believed to be generated under a stationary standing long wave. However on a macrotidal dissipative coast the reflection point of the long waves (whether considered at the shoreline or in the surfzone) can move cross-shore by several long wave wavelengths.

Simmonds et al (1995) showed how standing long waves might form bar-like features in the intertidal zone of a linear beach dominated by cross-shore long wave processes. They based their analysis upon a simple transport mechanism resulting from the correlation of the long waves with the incoming wave groups to demonstrate how intertidal bedform development might be initiated through a "tidal bar hypothesis". Using a monochromatic long wave envelope, a pattern for the *potential for erosion* across the beach face was shown to correspond well with observed scales of ridge and runnel morphology even around the mid-tide region, despite the inclusion of tidal modulation of the transport envelope across the beach face.

However, long waves observed in the field are generally broad-banded in nature (Huntley et al, 1993) and it might be predicted that the result of including of a realistic bandwidth of long waves would smear over the effect of the individual waves. This effect combined with tidal modulation of the reflection point would surely destroy any “memory” that the beach retains of the long wave structure – although Bowen and Huntley (1983) suggested that feedback, in the form of erosion of the bed and subsequent modification of long wave structure might result in a narrowing of the effective spectrum that shapes the beach through resonance.

A further criticism of the hypothesis is that given that there is a band of long waves why does there appear to be a stronger correlation at the shorter wavelength end of the measured band than at the longer scales?

We will investigate these criticisms by reference to an improved version of the original simulation outlined in Simmonds et al. (1995). It will be shown that under conditions recognised as precursory to ridge and runnel formation, rhythmic intertidal features are indeed predicted. We draw upon the geometry and field measurements of a particular example of ridge and runnel morphology. The aim is not to present a full sediment and hydrodynamic coupled model, but instead to show that the mechanism for forming intertidal bedforms involving standing long waves is feasible.

A Field Example of Rhythmic Intertidal Morphology

First of all it is useful to reintroduce the field example of ridge and runnel features (Simmonds et al, 1995). The macrotidal beach profile is shown in Figure 1 and is taken from a field site at Nieuwpoort on the Belgian coastline which was the

Figure 1. Ridge & Runnel profile at Nieuwpoort, Belgium

focus of the recent *MAST* project *Circulation and Sediment Transport Around Banks* (CSTAB —O'Connor et al, 1996). This illustrates the kind of intertidal features that are expected to be associated with long waves by virtue of their length scales. These ridges exist as low lying, shore-parallel bodies of sand with cross-shore scales of the

order of 50m separated by runnels. Their longshore extent is interrupted by shore-normal channels spaced every 500m or so, down which water is drained from the runnels on the ebb of the tide. They are exclusive to dissipative macrotidal beaches of medium sand sized material and fetch limited wave climate.

It is hard to justify that these particular features are merely swash bars formed at low and high still stands at Spring and Neap tide levels (King & Williams, 1949). Five bars are clearly visible. Other documented cases of ridge and runnel beaches exhibit even greater numbers of ridges (Mulrennan et al, 1992). Indeed the number and spacing of these particular features on low energy beaches is reported to be strongly related to the beach slope and this is more reminiscent of long wave structure where the node-anti-node spacings are also dictated by the beach slope β . Therefore this swash bar hypothesis should be rejected.

The scales involved are certainly too large for comparison with gravity wavelengths. So the question "Could long waves be responsible?" arises. Simmonds et al (1995) previously reported the identification of standing long wave activity, even during low energy conditions at this particular beach in the frequency band of 0.01-0.04Hz (100s to 25s wave period). The scale of the features was shown to be consistent with shortest of these long wave scales (0.04Hz) measured at the beach which had a slope of around 1%. It therefore seems likely that long waves are indeed responsible.

Long Wave Transport Mechanisms

The mechanism by which a memory of the structure of a standing long wave can come to be imprinted upon a beach is now discussed. The cartoon (Figure 2) illustrates two mechanisms that can be considered.

Figure 2 Transport mechanisms

The first involves sediment movement in response to the mass transport induced under a standing wave. This has been investigated in associated with sub-tidal bar formation (e.g. Carter et al. 1973). In this, the sediment is assumed to move in response to the drift velocities induced by the standing long wave structure. Sediment accumulates either at the nodes or anti-nodes according to different

investigators though there is no general agreement as to which, although the answer is thought to depend upon the sediment grain size.

The second is a mechanism based upon the correlation of short-wave groups with a bound long wave. O'Hare & Huntley (1994) have discussed a model that furthers the concept of short waves acting as sediment stirrers and correlated long waves acting as transporters (pseudo-steady currents). In the case of a bound long wave the long wave is generated through the radiation stress variation under wave groups so that the largest short waves occur around the long wave troughs and the smaller at the long wave crests. Such a correlation creates a net offshore transport when integrated over a long wave cycle.

If a planar beach face is considered, in the absence of any other processes, this offshore sediment flux would be predominantly modulated by the simple depth dependence of the short wave orbital velocity. The inclusion of a phase-locked reflected long wave, however, introduces a rhythmic cross-shore spatial variability in the sediment flux. The function which is the gradient of this can be interpreted as regions of net erosion or accretion.

Both of these two mechanisms would produce an erosion pattern that would predict features of the same scale. However, the efficiencies of the two in transporting sediment will have different magnitudes. We argue here that the correlation mechanism is likely to be more important.

In the first case the transport mechanism is related through a power law to the "drift velocity". This second order parameter arises from the non-linearity in orbital motion under the standing waves. In the case of long waves this is likely to be very small in relation to the orbital velocity of the long waves.

In the second, the net transport is the result of averaging the correlation between the square of the heights of the (stirring) short wave and the velocity of the (transporting) long waves. Again, it is difficult to estimate the relative importance of this quantity since the resulting transport over a long wave cycle will depend upon, amongst other factors, the amplitude of the long wave orbital velocity and the groupiness of the short waves — that is, the net effect depends upon the difference between the onshore and offshore directed correlation's.

However, the magnitudes of the latter velocities are much greater than those of the drift velocities, and so the second mechanism has the potential to be significantly greater.

Bias to Shorter Scales

If it is accepted that there is a process for the imprinting of long wave scales on the beach face the next question to address is "why is a stronger correspondence with the shorter end of long wave spectrum observed in the field?" As we stated earlier, the observed correlation between the measured long wave spectrum and the observed morphological scales at Nieuwpoort indicated a good agreement but only at

the shorter (0.04Hz) end of the long wave spectrum. This bias can be understood by considering the following arguments.

First, we should define what we understand by the description “broad banded” in relation to the long wave spectrum. If we take the naïve interpretation of “broad-bandedness” as implying equal wave heights at all frequencies in the spectrum, quite clearly the velocity (transporting) spectrum will be biased towards higher frequencies. This is because the velocity is obtained as the gradient of the time series. Put another way, a “white” amplitude spectrum corresponds to a “blue” velocity spectrum (predominance of higher frequencies).

We can also argue, on a geometric basis, that shorter long wave scales grow more rapidly. This is because the work done on the bed in changing from a flat to an undular bed is less if the undulations are of shorter wavelength (Figure 3). The distance that the centroid of sand has to move in order to create a depression and an adjacent hole is less for the shorter wavelength feature than the longer, although the

Figure 3 Geometric argument: mass centroid in (a) moves further than in (b)

amount of material that has moved is the same. It is therefore likely that the shorter scales are quicker to develop upon the beach and can be concluded that there is an inherent bias to short scales forming. This is especially important for a system in a state of dynamic equilibrium where features that require longer timescales in order to establish themselves will be discriminated against.

Simulation

Attention is now turned to the simulation reported in Simmonds et al. (1995). The simulation is used to predict the spatial cross-shore profile development. The basis for this is the assumption that the sediment transport is everywhere offshore directed due to the correlation mechanism outlined above. Obviously this is unrealistic—beaches do not simply disappear off-shore, (at least, in the short term), but this assumption is made so that the potential of this mechanism can be investigated in isolation. As such, other processes such as surf-zone and swash processes are not represented.

A bound long wave is assumed to interfere with a reflected free long wave to give a shallow water standing long wave. The sediment transport rate is assumed to be proportional to the product of the magnitude of the standing long wave orbital velocity and of the square of the short-wave envelope.

It is further assumed that the short wave envelope that stirs the sediment can be described by simple shoaling waves which break with a linear decrease in waveheight to the shoreline. The standing long wave envelope, calculated from the bessel function solutions of Lamb (op cite Kirby et al, 1981) defines the magnitude of the offshore flow. The product of these two represents an expression of the uncalibrated offshore sediment flux whose spatial representation is the sediment flux function. The gradient of this is the quantity that is of interest, and is referred to here as the *sediment flux convergence* (SFC). This is interpreted as an indication of zones of sediment accretion or erosion across the profile.

The bias to higher frequencies is incorporated in the model in terms of a "blue shift" of the velocity spectrum. This is generated by assuming uniform amplitude spectrum and hence a velocity spectrum biased linearly towards the high end of the frequency band.

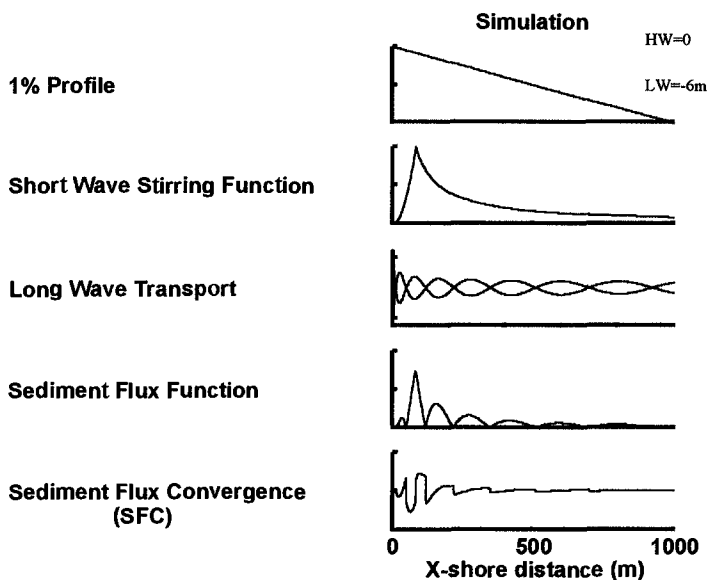

Figure 4. Components of the simulation

Taking parameters similar to those observed at the site at Nieuwpoort beach, a Spring tidal modulation of 6m height is introduced over a planar beach of 1% slope. Figure 4 shows how the simulation is constructed. This was implemented in the MATLAB language on a PC.

The simulation is also represented by the flow diagram (Figure 5). The model parameters specified include the short-wave height, the breaking depth, the long wave spectral amplitudes and the beach slope. From this information the standing long wave envelope (SLW env) is calculated and the short wave envelope (SW env). Multiplied together, these give the sediment flux function for a particular long wave frequency and reflection point on the profile.

The simulation has then been adapted to permit the summation of the sediment flux functions over a suitable spectrum of standing long waves at each position of the tide. The summation of the calculated sediment flux convergence functions is then performed to calculate the tidal average.

It is also possible to modify the short-wave envelope to allow for a degree of uncertainty in the short wave height and breaking criterion. This is desirable because, firstly, groupy waves do not all break at the same position, and, secondly, breaking is believed to be influenced by instabilities which determine that the nature of this process is chaotic (Longuet-Higgins, 1994).

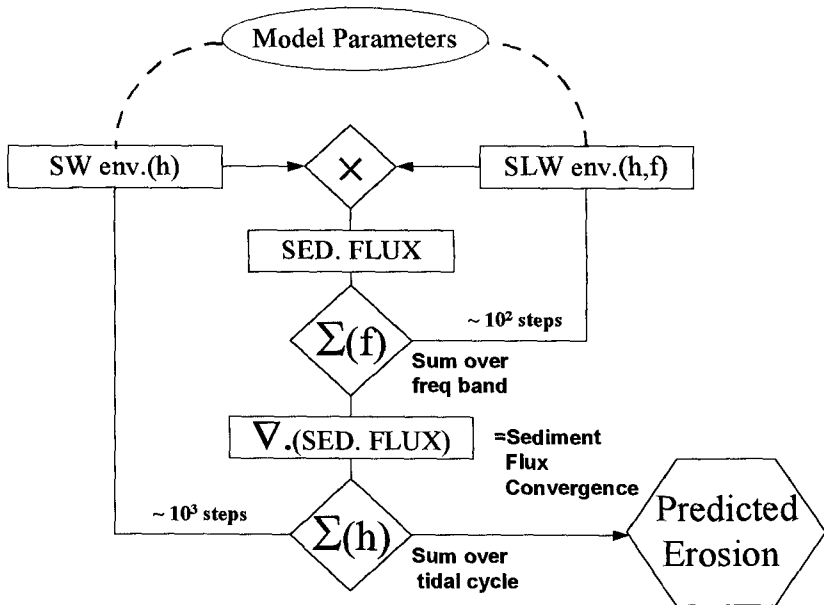

Figure 5 Flow-chart for improved simulation

As mentioned, the simulation involves two summations. Summation over frequency band and summation over all tidal amplitudes. An appropriate indication of the magnitude of the number of steps for these two summations is indicated in the figure. These have been selected to optimise processing time against numerical "noise".

It should also be pointed out that at each position of the tide the sum of the superimposed velocities is being calculated. It is therefore being assumed that all the different standing long wave modes occur simultaneously and, further, that their respective correlations with the short waves also all occur together. Whether this is realistic is a matter for debate. Usually the statistical analysis of a wave record is interpreted to mean that the spectrum of frequencies is stationary. It may be that, in reality, there is a "wandering" of the peak band of frequencies from long wave to long wave.

The present simulation is not sensitive to the order in which the two summations are calculated. However to develop the model further, feedback, in the form of bed evolution, is to be introduced before summing over the next tidal

Figure 6(a) Ridge & runnel profile. Monochromatic calculations of the SFC for (b) 6m tide & (c) 2m tide.

amplitude after the summation over frequency bandwidth.

Tidally averaged runs for Spring & Neap tides using values for these parameters obtained from the Nieuwpoort beach produces the results in figure 6(b) & (c) for monochromatic long waves (0.04Hz). As can be seen the predicted SFC shows good correspondence with the actual topography, Figure 6(a), in terms of scale.

A Realistic Bandwidth of Long waves

The main query regarding the above simulation is: "what effect does a realistic, broad long wave bandwidth have on these predictions?" This question will now be addressed and the sensitivity of this simple model to other parameters will also be discussed.

At first sight, Figure 7 indicates that calculating the SFC for a band of long waves destroys the intertidal undulations, except in the case of a very narrow bandwidth indeed. However this can be shown to be misleading by studying the

sediment flux functions. Figure 8(a) indicates that the flux function (the offshore transport) is dominated by the position of the breakpoint. This creates two relatively sharp peaks in the SFC near high and low water throwing the remaining details in to the shadows. The convergence here is emphasised by the fact that the breakpoint dwells at these two positions for the longest. As mentioned above, in reality the breaking of the short waves has a statistical variation caused by variations in the waveheight due to groupiness, return flows, interactions with preceding waves and an inherent chaotic instability in the breaking process.

To study the effect of this, an uncertainty in the breakpoint was modeled assuming a gaussian description of wave height and the breaking criterion. This was included in the description of the short wave envelope or "stirring function". The effect in the sediment flux function is evident in Figure 8(b). The breakpoint is rounded off and de-emphasised, allowing detail of the long wave structure to emerge. Figure 9(b) shows the effect of this in the predicted SFC which displays once again some undular detail across the profile, more obviously than in Figure 9(a). Again the scales correspond well with those observed in the field.

Figure 7 SFC calculated for different long wave bandwidths

The uncertainty in the breakpoint acts to widen the surf zone. Another way this can be achieved is to consider short waves with larger waveheight. As can be seen in Figures 8(c) and 9(c), the effect of this is to smooth off the breakpoint further and to bring out more intertidal profile detail. This remarkable result shows that despite summing over a band of long waves and averaging over a tide, the predicted SFC still shows details that correspond to the observed topography even in the mid tidal region. However, although larger wave heights are helpful in this model it is probably true, as Wright (1982) indicates, that in very high energy events other

processes will dominate and the surf zone “bulldozer” will mask the effects of this subtle mechanism.

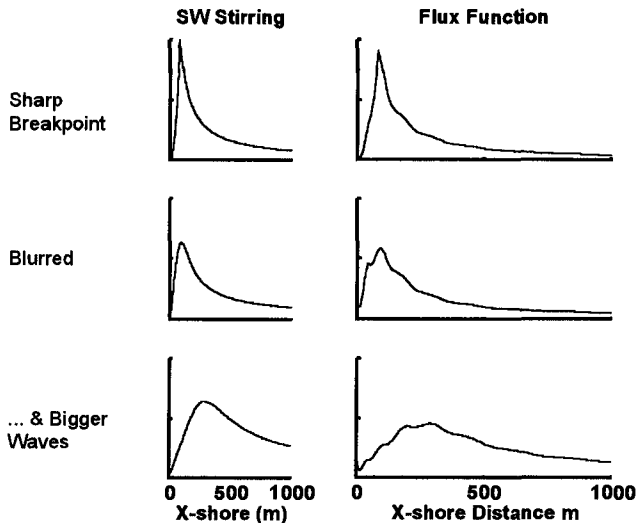

Figure 8 Short wave envelopes and sediment flux functions for (a) sudden breaking, (b) uncertain breaking, (c) uncertain breaking & larger wave height

Further Investigations

The simulation was also used to investigate other parameters, including shape of the tidal curve and of the spectrum. These predictably showed that a flatter tidal curve de-emphasised erosion at the high and low water marks, and that a “blue” long wave amplitude spectrum brought out even more detail in the undulations of the sediment flux convergence.

Time-scales

The results so far have all been calculated as averages over the tidal cycle. Figure 10 shows the sediment flux convergences calculated for averages over shorter fractions of a tide ($1/6$ ths). As can be seen, the tidally averaged result shows no indication of some of the features that can develop during the middle of the tide. Two features at 200m and 500m are clearly visible in the mid tide SFC but these are cancelled by the SFCs approaching high and low water.

It is likely that the bed will respond over shorter time-scales than that of a tide. If the bed is modified, the long and short wave field are changed accordingly

and the erosion patterns will be changed. It may be that the erosion pattern is capable of “tuning in” with the topography to favour growth of certain scales.

Southgate (1995) has remarked that since the interaction between hydrodynamics and the transport of sediment is non-linear, the chronology or sequencing of wave events is of direct influence. Further, in the macrotidal case, the erosion of the beach face will be dependent upon both the temporal variation of the long wave transport functions and the tidal variation.

Figure 9(a) SFC for a band of long waves (0.01–0.04Hz), (b) inclusion of uncertain breaking & (c) bigger short waves.

Summary & Discussion

Simmonds et al (1995) demonstrated that a standing long wave mechanism such as the bound long wave–short-wave correlation is capable of generating intertidal bedforms at scales observed in nature. This idea has been extended in this paper to the consideration of a band of long waves. It has been argued that there exists an inherent bias towards the quicker development of shorter scales. It has been shown that a band of longwaves will still generate undular intertidal topography, even in the mid–tide region so long as a smoothing of the breakpoint and hence a widening of the surfzone is introduced. This was necessary to de-emphasize the erosion at the high and low water levels caused by the constancy of the breaking at these places. The smoothing is justified by considering the uncertainty in the breaking process. The resulting predicted regions of sediment convergence agree remarkably well with the observed topography.

It has also been suggested that the current approach to integrating results over tidal timescales needs re-examining since it is that the bed will respond over much shorter timescales.

Figure 10 SFCs calculated for different sixths of the tide

The model helps us to explain the environment in which ridge and runnel features are found. For the mechanism to work, the cross shore tidal excursion must exceed the scale of the shorter long wave wavelengths otherwise no intertidal structure can be created. Broad, dissipative macrotidal beaches are ideal for this. The mechanism is, however relatively subtle, depending upon the long wave orbital velocities to carry out the transporting of the sediment, and would probably be masked by other processes in a more energetic environment. This might explain why these features are only found on fetch limited macrotidal coastlines.

Future developments of the model are envisaged that allow erosion of the bed as a feedback mechanism which perturbs the structure of the sediment flux function. It is hoped that such a coupled sediment transport and hydrodynamic model can be used to study the parameters that control the behaviour of these intertidal features and the time-scales of their development.

CHAPTER 240

MATHEMATICAL MODELS FOR WAVES AND BEACH PROFILES IN SURF AND SWASH ZONES

Akira Watanabe¹ and Mohammad Dibajnia²

Abstract

The paper presents mathematical models for wave deformation and for beach profile change in the surf and swash zones. Boussinesq-type equations including a breaker-induced energy dissipation term (Watanabe *et al.*, 1994) is extended to the swash zone by introducing a periodically moving shoreward boundary. Computation is made on the wave deformation on constant slope beaches, particularly on the runup and run-down heights as well as the wave heights at the still water shoreline, which are compared with existing formulas. Beach profile change is computed with the sediment transport rate formula proposed by Dibajnia and Watanabe (1992) after a further generalization, together with Lagrangian treatment for the sediment motion in the swash zone, using the near-bottom velocity obtained from the wave computation. The validity of the models is examined through comparisons with measurement data obtained in large wave flume experiments.

Introduction

The authors have presented a numerical model for profile change of sheet-flow dominated beaches based on Boussinesq-type wave equations and a sediment transport rate formula proposed by themselves (Watanabe *et al.*, 1994). It has been demonstrated that the model can predict well the cross-shore distributions of the wave height and the transport rate as well as the beach profile change in and around the surf zone. However, the model has a crucial limitation of the incapability of computing the wave behavior and the beach evolution in the surf zone, both of which are generally very important in practical applications and fundamental studies regarding

¹ Professor, Department of Civil Engineering, University of Tokyo, Hongo-7, Bunkyo-ku, Tokyo, 113, Japan.

² Associate Professor, ditto.

the coastal processes. A major effort in the present study is thus focused on the treatment of the swash zone dynamics both for waves and for sediment transport. Mathematical models are proposed for wave deformation and beach profile change and their validity is examined by comparing computations with measurements.

Mathematical Model for Wave Deformation

Watanabe *et al.* (1994) have presented a set of one-dimensional Boussinesq-type equations including a breaker-induced energy dissipation term as follows:

$$\frac{\partial \zeta}{\partial t} + \frac{\partial Q}{\partial x} = 0, \quad \zeta = \zeta(x,t), \quad Q(x,t) = \int_{-h}^{\zeta} u(x,z,t) dz \tag{1}$$

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x} \left(\frac{Q^2}{D} \right) + gD \frac{\partial \zeta}{\partial x} - \frac{1}{3} \bar{D}^2 \frac{\partial^3 Q}{\partial t \partial x^2} - M_D = 0 \tag{2}$$

where

$$D(x,t) = h + \zeta, \quad \bar{D}(x) = h + \bar{\zeta},$$

u is the horizontal velocity, and M_D corresponds to the momentum diffusion in the surf zone and has been expressed by Sato and Suzuki (1990) (See also Sato and Kabiling, 1994a, b) as

$$M_D = \frac{g\bar{D}}{\sigma^2} f_D \frac{\partial^2 Q}{\partial x^2} \tag{3}$$

in which σ is the angular frequency, and f_D is the following energy dissipation coefficient proposed by Watanabe and Dibajnia (1988).

$$f_D = \alpha_D \tan \beta \sqrt{\frac{g}{D}} \cdot \sqrt{\frac{\hat{Q} - Q_r}{Q_s - Q_r}} \tag{4}$$

where $\alpha_D = 2.5$, $\tan \beta$ is the bottom slope around the breaking point, \hat{Q} is the amplitude of the flow rate Q , and Q_s and Q_r correspond to \hat{Q} in the dissipation zone on a uniform slope and in the recovery zone of constant depth, respectively, defined in this study by

$$Q_s = 0.4(0.57 + 5.3 \tan \beta) C \bar{D}, \quad Q_r = \gamma_B \cdot C \bar{D} \tag{5}$$

where C is the wave celerity, and γ_B is a coefficient proportional to the ratio of the wave amplitude to the total mean depth. In the present model, we don't use any breaking criterion that determines the location of the breaking point *a priori* as employed in most previous models. Instead, by setting an appropriate value of γ_B and by equating f_D to zero in regions where $\hat{Q} \leq Q_r$, the model can automatically handle the problem of determining the breaking point and the dissipation zone as well as the recovery zone. This also makes it unnecessary to use the factitious increase of the value of α_D from 0 to 2.5 around the breaking point that is otherwise needed to avoid numerical wave reflection from there.

The Sommerfeld radiation condition is imposed on the offshore boundary of a computation domain in the same way as in the previous model (Watanabe *et al.*, 1994). On the other hand, the treatment of the shoreward boundary in the present model is completely different from the previous one that assumes the presence of a fictitious shoreward zone of constant depth and neglects the swash wave behavior. Here we adopt a periodically moving shoreward boundary (swash wave front) on which the condition $Q = 0$ is imposed all through the period of uprush and backwash.

Numerical computation is conducted by a finite difference method with a staggered grid scheme of the central difference except for the convection term that is treated with the upwind difference for the sake of stability.

Application of the Wave Model

Figure 1 shows one example of a time-series of wave profiles for one wave period in and near the swash zone computed by using the present model. The bottom consists of a uniform slope of 1/20 and a horizontal bed with a depth of 2 m. The time history of incident waves ($H_I = 0.45$ m, $T = 8$ s) has been calculated by the second-order cnoidal wave theory and given on the seaward boundary ($x = 0$ m). The swash wave behavior or runoff/run-down process seems to be simulated reasonably.

Fig. 1 Wave behavior near the shoreline; Runup and run-down.
($H_I = 0.45$ m, $T = 8$ s, $\tan \beta = 1/20$)

In order to examine the validity of the present wave model more quantitatively, swash-related parameters are computed and compared with existing formulas. Regarding the runup height R_u , Hunt (1959) proposed the following formula:

$$R_u / H_0 = \tan \beta / \sqrt{H_0 / L_0} \quad (6)$$

On the other hand, Ogawa and Shuto (1984) formulated the runup height R_u , on mild

slope solid beds as the summation of the rundown height R_d and the swash zone height S_h as follows (See their paper for details):

$$R_u / H_0 = R_d / H_0 + S_h / H_0 \tag{7}$$

Comparisons of the runup height R_u are shown in **Fig. 2** between the computations by the present model and the above formulas. The agreement of the computations with Ogawa and Shuto's formula is remarkably good.

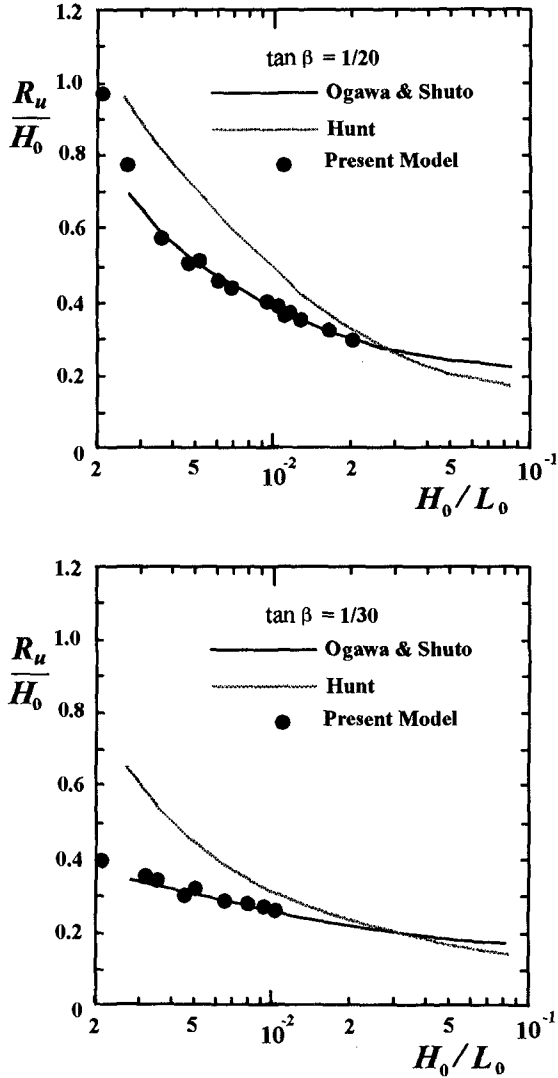

Fig. 2 Runup height R_u .

Similar comparisons are made in Fig. 3 for the rundown height R_d and the vertical length of the swash zone S_h . The agreement with Ogawa and Shuto's formula is worse for R_d and thus for S_h than for R_u in particular for the small deepwater wave steepness, but still fairly good.

Fig. 3 Rundown height R_d and swash zone height S_h .

Now we will discuss the accuracy of the present model for evaluating the wave height H_S at the still water shoreline. Sunamura (1984) has reported the following

empirical formula for H_S based on wide-range experimental data.

$$H_S / H_B = 2.5 \tan \beta \tag{8}$$

where H_B is the breaker height, which, according to Sunamura and Horikawa (1974), is related to the deepwater wave height H_0 , wavelength L_0 and the bottom slope as

$$H_B / H_0 = (\tan \beta)^{1/5} (H_0 / L_0)^{-1/4} \tag{9}$$

Substituting Eq. (9) into Eq. (8), we obtain

$$H_S / H_0 = 2.5 (\tan \beta)^{6/5} (H_0 / L_0)^{-1/4} \tag{10}$$

Figure 4 compares H_S between the computations and Eq. (10), also demonstrating the applicability of the present model to simulating the swash wave dynamics.

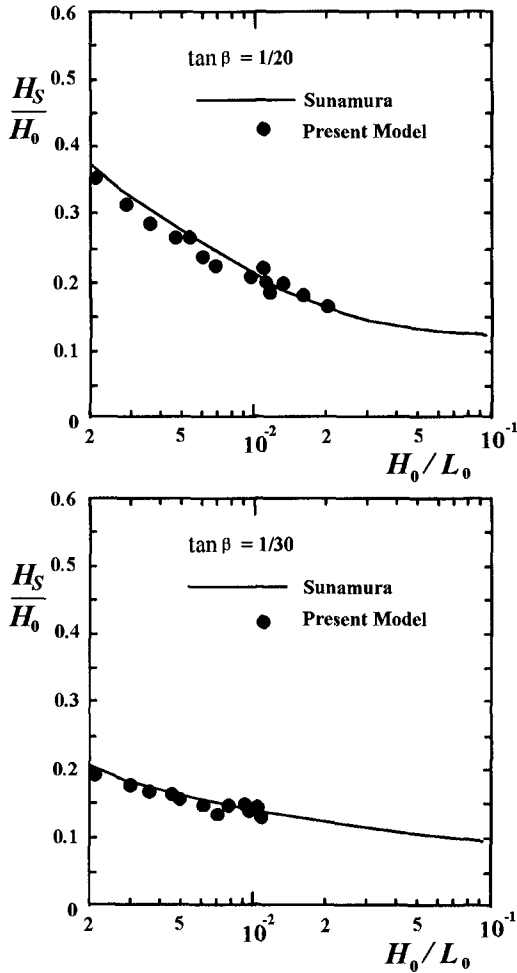

Fig. 4 Wave height H_S at the still water shoreline.

Mathematical Model for Beach Profile Change

The sediment transport rate formula proposed by Dibajnia and Watanabe (1992) is for the sheet flow in asymmetric oscillatory flow with superimposed steady flow, and has already been generalized by them for the bedload as well as for the suspended load over ripples (Dibajnia *et al.*, 1994). After a further slight modification, Dibajnia and Watanabe's sediment transport rate formula reads as follows:

$$\Phi = \frac{q_{\text{net}}(1 - \lambda_v)}{w_0 d} = 0.001 \cdot \text{sign}(\Gamma) \cdot |\Gamma|^{0.5} \quad (11)$$

where q_{net} is the net transport rate, and w_0 , d , and λ_v are the settling velocity, grain diameter, and porosity of the sediment, respectively. The quantity Γ is defined by

$$\Gamma = \frac{u_c T_c (\Omega_c^3 + \Omega_t^3) - u_t T_t (\Omega_t^3 + \Omega_c^3)}{(u_c + u_t) T} \quad (12)$$

in which u_c and u_t are the equivalent root-mean-square amplitudes and T_c and T_t are the periods of the onshore and offshore velocity, respectively, and $T (= T_c + T_t)$ is the wave period, namely,

$$u_c^2 = \frac{2}{T_c} \int_0^{T_c} (u_w + U)^2 dt, \quad u_t^2 = \frac{2}{T_t} \int_{T_c}^T (u_w + U)^2 dt \quad (13)$$

where u_w is the near-bottom orbital velocity and U is the steady flow velocity. Values of Ω_j are determined as follows:

$$\left\{ \begin{array}{l} \text{if } \omega_j \leq \omega_{\text{cr}} \\ \text{if } \omega_j > \omega_{\text{cr}} \end{array} \right\} \left\{ \begin{array}{l} \Omega_j = \omega_j \cdot \frac{2w_0 T_j}{d} \\ \Omega'_j = 0 \\ \Omega_j = \omega_{\text{cr}} \cdot \frac{2w_0 T_j}{d} \\ \Omega'_j = (\omega_j - \omega_{\text{cr}}) \cdot \frac{2w_0 T_j}{d} \end{array} \right. \quad (14)$$

where the subscript j is to be replaced by either c or t , and

$$\omega_j = \frac{1}{2} \cdot \frac{u_j^2}{sgw_0 T_j}, \quad s = \frac{\rho_s - \rho}{\rho} \quad (15)$$

$$\omega_{\text{cr}} = 1 - 0.97 \cdot \sqrt{\Lambda}, \quad \Lambda = \{1 - [(\Psi_{\text{rms}} - 0.2) / 0.4]^2\} \cdot \min(1, 2\lambda / d_0) \quad (16)$$

in which ρ and ρ_s are the densities of the water and sediment, respectively, Ψ_{rms} is the Shields number estimated in terms u_c and d , λ is the pitch length of ripples if any, and d_0 is the near-bottom orbital diameter.

Now one very important issue is how to apply this generalized formula to computing the sediment transport rate in the swash zone reasonably, where the wave-induced orbital velocity drastically varies over a distance of the periodical movement of sediment mass. In the present model for beach profile change, we will adopt a Lagrangian method, namely, assuming that the velocity of every sediment mass in

motion is given by the concurrent flow velocity, we trace the motion of a sediment mass over every wave period, memorize the velocity variation experienced by it, determine its mean position by taking the time-average, and evaluate its net transport rate at this position from the above formula with the velocity variation.

The undertow velocity, which is particularly large near the breaking point in the surf zone, is also incorporated in the computation of the transport rate (For details, readers are referred to Watanabe *et al.*, 1994). Change in beach profiles is obtained from the following conservation equation of sediment mass including the effect of local bottom slope (Watanabe *et al.*, 1986) through alternate computation of the wave deformation, the net transport rate, and the beach transformation itself.

$$\frac{\partial z_b}{\partial t} = -\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x} \left(q_{\text{net}} - \varepsilon_s |q_{\text{net}}| \frac{\partial z_b}{\partial x} \right) \quad (17)$$

where z_b is the bottom elevation, and a value of the coefficient ε_s is set equal to 2.0 in consideration of the repose angle of sand.

Application of Beach Profile Model

Now we will examine the validity of the model for the beach profile change. **Figures 5 and 6** show examples of comparisons of the wave height distribution and of the beach profile change between the computations and measurements. The measurement data are those obtained in large-wave-flume experiments by Shimizu *et al.* (1985). Figure 5 corresponds to an erosional condition, whereas Fig. 6 to a depositional case. For both the cases, the computed wave height distributions agree very well with the measurements except for the under-estimation near breaking points, which is attributable to the weak nonlinearity of Boussinesq-type equations. It is seen in Fig. 5 that the present model properly reproduces not only the formation of a bar but also the recession of the shoreline. Figure 6 also indicates high capability of the model in reproducing both the accretion near the shoreline and the berm formation.

Concluding Remarks

Mathematical models have been proposed in this paper both for the nearshore wave deformation and for the beach profile change in the surf and swash zones. The wave model is based on a Boussinesq-type equations including the breaker-induced energy dissipation and adopts a periodically moving shoreline boundary for the treatment of the swash zone dynamics. In the beach profile model, a Lagrangian method has been employed to evaluate the net rate of sediment transport in and near the swash zone. The validity and applicability of the proposed models have been verified through comparisons with the existing formulas and the experimental data both for the wave deformation and the beach profile change. Improvement of the computational efficiency and application to longer-term and H-2D conditions are left for future study.

CHAPTER 241

Comparisons of Erosion Models For Storms at Ocean City, MD

Jie Zheng¹ and Robert G. Dean²

Abstract

A new non-linear cross-shore sediment transport model called CROSS is developed based on equilibrium beach profile concepts and scaling relationships. CROSS and three other existing models, CCCL (Chiu and Dean 1984), EDUNE (Kriebel 1989) and two versions of SBEACH (version 2.0, Larson and Kraus 1989, and version 3.0, undocumented) are investigated by comparing erosion occurring from November 1991 to January 1992, at Ocean City, Maryland, the site of a major beach fill placed by the State of Maryland and Federal Government in 1988, 1990 and 1991. Among the four models, CCCL is the only one which overpredicts average dune erosion; the other three underpredict it. Overall CROSS and EDUNE yield better predictions than the other two models.

Introduction

Ocean City, Maryland, is located on Fenwick Island, a north-south oriented barrier island of the central Delaware-Maryland-Virginia coast. The Ocean City beach was nourished by the State of Maryland in 1988, and the Federal Government in 1990 and 1991 to protect the city against storm damage (Stauble et al. 1993). The project layout is shown in Figure 1. The entire project was finished in August 1991.

After the project, a series of storms occurred in late 1991 and early 1992. Among these 1991-1992 winter storms, the January 4, 1992 storm was very severe with a peak storm surge of 2 meters (Jensen and Garcia 1993). The initial pre-storm beach profiles were surveyed on November 2-4, 1991, and the post-storm profiles were surveyed on January 11, 1992. In this period, an additional storm occurred on November 11, 1991. For consistency with the measured pre-storm and post-storm profiles, both the November 1991 and January 1992 storms are included in the numerical simulations. A total of seven survey lines located from the southern (37th

Street) to northern (124th Street) portion of the project are available for both pre and post-storm surveys (Stauble et al. 1993, and Kraus and Wise 1993).

Four cross-shore sediment transport models are compared for the simulations of beach erosion at Ocean City during the November 1991 and January 1992 storms. These models are

- CCCL (Chiu and Dean 1984, 1986)
- EDUNE (Kriebel and Dean 1985, Kriebel 1986)
- SBEACH (Larson and Kraus 1989, Larson et al. 1989)
- CROSS (Zheng 1996, Zheng and Dean 1996)

Two versions (2.0 and 3.0) of SBEACH models will be included in the following comparisons. Version 3.0 was released in September 1994 by the U.S. Army Corps of Engineers after a study of storm erosion at Ocean City during the 1991-1992 winter storms. Three measures are presented for comparison of quantitative model performance.

Brief Description of Four Models

All four models discussed here are of the "closed loop" type and based on equilibrium beach profile concepts, which consider beach profile changes to be caused by deviations of a profile from its equilibrium. An equilibrium beach profile represents a dynamic balance of constructive and destructive forces acting on the beach. A change in the two competing types of forces will result in a disequilibrium. Considering wave energy dissipation per unit volume to represent the dominant destructive force, Dean (1977) proposed that a sediment of given size will be stable in the presence of a particular level of wave energy dissipation per unit volume, D_* , which is expressed as

$$D_* = \frac{1}{h} \frac{d(Ec_g)}{dy} \quad (1)$$

where h is the water depth, y is the shore-normal coordinate directed offshore, E is the wave energy density, and c_g is the wave group velocity. As a first approximation, D_* is assumed to dependent only on sediment size (Moore, 1982). With linear wave theory and shallow water assumptions, Eq (1) is integrated to

$$h = \left(\frac{24D_*}{5\rho g\sqrt{g}\kappa^2} \right)^{2/3} y^{2/3} = A y^{2/3} \quad (2)$$

where κ is the ratio of breaking wave height to water depth, and A is defined as a profile scale parameter.

CCCL Model

Under erosive water level and wave conditions, the time dependent beach recession, $R(t)$ is given by

$$R(t) = R_\infty (1 - e^{-K_R t}) \quad (3)$$

where R_∞ is equilibrium recession and K_R is a reciprocal time scale. At each time step, the equilibrium profile and recession are calculated by considering Eq. (3) and sand conservation. After the final computational time step, a factor of 2.5 is applied to the recession, in part to incorporate the alongshore variability of beach erosion.

EDUNE Model

The cross-shore sediment transport rate per unit beach width, Q , is considered as linearly proportional to the deviation of local wave energy dissipation per unit volume from the equilibrium,

$$Q = K_e(D - D_*) \quad (4)$$

where K_e is an empirical transport parameter and D is the local wave energy dissipation per unit volume. A beach steeper or milder than the equilibrium at a given depth will cause sediment transport offshore or onshore, respectively. Since the transport (Eq. (4)) has two variables, a continuity equation is used to close the system.

SBEACH Model

The cross-shore sediment transport rate is determined by

$$\begin{aligned} Q &= \pm K_s \left| D - D_* + \frac{\epsilon}{K_s} \frac{\partial h}{\partial x} \right|, & D > D_* - \frac{\epsilon}{K_s} \frac{\partial h}{\partial x} \\ &= 0, & D \leq D_* - \frac{\epsilon}{K_s} \end{aligned} \quad (5)$$

where ϵ is an empirical constant and K_s is a transport coefficient. This relationship is similar to EDUNE except for the last term which incorporates the effect of local slope. The beach profile evolution is solved by combining the transport relationship with the continuity equation. The direction of transport (\pm in Eq. (5)) is determined according to

$$\begin{aligned} \frac{H_0}{L_0} - 0.00070 \left(\frac{H_0}{w_f T} \right)^3 &< 0, + \\ \frac{H_0}{L_0} - 0.00070 \left(\frac{H_0}{w_f T} \right)^3 &> 0, - \end{aligned} \quad (6)$$

CROSS Model

Based on scale analysis and the Froude relationship, the cross-shore sediment transport rate per unit beach width, Q , should scale as

$$Q_r = L_r^2 / T_r = L_r^{3/2} \quad (7)$$

where L_r and T_r are length and time scales, respectively. To satisfy this scale relationship (7) and ensure convergence to the equilibrium beach profile, the following sediment transport relationship is proposed

$$Q = K_c (D - D_*)^3 \quad (8)$$

where K_c is a dimensional constant. Time dependent profile response is determined by solving the transport equation (8) and sand conservation equation.

Storm and Beach Profile Characteristics

Water depth and profile elevations used here are referenced to NGVD (National Geodetic Vertical Datum), which lies 2 cm below mean water level for Ocean City. The wave height, wave period and storm surge time histories during the two storms were measured by two gages located directly offshore of Ocean City in a water depth of 10 meters. The measured significant wave height, peak spectral wave period and storm surge are shown in Figure 2 for the January 4, 1992 storm (Stauble et al. 1993).

Figure 2. Water level, significant wave height and peak spectral wave period time history for the January 4, 1992 storm at Ocean City, MD (From Stauble et al. 1993).

Seven survey lines located at 37th, 45th, 56th, 74th, 103rd and 124th Streets (Stauble et al. 1993, Kraus and Wise, 1993) have both pre-storm and post-storm measured profiles available and are simulated. The mean grain sizes within each of 11 cross-shore morphologic zones are presented in Table 1. The seven measured pre- and post-storm profiles are shown in Figure 3 for the two surveys taken on November 2, 1991 and January 11, 1992, respectively. It appears that the storm-caused erosion is

quite different for profiles at different locations. After two storms, the profiles at 37th and 56th Streets had almost no erosion, whereas the other profiles experienced quite severe losses in the dune area. Based on the measured profiles, the net volume changes are calculated for each profile and presented in Table 2. It appears that the net volume changes during the two storms are quite different from zero for most profiles due to the gradients in longshore sediment transport. To remove this effect, each post-storm profile is adjusted by shifting the profile horizontally a distance Δy to yield zero net volume change. The value of Δy is calculated by

$$\Delta y = \frac{1}{h_{total}} \int_{y_0}^{y_*} (h_{mb} - h_{ma}) dy \quad (9)$$

where subscripts *mb* and *ma* denote profile elevation measured before and after storms, respectively, y_0 and y_* are offshore directed coordinates at the baseline and the limit of offshore profile change, respectively, and h_{total} represents the total elevation of the active storm profile. The sign of Δy is positive for a seaward translation. The profile retreat at the 3 meter contour and the eroded volume with and without the shifting adjustments are shown in Table 3. These parameters will be used as measures of the storm erosion and the performance of the numerical models.

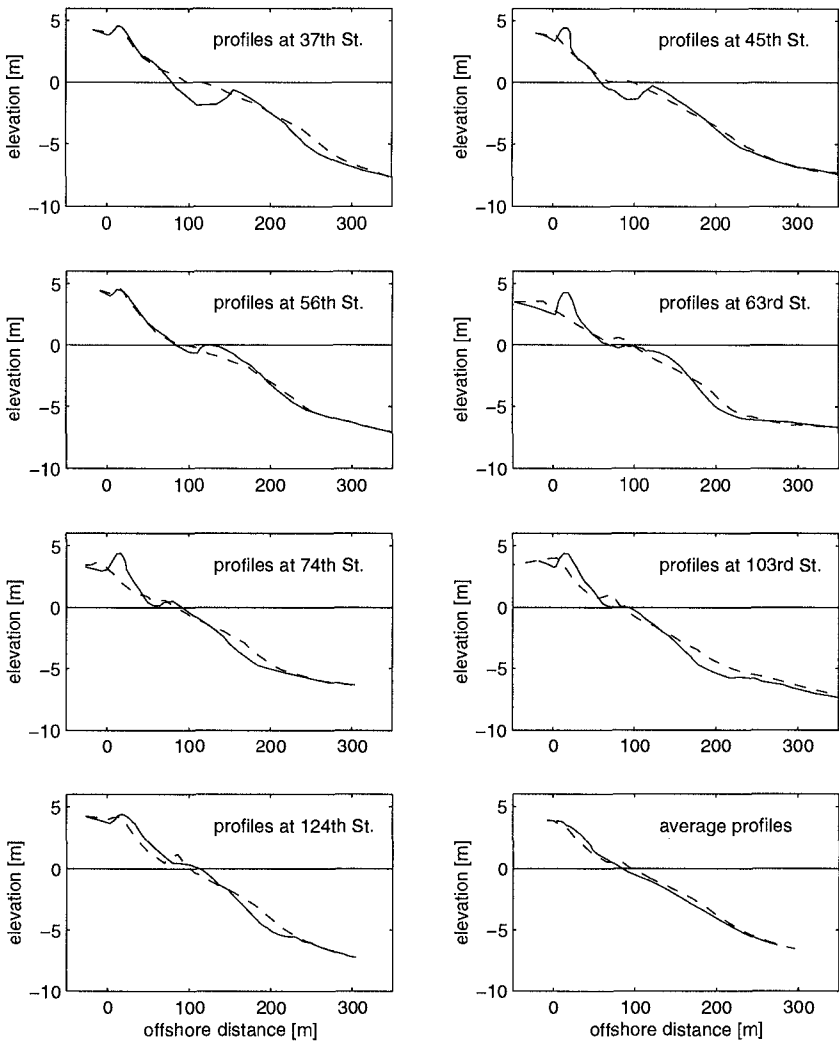

Figure 3 Measured pre-storm (solid line) and post-storm (dashed line) profiles.

Input Conditions for Each Model

The predictions of the four models are compared with the storm erosion measured at Ocean City, Maryland. The input parameters for each model in this study are selected to represent the conditions for which each model was calibrated. Among the four models, CROSS is the only one which can incorporate variable sediment size along a profile. The conditions run for each model are described briefly as follows.

Table 2 Measured volume change during the storm and adjustment Δy .

Street	Volume change (m ³ / m)			Adjustment Δy (m)	h_{total} (m)
	Gain	Loss	Net		
37 th	158.77	20.78	137.99	-11.29	12.22
45 th	81.01	49.42	31.59	-2.83	11.16

Average	55.71	24.97	30.74	-3.04	10.11

CCCL Model

This model has been used in establishment of the Coastal Construction Control Line (CCCL) in Florida. The CCCL is a line which depicts the landward limit of impact of a 100 year period storm event. The default dune slope is set to 1. Since this model cannot represent variable sediment size along a profile, a uniform grain size of 0.35 mm is applied. At each time, the significant wave height is used as the input wave height. The set-up at the shoreline is calculated based on linear wave theory as 0.23 times the incoming wave height. No wave run-up is included in the model. After running the storms, consistent with model calibration, a factor of 2.5 is applied to those contours which receded. This model does not incorporate a transport equation, but rather considers the profile to approach equilibrium with a folding time scale of 13 hours.

EDUNE Model

The default input dune slope is set to 1 and the input shoreline slope is taken as 0.05 which is the average shoreline slope of the measured pre-storm profiles. For the same reason as described for the CCCL model, a sediment size of 0.35 mm is used. The significant wave height is input at each time step. In EDUNE, the wave run-up is an input parameter held constant throughout the erosion simulation, and is used to control the location of the dune scarp above the peak water flood level. For the Ocean City storm erosion simulations, the run-up was fixed as 0.91 meters and 1.52 meters for the November 1991 and January 1992 storms, respectively, and was based on a combination of matching elevation of dune scarps and Hunt's equation (1958)

$$R = F_R H_b \frac{m}{\sqrt{H_b/L_0}} \quad (10)$$

where R is the run-up height measured vertically upward from the storm water level, F_R is a non-dimensional coefficient and is approximately 1, m is the average bed slope

from the run-up limit to the breaking point, and L_0 is the deep water wave length. In the application here, it was found that the best agreement was provided by using the maximum significant wave height of each storm in Eq. (10). The transport coefficient, K_e , for this application is the program default value of $8.73 \times 10^{-6} \text{ m}^4/\text{N}$.

SBEACH Model

Both versions (2.0 and 3.0) of SBEACH model are believed to incorporate wave run-up and set-up. The maximum slope that a predicted profile is allowed to achieve is required and is set to 17.5° as a default condition; this corresponds to a beach slope of 0.32. A constant sediment size of 0.35 mm is applied here, which was recommended by Kraus and Wise (1993) in their study. Both versions of the SBEACH model provide a choice of wave type (monochromatic or irregular). The option of irregular waves which requires an input of time history of significant wave height was chosen for this study. The default value for the transport coefficient, K_s , in both version is $1.50 \times 10^{-6} \text{ m}^4/\text{N}$.

CROSS Model

The dune slope and the offshore slope are set equal to 1 and 0.5, respectively, as default conditions, and the shoreline slope is set to the average shoreline slope of the measured pre-storm profiles (0.05). Two different sediment size distributions are compared in this model. First, along each measured profile, the variable sand size listed in Table 1 is applied. Second, as a basis for comparison with the other three models, a uniform grain size of 0.35 mm is used. During each storm, a random wave series is generated according to the time history of the measured significant wave height and spectral peak wave period. The wave-by-wave set-up is calculated based on linear wave theory, and the wave run-up limit is established from Hunt’s Equation (10). A transport coefficient value, K_c , of $7.14 \times 10^{-10} \text{ m}^8 \text{ s}^2/\text{N}^3$ is used for this field application.

Numerical Results and Comparisons

The numerical results from the four models are quantified in terms of several parameters. A comparison of measured and predicted entire active profile changes is provided by the residual parameter, Res, defined in non-dimensional form as:

$$Res = \frac{\sum_{i=1}^n (h_{pi} - h_{mai})^2}{\sum_{i=1}^n (h_{mbi} - h_{mai})^2} \tag{11}$$

where h is the profile elevation, the subscripts “p” and “m” denote predicted and measured, respectively, “b” and “a” indicate before and after storm conditions, respectively, “i” represents the i^{th} location on the profile, and the sums extend across the entire active profile. The minimum possible value of Res is zero, which would correspond to a perfect simulation. If the numerical simulation predicts no changes, the value of Res is 1, which therefore should represent an upper limit of Res.

The dune erosion agreement between calculated and measured values is quantified by the eroded volume and the beach retreat at the 3 meter contour. To provided a measure of erosion and retreat, two different errors are presented: the mean square error, ERR_{ms} , and the algebraic average error, ERR_{ave} . These are expressed as

$$ERR_{ms} = \frac{\sum_{j=1}^n (S_{pj} - S_{mj})^2}{\sum_{j=1}^n S_{mj}^2} \quad (12)$$

$$ERR_{ave} = \frac{\sum_{j=1}^n S_{pj} - S_{mj}}{\sum_{j=1}^n S_{mj}}$$

where S is an eroded volume or beach retreat, the subscripts "p" and "m" again represent the predicted and measured values, respectively, and "j" means the j^{th} beach profile. ERR_{ms} represents a factor of simulation accuracy and ERR_{ave} provides a measure of over or under-prediction of erosion. Compared with the measure, Res , which is based on local differences across the entire active profile, ERR_{ms} and ERR_{ave} are based on average differences of eroded volume or beach retreat at a particular elevation.

Comparisons between predictions and measurements for the profiles at 45th Street are presented in Figure 4. The ridge features presented on the measured post-storm profiles suggest that there was some beach recovery even though the post-storm profiles were measured only a week after the second storm. The predictions of CROSS with both variable and uniform sand size are presented. It appears that the results predicted with variable sand size provide more reasonable simulations for dune erosion while the predictions with the uniform sand size fit the entire profile better. After applying the factor of 2.5 to those contours which receded, the CCCL model tends to overpredict erosion for most profiles. Since the application purpose of CCCL is to establish the Coastal Construction Control Line, the 2.5 factor is included to incorporate the variability of beach erosion at different locations. As mentioned above for EDUNE, the wave run-up is determined, in part, according to measured post-storm profiles used throughout the entire time of numerical simulation. Since beach erosion is quite sensitive to water level, the numerical results of EDUNE will depend greatly on the storm duration time and the input of wave run-up. Among all four models, SBEACH version 2.0 is the only model which represents the offshore bar feature. The newly modified version 3.0 of SBEACH presents substantially better agreement than version 2.0.

Figure 4. Comparisons of predicted and measured profiles at 45th Street.

The corresponding residuals, eroded volumes and beach retreat at the 3 meter contour for each individual profile were calculated. Two examples of profiles at 45th and 103rd Streets are shown in Table 4. Because the net volume changes between measured pre-storm and post-storm profiles are quite different from zero due to gradients of longshore sediment transport, in addition to the measured profiles, results are included based on shifting each post-storm profile the horizontal distance, Δy , to yield zero net volume change. In the table, "without adjustment" means data given by the original measured post-storm profiles, while "with adjustment" means data resulting from horizontally shifted post-storm profiles. Since all four models discussed here included only cross-shore sediment transport, the data presented "with adjustment" are considered to be more appropriate.

Table 4 The residuals, eroded volumes and beach retreat at the 3-meter contour.

Profile	Model	Residual		Eroded vol. (m ²)	Retreat at 3-m contour (m)
		w/o adjust.	With adjust.		
45 th St.	CROSS(var. sand size)	0.525	0.496	20.13	8.71
	CROSS(fixed sand size)	0.287	0.280	19.39	8.36
	CCCL	1.067	0.851	60.56	18.34
	EDUNE	0.624	0.604	18.30	6.51
	SBEACH (ver. 2.0)	1.018	0.971	15.21	2.96
	SBEACH (ver. 3.0)	0.736	0.713	23.34	6.79
103 rd St.	CROSS(var. sand size)	0.329	0.274	35.18	15.23
	CROSS(fixed sand size)	0.261	0.251	28.88	13.41
	CCCL	2.233	1.499	123.05	28.92
	EDUNE	0.548	0.413	54.66	20.04
	SBEACH (ver. 2.0)	0.596	0.590	19.54	7.03
	SBEACH (ver. 3.0)	0.510	0.433	35.20	10.61

The residuals averaged over the seven measured profiles and the two errors defined in Eq. (11) for eroded volume and beach retreat at the 3-m contour with respect to the horizontal shifted profiles are presented in Table 5. Overall, CCCL overpredicts the dune erosion during the two storms, whereas the other three models underpredict it. It appears that CROSS with fixed sand size results in significantly less average residual than the others. The dune erosion errors of CROSS with variable sand size, EDUNE and SBEACH version 3.0 are comparable. It is noticed that dune overwash occurred during the January 1992 storm. Among the four models, only EDUNE and SBEACH incorporate dune overwash processes. In the CROSS model, the profile shoreward of the dune crest is treated as a horizontal beach with the same elevation as

the dune crest. Therefore, the numerical simulations of CROSS do not include the dune erosion part caused by overwash. It is expected that the underpredictions of CROSS could be improved by incorporating dune overwash processes in the model.

Table 5 The average residuals and errors of eroded volume and beach retreat at the 3-meter contour with respect to the horizontally shifted measured profiles.

Model	Averaged residual	Error of eroded volume		Error of retreat	
		ERR _{ms}	ERR _{ave}	ERR _{ms}	ERR _{ave}
CROSS (variable sand size)	0.725	0.227	-0.401	0.283	-0.359
CROSS (fixed sand size)	0.458	0.319	-0.511	0.327	-0.444
CCCL	1.331	0.707	0.847	0.480	0.561
EDUNE	0.792	0.182	-0.328	0.260	-0.324
SBEACH (ver. 2.0)	1.211	0.470	-0.663	0.623	-0.749
SBEACH (ver. 3.0)	0.752	0.183	-0.399	0.259	-0.479

Summary

This paper has presented comparisons of the predictions of the CROSS model and three other commonly used closed loop models (CCCL, EDUNE and SBEACH) for storm erosion at Ocean City, Maryland during the November 1991 and January 1992 storms. The "2.5" factor was applied in the CCCL model in this comparison. The wave run-up parameters used in the EDUNE model are determined according to the measured post-storm profiles and the maximum significant wave heights during two storms. Seven survey lines located from the southern (37th Street) to northern (124th Street) portions of the project are selected for evaluation of the four models. In most locations, the net volume changes in profiles are quite different from zero due to gradients in longshore transport. An adjustment is made by shifting the whole profile horizontally a distance Δy to yield a zero net volume change for each profile.

A non-dimensional mean square residual parameter is provided to evaluate the agreement between the entire measured and predicted profiles (including subaerial and subaqueous parts). Two kinds of error averaged with different methods (mean square and algebraic average) are provided to evaluate the prediction of dune erosion. It appears that the residuals are less affected by the shifting adjustment, while eroded volumes and beach retreat are affected more significantly by the shift. Among the four models, the CCCL model is the only one which overpredicts average dune erosion. CROSS yields the least average residual and presents the best prediction for an entire profile (including both subaerial and subaqueous parts). For errors of eroded volume and beach retreat, CROSS with variable sand size, EDUNE and SBEACH (version 3.0) provide reasonably comparable predictions. It is anticipated that by incorporating dune overwash, the under prediction of dune erosion by CROSS can be reduced.

CHAPTER 242

Measurements of Wave Generated Bedforms

Christopher D. Jetté¹ and Daniel M. Hanes²

Abstract

A 5 MHz multiple transducer array was used to measure wave generated bedforms near Duck, NC. The transducer array consists of 37 transducers with a center to center spacing of 1.2 centimeters. Seabed measurements were made with approximately 1 millimeter vertical and 2 centimeter horizontal resolution. Measured ripple dimensions are compared to three popular ripple prediction models. It is shown that errors of over 100 percent were found between measured and predicted ripple heights and lengths for all ripple models compared. Errors in predicting ripple steepness ranged from 37 to 55 percent.

Description Of Experiment

Field measurements of bedforms were made during an experiment at the Army Corps of Engineers Field Research Facility in Duck, NC during August 23-25, 1995. The instruments were deployed using a Sensor Insertion System (SIS) on the research pier. The SIS was positioned at multiple locations along the cross-shore profile during the experiment.

Bedform measurements were made using a multiple transducer array (MTA) developed at the University of Florida. The MTA consists of 37 ultra-sonic transducers operating at a frequency of 5 MHz. The center-to-center spacing of the transducers is 12 mm. Such configuration allows for O(1 mm) vertical resolution and O(2 cm) horizontal resolution. The MTA can scan a profile in approximately 4 seconds. The distance to the seabed is calculated from the elapsed time between the pulsing of the transducer and the time at which the return exceeds a software selectable threshold.

 - 2) Associate Professor, Department of Coastal and Oceanographic Engineering, University of Florida, PO Box 116590, Gainesville, FL 32611, USA.

Figure 1. Schematic of the MTA

In addition to the MTA, an under-water video camera was deployed in order to document bedform orientation. Electro-magnetic current meters and pressure transducers were deployed to measure the wave and current conditions. Measurements of the vertical distribution of suspended sediment by acoustical backscatter methods were also made.

The data was collected in 13 minute bursts. Each burst contained 131 profiles taken with the MTA. Current, pressure, and concentration profile data were collected at 4 Hz.

Conditions During Experiment

Exploiting the mobility of the SIS, measurements were made under a variety of wave and sediment conditions. During the experiment, an off-shore bar was present at approximately 210 meters from the high water line. Measurements were made at 8 separate cross-shore locations in the regions offshore of the bar, on the bar, in the trough, and on the nearshore beach-face. Depths where measurements were made ranged from 1.6 to 6.8 meters. The vertical lines in figure 2 indicate cross-shore locations where measurements were obtained.

Figure 2. Cross-shore profiles from North and South sides of pier during experiment.

The sediment characteristics varied greatly over the cross-shore profile. D_{50} values of the mostly quartz sediment ranged from 0.19 to 1.67 mm. The range of D_{50} values versus run number are plotted in Figure (3) along with H_{m0} (a), peak wave period (b), and water depth (c).

Figure 3. H_{m0} (a), peak wave period (b), water depth (c), and D_{50} (d) vs. Run number for SIS experiment

Most of the wave data taken over the three day period contained at least two, if not three frequency peaks in the surface elevation spectrum. For many of the runs there was a low frequency component (12-15 sec. period) generated from hurricane Felix, which was several hundred miles off-shore, as well as a moderate frequency component (6-8 sec. period), and generally in the afternoon, a higher frequency (4-5 sec. period) locally generated component. H_{m0} wave heights varied from 0.2 to 0.9 meters. During most of the experiment the predominate wave direction at the experiment site was directly on-shore.

For most of the runs measurements were made offshore of the breakpoint, however during runs 11 through 21 some waves were noted to break in the vicinity of the instruments. It is also noted that, after transforming the pressure spectrums into surface elevation spectrums, in the majority of cases the higher frequency component became the peak frequency. Consequently, the wave period used in model prediction was the lowest period component in the wave profile.

Figure 4. Representative corrected surface elevation spectrums from SIS experiment for runs 1 (a) and 13 (b) with H_{m0} wave heights of 0.72 and 0.28 meters respectively

Measurements

Bedforms were present throughout the experiment, however their geometries varied greatly over the beach profile. Measured bedform heights ranged from 7 to 50 mm, and bedform lengths ranged from 80 to 1000 mm. Active ripple conditions were observed during all times of data collection. For most of the files under-water video was available to document near-bed sediment motion and ripple orientation. Significant ripple migration was not observed during any of the 13 minute runs.

Bedform profiles were collected at a rate of ten profiles per minute. For the measurements presented herein, a single representative profile was found for each minute of data (10 scans). An example of the thirteen representative profiles for an entire run is shown in figure 5 (a-c). In these figures, each profile has been offset by -3 mm from the previous profile for comparative display. The top profile represents the first minute of data and contains circles at each of the 37 measured data points.

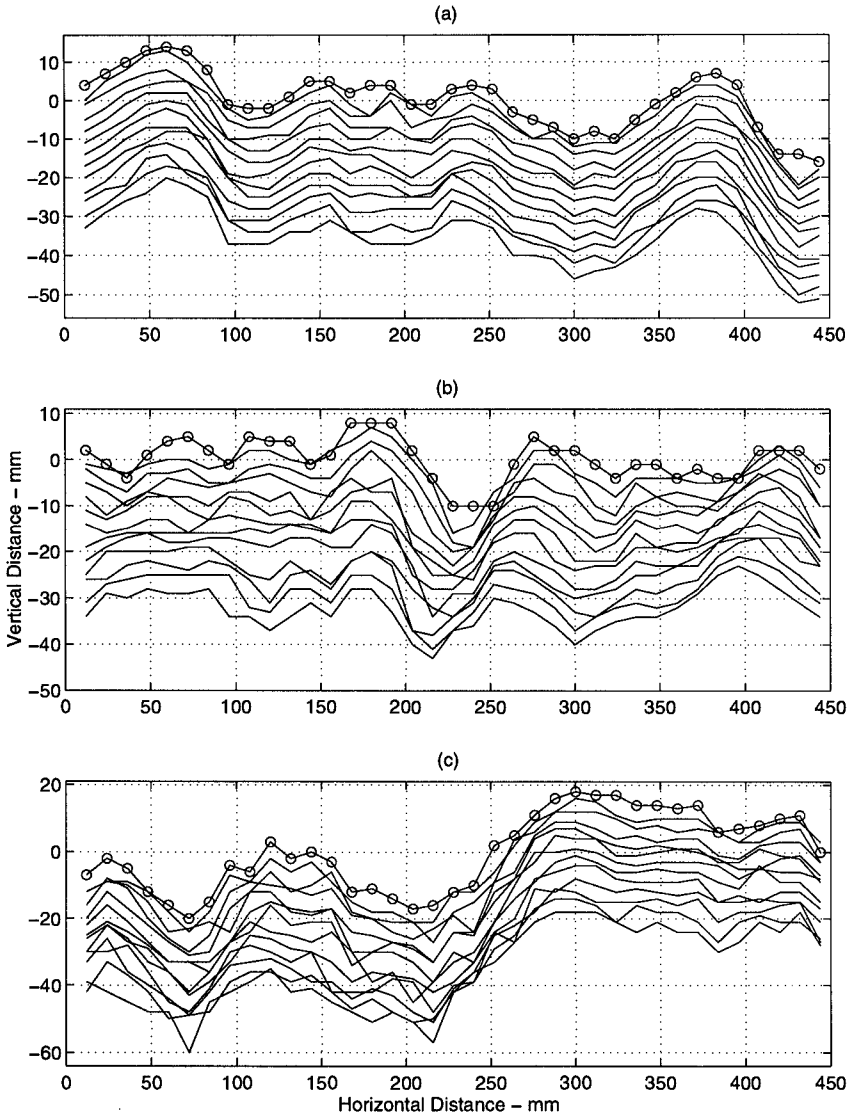

Figure 5. Representative profiles for each minute of a 13 minute run from runs 1(a), 13(b), and 26(c). Data from first minute of run is plotted with circles.

In order to compare these data to models, the bedforms need to be characterized in terms of a wavelength and height. In previous work this has typically been accomplished by visual inspection. We therefore chose a threshold method to determine ripple height and length dimensions for each representative ripple profile. This method first found the peaks and troughs along a profile. Then, if the distance between adjacent peaks and troughs met a certain threshold criterion, they were recorded. From these peaks and troughs average ripple heights and lengths were found. The threshold was chosen conservatively, that is, to maximize ripple heights and lengths. Figure (6) is an example of a representative profile with the threshold ripple crests and troughs marked.

For model comparisons, each run of data was summarized into four profiles. These profiles were from minutes 1, 4, 8, and 13 of each 13 minute run. The reasons for this were to minimize the amount of clutter in model comparisons, while at the

same time retain the range of ripple geometries present during each run. Measured ripple length (ltm) and height (htm) along with summaries of hydrodynamic and sediment conditions are presented in table 1 for each run.

Figure 6. Representative ripple profile with threshold method results for first minute of data from run number 13.

Model Comparisons

Measured bedform dimensions were compared to three predictive models; Nielsen (1981), Wiberg and Harris (1994), and Grant and Madsen (1981). For each run measured values of water depth, Hmo wave height, peak period, and sediment properties were entered into the predictive models. Measured bedform dimensions were plotted with the model curves, if possible, in order to better illustrate the relationships between measured values and predicted values.

Nielsen (1981) derived different predictive models for regular (laboratory) and irregular (field) conditions. Comparisons included herein refer to the irregular or field ripple models. The Nielsen (1981) bedform model characterizes flow conditions using sediment mobility number (Ψ), grain roughness Shield’s parameter ($\theta_{2.5}$), and the wave friction factor “ $f_{2.5}$ ” given by Swart (1974). These parameters are defined as follows

$$\theta_{2.5} = 0.5 f_{2.5} \psi \tag{equation 1}$$

$$f_{2.5} = \exp \left[5.213 \left(\frac{2.5 D_{50}}{A} \right)^{0.194} - 5.977 \right] \tag{equation 2}$$

$$\psi = \frac{(a \omega)^2}{(s - 1) g D} \tag{equation 3}$$

where “D” is the mean grain diameter, “a” is the near-bed wave semi-excursion, “s” is the sediment specific gravity, “g” is the acceleration of gravity, and ω is the

angular frequency of the waves. The Nielsen (1981) irregular wave model for non-dimensional ripple steepness, height, and length are respectively

$$\eta/\lambda=0.342-0.34(\theta_{2.5})^{0.25} \quad \text{equation 4}$$

$$\eta/a=21\Psi^{-1.85} \quad \text{for } \Psi>10 \quad \text{equation 5}$$

$$\eta/a=0.275 - 0.022\Psi^{0.5} \quad \text{for } \Psi<10 \quad \text{equation 6}$$

$$\lambda/a = \exp\left[\frac{693 - 0.37\ln^8\Psi}{1000 + 0.75\ln^7\Psi}\right] \quad \text{equation 7}$$

where η and λ represent ripple height and length respectively.

Relationships between measured ripple dimensions and the Nielsen (1981) model curves are illustrated in figure (8). As can be seen in figure 8(a), for all but 5 out of the 30 runs the Nielsen (1981) irregular wave ripple model over-predicted ripple height. The largest amount of over-prediction was found to occur at low values of sediment mobility number ($\Psi<20$). The Nielsen (1981) ripple length model agreed best with measured dimensions for higher values of mobility number ($\Psi>12$), however for lower values of mobility number ($\Psi<12$), the model over-predicted ripple length for all runs. Measurements of ripple steepness had better agreement with the Nielsen (1981) model curves than did ripple height or ripple length. Best agreement was found at higher values of the grain roughness Shield's parameter ($\theta_{2.5}>0.08$). For lower values of the Shield's parameter the Nielsen (1981) model over-predicted ripple steepness.

Figure 7. Nielsen (1981) irregular wave ripple comparison with measurements

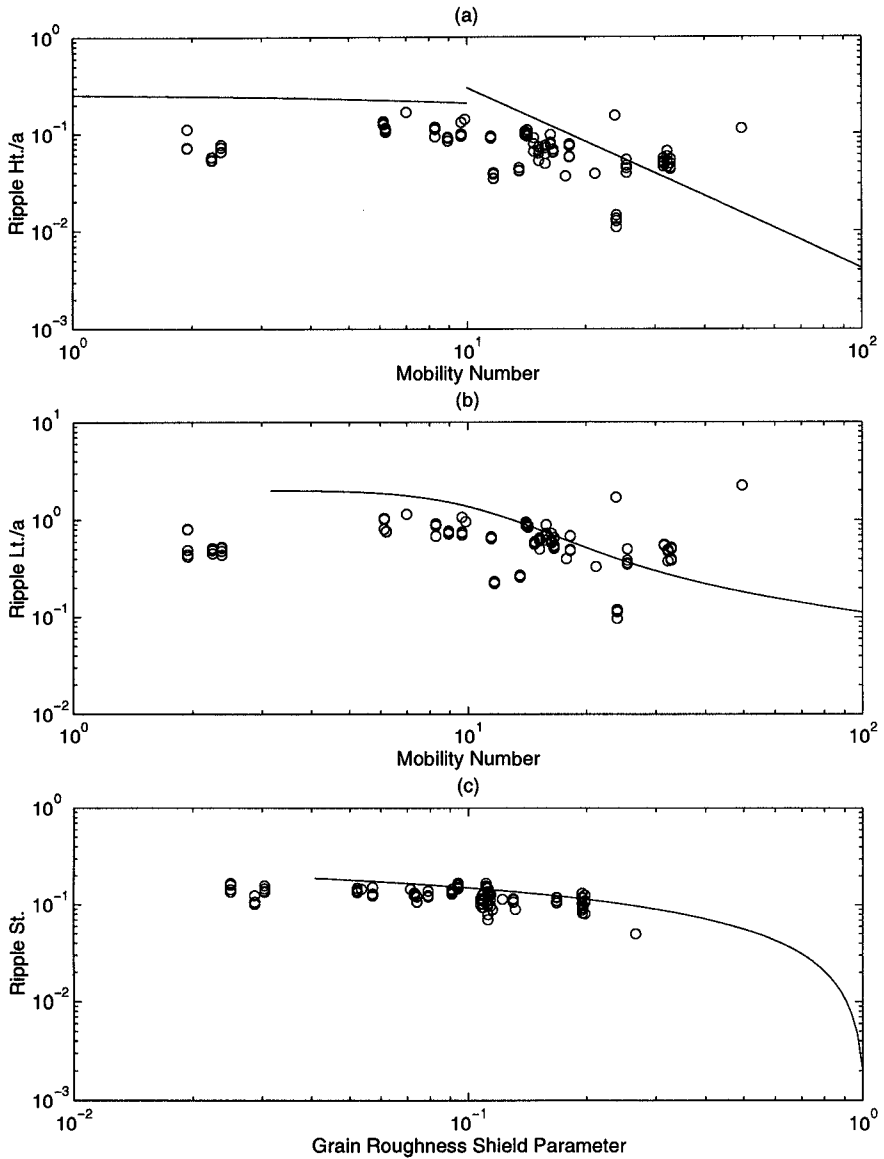

Figure 8. Comparison of measured field ripple dimensions and Nielsen (1981) model curves for height (a), length (b), and steepness (c).

Wiberg and Harris (1994) reexamined existing ripple data from oscillatory flows in both flume and field studies to construct a model to predict ripple geometry for all types of oscillatory flow environments. Wiberg and Harris (1994) classified

bedforms according to the ratio of the wave boundary layer thickness and ripple height (d_o/η). From this ratio, the ripples were classified as orbital, anorbital, or suborbital by the following criteria

Table 2. Wiberg and Harris (1994) ripple classification

flow conditions	ripple classification
$d_o/\eta_{ano} < 20$	orbital ripples
$20 < d_o/\eta_{ano} < 100$	suborbital ripples
$d_o/\eta_{ano} > 100$	anorbital ripples

The Wiberg and Harris (1994) equations for ripple length and steepness for orbital ripples are:

$$\lambda_{orb} = 0.62d_o \quad \text{equation 8}$$

$$(\eta/\lambda)_{orb} = 0.17 \quad \text{equation 9}$$

for anorbital ripples

$$\lambda_{ano} = 535 D \quad \text{equation 10}$$

$$\frac{\eta}{\lambda} = \exp \left[-0.095 \left(\ln \frac{d_o}{\eta} \right)^2 + 0.442 \ln \frac{d_o}{\eta} - 2.28 \right] \quad \text{for } d_o/\eta > 10 \quad \text{equation 11}$$

and for suborbital ripples

$$\lambda_{sub} = \exp \left[\left[\frac{\ln \left(\frac{d_o}{\eta_{ano}} \right) - \ln 100}{\ln 20 - \ln 100} \right] \left(\ln \lambda_{orb} - \ln \lambda_{ano} \right) + \ln \lambda_{ano} \right] \quad \text{equation 12}$$

where “ d_o ” is the near bottom orbital diameter, and “ D ” is the mean sediment size.

In figure (9), measured non-dimensional ripple dimensions are plotted versus the parameters used in the Wiberg and Harris (1994) ripple model. Where possible, the model curves were included. It is noted that in figure (9d) the x-axis is near bottom orbital diameter divided by measured ripple height. For these plots, the dashed and solid curves refer to the orbital and anorbital ripple models respectively. The data in figure (9) is also plotted according to the Wiberg and Harris (1994) ripple classification scheme. Each data point is plotted as an “o”, “+”, or “*” indicating ripple types of orbital, suborbital, or anorbital ripples, respectively. The Wiberg and Harris (1994) model also over-predicted ripple length and height for most of the runs. It is also interesting to note that only 2 of the 30 runs were classified as anorbital ripples.

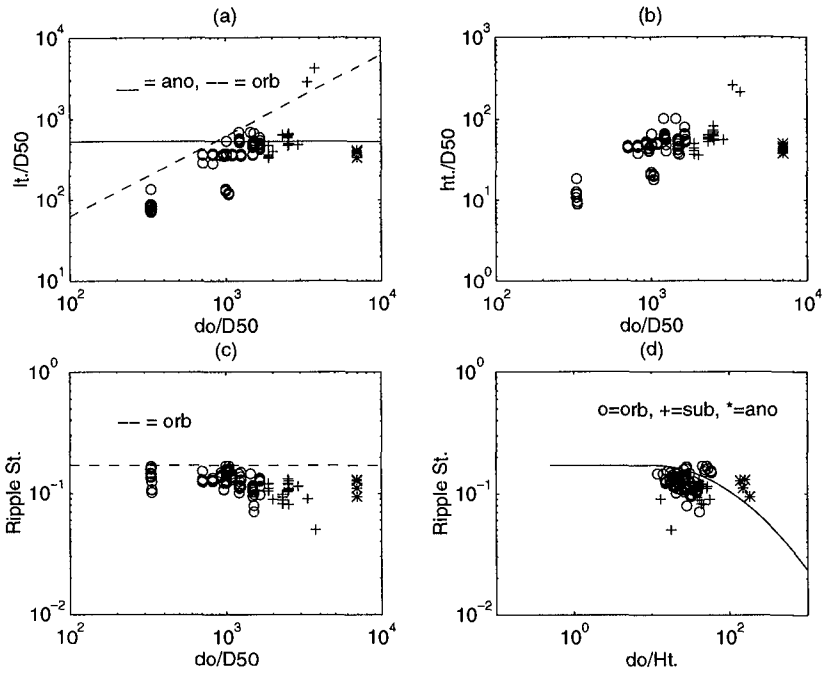

Figure 9. Wiberg and Harris (1994) ripple models with measured values.

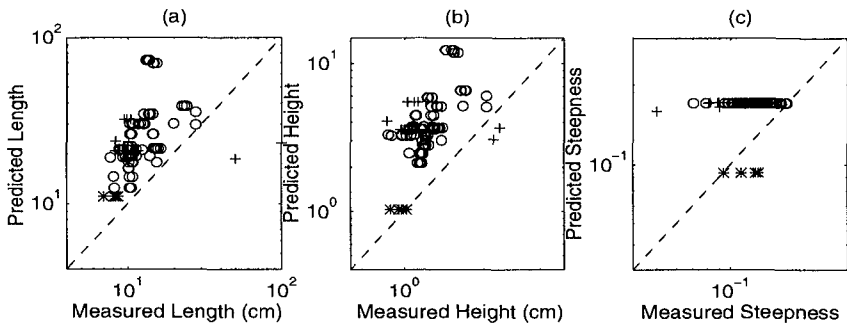

Figure 10. Wiberg and Harris (1994) model ripple comparison with measurements

The Grant and Madsen (1982) ripple model uses the ratio of the maximum value of the skin friction (shear stress) under the wave (τ_{*sf}) to the critical value of shear stress for the initiation of sediment motion (τ_{*cr}). Also a dimensionless sediment parameter (S_*) is used. This ripple model was based primarily on the Carstens et al. (1969) laboratory oscillatory ripple study.

Two separate regions of transport stages were used in the Grant and Madsen (1982) model. The first stage, when the flow conditions are less than the breakoff point defined by equation (18), is known as the equilibrium stage. Within the equilibrium range, ripple steepness is a maximum and the ripple length is said to scale with the near-bottom excursion amplitude. When flow conditions exceed the breakoff point, conditions are said to be in the breakoff region; the ripple length is said to no longer be in equilibrium and a decorrelation between ripple length and near-bottom excursion amplitude occurs (Grant and Madsen (1982)). As the flow intensity increases within the breakoff region, ripple steepness continues to decrease to a point where ripples are no longer present.

The Grant and Madsen (1982) ripple prediction model is as follows:
when the transport stage is less than the breakoff point

$$\eta/\lambda = 0.16 \left(\tau_{*sf} / (\tau_*)_{cr} \right)^{-0.04} \quad \text{equation 13}$$

$$\eta / a_o = 0.22 \left(\tau_{*sf} / (\tau_*)_{cr} \right)^{-0.16} \quad \text{equation 14}$$

and at higher transport stages, above the breakoff range

$$\eta/\lambda = 0.28 S_*^{0.6} \left(\tau_{*sf} / (\tau_*)_{cr} \right)^{-1.0} \quad \text{equation 15}$$

$$\eta / a_o = 0.48 S_*^{0.8} \left(\tau_{*sf} / (\tau_*)_{cr} \right)^{-1.5} \quad \text{equation 16}$$

where

$$S_* = (d / 4\nu) [(S - 1)gD]^{0.5} \quad \text{equation 17}$$

and the breakoff point is defined as

$$\left[\tau_{*sf} / (\tau_*)_{cr} \right]_B = 1.8 S_*^{0.6} \quad \text{equation 18.}$$

where 'v' is the kinematic viscosity of water, 'D' is the grain diameter, 'S' is the specific gravity of the sediment, and 'g' is the acceleration of gravity.

A comparison of Grant and Madsen (1982) predicted ripple heights and lengths versus measured values is shown in figure 11. It can be seen that the Grant and Madsen (1982) model over-predicted ripple length and height for almost every run.

Figure 11. Grant and Madsen (1982) model ripple comparison with measurements

In order to evaluate the performance of the predictive models, the relative error was computed between measured and predicted values. The relative error is defined as:

$$\Delta = \exp \left\{ \left[\frac{1}{n} \sum_1^n (\ln(y) - \ln(\hat{y}))^2 \right]^{1/2} \right\} \quad \text{equation 19}$$

where y is the measured value and \hat{y} is the predicted value. This quantity is a multiplicative factor that indicates the possible variation about the predicted value (Wikramanayake, 1993). For example if Δ equals 1.34, the average error is equal to 34 percent.

Table 3 contains values of the relative error for each of the different predictive models. It can be seen that the predictive models performed much better at predicting ripple steepness than ripple height or length independently. The Nielsen (1981) and Grant and Madsen (1982) ripple steepness models performed the best at predicting ripple steepness with an average error of 37 percent, the Wiberg and Harris (1994) model had an average error of 55 percent. The Nielsen (1981) model predicted ripple height the best, however the average error was found to be 153 percent. The Wiberg and Harris (1994) and Grant and Madsen (1982) models had even greater error. Ripple length comparisons showed the Wiberg and Harris (1994) model having the least error with an average error of 125 percent. The Nielsen (1981) and Grant and Madsen (1982) ripple length models had slightly higher relative errors with 150 and 154 percent respectively.

TABLE 3. Relative Error for model predictions and measured values.

	Ripple Length	Ripple Height	Ripple Steepness
Nielsen (1981) Field	2.50	2.53	1.37
Wiberg & Harris (1994)	2.25	2.84	1.55
Grant and Madsen (1982)	2.54	3.03	1.37

Conclusions

The multiple transducer array (MTA) has proven the ability to measure bedforms in the field environment with $O(1 \text{ mm})$ vertical and $O(2 \text{ cm})$ horizontal resolution. Comparisons of oscillatory field ripple data collected with the MTA and the most popular predictive models show errors of over 100 percent for all models in predicting ripple heights and lengths. Average errors of 37 to 55 percent were found in predicting ripple steepness. Such errors could be due to errors in the previously collected data sets used to construct these models, or to the current understanding of the mechanics of ripple formation and geometric equilibrium with the flow field. More investigation is necessary in this field in order to improve bedform prediction models.

CHAPTER 243

Field Measurement of Bed Roughness for Waves on an Off-Shore Reef

Raymond C. Nelson¹

Abstract

This paper takes advantage of fortuitous, near ideal conditions which existed for a subset of field data, to obtain the hydraulic roughness of the surface of a coral reef platform. This was accomplished by observing the transformation of natural, unbroken, oscillatory wave trains, propagating over the reef top in water of constant depth, where wave bed friction damping was the only active wave transformation process. The paper also demonstrates that while coral reefs may be perceived as being much rougher than sandy beds, they may in fact be no rougher in hydraulic terms, than many sandy beds experiencing the same wave and water depth conditions.

Introduction

The bed friction factor (f) associated with wave motion, is a function of a Reynolds number and a relative roughness.

$$f = \phi_1 \left(R_e, \frac{r}{a} \right) \quad (1)$$

R_e is the Reynolds number associated with the oscillatory water movements at the bed as estimated from linear wave theory.

$$R_e = \frac{aU}{\nu} \quad (2)$$

a is the amplitude of the oscillatory bed movements, U is the amplitude of the periodic bed velocity, and ν is the kinematic viscosity of the fluid. r/a is the relative roughness where r is the hydraulic roughness. For all turbulent flow conditions, the friction factor can be expressed in the form of Eq. 1. However,

¹ Senior Lecturer, School of Civil Engineering, University of New South Wales, University College, Australian Defence Force Academy, Canberra, ACT, 2600, Australia

for all prototype wave conditions of engineering significance, the oscillatory flow at the bed is always fully developed rough turbulent flow (Jonsson, 1963 and 1966; Swart, 1974). In this regime the friction factor is independent of Reynolds number, reducing Eq. 1 to Eq. 3 for field conditions.

$$f = \phi_2 \left(\frac{r}{a} \right) \quad (3)$$

On a movable bed, both r and a are variables, depending on the wave and water depth conditions, the changes in r being caused by the variability of bed form (Nelson, 1989 and 1995).

On fixed beds, such as coral reef platforms, a still varies with wave and water depth conditions, but r remains constant. A measured value of this fixed roughness is far more useful than a measured value of friction factor. The latter is only applicable to wave and water depth conditions that produce the same value of a existing when the measurement was made, while the hydraulic roughness value can be used to obtain wave friction factors for all wave and water depth conditions.

This paper presents values of reef top hydraulic roughness derived from the observed transformation of natural random waves, propagating in water of constant depth, over the fixed bed of a platform coral reef. The resulting values are to some extent site specific. However, from an engineering viewpoint, the use of a measured roughness that can be varied by visual comparisons and reasoning, is far more desirable than the use of a *guesstimate*.

Experiment Description

The experimental data were collected from John Brewer Reef, located inside the line of the Barrier Reef approximately 70 km north east of Townsville, Australia. The reef is elliptical in shape (6 km by 3 km - see Fig. 1) with a major axis approximately normal to the prevailing south easterly winds. The windward reef platform is a continuous reef flat 200m to 300m wide and uniform in elevation at a level approximating Lowest Astronomical Tide. High tide water depths over the reef platform seldom exceed 3m. Seaward of the windward edge, the reef drops rapidly to a depth of about 50m below the reef platform, while the lagoon enclosed by the whole of John Brewer Reef averages about 10m in depth.

Wave and current measuring instruments were deployed on the windward side of the reef (Fig. 1). WR1 was a Waverider buoy located about 500m seaward of the reef front and transmitted incident wave data to a receiver located in the floating hotel. ZP1, ZP2, ZP3 and ZP4 were 6m high, surface piercing wave transducers known as Zwarts Poles (Zwarts, 1974). These were aligned normal to the reef front and parallel to the prevailing south east winds. ZP1 and ZP4 are of special interest to this study. ZP1 was 27m from the reef front while ZP4 was located at a further interval of 141m. Most of the time the line of Zwarts Poles was located along the line of the reef top wave orthogonal but there were some exceptions at high tide during incident wave events with very low energy.

Each wave sample collected from WR1 contained 2048 readings at intervals of 0.391 seconds (sample length about 14 minutes). Each wave sample from each Zwarts pole contained 4800 readings at an interval of 0.25 seconds (sample length about 20 minutes). Data sets consisted of wave samples collected concurrently

from all 5 wave instruments with the recording commencement times for each instrument being identical. The interval at which data sets were recorded was sometimes 1 hour and at other times 2 hours.

CM1 was an S4 electromagnetic XY current meter that measured reef top currents. Every 10 minutes it took 120 readings at 0.5 second intervals of both the easterly and northerly velocity components and logged the average.

Fig. 1 John Brewer Reef and Instrument Locations

Data Selection

The extraction of bed friction effects from other interacting sub-processes, increases the uncertainties incorporated in the results, the preferred option being to have a prototype location and wave motion where bed friction damping is the only active sub-process. Some of the John Brewer Reef Zwart's Pole data conformed with this requirement. The water depths were, for all practical purposes, uniform eliminating the effects of shoaling and refraction. There were no barriers around which diffraction could occur, and careful selection of data sets ensured that the effects of wave breaking were all but eliminated.

The data base used in this study contained 72 consecutive data sets, some times recorded at one hourly intervals, and at other times, two hourly intervals. They spanned a sustained period of high incident wave energy and some periods of low incident wave energy, both coupled with large tide ranges. This provided a wide range of reef top wave and water depth combinations. These data are presented as a time series in Fig. 2.

Incident high wave energy events were dominated by sea states with peak energy periods of between 4 and 6 seconds with direction determined by the

dominant south east wind. During low energy events, when the sea state was minimal, longer peak energy periods were observed when small amounts of wave energy from distant sources became significant relative to the local sea state. The direction of this longer period wave energy was unknown and it was necessary to eliminate it from the data records. All characteristic spectral wave parameters have been restricted to the wind wave component by only considering wave frequencies greater than or equal to 0.16 Hz.

Fig. 2 Wave and Tide Summary

The selected subset of wave records were to be free of wave breaking influences, with the wave energy dissipation over the flat bed between ZP1 and ZP4 (Fig. 1) due only to bed friction damping. However, for most data sets at John Brewer Reef, waves broke at the reef edge due to depth limiting effects and dissipated energy, primarily through the turbulence associated with the breaking process, until stable wave heights compatible with reef top water depths were attained. The waves then reformed into stable oscillatory waves. It was established that even the largest waves in any of the recorded incident wave trains, reformed into oscillatory waves before reaching ZP4 (Nelson, 1994). However, this was not the case at ZP1 making it necessary to delineate which data sets were largely free of breaking waves at this station. These will obviously be those biased towards lower incident wave energy and larger reef top water depths.

This screening was made using the criterion of Nelson (1994) for the maximum stable oscillatory wave heights sustainable over horizontal beds, namely Eq. 4, and the fact that this criterion was shown to be applicable to the individual waves of a naturally occurring random wave train.

$$\frac{H}{h} = \frac{F_c}{22 + 1.82F_c} \quad (4)$$

F_c is a non-linearity parameter after Swart and Loubser (1979), as defined in Eq. 5. F_c values less than 10 indicate deep water waves, those between 10 and 500 indicate transitional water depth waves, and values greater than 500, shallow

water waves when H/h approaches a value of 0.55.

$$F_c = \frac{g^{1.25} H^{0.50} T^{2.50}}{h^{1.75}} \quad (5)$$

Waves with larger H/h ratios can exist on horizontal beds but these would be turbulent breaking waves losing height rapidly by the turbulent dissipation of energy.

A wave by wave analysis of all 72 wave records at ZP1 determined the H/h population for each record and the value of F_c associated with each H/h value. This took into account the effect of tide and infragravity wave activity in varying the effective water depth on which the wind waves were superimposed, since the maximum wave height that could be sustained varied with time because local water depth was time dependent. The F_c value assigned was based on the wave height and water depth associated with each wave and the wave period equal to the lapsed time between the crest of this wave and the crest of the previous wave (see Nelson, 1994 for greater detail).

The results for all 72 wave records were compared with the criterion of Eq. 4. Wave records with little or no wave breaking were those for which none (or at least very few) of the observed values of H/h exceeded the value given by Eq. 4 when using the observed value of F_c . Based on this criterion 20 wave records were available for further consideration.

A further 6 of these 20 records were rejected because the reef top wave orthogonal was not sufficiently aligned to the line of wave poles. There remained 14 acceptable data sets.

Fig. 3 ZP1: H/h versus F_c for all Waves in all 14 Data Sets

Fig. 3 shows the results for all waves in all 14 data sets plotted on the H/h versus F_c plain. The solid line is Eq. 4 and the dotted line is the deep water wave steepness limit at F_c values less than 10. The average number of waves per wave record is 357, and on average, only 1 or 2 waves per record significantly exceeded the envelope curve. While it is possible some waves did break at H/h values less than the envelope curve (Nelson 1987), it is reasonable to assume that this impact was slight, and that for the 14 selected data sets, all wave energy dissipation between ZP1 and ZP4 was due to bed friction damping only.

Table 1 summarises the characteristic parameters associated with the adopted 14 data sets. The data set number is the location of the data set within the consecutive order of the original 72 data sets. The day and time indicate the common instrument commencement time for the recording of each data set. H_1 and H_4 are respectively the spectral estimates of significant wave height (H_{mo}) of the wind wave component at ZP1 and ZP4 and H is the mean of these two values. T_p is the mean of the four peak energy periods at ZP1, ZP2, ZP3, and ZP4 for the wind wave component. h is the mean, reef top water depth during the data set.

Reef Top Wave Energy Dissipation Factors

Two wave related friction factors are in common use. The wave friction factor (f_w) is defined by Eq. 6.

$$\tau_{max} = 0.5\rho f_w U^2 \quad (6)$$

τ_{max} is the maximum bed shear stress due the horizontal oscillatory water particle velocities at the bed and ρ is the water density. The determination of f_w requires the direct or indirect measurement of bed shear. The wave energy dissipation

factor (f_e) is defined in terms of the time averaged rate of wave energy dissipation due to bed friction as given in Eq. 7.

$$\frac{dE_f}{dx} = (\tau u)_{mean} = \frac{2}{3\pi} \rho f_e U^3 \quad (7)$$

E_f is the wave energy flux, τ is the instantaneous bed shear stress, u is the instantaneous bed velocity, and U is the amplitude of the of the bed velocity variations. The determination of f_e requires the measurement of wave energy loss over a known distance.

The second of the above procedures was adopted at John Brewer Reef, but in so doing it is important to note the following. The two wave related friction factors are different according to how they are defined and measured. However, it has been shown that for fully developed rough turbulent oscillatory flows, $f_w \approx f_e$ (Jonsson, 1963; Swart, 1974; Nielsen, 1992; Raudkivi, 1988). The oscillatory flow at the bed is fully developed rough turbulent flow for all prototype wave conditions of engineering significance. Therefore, for all practical purposes, the field estimates of f_e can be interchanged with f_w . This will be important when estimates of the reef top hydraulic roughness are made.

f_e can be evaluated two ways. The first considers the attenuation of the total energy using only characteristic spectral parameters. The second considers the attenuation of individual frequency components in the spectrum, based on the assumption that these components travel independently of all other spectral components and that there are no non-linear interactions. Experimental limitations dictated the use of the first method. Despite the difficult and hostile environment, the field measurements of small total energy deficits between poles 1 and 4 displayed good consistency and trends. To deal with still smaller energy deficits within individual frequency components introduces anomalies due to the lesser confidence associated with these components relative to that of the total wave energy measurement.

In water of constant depth, the loss rate of wave energy per unit surface area (left hand side of Eq. 7) can be expressed as,

$$\frac{dE_f}{dx} = \frac{\rho g C_g}{8} \frac{dH^2}{dx} \quad (8)$$

where C_g is the group velocity and g is the acceleration due to gravity. The right hand sides of Eqs. 7 and 8 can be equated, integrated, and re-arranged to yield the solution for f_e shown in Eq. 9, and can be applied directly to the John Brewer Reef data shown in Table 1. Δx is the distance between ZP1 and ZP4 namely 141m.

$$f_e = \frac{3g}{8\pi^2} \frac{(H_1 - H_4)}{H_1 H_4} \frac{C_g}{\Delta x} (T_p \sinh(kh))^3 \quad (9)$$

The resulting values of f_e are shown in Table 2. Also shown are the associated values of a , U , and R_e obtained using the values of H , h , and T_p given in Table 1.

A plot of f_e versus R_e is shown in Fig. 4. At first glance the scatter appears considerable with f_e values of between 0.1 and 0.2 over a Reynolds number range

Fig. 4 f_e versus R_e - Reef Data

of between 50000 to 150000. To some extent, the perceived scatter is more apparent than real, accentuated by the linear scales. More common practice is to use log log axes for such plots (e.g. see Fig. 5), masking the extent of the scatter. While much of the scatter must remain unexplained, some can be attributed to

the different characteristic values of relative roughness associated with each data set, and the dependence of f_e on that value (see Eq. 3). The values shown beside each point are the a values given in Table 2. These alone are an indicator of relative roughness ($= r/a$) because the reef top roughness remains unchanged for all data sets. Based on this indirect measure of relative roughness the results can be divided into two groups. Group 1 data has a values between 0.25m and 0.32m (mean=0.29m) and a mean f_e value of 0.13. Group 2 data has a values between 0.19m and 0.23m (mean=0.21m) and a mean f_e value of 0.19.

Analyses demonstrated that the small prevailing pole line current that existed on the reef (average value of 0.06 m/s for the 14 data sets) would have had little influence on the computed values of f_e shown in Table 1.

Reef Top Hydraulic Roughness

Kamphuis (1975) used an oscillating water tunnel to measure the maximum shear stresses on a smooth bed and 5 different artificially roughened beds. The shear stress values, measured using a shear plate incorporated in the bed, enabled the computation of wave friction factor, f_w (Eq. 6). Kamphuis summarised the results in a friction factor diagram reproduced here in Fig. 5. The results are consistent with the friction factor being independent of Reynolds number for fully rough turbulent flow. In this region, f_w and f_e (the wave energy dissipation factor) are for all practical purposes, interchangeable as indicated on the vertical axis of Fig. 5. The John Brewer Reef data in Fig. 4 fall well within the fully rough turbulent region of Fig. 5 ($0.1 < f_e < 0.2$ and $50000 < R_e < 150000$) and can be used to estimate values of reef top hydraulic roughness in conjunction with Fig. 5.

Fig. 5 f_e versus R_e (after Kamphuis, 1975)

The group 1 data has a mean f_e value of 0.130, corresponding to a relative roughness (r/a) value in Fig. 5 of about 0.2. Based on the mean a value of 0.29m

for the group 1 data, the hydraulic roughness (r) of the reef top is estimated as $0.2 \times 0.29 = 0.06\text{m}$. Similarly for group 2 data, the mean values of $f_e = 0.183$ and $a = 0.21\text{m}$ lead to values of $r/a \approx 0.3$ and $r = 0.3 \times 0.21 = 0.06\text{m}$. Hence, one estimate of the reef top roughness is 0.06m .

A second independent estimate of hydraulic roughness can be made using the work of Jonsson (1963) who developed the following implicit equation for fully rough turbulent oscillatory flow over a fixed immobile bed.

$$\frac{1}{4f_w} + \log\left(\frac{1}{4\sqrt{f_w}}\right) = -0.08 + \log\left(\frac{a}{r}\right) \tag{10}$$

Swart (1974) presented Eq. 11 as an explicit alternative to Eq. 10. The author has replaced f_w in Swart's equation with f_e as has been previously justified in this paper for fully rough turbulent flow.

$$f_e = \exp\left(5.213\left(\frac{r}{a}\right)^{0.194} - 5.977\right) \tag{11}$$

Fig. 6 shows the John Brewer Reef data over-plotted with curves corresponding to fixed values of r computed from Eq. 11. These show that the best estimate of reef top hydraulic roughness is 0.07 m , and this closely approximates the previous estimate of 0.06m .

Fig. 6 f_e versus a - Reef Data

Movable Sand Bed Equivalents

An interesting comparison has been made between the influence of this fixed reef surface on wave damping and that of a movable bed of sand using the dimensionless function of Nelson (1995). This expresses the wave energy dissipation

factor (f_c) and the physical state of a movable bed as a function of two dimensionless parameters namely $T_c = T\sqrt{g/D}$ and $D_c = D/a$. A range of bed particle sizes were used in the function for each reef top wave and water depth condition listed in Table 1. It was found that movable bed f_e values, comparable with the observed fixed bed reef top values, occurred most consistently when the bed particle size was equal to 0.6 mm. The comparative results are shown in Fig. 7.

Fig. 7 Movable Bed versus Reef Top Friction Factors

The scatter in the plot results from the fact that a movable bed of given particle size no longer has a constant roughness because the bed form varies with the prevailing wave and water depth conditions. Nevertheless, the comparison demonstrates that while coral reefs may be perceived as being much *rougher* than sandy beds, they may in fact be no rougher, in hydraulic terms, than many sandy beds.

Comments and Conclusions

Field observations have enabled the hydraulic roughness for the fixed bed of a coral reef platform to be determined. In so doing, advantage has been taken of fortuitous and near ideal conditions, where natural trains of random, stable and unbroken oscillatory waves were propagating in water of constant depth, such that wave bed friction damping was the only active wave transformation process present. The roughness estimate of 60mm to 70mm was based on small total energy deficits measured over a known length of wave orthogonal.

The measured fixed bed roughness value is of more use to wave transformation modelers than any of the measured values of wave friction factor. The latter change with wave and water depth conditions while the former remains unchanged, so that the applicable relative roughness and wave friction factor can be determined no matter what wave and water depth conditions prevail.

The measured hydraulic roughness value is transferable to other similar reefs. If differences between reefs are perceived, the measured roughness is a datum value that can be varied based on visual comparisons and reasoning.

The paper has demonstrated that, while coral reefs may be perceived as being much rougher than sandy beds, they may in fact be no rougher in hydraulic terms than many sandy beds experiencing the same wave and water depth conditions.

CHAPTER 244

Effect of Wave-Induced-Pressure on Seabed Configuration

Tetsuo Sakai¹, M. ASCE and Hitoshi Gotoh²

Abstract

In almost all of the previous studies on the seabed configuration, the seabed configuration is classified based on the bottom shear stress, or Shields number. While, in the wave field, the wave-induced-water-pressure change can have a secondary effect on the sediment transport. The laboratory experiment on the seabed configuration under the coexistence of the oscillatory flow and the water-pressure change is conducted in this study, to investigate the effect of water-pressure change on the seabed regime classification.

The existing region of various bed configurations, such as no-motion, bed-lad, suspension over ripple and sheet flow, changes with the change of the amplitude of water-pressure change. The ripple geometry, or flatness of ripple, are also affected by the water-pressure change. The mechanism of these changes are discussed related to the lift force due to the porewater-pressure distribution in sand layer.

Introduction

Seabed configuration, which is formed as the result of sediment transport, is quite different under the various conditions of wave and current. On the other hand, the mode of sediment transport depends on the seabed configuration.

Although there is an interactive structure among the wave-current field, the sediment transport and the seabed configuration, the time scale of the development of seabed configuration is sufficiently longer than that of others. Therefore, to describe

Figure 1. Forces acting on seabed under the wave propagation

the sediment transport process based on the mechanics of the motion of sediment particles, it is essential to know the relation between the seabed configuration and the bottom shear stress, or Shields number, due to wave and current.

These relation has been investigated through some experimental studies; while the effect of wave-induced-water-pressure change on the seabed configuration was not examined in detail. Fig. 1 shows the schematic expression of external forces acting on seabed due to the wave propagation. High water pressure acts on the seabed under the crest of a wave, then the particle density of the bed becomes to be dense. On the other hand, low water pressure acts on the seabed under the trough of a wave, then the particle density of the bed becomes to be loose. In both situations, the bottom shear stress is the dominant driving force of sediment motion. To discuss the additional effect due to the water-pressure change by wave propagation in detail, porewater pressure distribution should be investigated.

In this study, the experiment on the seabed configuration under the coexistence of the oscillatory flow and the water-pressure change is performed by using an oscillating water tunnel with cylinder system for the control of the water pressure.

Laboratory experiment

experimental apparatus

Figure 2 shows the oscillating water tunnel with the water-pressure-control system. Both sides of the rectangular water tank are connected to the water circulating pipe, at the top of which a water-circulating-propeller system, or an oscillatory-flow generator,

Figure 2. Oscillating water tunnel with water-pressure-changing system

is installed. Lower part of the water tank is a sand pit, the depth of which is 600 mm. The front and back sides of the water tank is made by glass wall for the observation of the motion of sediment particles. In the back side wall, porewater-pressure sensors are flash mounted. In order to generate the water-pressure change, a oil-hydraulic-pressure-driven piston system is connected to the water-circulating pipe. The electromagnetic current meter and the water-pressure sensors are equipped to monitor the discharge of current and the changing water pressure, which are used as the feedback signal of the personal-computer based current-water-pressure control system. Although various kinds of the time series of current-velocity and water-pressure can be generated by using this apparatus, the in-phase sinusoidal time series of current-velocity and water-pressure, which correspond to the condition of a progressive small amplitude wave, are generated.

procedure of experiment and experimental conditions

The transition of bed configuration occurs with the increase of the bottom shear stress in the following order: (i) no motion; [critical state for sediment movement]; (ii) bed-load motion; (iii) suspended load over ripples; and sediment transport in sheetflow regime. In the experiment, the flow-velocity amplitude is gradually increased with keeping the amplitude of water-pressure change, to observe the transition of bottom

Table 1. Experimental conditions

	oscillatory flow	oscillatory flow and pressure
velocity amplitude u_b (cm/s)	3.0 - 78.0	3.0 - 78.0
total pressure amplitude p_0 (m)	0.0	0.5, 1.0, 1.5
period T (s)	6.0	6.0

configuration mentioned above. The series of the experiment were conducted with changing the magnitude of the amplitude of the water-pressure change, to investigate the effect of the water-pressure change on the transition of the bed configuration.

The ripple geometry affected by the amplitude of water-pressure change is examined based on the detailed observation of sediment motion over ripples, and the mechanism to determine the ripple geometry is considered.

Table 1 shows the experimental conditions. The test particle are the two kinds of the uniform sand, the diameter of which are $d=0.025$ cm and $d=0.035$ cm. The specific density of the sand is 2.65.

Classification of the seabed configuration

Figure 3 shows the experimental results of the bed configuration under the action of oscillatory flow for the cases of $d=0.025$ cm and $d=0.035$ cm. The lines in this figure shows the division of the bed configuration proposed by Shibayama and Horikawa (1982). In the figure, u_b =amplitude of the flow velocity in the neighbourhood of the bottom; w =terminal fall velocity of sediment particle; and Ψ =Shields number defined as $\Psi = f_w u_b^2 / 2(\sigma / \rho - 1)gd$ (f_w =friction coefficient proposed by Jonsson (1966); σ =density of sediment; ρ = density of water; and g =gravitational acceleration). The flow velocity in the neighborhood of the bottom is estimated by extrapolating the measured velocity near-bottom-wall region by supposing the logarithmic velocity profile. The friction coefficient was calculated by using the explicit expression proposed by Tanaka (1990). The thresholds of four modes, such as no motion, bed-load motion, suspension over ripples and sheetflow, estimated from the present experiment show fairly good agreement with the empirical relation proposed by Shibayama and Horikawa, which was determined based on the existing experimental results.

Figure 3. Classification of seabed

Figure 4 shows the classification of the bed configuration, namely, no motion, bed-load, suspension over ripple and sheetflow, under the various combination of flow-velocity amplitude, u_b , and total water-pressure-change amplitude, p . In this figure, the experimental results of the cases of the particle diameter $d=0.025$ cm are shown. The critical shear stress of the sediment movement decreases with the increase of the amplitude of water-pressure change. In other words, the no-motion region decrease with the increase of the amplitude of water-pressure change. The suppression of the ripple generation increases with the increase of the amplitude of water-pressure change, consequently, the be-load region increase with the increase of the amplitude of water-pressure change. In contrast with the ripple generation, the generation of the sheetflow is promoted by the increase of the amplitude of water-pressure change.

The changing porewater pressure is induced in the sandy bed constituted by fine sediment under the action of water-pressure change on the bed surface. Because of the phase lag between the porewater pressure and the water-pressure acting on the sand surface, an additional lift force acts on the sediment layer near the sand surface. This additional lift force depends on the porewater-pressure profile, and the positive lift force acts on the sediment layer when the changing water-pressure is smaller than the average, namely in wave-trough phase. The decrease of the critical bottom shear stress of sediment movement is caused by the action of this additional lift force.

Figure 5 shows the classification of the bed configuration under the various combination of flow-velocity amplitude, u_b , and water-pressure-change amplitude, p ,

Figure 4. Classification of the bed configuration ($d=0.025$ cm)

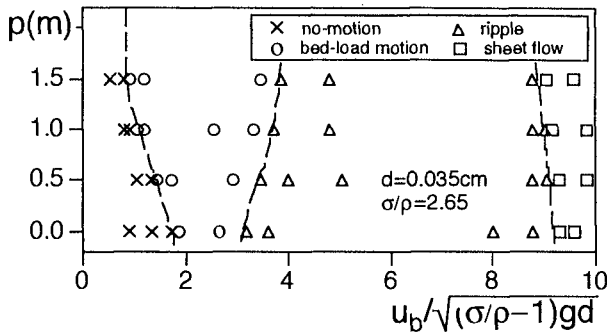

Figure 5. Classification of the bed configuration ($d=0.035$ cm)

for the particle diameter $d=0.035$ cm. Although the tendency of the transition of bed configuration shown in Fig. 5 is the same as in Fig. 4, the effect of the amplitude of the water-pressure change to the transition of the bed configuration is stronger in Fig. 4 than that in Fig. 5. To clarify this point, the bottom neighboring flow velocities, u_{cp} , at three threshold such as the transition point from no motion to bed load, from bed-load to suspension and from suspension to sheetflow for the change of the amplitude of water-pressure change are shown in Fig. 6. The bottom neighboring flow velocities, u_{cp} , are normalized by that of oscillatory flow condition, u_c . Fig. 6 shows that the transition points of the bed configuration clearly depend on the magnitude of the

Figure 6. Transition points of the bed configuration

amplitude of water-pressure change. This tendency is most clearly detected in the transition point from no motion to bed load. By comparing the cases of $d=0.025$ cm and the cases of $d=0.035$ cm, the change of the threshold of bed configuration against the change of the amplitude of water-pressure change in small size sediment is more significant than that in large size sediment.

Under the action of critical bottom shear stress of sediment movement, hydrodynamic force, or driving force, acting on the sediment particle balances with the bottom frictional force, or resistant force. Therefore the sediment motion is keenly affected by the additional lift force due to the changing porewater pressure in sand layer. While, in the cases of the transition from suspension to sheetflow, the amplitude of the bottom shear stress are sufficiently larger than that of no-motion-bed-load transition. Hence the bottom shear stress plays a significant role in the transition from suspension to sheetflow, and the change of the threshold from suspension to sheetflow against the change of the water-pressure amplitude is smaller than that from no motion to bed load.

Geometry of ripples under coexistence of shear and water-pressure changes

The geometry of ripples in suspension mode is also affected by the change of the amplitude of water-pressure change. Maeno et al. (1989) conducted the experiment on the ripple geometry under the action of porewater pressure in sandy bed. They mainly discussed the energy dissipation due to the ripples based on the measurement of the porewater pressure change. While in this study, the role of the porewater pressure

Figure 7. Relation between ripple wave length and excursion length of water particle

change in sandy bed is investigated as a part of the mechanism to determine the ripple geometry.

Figure 7 shows the relation between ripple wave length, λ , and excursion length of water particle, d_0 . In this figure, the cases of three kinds of total water-pressure amplitude, $p=0.0, 0.5$ and 1.0 m are shown with the experimental result by Sato et al. (1984) and Watanabe et al. (1989). In the region of $15.0 < d_0/d < 25.0$, the ripple wave length decreases with the increase of amplitude of water-pressure change; while, in the region of $25.0 < d_0/d$, the dependence of ripple wave length on the amplitude of water-pressure change becomes less significant, and the ripple wave length is regarded to be constant.

Figure 8 shows the relation between ripple wave steepness, η/λ , and Shields number, Ψ (η =ripple wave height). In this figure, the cases of three kinds of total water-pressure amplitude, $p=0.0, 0.5$ and 1.0 m are shown with the experimental result by Sato et al. (1984) and Watanabe et al. (1989). In the region of small Shields number, or in the region of ripple generation, the ripple wave length decreases with the increase of amplitude of water-pressure change. In other words, ripples become flatter with the increase of amplitude of water-pressure change. This tendency becomes less significant with the increase of Shields number. In the neighborhood of $\Psi=0.3$, the dependence of the ripple wave length on the amplitude of water-pressure change is not clear.

Figure 9 shows the change of the transition from two-dimensional ripples to three-dimensional ripples with the change of the amplitude of water-pressure change. The dashed lines in this figure shows the threshold of two- and three-dimensional

Figure 8. Relation between ripple wave steepness and Shields number

ripples proposed by Watanabe et al. (1989). In the pure oscillatory cases, $p=0.0$ m, the experimental results agree fairly well with the proposal by Watanabe et al. The transition point from two-dimensional ripple to three-dimensional one gradually decreases with the increase of d_0/d . In the coexistence cases of oscillatory flow and water-pressure change, the transition point from two-dimensional ripple to three-dimensional one shifts upward, and the dependence of the transition point to the excursion length of water particle becomes smaller.

Two-dimensional ripples are dominantly observed when the ripple wave length and the ripple wave steepness is affected by water-pressure change. The motion of sediment in the neighborhood of the crest of ripple was recorded by a CCD video camera, to investigate the flattening process of ripple due to the water-pressure change in detail. Table 2 shows the experimental condition. Figure 10 shows the behavior of sediment at every $3/\pi$ intervals on the symmetric ripple, which is generated in the pure oscillatory flow condition, $p=0.0$ m. On the other hand, Fig. 11 shows the behavior of sediment on the asymmetric ripple, which is generated in the oscillatory flow and water-pressure change coexisting condition ($p=1.0$ m).

For the simplicity, direction of the current from left to right is taken positive, and the opposite one is taken negative. In this study, the oscillating flow is in phase with the water-pressure change, hence the pressure difference from the average is positive when the current direction is positive; while the pressure difference from the average is negative when the current direction is negative.

In the pure oscillatory flow case, the time series of the current velocity follows the sinusoidal curve, then the flow velocity is symmetric between the positive-current phase and negative-current phase. Two ripple geometry with the phase lag π are

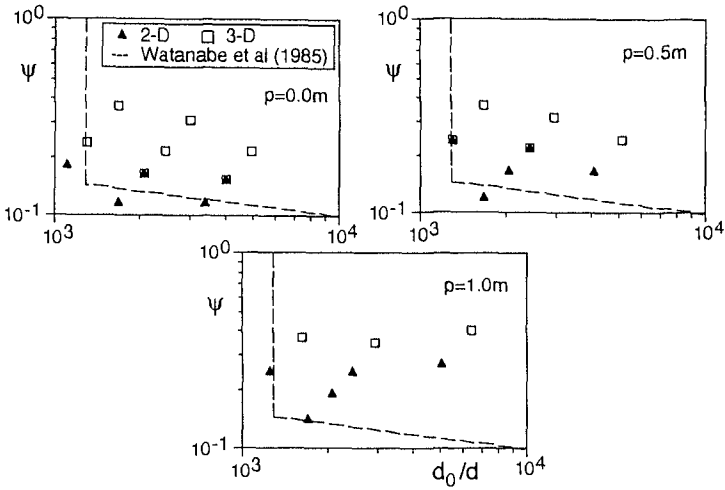

Figure 9. Transition from two-dimensional ripples to three-dimensional ripples

ripple wave length λ (cm)	20.0	23.0
ripple wave height η (cm)	2.5	2.0

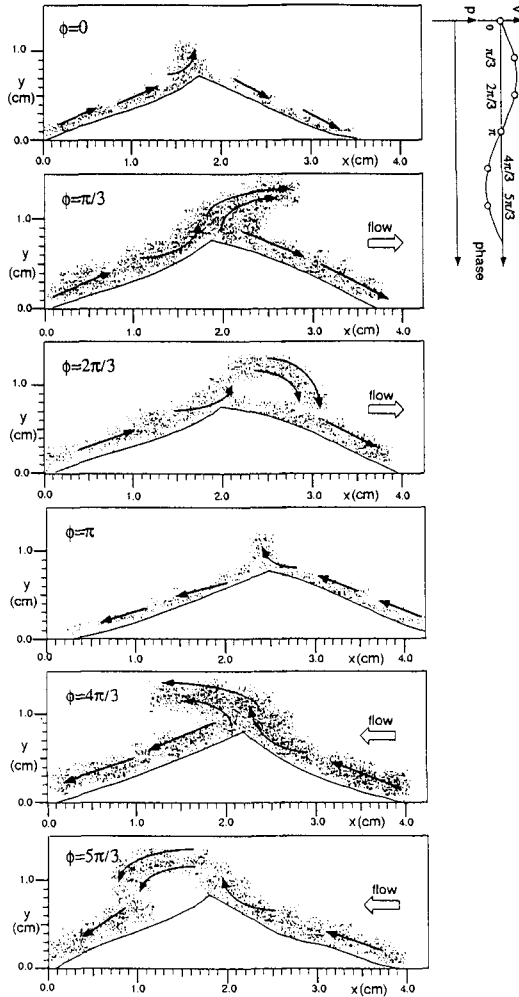

Figure 10. Behavior of sediment at every $3/\pi$ intervals on the symmetric ripple

symmetric. On the contrary, under the coexistence of oscillatory flow and water-pressure change, a significant asymmetric ripple geometry is detected between the positive-current phase and the negative-current phase. Suspended sediment transported along a backward slope of the ripple in the negative-current direction at the phase $\phi=4\pi/3$ is significantly larger than that in the positive-current direction at the phase

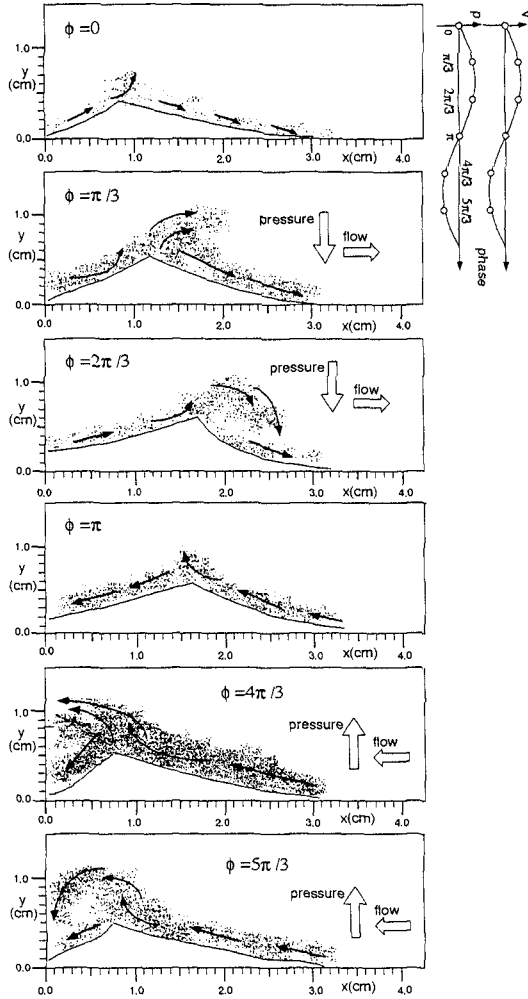

Figure 11. Behavior of sediment at every $3/\pi$ intervals on the asymmetric ripple

$\phi = \pi/3$. When the pressure difference from the average is negative, or the current direction is negative, the additional lift force due to the porewater pressure in sand layer acts on the sediment particles near the surface of sand layer. Because of this additional lift force, sediment particles are promoted to be dislodged, consequently the sediment transport rate increases. On the other hand, when the pressure difference

Figure 12. Movement of the crest of ripple

from the average is positive, or the current direction is positive, the negative lift force, or the additional force acting in downward direction, due to the porewater pressure in sand layer acts on the sediment particles near the surface of sand layer. This force increases the resistance of the sediment particle against the dislodgment and, consequently the sediment transport rate decreases.

Figure 12 shows the movement of the crest of ripple during one oscillating cycle. In the symmetric ripple, which is generated under the pure oscillating flow ($p=0.0$ m), the moving path of the crest toward right and that toward left overlap with each other. In other word, the vertical displacement of the crest of ripple is sufficiently small compared with the horizontal motion of the crest of ripple. On the contrary, in the case of the coexistence of the oscillatory flow and water-pressure change, the moving path of the crest during the positive-current-direction phase and that during the negative-current direction phase is significantly different. The moving velocity of the crest is slower during the positive-current-direction phase (1-3 in Fig. 12) than during the negative-current-direction phase (4-6 in Fig. 12). The crest of ripple moves upward during the positive-current-direction phase and moves downward during the negative-current-direction phase. Because the ripple wave length is approximately constant in all phases, this characteristics of the ripple wave height, or the movement of the crest in vertical direction, are interpreted as the change of the ripple wave steepness. The ripple wave steepness is larger during the positive-current-direction phase than during the negative-current-direction phase. The additional force due to porewater pressure induced by water-pressure change acts in upward direction during the negative-current-direction phase. This additional force brings the decrease in the apparent angle of

repose of sand, and the resultant flattening of ripple geometry.

Conclusion

In this study, the experiment on the seabed configuration under the coexistence of the oscillatory flow and the water-pressure change is performed by the oscillating water tunnel with cylinder system for the control of the water pressure.

The existing region of various bed configurations, such as no-motion flat bed mode, bed-load mode, suspension over ripple bed and sheet flow, changes with the change of the amplitude of water-pressure change. Furthermore, the ripple geometry, such as ripple wave length and wave steepness, or flatness of ripple, are also affected by the amplitude of water-pressure change.

Lift force due to the porewater-pressure distribution in sand layer acts in both upward and downward direction. The upward lift force promotes a sediment motion; while the downward force, or negative lift force, suppress a sediment motion. These difference of the sediment motion is the reason of the change of the existing region of the dominant bed configuration and the asymmetric characteristics of ripple geometry.

CHAPTER 245

The Measurement of Bed Form Shapes in Hydraulic Models

Ian E Shepherd¹

Abstract

Mobile bed hydraulic models have been used in the laboratory for a very long time. Attempts to predict the consequences of river engineering works, dams and barrages, flood protection schemes and dredging methods have led to wide ranging scientific research in material scaling. The design of breakwaters, beach protection systems and sea walls have long been studied in physical models. All of these require a method for measuring the effects of water movements and the resultant erosion, deposition and scouring of materials. This paper reviews some methods that have been used on laboratory models, and attempts to suggest ways forward in the future.

Introduction

Laboratory models of mobile bed properties require measurements of the topography resulting from water moving over the surfaces. This ranges from sedimentation effects in rivers to wave action on beaches. Measurements can be on the macro scale (ie, methods for producing 3D contours over the complete surface) or local 2D tracks of surface elevation (eg, scour around pile structures). It is a difficult measurement, as a wide range of materials and circumstances is encountered. Many experimental laboratories have developed specific techniques to suit particular projects, so it has always been difficult to design equipment and methods that are easily transportable between investigations.

¹HR Wallingford Ltd, Howbery Park, Wallingford, Oxon, OX10 8BA, UK

The durability of this style of investigation is confirmed by the fact that they still occur, and the long history (Hydraulic Models, 1942). In this reference, a description is given of a mechanical system for lowering a small probe onto the surface of the bed from a bridge over the model, and a scale to indicate its elevation. It is a source of surprise and regret that little real progress has been made in the last 50 years. This is partly due to the reluctance of civil engineering laboratories in all areas (government, private and university) to adequately invest in instrumentation development. Recent work by Jetté (1996) has shown what can be achieved by individual innovation, in this case to solve a specific field measurement problem.

This paper reviews some options, but concludes that a simple, adaptable, universal method has still only been possible using old technology, with the advantage of PC control. There must be better ways but time and resources have not permitted their development, underlining the comments above about lack of investment.

In recent years there has been a continuing interest at HR Wallingford in the effects of flowing water and waves over mobile beds. The range of work has included:

- (a) Under-mining of sea walls
- (b) Loss of sand from amenity beaches
- (c) Prevention of siltation in navigation channels
- (d) Research on the combined effects of waves and currents on bed load transport
- (e) Embankment erosion and protection
- (f) Scour around bed mounted structures

Most of this work requires the measurement of bed form disturbance to assess the effects of the existing regime and the consequences of engineering changes to the environment. Some researchers have used remote optical techniques (for example Oesch et.al., 1985) but most of these are time consuming to set-up, require sophisticated and expensive equipment, and cannot record what is happening underwater.

To overcome these objections a number of different mobile probe measurement methods have been developed by several laboratories.

TABLE 1 - COMPARISON OF METHODS

Table 1 shows some sensing methods that have been used and typical performance comparisons. There is only one universally applicable method, that of the touch sensitive, incremental technique. HR Wallingford has used optical servo probes for many years (HRS 1968), and the Delft conductivity probe has been popular (Delft 1985, and Villanueva, 1989). They are all subject to the limitations in the table. Models in flumes, for example, can be measured either by draining the water out or by flooding; it is always inconvenient, and a method which will traverse the (shallow) air-water boundary is better, even if the measurement process itself is slower. Early designs of touch probe were used by SOGREAH (Limnidyn, 1985) for a mobile bed river model, and by KENEK in Japan. The design requirements for an instrument include:

- (a) Must operate in air, underwater, and through the air-water boundary in both directions.
- (b) Must be suitable for sand, mud, coal dust, rocks, plastics, saw dust and in fresh or saline water.
- (c) Vertical resolution to be better than 1mm, horizontal resolution to be better than 5mm in a working range of 10m. Horizontal range ideally unlimited.
- (d) Options for use in flowing water to be available.
- (e) Should be easy to move from one location to another, and be cheap to build.

- (f) Expandable from 2D to 3D operation.
- (g) Must be able to operate over steep rock faces.
- (h) Automatic pc control and data logging.
- (i) Good vertical range.
- (j) Remote control options

There is an obvious choice of sensor operation, either

- (a) Remote sensing probe with a large gap between the probe tip and the bed, or
- (b) Servo operated probe following the bed surface with a small gap.

Option (a) is ideal for flowing water (to prevent scour around the probe tip) but has a poorly defined horizontal "footprint".

Option (b) provides good horizontal and vertical resolution but is unsuitable for use in flowing water or under waves.

The well-equipped experimental hydraulic laboratory should have the capability to use any of the techniques described above, so that the varied demands of different experiments can be accommodated. Each method is described in more detail below.

Methods Available

Most of the techniques depend on a probe that is servo-driven so that its tip is near to the measured surface. The error between a reference value and the value of the measured variable is used to maintain a 'constant' following distance of the probe above the surface. Exceptions to this are the photographic, laser distance and image analysis methods.

Conductivity

This option has been available for a long time (Wilkie, 1954), and had been used even earlier using the water surface as a reference (Anon 1952). Essentially it consists of a probe that can measure the bulk conductivity of the water surrounding a probe tip, and variations that depend on the proximity of non-conducting surfaces. Figure 1 (a) shows the principle. Since the water properties affect the measured values, some method must be used to eliminate the problems caused by water conductivity variations.

Figure 1 Conductivity Probes

The usual approach is to use an additional electrode (1) which is not affected by the surface proximity, and to use the bulk conductance measured between (1) and (2) as a form of compensation in a 'bridge'-type of arrangement.

At HR Wallingford we have experimented with a range of different probe tip designs, some of which are shown in figure 1(b). We have found that the following height H in 1(a) varies depending on the steepness of the surface. This would, of course, be expected, as the modification to the conductive path depends on the shape of the surface as well as the spacing. This is a very subjective problem, and care must be taken in the interpretation of results. The retro-reflective optical probe also has the same problem.

Optical retro-reflection

Again, this method has been used for a very long time (HRS 1968). It can be used in air (whereas the conductivity method cannot) but must be carefully optimised for the type of material over which it is working. It is also independent of water conductivity variations. The basic principle is to shine pulsed (infra-red) light on to the surface and detect the back scattered light. A convenient way to make a small diameter probe without active electronics

in the water is to use fibre optic guides so that the source and detector are above water level, as in figure 2 (a).

Figure 2 Optical and ultrasonic methods

The use of pulsed infra-red and synchronous detection helps to minimise the effects of ambient lighting. For effective operation, the surface must be a good homogeneous reflector such as sand or light plastics. It will not work satisfactorily over coal or gravel of mixed size and colour. Although it will operate in air or in water, the following height is different due to changes of refractive index. It can be adjusted to operate through the air-water boundary (with a step change of level at the boundary), but not the other way round. We have found that the probe collects water droplets at its tip as it emerges from the water, and this causes internal light reflections.

During some experiments, where the water has been drained away from a rippled sand bed, problems again occur even though the probe is always in air. This is because small pools of water are trapped between the ripples and cause surface reflection. The optical probe method has been used successfully over an eroded mud bed in a greenhouse to measure the effects of irrigation sprays.

Both the conductivity probe and the optical probe can also be adjusted

to detect the water surface location, which is useful for datum location. The HR optical probe has been mounted on a reversible carriage and used to traverse a rippled sand bed by ourselves for many projects, and also by others (Richards, 1986), using computer based logging.

Ultrasonic

The use of ultrasonics for hydrographic survey work in the field has been developed to an extremely sophisticated level, and impressive imaging is achieved with side scan sonar. Sensors have also been used for sand ripple measurements (Jetté, 1996). Hydraulic modelling is not in the same price/performance environment, so the same intense development has not occurred.

Some laboratories have used ultrasonic probes, but there is a minimum water depth for satisfactory operation. This depends on the sensor frequency (hence the transmitted wavelength) and the accuracy of the time resolution of the returned pulse within the electronics. Figure 2 (b) shows the usual principle. It is clear that there must be enough time for the transmitted pulse to be detected back at the source before the next pulse is transmitted. Theoretically, bed slope could be measured by driving the probe at a constant horizontal speed, and then detecting the Doppler shift of the backscattered acoustic signal.

A potentially more important limitation is the transmitted beam width. The beam pattern of an acoustic source is complex, and the reader is referred to Stansfield for information. Simply, if the beam angle is 10° , then at a distance of 160mm above the bed, the horizontal projection 'd' will be about 28mm. A narrowed beam angle will improve this, but a larger spacing will degrade it. This sort of horizontal resolution is often inadequate for ripple measurements in models. A typical result is shown in figure 3. Steep ripples and edges of small stones are not measured accurately. This performance has been achieved with a 2.5 MHz probe mounted about 160mm above the bed. Ideally, a vertically driven servo probe (as with the HR systems) would be used, but has not yet been tried. In addition, the vertical resolution is limited by the wave length (0.6mm at 2.5 MHz).

(a) Result from 'shiny' surfaces (mm)

(b) Objects as (a) covered with fine coal dust (mm)

Figure 3

Objects detected by a 10° ultrasonic beam with a source 160mm above the bed $f = 2.5$ MHz

Laser distance sensors

A wide range of solid state laser displacement sensors have become available in recent years. Some of these have been described by Shepherd (1994). At HR we have used the 'Keyence' type of sensor for bed measurements. The probe was packaged in a waterproof perspex housing and used on a fixed support underwater. A great advantage of this type of sensor is that it can be used with a good "stand off" (distance between the probe and the surface) so that flowing water does not cause scour of the bed. Used in this way, it is not necessary to operate the probe on a vertical servo drive unless the total range required is beyond the range of the sensor.

The method again relies on scattered reflected infra-red light, and will work well on sand but generally requires a good homogeneous light scattering surface. It is not satisfactory on shiny reflecting surfaces. The typical optical path is shown in figure 4, and the calibration is different in water than in air. The horizontal resolution is very good as the projected light spot has a diameter of less than 1mm. Calibration in air was linear but underwater it was non-linear.

Figure 4 Laser Position Detector

There are other longer range optical 'time-of-flight' laser distance detectors and scanners that are potentially useful, but we have not yet investigated these. They are generally much more expensive than the short range distance detectors.

Touch sensitive detector

This is an extension of the retro-reflective probe described above, and as can be seen from Table 1, the only universal technique. This relies on the use of a 'diving bell' type of attachment as shown in figure 5, attached to the bottom of the optical probe. The very light weight (< 5g) piston has a good reflecting surface on its top, so that the intensity of the collected light is independent of the type of bed material.

Figure 5 Universal Touch Probe

In operation, the probe is driven down to the bed, the piston tip contacts the bed and deflects by an amount which produces a repeatable level of light reflection at its top. The light level is compared with a fixed threshold which generates the error signal for the probe drive. The air gap is retained when the probe is underwater, so that the optical detection path is unchanged. Use through the air-water boundary has no effect on

operation, and any type of bed material can be detected. The weight of the piston does not produce significant bed deformation.

Remote photography

An early example of remote measurements used Moiré fringe techniques (Oesch et al 1985), and a method used for height detection has potential for bed profiling (Nagle et al ca 1988). Early attempts to use digital image analysis on a rock beach at HR was not very successful due to the variations of surface reflection from wet and dry rock faces.

More recently Lowe and Steele at HR have been developing a method suitable for wide area beach contour measurement.

In principle, it consists of arranging suitable lighting to illuminate the edge of the water at the beach so that it produces adequate contrast to provide a good photographic image from an overhead camera. The water level is changed in known increments, and successive photographic images of the water edge produced, which can then be digitised as two coordinates. The values are then subject to numerical calibration based on the location of the data point and the measured projections of vertical calibration rods located at known positions on the model. Future plans include automatic image analysis of the photographic or video based images. Image processing has already been used for surface float tracking in hydraulic models, and it is probable that these techniques will be adopted for beach movement measurement.

Typical Equipment and Results

Application examples were presented at the Conference, together with results. Figure 6 shows a typical result of a changing profile resulting from wave action. We have used profile measuring equipment for beach erosion studies, sea wall armour research, sediment transport, sand ripple propagation and mud erosion measurements. It is difficult to design universally applicable equipment, as detailed requirements vary with the type of experiment. However, it is possible to make available a range of methods that can be adopted for differing needs.

Figure 6 Profile Measurements on a Model Beach

Typical problems include the sag of instrument beam supports, either due to the weight of a moving carriage, or due to the weight of the beam itself. This can be remedied in several ways, for example:

- (a) Use of a water surface datum location
- (b) Software correction for measured values which are dependent on carriage position
- (c) Overhead fixed datum reference compensation.

In most of our applications adequate support for traversing beams can be provided so that vertical errors due to sag effects are less than 1mm.

Conclusions

Measurements of bed profiles in hydraulic modelling have been very popular in recent years. Project specific studies and basic research both demand this type of measurement. The advances in numerical techniques also require experimental data to help prove computational models. Various methods have been used, but we have found that the touch sensitive technique is the only method completely independent of bed material, slope steepness and air-water boundaries. Photographic and image analysis methods are still in development, and solid state lasers will be important in the future.

Acknowledgements

I am greatly indebted to all my colleagues at HR Wallingford, many of whom have contributed to the successful instrument developments. In particular I want to thank Les Smith and Ian Payne.

CHAPTER 246

Asymmetric boundary layer flow above sand ripples under progressive waves

Takao Toue¹, Kazuo Nadaoka² and Hidehiro Katsui³

Abstract

Boundary layer flow above sand ripples under both oscillatory flow and progressive waves is examined by two dimensional numerical simulation. The simulation shows the difference of the flow between under an oscillatory flow and progressive waves. The boundary layer flow under oscillatory flow is symmetric, on the other hand, the flow under progressive waves is asymmetric. The mechanism of the asymmetric flow is explained by the convection effects of progressive waves.

Introduction

To understand the boundary layer flow above sand ripples is important for the mass transport rate and the sediment transport. The boundary layer flow above sand ripples is characterized by vortices which are generated at ripple crests. The generation, development, movement and dissipation of the vortices should be carefully examined for the understanding of the boundary layer flow.

Many experimental and numerical studies for the boundary layer flow above ripples have been carried out. There are several types of numerical simulation such as the vortex method, the turbulent simulation by $k-\epsilon$ and the direct numerical simulation (DNS). The discrete vortex method is performed by Longuet-Higgins (1981), Smith and Stansby (1985) and Ismail and Syuto (1985). Sato, Uehara and Watanabe (1985) simulated the boundary layer flow using the $k-\epsilon$ model, and Penasantana, Watanabe and Isobe (1990) examined the accuracy of the three types of $k-\epsilon$ turbulent model. Both Blondeaux and Vittori (1990) and Hamanaka and Sato (1992) simulate the boundary layer flow by DNS using the spectral method or the pseudo spectral method, and examine the characteristics of the vorticity.

In most of the numerical studies, the main flow, i.e., the flow above boundary layer, is an oscillatory flow. Nadaoka and Yagi (1988) report the difference of the

2 Dr. of Eng., Professor, Department of Mechanical and Environmental Informatics, Graduate School of Information Science and Engineering, Tokyo Institute of Technology

3 Dr., Manager Dep. of Coastal and Hydraulics Eng., Tech. Res. Center, Taisei Corp.

boundary layer flow between under an oscillatory flow and progressive waves over a horizontal bed. Takigawa, Kim and Gonotani (1989), and Toue, Nadaoka and Katsui (1993) also show the differences above ripple beds. According to Nadaoka et al (1988), the difference are caused by the vertical convective effects of progressive waves. Takigawa et al (1990) showed the differences of the vortex formation between at left side of a ripple and at right under progressive waves, but the shape of the ripples is asymmetric.

The vertical convective effects also exist above symmetric ripples, and the boundary layer flow can be asymmetric under progressive waves. In this report, the boundary layer flow under progressive wave above symmetric ripples is numerically simulated, and then the difference of the flow under an oscillatory flow and progressive waves are shown, and finally the mechanism of the asymmetry is also stated.

Methodology of Numerical Simulation

The method of the numerical simulation used is based on the method of Blondeaux et al (1990) or Hamanaka et al (1992). The basic equations are followings.

$$\omega_t = \{-\Psi_\eta \omega_\xi + \Psi_\xi \omega_\eta + v(\omega_{\xi\xi} + \omega_{\eta\eta})\} / J \quad (1)$$

$$\Psi_{\xi\xi} + \Psi_{\eta\eta} = -J\omega \quad (2)$$

where ω is the vorticity, Ψ is the stream function, t is the time, ξ and η are the boundary fitted coordinate system and J is the Jacobian. Sub-scripts denote the differentiation. ξ , η and J are expressed as below.

$$x = \xi + ae^{-\eta} \cos \xi \quad (3)$$

$$y = \eta - ae^{-\eta} \sin \xi$$

$$J = 1 - 2ae^{-\eta} \cos \xi + a^2 e^{-2\eta} \quad (4)$$

where x and y are the horizontal and vertical coordinate in Cartesian coordinate system and a is the ripple height. All variables are non-dimensionalized by the ripple wave number, $k^* = 2\pi/l^*$ and σ^* is the angular frequency, where l^* is the ripple length. Furthermore, to generate finer meshes near the bottom, the new variables, ζ , is introduced as below.

$$\eta = \eta_r \frac{e^{b\zeta} - 1}{e^b - 1} \quad (5)$$

where η_r is the non-dimensional height of the calculation region, and b is the coefficient to adjust the mesh size.

The lateral boundary condition is the periodic condition, and at the top of the boundary,

$$\omega = 0 \quad (6)$$

$$\Psi = u_{\infty} n_r \sinh \frac{\eta_r}{n_r} \sin\left(\frac{\xi}{n_r} - t\right) \quad \text{for progressive waves} \quad (7)$$

$$\frac{d\Psi}{d\xi} = u_{\infty} \sin(t) \quad \text{for an oscillatory flow} \quad (8)$$

where u_{∞} is the horizontal velocity amplitude at the top of the boundary layer and n_r is the number of ripples in one wave length. At the bottom, the following boundary conditions are used ;

$$\Psi = 0 \quad (9)$$

$$\omega = -J^{-1} \left(\frac{\partial \xi}{\partial \eta} \right)^2 \frac{2\Psi(\Delta \xi)}{\Delta \xi^2} \quad (10)$$

Toue et al (1992) analyze the boundary layer flow by this method. They apply the method to high-Reynolds number flows ($Re=3400$). The calculation can not reach the steady condition, and the time-averaged flow can not be symmetric under an oscillatory flow above a symmetric ripple. Exact two dimensional simulation can express the two dimensional high Reynolds-number flow, but not the three dimensional flow that we usually observe. The method, however, can simulate the boundary layer flow exactly as long as the Reynolds number is small, around 600, and is quite useful to understand the difference of the boundary layer.

In this study the calculation condition is limited to the low Reynolds number, but the flow has vortex sheddings. According to Hamanaka et al (1992), the phenomena are controlled by the non-dimensional ripple height, a , Reynolds number, Re , and Strohal's number, S_t , being expressed as below.

$$Re = 2\pi \frac{u_{\infty}}{\nu} \quad (11)$$

$$S_t = \frac{2\pi}{u_{\infty}} \quad (12)$$

where ν is the non-dimensional viscous coefficient.

Nadaoka et al (1988) showed the ratio of the representative horizontal velocity, u , to wave celerity, C , u/C , is another control parameter for progressive waves. If u/C is large, the vertical convective effects is large. u/C is also expressed as

$$u/C = u_{\infty} / n_r \quad (13)$$

in our formulation. The calculation condition is listed in Table-1.

Table-1 Condition of Calculation(p-1 and p-2 are for verification)

Verification of Method

To verify the the numerical method, the boundary layer flow above a flat bed are calculated. Fig.1 is the velocity distribution under oscillatory flow. The theoretical value is the 1st order solution. The agreement is quite well. Fig.2 shows the distribution of the vorticity under progressive waves. Fig.2 (a) is the analytical value

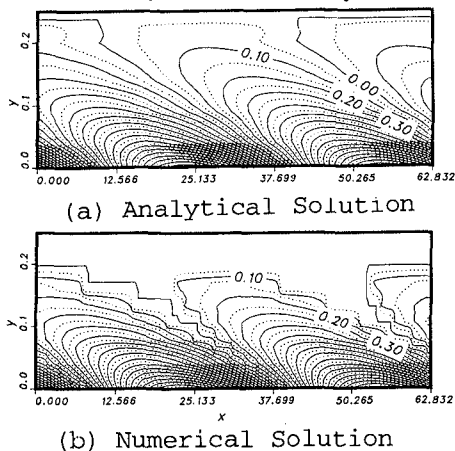

Fig.1 Comparison of Vertical Velocity Profile in Laminar Oscillatory Boundary Layer over Flat Bed between Numerical Simulation and Analytical solution.

Fig.2 Comparison of Vorticity Profile in Laminar Wave Boundary Layer over Flat Bed between Numerical Simulation and Analytical solution.

, and Fig.2 (b) is the numerical one . Both have quite good agreements.

Time Averaged Vorticity and Stream Function

The time averaged vorticity is shown in Fig.3. A pair of the symmetric vorticity cell can be seen in the case of oscillatory flow, i.e. case1-0, case4 and case5. On the other hand, the profile of the vorticity is asymmetric in case1-1, case1-2 and case1-3 which are the cases of progressive waves. When the flow become high Reynolds number, the calculation could not obtain steady state. Those cases are case2 and case3, and they are not analyzed further.

Asymmetry of the time averaged vorticity means the existence of the residual components of the circulation in a ripple, and the residual components cause steady currents. Fig.4 is the time averaged stream function in case 1-1. The profile of the stream function above all ripples should have been the same for each ripple, but since the calculation has not reached the complete steady condition, there are small differences among the stream functions. In spite of the minor differences, unidirectional and uniform steady currents can be seen near the top boundary.

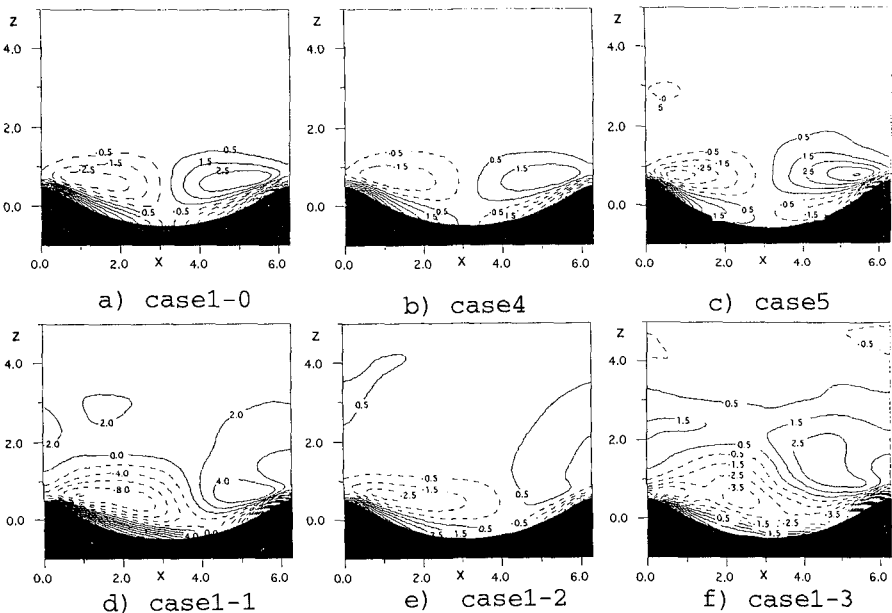

Fig.3 Time Averaged Vorticity (a) case1-0 b) case4 c) case5 d) case1-1 e) case1-2 f) case 1-3)

General Feature of Vorticity Development under Progressive Waves

Fig.5, Fig.6 and Fig.7 are the instant vorticity and the stream function for case1-1, case1-2 and case1-3 respectively in one wave length for $t = \pi/4$. In the figures, waves propagate from the left to the right, and when $t=0$, the horizontal

Fig.4 Time Averaged Stream Function for case 1-1

velocity and the vertical velocity on the top boundary are 0 and maximum at the center respectively. Since the calculation has reached almost a steady condition after the third cycle, the figure can be regarded as the time evolution of both vorticity and stream function at every $\pi/5$ for case 1-1, $2\pi/5$ for case 1-2 and $2\pi/15$ for case 1-3 when they are looked from the right to the left. It is clear that the dynamics of the vorticity are quite different between the positive vorticity and negative one.

The positive vorticity, denoted by A, is generated at Ripple 9 in Fig.5 where the horizontal velocity is negative. The vorticity A is convected upward by the vertical velocity of waves, and finally disperse during a half period of the waves. On the contrary, the negative vorticity, denoted by B, is generated at Ripple 5 in Fig.5 where the horizontal velocity is positive. The vorticity B is pressed down to the bottom also by the vertical velocity of waves. The another positive vorticity can be found at Ripple 3 on the bottom. That is generated by the velocity of the vortex which consists of vorticity B. The vorticity B and the positive vorticity on the bottom interact and then diminished each other. In other word, the vorticity B is diminished by the bottom friction. The positive vorticity convected upward is at far from the bottom, thus, they can not be affected by the bottom friction so much.

The differences mentioned above is related to the phase of the vorticity developing and the direction of the velocity of the main flow. When the positive vorticity is developing, the horizontal velocity is negative and the vertical velocity being directed upward. On other hand, the negative vorticity is developing, the horizontal velocity is positive and the vertical velocity being directed downward.

The phase when the vorticity stop developing is not clear, but it would be the phase during the velocity decreasing in its amplitude. These processes seem to occur at the phase between ripple 2 and 3 for the positive velocity, and 7 to 8 for the negative velocity.

The similar phenomena can be seen in case 1-2 and 1-3 in Fig.6 and 7. In case 1-2, the convection is stronger than case 1-1 and case 1-3. Thus, the positive vorticity A disperse and the negative vorticity B dissipate more quickly. In case 1-3, the

Fig.5 Instantaneous Stream Function and Vorticity in One Wave Length at $t = \pi/4$ for case 1-1 (a) Stream Function $\Delta \psi = 1.0$ b) Vorticity $\Delta \omega = 2.0$, Top Figure shows the phase of the horizontal velocity on the top boundary)

Fig.6 Instantaneous Stream Function and Vorticity in One Wave Length at $t = \pi/4$ for case 1-2 (a) Stream Function $\Delta \psi = 1.0$ b) Vorticity $\Delta \omega = 2.0$, Top Figure shows the phase of the horizontal velocity on the top boundary)

Fig.7 Instantaneous Stream Function and Vorticity in One Wave Length at $t = \pi/4$ for case1-3 (a) Stream Function $\Delta \psi = 1.0$ b) Vorticity $\Delta \omega = 2.0$, Top Figure shows the phase of the horizontal velocity on the top boundary)

convection effects is weak, thus, the negative vorticity B still remain when the positive velocity change the direction. The survived negative vorticity B and the part of the generating positive vorticity interact, and then they goes upward by their own self-propelling velocity.

Vorticity Flux over Ripple Crest

To examine this more quantitatively, the vorticity flux, $u\omega$, in case1-1 that goes across a ripple crest is examined next. In Fig.8, the vertical profiles of $u\omega$ at the left crests of ripples are shown. Fig.8 (a) is the vorticity flux when the velocity is positive, and (b) is for negative velocity. From Fig.8 (a) , when the horizontal velocity is positive, the negative vorticity enters near the bottom and the positive vorticity enters near the top boundary. On the contrary, in the case of the negative velocity, the positive vorticity goes into near the bottom. By comparing the strength of the vorticity flux between the positive and the negative, it is clear that $u\omega$ which goes across a ripple crest is also quite asymmetric.

a) Horizontal velocity is positive

b) Horizontal velocity is negative

Fig.8 Vertical Distribution of Vorticity Flux at Ripple Crests (a) The horizontal velocity is positive, b) The horizontal velocity is negative.)

Circulation in A Ripple

The time evolution of the circulation that a ripple obtain for case1-1 is shown in Fig.9 from $t=0$ to $t=\pi$ of the first wave cycle. The time evolution of the circulation for case 1-0 is also shown in Fig.9. The reason why the results of the first cycle is examined is to eliminate the effect of the vortex that is formed at a half cycle before and the effects of the steady currents. The circulation are divided into four layers which are shown in Fig.10 to understand how the vorticity which is generated at the bottom transfer to upward. The circulation of Fig.9 (b) is the value for Ripple 6 in Fig.5, and that of Fig.9 (c) is the value for Ripple 1. Fig.9 (a) is the circulation under an oscillatory flow, (b) and (c) are the circulation under progressing waves. In Fig.9 (a) and (b), the horizontal velocity is positive, and the horizontal velocity is negative in Fig.9 (c).

In Fig.9 (b) and (c), the circulation in the lowest layer (Layer 1) has some value from the beginning, because even though the main flow is exactly zero at $t=0$ at the crest, the velocity is not zero above the other part of the ripple. The circulation in Layer 1 develop first since the source of the vorticity exists on the bottom. The value of circulation monotonously decreases in (b) and that monotonously increase in (c). The value has a peak before $\pi/2$, since the opposite sign of vorticity is generated on the bottom beneath a vortex. This opposite sign of vorticity is caused by the velocity of the vortex that has oppsite sign to the main flow. Before the peak of the circulation in Layer 1, the circulation in Layer 2 and Layer 3 start to develop, because the vorticity near the bottom disperses and the vortex at a ripple begins to form. The characteristics of the circulation mentioned above are common in Fig.9 (a) to (c).

The circulations of (b) and (c) in Layer 1 are the same up to around $t=0.5$, though the sign is different. After this stage, the differences between (b) and (c) can be seen. The circulation of (c) develops more than that of (b), because the negative vorticity remains near the bottom, thus, the positive vorticity beneath the negative vorticity develops. In Fig.9 (c), the positive vorticity is conected upward

a) Under Oscillatory Flow(case1-0) b) Under Progressive Waves; Horizontal Velocity is positive(case 1-1) c) Under Progressive Waves; Horizontal Velocity is negative(case 1-1)

Fig.9 Evolution of Circulation in a Ripple (a) under Oscillatory Flow b)under Progressive Waves and Positive Horizontal Velocity c) under Progressive Waves and Negative Horizontal Velocity)

, thus, the negative vorticity on the bottom beneath the vortex is small. Also comparing the circulation in Layer 2 and 3 between (b) and (c), the circulation in (b) has a peak earlier than (c) has a peak, and the peak value of (b) is smaller than that of (c). This means that the positive vorticity goes upward more easily than the negative vorticity as mentioned before.

Difference of Phase in Separation

From the difference of the time development of the circulation among Fig.9 (a), (b) and (c), there might be a phase difference in vorticity separation. Fig.11 is the vorticity distribution at $t = \pi/4$ of Ripple 5 and 1 in case1-1 in the first cycle. When the velocity is negative, the vorticity forms along the bottom topography, but the vorticity starts to separate when the velocity is positive. The separation time (phase) of the vorticity is earliest when the velocity is positive under progressive waves (see the right side of the bottom figure of Fig.11). The separation time under oscillatory flow is next and that is latest when the velocity is negative under progressive waves. This is caused by the difference of the attack angle of the velocity against the ripple crest. In the vortex evolution, i.e., $t=0$ or $\pi/2$, the positive velocity of the progressive waves attack with a steep angle, and the angle becomes milder in oscillatory flow, and much milder for negative velocity. This is also effects of the vertical velocity.

Concluding Remarks

Boundary layer flow above ripples under both an oscillatory flow and progressive waves is examined by two dimensional numerical simulation. The simulation shows the differences between the flow under an oscillatory flow and progressive waves. The boundary layer flow under an oscillatory flow is symmetric, on the other hand, the flow under progressive waves is asymmetric. The mechanism of the asymmetric flow is explained by the vertical convection of waves. Furthermore, there are the differences of the phase of the vortex separation.

Fig.10 Explanation of Layers

Fig.11 Instantaneous Vorticity Distribution at $t = \pi/4$ of The First Wave Cycle in case1-1 (Top figure is for Ripple 5 where the horizontal velocity is negative and the bottom is for Ripple 1 where the horizontal velocity is positive.

The Reynolds number of the flow is small and the relation of main flow and the dimension of ripples are neglected in this simulation because this calculation is to examine the mechanism of the asymmetric flow. It is necessary to calculate the high Reynolds number flow by including the appropriate turbulent model for further quantitative discussion.

CHAPTER 247

Undertow Profiles in the Bottom Boundary Layer under Breaking Waves

Daniel T. Cox¹ and Nobuhisa Kobayashi²

ABSTRACT: The vertical distribution of the mean shear stress inside the surf zone is compared to the terms in the time-averaged horizontal momentum equation using one set of laboratory measurements of the free surface elevations and fluid velocities u and w induced by regular waves spilling on a plane slope. The vertical distribution of the eddy viscosity is estimated directly from the measured mean shear stress and velocity. The shear stress distribution in the surf zone is shown to vary linearly with depth until the bottom boundary layer where it reached a nearly constant, negative value. The shear stress variation in the transition region differs distinctly from the inner surf zone. The vertical variation of \overline{uw} is shown to be small outside the surf zone except near the bottom. Inside the surf zone, it is shown that the \overline{uw} term of the horizontal momentum equation is likely to be important in the transition region and that its importance diminishes in the inner surf zone. The vertical distribution of the eddy viscosity has a form which is small near trough level, increases to a maximum value about one-third of the depth below trough level, and then decreases toward the bottom. The eddy viscosity in the middle of the bottom boundary layer is two orders of magnitude less than the eddy viscosity in the interior.

INTRODUCTION

Detailed cross-shore sediment transport models require accurate prediction of near-shore currents, particularly an accurate description of the flow in the bottom boundary layer under breaking waves. The horizontal component of the mean cross-shore flow, or undertow, is driven by the vertical imbalance of the depth-varying momentum flux and the depth-uniform pressure gradient due to the setup (Dyhr-Nielsen and Sørensen, 1970). In the last decade, several undertow models have been developed based on this concept and vary in the degree of empiricism, choice of boundary conditions, specification of eddy viscosity, and treatment of the bottom boundary layer (e.g., Dally and Dean, 1984; Svendsen, 1984; Stive and Wind, 1986; Svendsen *et al.*, 1987; Deigaard *et al.*, 1991; Stive and de Vriend, 1994). Cox *et al.* (1994) presented for the first time detailed laboratory measurements of the instantaneous velocities and shear stresses in the bottom boundary layer of about 1 cm thickness under breaking waves. In the present paper, these measurements are used to compare the vertical distribution of the mean shear stress to the terms of the time-averaged horizontal momentum equation and to estimate the vertical distribution of the eddy viscosity used to express the mean shear stress in terms of the mean horizontal velocity.

The time-averaged horizontal momentum equation may be written

$$\frac{\partial}{\partial z} \left(\frac{\bar{\tau}}{\rho} \right) = g \frac{\partial \bar{\eta}}{\partial x} + \frac{\partial}{\partial x} (\overline{u^2} - \overline{w^2}) + \frac{\partial \overline{uw}}{\partial z} = \alpha(x, z) \quad (1)$$

where x is the horizontal coordinate, positive onshore; z is the vertical coordinate, positive upward with $z = 0$ at the still water level (SWL); τ is the shear stress; ρ is the fluid density; η is the free surface elevation; u and w are the horizontal and vertical components of the fluid velocity; g is the gravitational acceleration; α is the vertical gradient of $\bar{\tau}/\rho$; and the overbar denotes time-averaging over the wave period. The subscripts x and z are used later to denote differentiation with respect to the horizontal and vertical coordinates. The mean shear stress $\bar{\tau}$ is generally related to the vertical gradient of the mean horizontal velocity \bar{u} through an eddy viscosity ν_t in the following form:

$$\frac{\bar{\tau}}{\rho} = \nu_t \frac{\partial \bar{u}}{\partial z} \tag{2}$$

In this paper, each of the terms in (1) are analyzed using the laboratory measurements of Cox *et al.* (1994). The eddy viscosity is estimated using (2) with the measured values of $\bar{\tau}/\rho$ and \bar{u} .

The data of Cox *et al.* (1994) consists of free surface and velocity measurements for the case of regular waves spilling on a rough, impermeable 1:35 slope. The roughness consisted of a single layer of sand grains glued on the plane slope. The median diameter of the sand grains is $d_{50} = 0.10$ cm. The velocity profiles were measured at six vertical lines in the cross-shore direction to include the shoaling region seaward of breaking (denoted L1), the break point (L2), the transition region (L3) and the inner surf zone (L4, L5, and L6). Each of the measuring lines include measuring points at a fraction of the grain height above the rough, fixed bottom. Table 1 lists basic statistics of the data set where x is the cross-shore coordinate with $x = 0$ at L1 and $x = 980$ cm at the still water shoreline, H is the wave height, \bar{h} is the local water depth including the setup, k is the wavenumber, η_{min} is the trough level, and $\bar{\eta}$ is the setup. The wave period is $T = 2.2$ s, and the free surface statistics are based on the phase-average of 50 waves.

ANALYSIS OF HORIZONTAL MOMENTUM EQUATION

The shear stress appearing in (1) is estimated from the measurements assuming $\bar{\tau}/\rho = -\bar{\sigma}_{uw}$ where $\bar{\sigma}_{uw}$ is the time-average of the phase-averaged covariance of the measured horizontal and vertical velocity components (Cox *et al.*, 1995). Fig. 1 shows the vertical variation of $\bar{\tau}/\rho$ below trough level at the four measuring lines inside the surf zone. Outside the surf zone, $\bar{\tau}/\rho \simeq 0$ even in the bottom boundary layer (Cox *et al.*, 1995).

The mean water level and trough level corresponding to $\bar{\eta}$ and η_{min} of Table 1 are indicated in the figure with the long and short horizontal lines, respectively. The vertical variation of $\bar{\tau}/\rho$ below trough level increases from the transition region (L3) to the inner surf zone (L4). For the three measuring lines in the inner surf zone, the vertical variation of $\bar{\tau}/\rho$ is fairly linear and decreases with depth, as shown in Okayasu *et al.* (1988); but $\bar{\tau}/\rho$ is negative and almost constant in the bottom boundary layer. In the transition region, $\bar{\tau}/\rho$ also decreases linearly with depth, but the thickness for which $\bar{\tau}/\rho$ is negative is much larger.

The variations of $\bar{\tau}/\rho$ in the bottom boundary layer are shown in detail in the bottom panel of Fig. 1. A second vertical coordinate z_b is introduced and is related to the vertical coordinate z by $z = (z_b - d)$ where d is the depth below the SWL. This figure clearly shows that $\bar{\tau}/\rho$ is non-zero and negative near the bottom in the inner surf zone and could be modeled as depth-invariant near the bottom. The solid circle at $z_b = 0$ indicates $\bar{\tau}_b/\rho$ computed by a linear regression analysis assuming a logarithmic profile of the mean velocity in the bottom boundary layer (Cox and Kobayashi, 1996). The thick line indicates the 95% confidence interval from the regression analysis. These points are added as a check of the $\bar{\tau}/\rho$ estimates near the bottom. The temporal variations of the bottom shear stress τ_b were discussed in Cox *et al.* (1996).

The solid line in the upper and lower panels is a piecewise continuous line approximated by a constant shear stress in the bottom boundary layer and a linear best-fit line through the interior points. The constant shear stress was computed using a number of measured points, j , above the bottom as listed in Table 2. The number j was determined at each measuring line by choosing all of measured values for which $\bar{\tau}/\rho < 0$ near the bottom. The best-fit line through the interior points was estimated using the interior points from the j th point to the trough level. Because of the large scatter in $\bar{\tau}/\rho$ in the interior and because of a regression analysis minimizing the squared error, it was necessary to use a weighting function which emphasized the j th point by counting it ten times. The j th point is indicated in the figure with an open circle.

Table 2 lists the average shear stress in the bottom boundary layer, denoted $\bar{\tau}_b$. These values are reasonably close to the values obtained by Cox and Kobayashi (1996) as indicated in Fig. 1. Table 2 lists the vertical gradient of $\bar{\tau}/\rho$, denoted α , for the interior points using the weighted best-fit line. The uncertainty using a 95% confidence interval is indicated in parenthesis. The value of α without the weighting, denoted α_* , is also indicated in Table 2 with the 95% confidence interval. The values of α and α_* are similar, and the effect of the weighting is to change the intercept of the best-fit line rather than its slope. The confidence intervals, however, were affected since the weighting function effectively doubled the number of points in the regression analysis; hence, the uncertainties based on the unweighted regression analysis are adopted hereafter as realistic estimates. For completeness, Table 2 lists an estimate of the boundary layer thickness δ defined here as the location where the shear stress changes sign from negative to positive. The boundary layer thickness is approximately $\delta \simeq 0.9$ cm in the inner surf zone, similar to the values obtained by Cox *et al.* (1996). At L3, the shear stress changes sign at a much higher elevation, $\delta \simeq 5$ cm, which may not give a good indication of the actual boundary layer thickness in the transition region.

The setup gradient $\bar{\eta}_x$ is the dominant term on the right-hand-side of (1) in the surf

Table 2: Shear stress estimates and gradients for L3 to L6.

Line. No.	j	$\bar{\tau}_b/\rho$ (cm^2/s^2)	α (cm/s^2)	α_* (cm/s^2)	δ (cm)
L3	14	-1.1	1.1 (0.2)	1.1 (0.6)	4.5
L4	10	-0.8	2.6 (0.5)	2.3 (1.0)	1.0
L5	9	-0.5	1.9 (0.3)	1.7 (0.5)	0.7
L6	8	-0.6	2.8 (0.3)	2.6 (0.5)	0.8

zone. The estimates of $\bar{\eta}_x$ are listed in Table 1, where the m subscript is used to denote the gradient estimated from the measured $\bar{\eta}$. For L1, $\bar{\eta}_x$ is estimated by a forward difference of the measured values at L1 and L2. For L2, no estimate is given, although $\bar{\eta}_x \simeq 0$ at the break point (e.g., Bowen *et al.*, 1968). For L3 to L6, $\bar{\eta}_x$ is estimated using a linear regression which includes an additional measuring value of $\bar{\eta} = 1.45$ cm at $x = 840$ cm (Cox *et al.*, 1995). The regression analysis indicated

$$\bar{\eta}_x = (3.3 \pm 0.6) \times 10^{-3}, \quad \gamma_{xy}^2 = 0.988$$

where the uncertainty is estimated by a 95% confidence interval and γ_{xy}^2 is the square of the correlation coefficient. To check the accuracy of $\bar{\eta}_x$ estimated from the measurements, comparisons were made with $\bar{\eta}_x$ estimated using the analytical expression in Bowen *et al.* (1968). These analytical values are listed in Table 1 and are indicated with the B subscript. The agreement is good except at L3 where the analytical $\bar{\eta}_x$ may be overpredicted.

The second term on the right-hand-side of (1) involves the horizontal and vertical velocities, u and w , which can be expressed as the sum of the orbital velocity, denoted with a tilde, and the mean velocity, denoted with an overbar,

$$u = \tilde{u} + \bar{u} \quad \text{and} \quad w = \tilde{w} + \bar{w} \tag{3}$$

The time-average of the squared velocities may be written

$$\overline{u^2} = \overline{\tilde{u}^2} + \bar{u}^2 \quad \text{and} \quad \overline{w^2} = \overline{\tilde{w}^2} + \bar{w}^2 \tag{4}$$

Undertow models based on (1) generally assume that $u \simeq \tilde{u}$ and $w \simeq \tilde{w}$. As a further simplification, it is often assumed that $\overline{u^2}$ is depth-invariant and that $\overline{\tilde{w}^2}/\overline{u^2} \ll 1$. Fig. 2 shows the vertical variation of $\overline{u^2}$, $\overline{\tilde{u}^2}$, and $\overline{w^2}$ for L1 to L6. This figure indicates that $\overline{u^2}$ is nearly constant over depth, except very near the bottom and that $\overline{\tilde{w}^2}/\overline{u^2} \ll 1$ is a reasonable assumption, except near the trough level. Outside the surf zone, the approximation of $u \simeq \tilde{u}$ is also quite good since $\bar{u}^2 \simeq 0$ everywhere below trough level. Inside the surf zone, however, the magnitude of \bar{u}^2 is sufficiently large compared to $\overline{u^2}$. Table 3 lists the depth-averaged values of $\overline{u^2}$, $\overline{\tilde{u}^2}$, and \bar{u}^2 where the a subscript denotes averaging from the trough level to the bottom. Outside the surf zone, $[\overline{\tilde{u}^2}]_a/[\overline{u^2}]_a \simeq 0.05$, and inside the surf zone, $[\overline{\tilde{u}^2}]_a/[\overline{u^2}]_a \simeq 0.25$. Table 3 also indicates that the vertical velocity component is negligible both outside and inside the surf zone, $[\overline{w^2}]_a/[\overline{u^2}]_a \simeq 0.05$, except near trough level where $[\overline{w^2}]_{tr}/[\overline{u^2}]_{tr} \simeq 0.15$.

Table 3: Depth-averaged values and horizontal gradients of $\overline{u^2}$, $\overline{\tilde{u}^2}$, and $\overline{u^2}$ for L1 to L6.

Fig. 3 shows the cross-shore variation of the depth-averaged values of $\overline{u^2}$, $\overline{\tilde{u}^2}$, and $\overline{u^2}$ with the horizontal gradients. The estimates of the horizontal gradients are listed in Table 3. At L1, L2 and L3, the gradients were computed using finite differences as follows: L1, forward difference with $(L2 - L1)/(\Delta x)$ with $\Delta x = 240$ cm from Table 1; L2, central difference with $(-L1 - 3L2 + 4L3)/(6\Delta x)$ with $\Delta x = 120$ cm; and L3, central difference with $(L4 - L2)/(2\Delta x)$ with $\Delta x = 120$ cm. The horizontal step size is large given that the vertical resolution of the measuring points is only a few centimeters in the interior and a few millimeters near the bottom. The gradients for L4, L5 and L6 were computed using linear regression which gave

$$\begin{aligned}(\overline{u^2})_x &= -0.5 \pm 0.3 \text{ cm/s}^2, & \gamma_{xy}^2 &= 0.98 \\(\overline{\tilde{u}^2})_x &= -0.4 \pm 0.5 \text{ cm/s}^2, & \gamma_{xy}^2 &= 0.90 \\(\overline{u^2})_x &= -0.2 \pm 0.2 \text{ cm/s}^2, & \gamma_{xy}^2 &= 0.93\end{aligned}$$

Although there is large uncertainty in the horizontal gradient estimates, the analysis based on the depth-averaged values of $\overline{u^2}$, $\overline{\tilde{u}^2}$, and $\overline{u^2}$ indicates that the approximation of $u \simeq \tilde{u}$ is reasonable for estimating the horizontal gradient of the $\overline{u^2}$ term in (1) in the surf zone.

Deigaard and Fredsøe (1989) indicated the importance of \overline{uw} appearing in the third term on the right-hand-side of (1). Fig. 4 shows the temporal variation of uw with u and w at five elevations $z = -7.9, -15.9, -23.9, -26.9,$ and -27.8 cm, indicated (a) to (e), respectively, for L1. In this figure, uw is reduced by a factor of 10 to facilitate plotting, and the phases have been adjusted such that the zero upcrossing of the free surface elevation is at $t = T/4 = 0.55$ s. The figure shows that the variation in uw is large, especially in the upper portion of the water column $z = -7.9$ cm (a) where uw reaches a maximum value of $uw \simeq 500 \text{ cm}^2/\text{s}^2$. Near the bottom at $z = -27.8$ cm (e), uw is small since the vertical velocity component is approximately zero.

Fig. 5 shows the vertical variation of the time-averaged value of \overline{uw} below trough level for L1 to L6. The time-averaged values for the five elevations in Fig. 4 are indicated by a solid circle for L1. The magnitude of \overline{uw} is $10 \text{ cm}^2/\text{s}^2$ which is an order of

magnitude less than the fluctuations of uw shown in Fig. 4. Outside the surf zone, $\overline{w\overline{w}}$ is nearly depth-invariant except near the bottom. Inside the surf zone, the variation of $\overline{w\overline{w}}$ is noisy. Nevertheless, crude estimates of the vertical gradients of the $\overline{w\overline{w}}$ at L3 and L4 may be made. At L3, $(\overline{w\overline{w}})_z \sim (-2.7) \text{ cm/s}^2$ in the lower portion of the water column, and $(\overline{w\overline{w}})_z \sim 2.3 \text{ cm/s}^2$ in the upper portion. These estimates were made "by eye" using the curves of Fig. 5 re-plotted on a separate sheet of graph paper. The uncertainties are roughly $\pm 50\%$. For L4, $(\overline{w\overline{w}})_z \sim (-2.5) \text{ cm/s}^2$ in the lower portion of the water column. In the upper portion, $(\overline{w\overline{w}})_z$ is approximately zero. For L5 and L6, $(\overline{w\overline{w}})_z$ is small. Again, these are very crude estimates based on time-averaged quantities that are an order of magnitude less than the fluctuating quantities.

Considering (3), the $\overline{w\overline{w}}$ term can be expressed as

$$\overline{w\overline{w}} = \overline{\overline{w\overline{w}}} + (\overline{u\overline{w}}) \tag{5}$$

and the assumption of a weak current gives $\overline{w\overline{w}} \simeq \overline{\overline{w\overline{w}}}$. Fig. 5 indicates that the $(\overline{u\overline{w}})$ term is indeed small below trough level and in the bottom boundary layer outside the surf zone. Inside the surf zone, the $(\overline{u\overline{w}})$ term appears to give a substantial contribution to the $\overline{w\overline{w}}$ term.

Table 4 summarizes the quantification of the terms in the horizontal momentum equation (1) based on the measurements of Cox *et al.* (1994) inside the surf zone. The uncertainties are indicated in parenthesis. The table indicates that for L4 and L6 in the inner surf zone, the shear stress gradient is balanced by the sum of the first two terms on the right-hand-side of (1). The relative error is less than 5% for both L4 and L6 which is well within the uncertainty of the estimates. For L5, the measured shear stress gradient is smaller than for L4 and L6, but the gradient is still balanced by the first two terms within the uncertainties of the measurements. At L3 however, the measured shear stress gradient is smaller than the sum of the first two term by a factor of two. Therefore, it is likely that the $\overline{w\overline{w}}$ term plays an important role in the transition region and that its importance decreases in the inner surf zone. Outside the surf zone, the gradient of $\overline{w\overline{w}}$ is small, except in the bottom boundary layer.

ESTIMATE OF EDDY VISCOSITY

The use of (2) in undertow models requires the specification of an eddy viscosity, ν_t . Several forms have been proposed including depth-invariant, two-layer, parabolic, and piecewise continuous. The eddy viscosity is specified empirically, with a velocity scale related to the wave celerity or to the local turbulent kinetic energy and a length scale related to the local water depth.

In this paper, ν_t is estimated from (2) using the measured values of $\bar{\tau}/\rho$ and \bar{u} . The left panel of Fig. 6 shows the vertical variation of the measured \bar{u} with a best-fit cubic spline at L4. The values of the seaward volume flux, Q_s , per unit width listed in Table 1 were calculated by integrating this curve from the bottom where $\bar{u} = 0$ to just above trough level where again $\bar{u} = 0$. The middle panel of Fig. 6 shows the measured values of $\bar{\tau}/\rho$ below trough level and is the same as that plotted at L4 in Fig. 1. The right panel shows the eddy viscosity at L4 estimated from

$$\nu_t = \frac{\bar{\tau}/\rho}{(\bar{u})_z} \quad (6)$$

where $\bar{\tau}/\rho$ is given by the piecewise continuous best fit curve and the vertical gradient of the horizontal velocity is estimated from the best-fit cubic spline using a finite difference approximation with a vertical resolution of $\Delta z = 0.01$ cm. The figure shows that from trough level, the eddy viscosity increases downward to a maximum value about one-third of the depth below trough level and then decreases. The variation in the eddy viscosity is unrealistically large as the velocity gradient approaches zero at $z \simeq (-12)$ cm. This is the major limitation of the eddy viscosity approach. Near the bottom, the eddy viscosity is small as the velocity gradient becomes large.

Fig. 7 shows the vertical variation of the measured eddy viscosity at the four measuring lines inside the surf zone similar to the right panel of Fig 6. Only those portions for which (6) gave reasonable estimates are shown. The vertical distribution of the eddy viscosity is qualitatively similar for L4, L5, and L6 in the inner surf zone. For L3, reasonable estimates could not be obtained over most of the depth. The magnitude of ν_t in the bottom boundary layer for the four measuring lines is

$$\nu_t = 0.10 \pm 0.05 \text{ cm}^2/\text{s} \quad \text{at } z_b = 0.5 \text{ cm}$$

and is about two order of magnitude smaller than ν_t estimated in the interior. This large decrease is consistent with the assumption made by Svendsen *et al.* (1987).

CONCLUSIONS

The following conclusions are supported in this paper based on the analysis of one set of laboratory measurements of regular wave spilling on a rough, plane slope.

- The mean shear stress distribution in the inner surf zone varies linearly with depth until the bottom boundary layer where it reaches a nearly constant, negative value. The bottom shear stress is also negative. The shear stress variation in the transition region differs distinctly from the inner surf zone in that the negative shear stress extends much higher in the water column.

- The $\overline{w^2}$ term is negligible compared to $\overline{u^2}$ except near the trough level.
- Outside the surf zone, $\overline{u^2}/\overline{u^2} \ll 1$. Inside the surf zone, $\overline{u^2}$ contributes significantly to $\overline{u^2}$. The approximation of $u \simeq \tilde{u}$, however, is reasonable for estimating the horizontal gradient of $\overline{u^2}$ inside the surf zone.
- The vertical variation of \overline{uw} is small outside the surf zone except near the bottom.
- The shear stress gradient can be balanced by the first two terms of the horizontal momentum equation (1) in the inner surf zone.
- The \overline{uw} term is likely to be important in the transition region and its importance diminishes in the inner surf zone.
- The vertical distribution of the eddy viscosity in the surf zone estimated from the measured mean shear stress and horizontal velocity has a form which is small near trough level, increases to a maximum value about one-third of the depth below trough level, and then decreases toward the bottom.
- The eddy viscosity in the middle of the bottom boundary layer is two orders of magnitude less than the eddy viscosity in the interior.

Dynamic undertow models based on (1) and (2) are difficult to apply with confidence because of the many uncertainties involved in estimating the terms in (1) and the eddy viscosity in (2). An alternative kinematic model is proposed by Cox and Kobayashi (1996). This model relates the horizontal velocity, bottom shear stress, and boundary layer thickness in a simple but general manner.

CHAPTER 248

A Comparison of Field Observations and Quasi-Steady Linear Shear Instabilities of the Wave Bottom Boundary Layer

D. L. Foster¹, A. J. Bowen¹, R. A. Beach² and R.A. Holman²

Abstract:

Field observations of near-bed high frequency velocity fluctuations and suspended sediment are compared with predictions of momentary flow stability by a quasi-steady linear instability model. Field observations were made as part of the Duck94 cooperative field experiment and consisted of a vertical array of four hot-film anemometers and 19 fiber-optic backscatter sensors located within the wave bottom boundary layer. Predicted instabilities for the quasi-steady model occur over length scales ranging from 2 cm to 1 m and therefore may be assumed to be a plausible mechanism for the generation of turbulence and suspension of sediment. However with the quasi-steady model, the instabilities are at the same phase as the sediment suspension events, but are occurring too late in the wave phase for them to be generating the observed turbulence.

Figure 1: A schematic showing the instrument cantilever as deployed from the Sensor Insertion System on the FRF pier (top panel) and positions of the pressure sensor, FOBS probe, hot film anemometer array, and electromagnetic current meter (bottom panel) (Foster, et al., 1996).

1 Introduction

The seemingly random occurrence of sediment suspension events in the surf zone has long been the topic of research for coastal oceanographers and engineers. These short-lived events are the first step in morphologic evolution and consequently hold significance in our understanding of coastal dynamics. Intuition suggests that suspension events are a result of rapid increases of turbulence levels in the near-bed region. The wave bottom boundary layer is the region of fluid bounding the seabed which responds to the oscillatory surface waves. Within this relatively small region ($\delta \sim O(5 \text{ cm})$), the velocity transitions from the free stream value ($u \sim O(100 \text{ cm/s})$) to zero. Thus far, most of the previous research on the introduction of turbulence to the wave bottom boundary layer has focussed on bottom shear generation. An additional and equally plausible mechanism is the generation of turbulence from within the wave bottom boundary layer through a shear instability. Using a piecewise continuous linear instability model, Foster, et al. (1994) showed that at particular wave phases, the high shears in this region may lead to shear instabilities. With laboratory observations of oscillatory boundary layer flow, Hino et al. (1983) concluded that increased levels of turbulence during the decelerating phase of the flow were triggered by a shear instability.

The objective of this paper is to compare Duck94 field observations of near-bed high frequency velocity fluctuations and suspended sediment with predictions of momentary flow stability by a quasi-steady linear instability model. This paper is organized in the following manner. An overview of the field experiment and data collection technique is given in section 2. The theoretical formulation and solution method of the shear instability problem is presented in section 3. Comparisons between the theory and observations are made in section 4. Finally, the conclusions are given in section 5.

2 Observations

The experiment was conducted at the Army Corps of Engineers, Field Research Facility (FRF) in Duck, NC (Figure 1) on August 17, 1994, as part of the Duck94 field experiment. The significant offshore wave height, angle, and period measured in 8 m water depth were 0.83 m, 50 from the southeast, and 4.54 s, respectively. The observations were made in 2 m water depth on the crest of the bar over flat bed conditions. The instruments were deployed from a cantilever arm attached to the lower boom of the sensor insertion system on the FRF pier, see Figure 1. Near bed velocity observations were made with an array of 5 hot-film anemometers, sampled at 256 Hz, separated with a 1 cm vertical spacing, Figure 1. The velocity outside the wave bottom boundary layer was measured with an electromagnetic current meter. The bed elevation and suspended sediment were measured with a vertical stack of 19 fiber-optic backscatter sensor probe (FOBS), sampled at 16 Hz. The bed elevation is determined by examining each independent sensor for burial. A thorough presentation of field techniques and instrument calibration may be found in Foster et al. (1996).

3 Theoretical Formulation

As formulated in Foster, et al. (1994), let the total velocity be partitioned into perturbation and wave components and given by

$$\begin{aligned} u^T(x, z, t) &= u(x, z, t) + U(z, t) \\ w^T(x, z, t) &= w(x, z, t), \end{aligned} \quad (1)$$

where x and z are the horizontal coordinates (x being positive offshore from the shoreline and z being positive up from the seabed), t is time, u and w are the perturbation velocities, and U is the known horizontal oscillatory background velocity. In a linear instability analysis, it is assumed that perturbation velocities are significantly smaller than the background velocity, simply $u, w \ll U$. Substituting (1) into the continuity equation, subtracting the linearized wave bottom boundary layer equation and neglecting terms of $O(u^2)$, we obtain the governing equation:

$$\begin{aligned} u_t + Uu_x + wU_z &= -\frac{1}{\rho}P_x + \nu(u_{xx} + u_{zz}) \\ w_t + Uw_x &= -\frac{1}{\rho}P_z + \nu(w_{xx} + w_{zz}), \end{aligned} \quad (2)$$

where P is the pressure and ν is the kinematic viscosity. By assuming conservation of mass and two-dimensional flow, it is possible to represent u and w in terms of the stream function, Ψ , such that

$$\begin{aligned} u &= \Psi_z \\ w &= -\Psi_x. \end{aligned} \quad (3)$$

Substitute the stream function definitions into (2), cross differentiate, and subtract to eliminate the pressure reducing to one equation

$$\left(\frac{\partial}{\partial t} + U \frac{\partial}{\partial x} + \nu \nabla^2 \right) (\nabla^2 \Psi) - U_{zz} \Psi = 0. \quad (4)$$

For this investigation, we neglect the effect of viscosity.

The quasi-steady model assumes that the time-varying background profile may be represented with a series of time-independent profiles, such that $U(z, t) \equiv U_n(z)$. At each instant in time, t_n , we assume a solution of the form

$$\Psi_n(x, z, t_n) = \phi_n(z) e^{i(k_n x - \sigma_n t_n)} \quad (5)$$

where k is the real wavenumber and $\sigma = \sigma_r + i\sigma_i$ is the complex frequency. The substitution of (5) into (4) results in the well known Rayleigh equation

$$(U_n - c_n) (\phi_{nzz} - k_n^2 \phi_n) = U_{nzz} \phi_n. \quad (6)$$

The boundary conditions are specified by assuming that there is no mass flow through the bottom and that the perturbation must decay as $z \Rightarrow H$, where H is the water depth, and

are given by

$$\begin{aligned}\phi(z = z_o) &= 0 \\ \phi_z(z = \delta) &= -k\phi(z = \delta).\end{aligned}\tag{7}$$

(6) may be solved with a finite centered difference approximation scheme. For this model, we assume that the background flow may be approximated with a time- and depth-dependent eddy viscosity model (Foster, 1996). The wave bottom boundary layer background flow model was forced with a 256 second record of velocity measured at 13 cm above the bed. The system is discretized into 100 nodal points and solved numerically as an eigenvalue problem (Dodd, et al., 1992), where the wave celerity, $c = \sigma/k$, is the eigenvalue and the stream function, Ψ , is the eigenfunction. The momentary flow stability is examined by searching for the fastest growing mode at each instant in time over a given wavenumber range of interest.

The concept of momentary stability (Shen, 1961) implies that when $\sigma_i > 0$ the disturbances are growing relative to the background flow and the flow may be considered to be "momentarily unstable". Conversely, when $\sigma_i < 0$ the disturbances are decaying relative to the background flow and the flow may be considered to be "momentarily stable".

4 Results

Flow stability was determined at 1/8 second intervals using the eddy viscosity model-generated background velocity profile, $U(z, t)$. An example of this can be seen in Figure 2. Notice that at times a and d the flow is stable and that at times b and c, when the free stream flow is decelerating and there exists an inflection point in the profile, the flow is unstable. The peak growth rate occurs prior to flow reversal when the near-bed internal shear is largest. The oscillatory perturbation frequency, σ_r , is nearly zero in the two unstable cases, b and c, indicating that there will exist a fixed spatial pattern which grows exponentially in time. This may be a possible explanation for ephemeral ripples which form over a wave phase following a suspension event. An example of the eigenfunction amplitude and phase structures for 3 wavenumbers is given in Figure 3. For cases b and c, the peak phase shift is as large as $\pi/2$.

A 60 second time series of near bed cross shore velocity, turbulent variance, concentration, and predicted growth rates is given in Figure 4. The perturbation growth rates, concentration, and turbulent variance all have 'event-like' structures. Although instabilities are predicted during each 1/2 wave and more often than concentration or turbulent variance events, the larger perturbation growth rates are correlated to the highly correlated concentration and turbulent variance events. The concentration (increasing with increasing proximity to the bed) and turbulent variance (decreasing with increasing proximity to the bed) magnitudes vary over the vertical (Foster, 1996), however the temporal event-like structure is uniform throughout this near-bed region. For further comparisons, we use one FOBS sensor located at 3 cm above the bed and the vertically averaged turbulent variance.

To examine the evolution of the growth rates, concentration, and turbulent variance

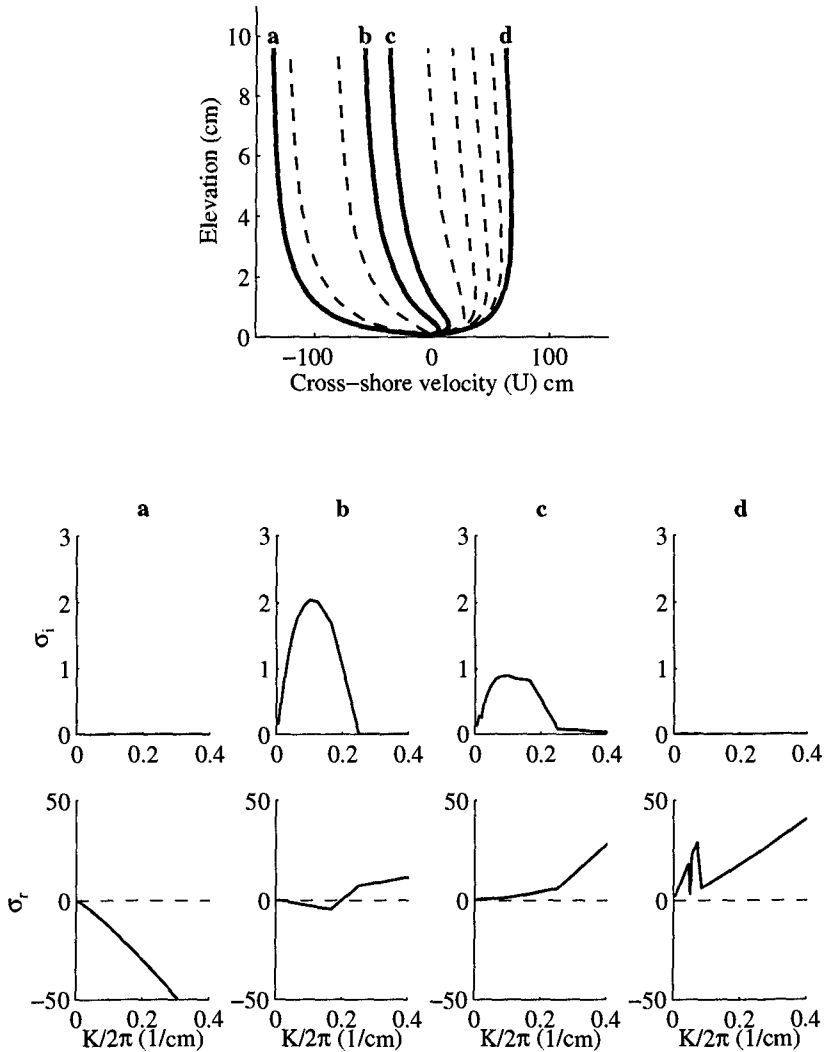

Figure 2: The top panels shows the vertical structure of $U(z, t)$ at 1/4 sec intervals over a 2.5 second record. At 4 of these times, a-d, we have shown the predicted perturbation growth rates, $\sigma_i(k)$ (Hz) (middle panels), and the real frequencies, $\sigma_r(k)$ (Hz) (bottom panels).

Figure 3: The top panels show the eigenfunction phase, $\Theta\phi(z)$, and the bottom panels show the amplitude, $|\phi(z)|$, for each of the 4 cases (a-d) for 3 selected wavelengths (straight line, 4 cm; dashed line, 10 cm; and dashed-dotted line, 20 cm).

over the course of the wave, we use a phase space averaging (PSA) technique. The PSA technique averages quantities of similar velocity and accelerations bins over a 256 second record. The acceleration is determined in the frequency domain with a tapered 1 Hz low pass cutoff frequency. This technique allows us to evaluate the phase averaged temporal event structure as it corresponds to the magnitude and phase of the background wave. The PSA for the growth rates, concentration, and turbulent variance are given in Figures 5, 6, and 7, respectively. The growth rate PSA shows two peaks, one prior to each of the flow reversal on the larger waves (the outer part of the wave ellipse), with the largest peak occurring after the wave crest when the internal shears are largest. The concentration PSA shows one peak during the flow reversal period following the wave crest prior to flow reversal at relatively the same phase as the growth rate. This peak also occurs at the outer part of the wave ellipse, indicating, not surprisingly, that concentration events are closely associated with the larger waves. The second peak in the concentration PSA occurs following the flow reversal and may be a result of the sediment plumes being advected back through the instrument array. The turbulent variance PSA shows a peak intensity at and following the large wave crest, leading to the concentration and predicted growth rates peaks. This indicates that the turbulence is occurring too early in the wave phase for it to be a result from the instabilities predicted here.

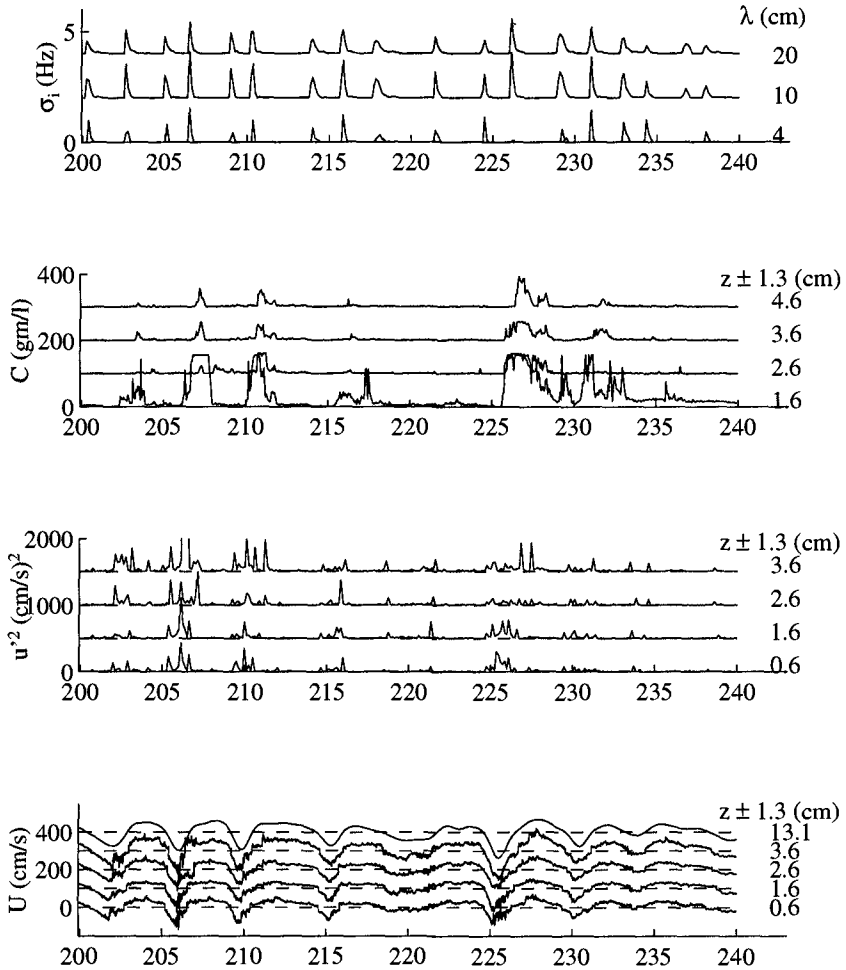

Figure 4: This example 60 sec time series shows near bed velocity as measured by four hot film anemometers and the free stream velocity as measured by an EMCM (bottom panel); high frequency VITA velocity variance at four elevations above the bed (lower middle panel); and concentration at 4 elevations above the bed (upper middle panel). The average distance of each sensor as measured by the FOBS is listed in the right column. The predicted growth rates at three wavelengths (4, 10, 20 cm) listed in the right column are given in the upper panel. Each velocity, variance, concentration, and predicted growth rate time series is offset by 100 cm/s, 500 (cm^2/s^2), 100 g/l, and 2 Hz, respectively. Offshore directed flow is defined with positive velocities.

5 Conclusions

Predicted instabilities for this quasi steady model occur over the appropriate length scales for them to be a plausible mechanism for the generation of turbulence and suspension of sediment. With this quasi-steady model, the instabilities are at the same phase as the sediment suspension events, but are occurring too late in the wave phase for them to be generating the observed turbulence. Work in progress indicates that considering the time-dependent nature of the background flow may yield growth rates which are larger and earlier in the wave phase.

Figure 5: The phase space average of perturbation growth rate shows the background flow phases where the flow is momentarily unstable. The velocity and acceleration are binned at 20 cm/sec and 40 cm/sec² intervals, respectively. Note that the flow moves clockwise around the figure, and that zero acceleration and maximum negative velocity corresponds to the wave crest. The units of the grayscale colorbar are in Hz.

Figure 6: The phase space average of concentration at 3 cm above the bed shows the background flow phases where the suspension events occur. The velocity and acceleration are binned at 20 cm/sec and 40 cm/sec² intervals, respectively. Note that the flow moves clockwise around the figure, and that zero acceleration and maximum negative velocity corresponds to the wave crest. The units of the grayscale colorbar are in Hz.

Figure 7: The phase space average of average turbulent variance over the 4 hot-film sensors shows background flow phases where the turbulent variance events occur. The velocity and acceleration are binned at 20 cm/sec and 40 cm/sec² intervals, respectively. Note that the flow moves clockwise around the figure, and that zero acceleration and maximum negative velocity corresponds to the wave crest. The units of the grayscale colorbar are in Hz.

CHAPTER 249

Wave Boundary Layer Flows and Pore Pressures in Permeable Beds

H. H. Hwung¹ K. S. Hwang² B. H. Lee³

Abstract

The boundary layer flows and wave-induced pore pressures inside porous beds are both investigated in wave tank. Two kinds of porous beds are composed of two different grades of quartz sands which the porosities are 0.437 and 0.472 respectively. According to the experimental results, it is found that the larger pore pressure in permeable bed is induced by the longer wave period, and the pore pressure has an exponential attenuation with the wave steepness increasing.

From the elaborate measurements in the boundary layer, the overshooting induced by wave motion is effected by bed porosity and it becomes smooth. In the experimental cases, the maximum horizontal overshooting occurs at $\tilde{z}/\delta \approx 1.2$, which is lower than the impermeable case of $\tilde{z}/\delta \approx 2.7$ obtained by Hwung and Lin (1989). Furthermore, the vertical overshooting has also been found in our experiments.

Introduction

The natural sea beds are usually permeable, however, most investigations about the bottom wave boundary layer flow were conducted on rigid impermeable beds. Longuet-Higgins (1953, 1958), Collins (1963), Jonsson (1966), Kajiura (1968) and so on, analyzed the characteristics of boundary layer flows with linear or nonlinear wave theory in uniform water depth. Furthermore, Du Toit and Sleath (1981), Sleath (1982, 1984, 1987), Hwung and Lin (1989) and other investigators detected the velocity profile of boundary layer on rigid bottom.

Concerning the pore pressure induced by wave motion in permeable bed, many researchers have paid more attention on the theoretical studies, such as Putnam (1949), Sleath (1970), Liu (1973) and so on. However, only a few of experimental studies has been done in the past years. Therefore, the elaborate experiments including the pore pressure and boundary layer flow in permeable beds have been carried out in this paper.

Experimental set-up

Two different grade of quartz sand of which the porosities are 0.437 and 0.472 respectively, are used in the experiments. The wave flume and related facilities are schematically illustrated in Figure 1. Within the wave flume, a section which 120 cm x 30 cm x 26 cm is filled with quartz sands as the testing section. Four pore pressure transducers are buried inside the porous bed to measure the pore pressure, while a Laser-Doppler velocimetry is used to detect the velocities above the porous bed. The enlargement testing section with the experimental installation are shown in Figure 2.

Fig. 1 The layout of wave flume

Fig. 2 The installation of test section

Herein, there are three kinds of experimental wave conditions listed in Table-1.

Table-1 The experimental wave conditions

Test Cases	T (sec)	d (cm)	H (cm)	H/L
Case 1	1.00	20	5.0	0.041
Case 2	0.95	20	7.0	0.062
Case 3	1.20	20	5.0	0.033

Results and Discussions

According to the experimental results, Figure 3 shows the original measurements of water surface elevation and horizontal, vertical velocities. Due to the wave reflection and boundary turbulent effect, we can see the fluctuations are existed in the velocity measurements. And Figure 4 is the original measurements of water surface elevation and the corresponding dynamic pore pressure. It is obviously to see that the dynamic pore pressure is decreasing from surface to bottom.

From the above original measurements, it shows that the length of each wave cycle in wave flume is not exactly the same due to wave reflection. This phenomena will lead to phase time shifting and create a false image of wave component by the phase average method. Therefore, according to the modified phase average method proposed by Hwung *et al.* (1988), the quantities of phase average can be express as

$$\langle Q \rangle = \frac{1}{N} \sum_{j=1}^N \tilde{Q} \left(\frac{T_j}{T} \cdot t_i \right) + \bar{Q} \quad i=1 \sim M$$

where $\langle Q \rangle$: the quantities of phase average,
 \tilde{Q} : the quantities of wave component,
 \bar{Q} : the quantities of time average,
 N : numbers of testing wave cycle,
 M : numbers of phase time within one wave cycle.

After using the modified phase average method, the water surface elevation, velocities and dynamic pore pressure measurements are shown in Figure 5 and Figure 6 respectively, and the quantities of velocities and dynamic pore pressure at any phase time can be calculated from the above figures.

From the above measurements and analysis, we obtained the relationship between dimensionless pore pressure attenuation and wave period for the two different quartz sands in Figure 7. It shows that the pore pressure increases linearly as

Fig. 3 The surface elevation and velocity measurements

Fig. 4 The surface elevation and pore pressure measurements

Fig. 5 The surface elevation and velocity measurements of the modified phase average

Fig. 6 The surface elevation and pore pressure measurements of the modified phase average

wave periods increasing, and the larger porosity bed has larger pore pressure at the same permeable depth. Besides, Figure 8 shows the relationship between dimensionless pore pressure attenuation and wave steepness. From the results, we found that the pore pressure decreases as wave steepness increasing, and it seems to have an exponential attenuation in this figure.

Fig. 7 The relationship between pore pressure attenuation and wave period

Fig. 8 The relationship between pore pressure attenuation and wave steepness

In addition, we also made the comparison between the dynamic pore pressure and previous theoretical studies as shown in Figure 9. We see that it has similar variation for the measurements and theoretical values, however, there is a little difference at the bottom, due to the reflection of rigid bed.

Fig. 9 The comparison between pore pressure measurements and theoretical values

In order to understand the boundary flows on permeable beds, a two-dimensional LDV system was employed to detect the horizontal and vertical velocities simultaneously. Figure 10 shows the horizontal velocity distributions on the permeable bed of porosity is 0.437 at seven different time phases. We can see that it also has overshooting in the boundary layer at $\tilde{z}/\delta \approx 1.2$, and it is less than on rigid smooth bottom which the overshooting is at $\tilde{z}/\delta \approx 2.7$ obtained by Hwung and Lin (1989). Figure 11 shows the horizontal velocity distributions on the permeable bed of porosity is 0.472 at different time phases. And the overshooting phenomena disappears in this larger porosity case.

Further, the extreme horizontal velocity distributions of all experiments are plotted in Figure 12, we can see that the overshooting phenomena in the boundary layer is clearer in shorter wave period and the overshooting disappears in longer wave period. The another cases of the extreme horizontal velocity distributions on the permeable bed of porosity is 0.472 as shown in Figure 13. From the comparison with Figure 12, we see that the boundary layer flows are more uniform in larger porosity bed.

Finally, the extreme vertical velocity distributions in bottom boundary layer on the permeable beds are shown in Figure 14 and Figure 15 respectively. It is interesting to see that the velocity in lower layer are larger than in upper layer within the boundary layer, and the velocities are more scattering due to the effect of vertical low passing through the porous material. From the vertical velocity distribution, we found the overshooting phenomena also occurs in porous bottom boundary layer.

Fig. 15 The extreme vertical velocity distributions on permeable bed of $n=0.472$

Conclusions

The results summarized above indicate that the permeability of the bottom would result in interesting phenomena in wave boundary flows and dynamic pore pressure. Some remarkable conclusions would be described as follows:

1. In permeable beds, the larger pore pressure is induced by the larger wave period, and the dynamic pore pressure decreases exponential with the wave steepness increasing.
2. On the same wave condition, the larger porosity bed has larger dynamic pore pressure.
3. In the boundary layer, the horizontal overshooting induced by wave motion is influenced by bed porosity and becomes smoother. In our experimental cases, the maximum horizontal overshooting occurs at $\bar{Z} / \delta \approx 1.2$, which is lower than the impermeable case of obtained by Hwung and Lin (1989).
4. From the vertical velocities measurements, we found that the vertical overshooting phenomena also occurs within bottom boundary layer.

CHAPTER 250

Backfilling Of Trenches Exposed to Waves

Jacob Hjelmager Jensen¹ and Jørgen Fredsøe²

Abstract

This paper treats the numerical prediction of initial and long-term morphology of small pipeline trenches. For this purpose a refined flow and sediment transport description is applied such that the entire mathematical problem is formulated and solved on a curvilinear grid using a $k - \epsilon$ turbulence-closure.

The backfilling process of trenches exposed to either waves or a steady current is of importance in relation to the implementation of pipelines in the marine environment. With respect to the sedimentation of trenches, the non-dimensional Trench-Keulegan-Carpenter number, $KC = a/L$, where a is the excursion length of a particle in waves and L the trench length, is investigated in detail, and an optimal KC -number for the backfilling rate is found. Coherent structures in the non-uniform unsteady trench-flow are shown to dominate the deposition rate when present.

The importance of a detailed description of the flow is further justified by comparing predictions of a very simple flow-model neglecting convective terms with the sophisticated flow-model.

Introduction

The morphodynamics of trenches or other man-made excavations in the marine environment involves the process of natural backfilling. In some cases backfilling is intended, as is the case with pipeline trenches, yet, in other cases, such as navigation channels, self-maintenance is striven for. For scientific as well as for economic reasons it is desirable to fully understand and control the mechanisms responsible for this specific morphological process.

A number of investigations of flow and sediment transport processes in a trench or a navigation channel have been conducted during the years. Bijker (1980), van Rijn (1986) and the analytical work of Fredsøe (1979) focus on the sediment transport processes. Other papers such as Alfrink's (1983) and Basara's (1995) focus on the sophisticated modelling of the hydrodynamics. These papers are all confined to the steady current case, and treat waves, if modelled, as a stirring mechanism for sediment only.

²Professor, ISVA, Tech. Univ. of Denmark, DK-2800 Lyngby, Denmark.

Deposition of sediment takes place whenever a suspended particle advected by the flow starts adapting to an environment with less capacity. This might happen when the velocity or the turbulent kinetic energy level of the fluid decreases. A change in fluid capacity is exactly what a particle travelling with the flow across a trench will experience. A net deposition of sediment within the boundaries of the trench may therefore take place. On top of that the bottom concentration of the suspended sediment decreases, which means that less sediment will erode from the bed. Another important contribution to the backfilling process is the action of gravity on bed-load particles moving on a sloping bed that makes particles go downhill more easily than uphill.

For particles carried by a steady stream past a trench the maximum change in capacity (depth-averaged velocity for instance) is obviously some function of the maximum expansion in depth. However, in the case of an oscillatory flow crossing the trench a suspended particle might not experience the maximum expansion in depth. For a given wave situation the expansion felt by a particle advected with the flow generally becomes a function of both the Trench-Keulegan-Carpenter-number and the maximum expansion in depth.

Problem

The trench is initially sinusoidal and characterized by a length, L , and a depth, h , see figure (1). The water depth is called D .

Figure 1: Sketch defining some of the key parameters used in the text.

The bed sediment is characterized by a fall velocity, w_s , and a diameter, d . The flow is generally combined by waves and currents (co-directional) and these are separately characterized by the fluxes, V and U_{1m} . The excursion length for a particle in a wave motion is symbolized by a . The wave is simulated by an oscillating pressure gradient neglecting any deformations of the water surface.

The initial backfilling rate is generally a function, Π , of all above-mentioned quantities, i.e.:

$$\Delta q = \Pi(L, h, D, d, w_s, a, V, U_{1m}, g)$$

where Δq is the amount of trapped sediment. A natural selection of non-dimensional

parameters from these quantities become:

$$\Delta\phi = \Psi\left(\frac{h}{L}, \frac{h}{D}, \theta, Z, KC, \frac{V}{V + U_{1m}}, \frac{k_N}{D}\right)$$

The parameters are in order of appearance referred to as: steepness, expansion, Shields, ($\theta = U_f^2/((s-1)gd)$) and Rouse parameter ($Z = U_f/(\kappa w_s)$), Trench-Keulegan-Carpenter number (a/L) and the wave/current parameter, where U_f is the friction velocity at a reference point far from the trench. The spatial coordinates, x (horizontal) and z (vertical), are non-dimensionalized by D and the time, t , by $(U_{1m} + V)/D$. For the present case the wave/current parameter is either 0 or 1, that is for waves and currents, respectively. All intermediate points define a combined wave/current flow. Furthermore, we will confine ourselves to an analysis based on the expansion parameter and the KC -number.

Solution of flow and sediment-transport equations

The finite volume concept (see Patankar (1980)) formulated in curvilinear orthogonal multi-block coordinates is applied, solving the transformed continuity equation and the fully 2D transformed Reynolds-averaged Navier-Stokes equations employing the standard $k - \epsilon$ closure of turbulence. A thorough description of the present model is reported by Tjerry (1997).

The partial differential equations of the turbulence model in Cartesian form, i.e. turbulent kinetic energy, k , and dissipation of turbulent kinetic energy, ϵ , are given by:

$$\frac{\partial k}{\partial t} + \frac{\partial u_j k}{\partial x_j} - \frac{\partial}{\partial x_j} \left(\frac{\nu_T}{\sigma_k} \frac{\partial k}{\partial x_j} \right) = \nu_T \frac{\partial u_i}{\partial x_j} \left(\frac{\partial u_j}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - \epsilon \quad (1)$$

$$\frac{\partial \epsilon}{\partial t} + \frac{\partial u_j \epsilon}{\partial x_j} - \frac{\partial}{\partial x_j} \left(\frac{\nu_T}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial x_j} \right) = C_{\epsilon 1} \frac{\epsilon}{k} \nu_T \frac{\partial u_i}{\partial x_j} \left(\frac{\partial u_j}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) - C_{\epsilon 2} \frac{\epsilon^2}{k} \quad (2)$$

Here, t is time, x_i the spatial coordinates, u_i the velocities and ν_T is the eddy-viscosity, calculated from:

$$\nu_T = C_\mu \frac{k^2}{\epsilon} \quad (3)$$

The set of constants that appears in the $k - \epsilon$ model is standard choice and originally proposed by Launder (1974):

C_μ	σ_k	σ_ϵ	$C_{\epsilon 1}$	$C_{\epsilon 2}$
0.09	1.0	1.3	1.44	1.92

The transport of sediment, q , is divided into a bed and a suspended load contribution and corrected with the porosity, n , implicitly. The non-dimensional bed load, ϕ_B , is calculated using the Meyer-Peter formula modifying tractive stresses with slope effects as suggested by Fredsøe (1978):

$$\phi_B = \frac{q_B/(1-n)}{\sqrt{(s-1)gd^3}} = \frac{8}{(1-n)} (\theta - \theta_c - 0.1 \frac{\partial h}{\partial x})^{3/2} \quad (4)$$

where q_B is the bed load, $\partial h/\partial x$ the slope of the bed, g the acceleration of gravity, s the relative density and θ_c the critical Shields parameter (~ 0.05).

The concentration of suspended sediment is derived by solving the transport equation:

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial z} = w_s \frac{\partial c}{\partial z} + \frac{\partial}{\partial x}(\nu_T \frac{\partial c}{\partial x}) + \frac{\partial}{\partial z}(\nu_T \frac{\partial c}{\partial z}) \quad (5)$$

The non-dimensional suspended transport, ϕ_S , is found as:

$$\phi_S = \frac{q_S/(1-n)}{\sqrt{(s-1)gd^3}} = \frac{\int_{-h}^1 cudz/(1-n)}{\sqrt{(s-1)gd^3}} \quad (6)$$

where q_S is the suspended transport, and u and v are the longitudinal and vertical velocities, respectively.

Intra-wave calculation is applied for the sediment-transport model in order to take into account non-linear and phase-lag effects.

In the present model the water surface is taken to be plane, and the waves are introduced as an oscillatory motion caused by an oscillatory pressure gradient. At the water surface the flow equations apply symmetry conditions while the c -equation applies a no-flux condition. At the bed boundary a no-slip condition is used for the momentum equations, and a Dirichlet condition is used for the c -equation as the Engelund-Fredsoe formula (1976) is applied, i.e. $c_b = c_b(\theta)$, where c_b is the concentration at bed level.

Furthermore the k -equation uses a no-flux condition at the bed, and the bed condition for the ϵ -equation reads: $\epsilon = (30C_\mu^{0.75})/(\kappa k_N/D)k^3/2$, where k_N/D is the relative roughness of the sea-bed and κ the von Karman mixing length constant. On the in- and outlets Dirichlet and Neumann are applied, respectively, if not, periodic conditions are used.

The total flux of sediment is used in a continuity equation, which governs the morphodynamics. This reads:

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} = 0 \quad (7)$$

stating that the divergence of depth-integrated sediment flux, $q = q_B + q_S$, is equal to the rate of change in bed elevation, h . This equation is discretized with a second order accurate scheme minimizing numerical diffusion. This is crucial when predicting diffusive processes such as backfilling of trenches.

If the entire flow, sediment, and morphological modules are run together, the dynamics of a mobile bed can be described and the backfilling tracked.

Backfilling in currents

In addition to the $k - \epsilon$ model an alternative flow description of the depth-averaged type is employed for the steady state case to emphasize the effect of including a more refined flow description. The depth-averaged approach uses a prescribed logarithmic velocity profile matched by the flux of water and a parabolic eddy-viscosity distribution

scaled with the friction velocity. This is identical to a flow solution where convective terms have been ignored, i.e. local equilibrium.

Figure 2: The Shields parameter along with the non-dimensional bed and suspended load distributions across a trench with the deepest section of the trench at $x = 26$ predicted by a $k - \epsilon$ model and a depth-averaged model. Reference flow: \rightarrow . Parameters are: $L/h=10$, $\theta=1$, $h/D = 0.25$ and $Z=0.6$. $k - \epsilon$ model: —, Depth-averaged model: - - -.

The depth-averaged approach has earlier been applied in the field of sediment transport for analytical purposes, and it is therefore of interest to compare the performance of these flow models with respect to morphology (cf. e.g. Fredsøe (1979)).

The shear stress along with the non-dimensional bed and suspended load predicted by the two flow models typically vary as illustrated in figure (2). It is obvious from the shear-stress variation (i.e. $\theta(x)$) that the depth-averaged approach cannot in detail capture the complex behaviour of flow over a negative bump, which involves separation (or retardation), a phase shift between shear stress and bed form, speed-up and the relaxation of speed-up.

It is seen from figure (2) that both models predict erosion and deposition on the down- and upstream trench side, respectively. The additional shear stress features uncovered by the $k - \epsilon$ model relate in a morphological sense to a faster migration, a slower backfill (partly due to the above mentioned phase shift) and a more violent downstream deformation. The progressing asymmetrical shape of the bed, $h(x)$, is captured with both models as seen in figure (3), where bed forms at $T = tV/D=3000$, 9000, 18000 and 28000 are shown.

It is surprising how well the depth-averaged flow model performs in general and with respect to backfilling in particular. One reason for this is that the sediment transport mechanics such as the response length of suspended sediment is the governing parameter for the backfilling, and that very detailed flow mechanics to some extent is unnecessary. However, for $h/D \rightarrow 0$ (deep-water case) the depth-averaged model must fail since the gradient in capacity as well as in bottom concentration approaches zero in the limit. In this case the depth-averaged mechanism is not capable of explaining the deposition process, and a detailed description of the flow past a trench, including separation or even flow retardation, becomes necessary.

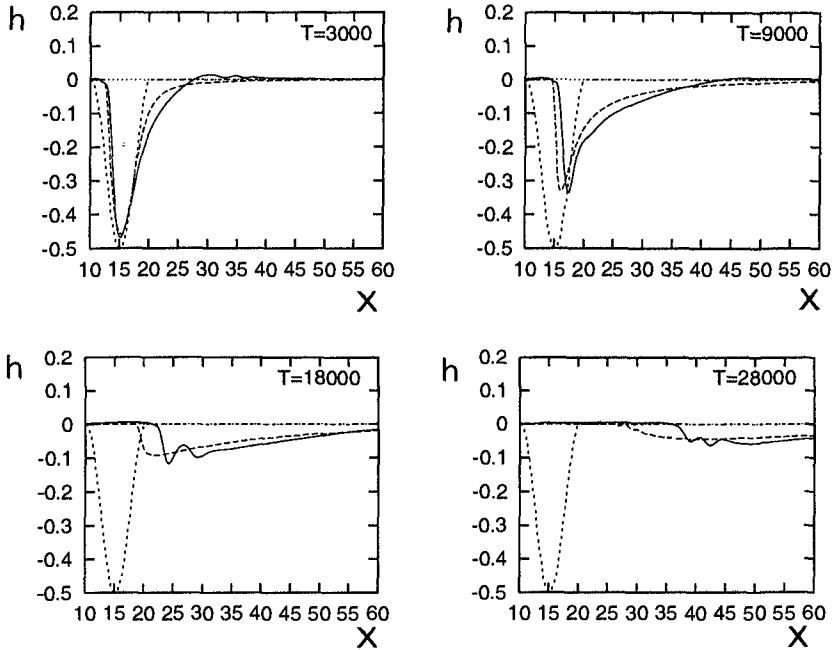

Figure 3: Shape of trench at four stages of its morphological evolution, for $k_N/D = 0.001$, $w_s/V = 0.02$ and $\theta = 0.25$. Reference flow (current alone): \rightarrow . $k - \epsilon$ model: --- , Depth-averaged model: - - - , Initial trench shape:

Backfilling in waves

If wave effects are included matters become more complicated. The waves introduce an additional parameter that in non-dimensional form is described by a KC -number. This is the Keulegan-Carpenter number well-known from the offshore hydrodynamics where it is defined as:

$$KC = \frac{2\pi a}{D_c}$$

in which D_c = the diameter of the cylinder. For small KC -numbers ($< 1-2$) flow separation will not occur, while at larger KC -numbers ($> 10-20$), the flow is fully separated. In trenches, the flow may also separate if the slope is steep enough, and the equivalent KC -number is sufficiently large. In the following we define this number by:

$$KC = a/L$$

With respect to the sedimentation of trenches the KC -number involves at least one important aspect other than flow-separation. For $KC \sim 1$ it is seen that a sand particle picked up on the plane bed may reach the deepest part of the trench where it may settle due to a reduced capacity. The capacity is reduced on the upstream slope as the depth increases (non-uniformity) and as the flow decelerates (unsteadiness), which

gives rise to smaller flow velocities as well as a decrease in intensity of turbulent kinetic energy.

So this is what happens: As suspended particles adapt to the local flow capacity by settling, they might get trapped in the separation bubble growing simultaneously on the upstream slope. If the vortex (former separation bubble) maintains its rotation and is able to keep the particles 'alive' when ejected at flow reversal, particles will be convected out of the trench and into the outer flow with the vortex.

The situation described is captured in figure (4) where time series of contours of concentration and turbulent kinetic energy are shown side by side for a short span of time around flow reversal. The phase in the wave period is symbolized as a dot on the sine-curve (positive values indicate left- to right-going flow).

Figure 4: Time series of contours of concentration (left hand side of figure) and turbulent kinetic energy (right hand side of figure) around flow reversal. For $L/h=5$, $\theta=1$, $h/D=0.25$, $w_s/U_{1m}=0.02$ and $KC=1$.

While the separation develops on the upstream slope, the speed-up of fluid on the downstream trench-shoulder creates high shear-stress levels, which causes a large amount of sediment to suspend. This is seen in figure (5) where time series of profiles for horizontal velocities and contours of concentration are placed side by side at a phase close to flow reversal. The speed-up process in the converging section is visualised by sediment being bursted off the sloping trench bed. This results in an overloaded cloud of sediment that returns with the reversing flow to deeper parts of the trench where it most likely will be deposited. This process, captured in figure (5), may intensify the backfilling.

The time series of concentration contours shown in figure (5) are created by shutting off the bed erosion shortly before the reversal of the flow occurs.

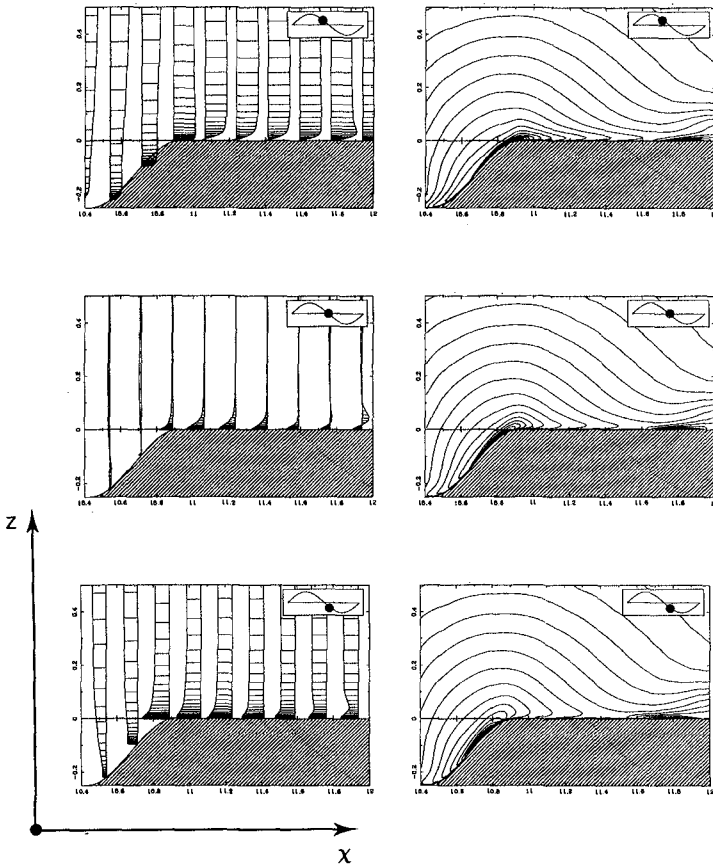

Figure 5: Time series of profiles of horizontal velocities (left hand side of figure) and contours of concentration (right hand side of figure). For $L/h=5$, $\theta=1$, $h/D=0.25$, $w_s/U_{1m}=0.02$ and $KC=1$.

The non-uniform and unsteady flow separates and will speed-up succeedingly, which in the period-averaged sense will create a near bed flow directed towards the banks. A return flow, required for reasons of continuity, is therefore directed towards the centre of the trench so that the time-averaged streamline pattern, depicted in figure (6), shows two cells rotating clock- and anti-clockwise on the left and right hand side, respectively. It is also worth noticing that two additional rotating cells will develop on the shoulders of the trench.

Figure 6: Two patterns of instant streamlines just before flow reversal occurs (in both cases the direction of main flow: \rightarrow) along with the corresponding period-averaged streamline pattern. $KC=0.5$, $h/D=0.1$, $L/h=10$, $k_N/D=0.001$.

The result seen on the right hand side of figure (6) is a time-integrated effect from using a detailed flow-description.

Distributions of the time-averaged bed and suspended loads are shown in figure (7). With the streaming pattern in mind it is interesting to study the period-averaged bed load distribution in the neighbourhood of the trench. The resulting transport rate is an outcome of a battle between the action of gravity and the time-averaged shear stress. It is seen that the gradient, $\partial q_B/\partial x$, which determines whether the sinusoidal trench is being eroded (positive) or sediment is being deposited (negative) in some cases may shift sign at the centre of the trench, such that the deepest regions of the trench is eroded. The cases where the deepest regions are eroded are, for this particular span of parameters, found (see left hand side of figure (7)) as the KC -number is increased and the steepness parameter decreased, thus the time-averaged hydrodynamical forces are strengthened and the gravitational forces weakened.

The period-averaged rotating cells which appear on top of the shoulders are reflected in the bed transport, $\bar{\phi}_B$, at that particular location. This is shown on the left hand side of figure (7). The bed transport here are, however, damped by the vortices (increases in strength with the KC -number) which pass through the shoulder region shortly after flow reversal.

The influence of the vortex on $\bar{\phi}_B$ and $\bar{\phi}_S$ at a given location on the flat bed is recognized as a departure from $\bar{\phi}_B = 0$ and $\bar{\phi}_S = 0$. The vortex disturbs the flat bed region at a distance which is of the same order as the excursion length and is for obvious reasons amplified as h/L is increased. On the flat bed the sediment transport is, in the time-averaged sense, directed away from the trench by the strength of the advected vortex.

Figure 7: Distribution of period-averaged bed (left-hand side) and suspended sediment transport (right hand side) for a steep ($L/h = 4$ for the top of figure) and a moderate trench slope ($L/h = 10$ for the bottom of figure). $KC = 1.0$: \cdots , $KC = 0.5$: $---$, $KC = 0.25$: $- \cdot -$, with $h/D = 0.5$, $\theta = 0.65$ and $w_s/U_{1m} = 0.02$. The trench height depicted is highly distorted.

At the deeper regions of the trench the suspended sediment transport, $\bar{\phi}_S$, is directed towards the centre (see right hand side of figure (7)), implying that suspended material will be deposited here as opposed to erosion of the shoulder region.

More generally the backfilling process can be analysed by looking at period-averaged trapped sediment within control boxes (CB). Figure (8) shows the amount of trapped sediment as a function of the KC -number for three expansion parameters in two control boxes; an inner and an outer. The outer control box surrounds the entire trench from shoulder to shoulder, and the inner control box is bounded by the two steepest sections of the trench.

The trapped sediment is furthermore divided into contributions from bed and suspended load and where deposition is assigned with positive values. The Shields parameter in these calculations are: $\theta = 1$, and the steepness: $h/L = 0.1$.

An interesting feature of figure (8) is that an optimal backfilling rate takes place at $KC \sim 0.2$ for the suspended sediment. This is before the vortex mechanism becomes dominant. At this point the backfilling rate drops as the separation bubble grows in size

and strength. However, beyond a certain KC -number the strength of the separation bubble will not increase any more, which is evident in figure (8) where a small increase in deposition of suspended sediment is seen for large KC -numbers.

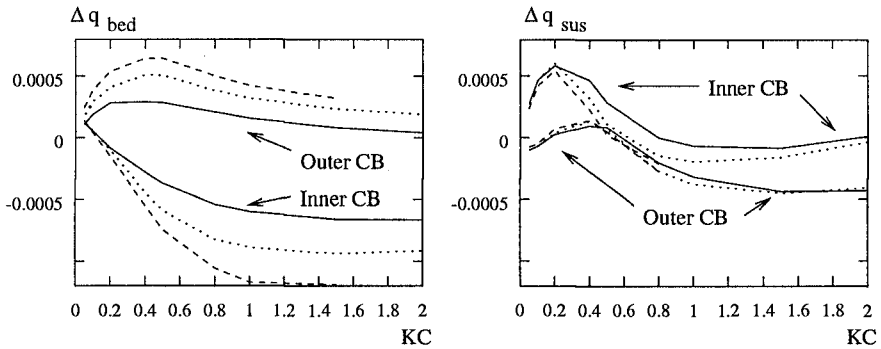

Figure 8: Trapped bed, (left hand side) and suspended load (right hand side) within control boxes (CB) for $h/D = 0.05$: - - -, $h/D = 0.10$: ····· and $h/D=0.25$: ———, and $L/h = 10$, $\theta = 1$, $Z = 0.6$.

The trapped sediment originating from bed load is of the same order of magnitude but negative as the trapped suspended load (at least when $\theta = 1$ and $L/h = 10$) even though $q_{S,max} \gg q_{B,max}$. It is seen from the left hand side of figure (8) (inner CB) that the action of gravity for this particular steepness parameter is merely capable of reducing the forces from the time-averaged shear-stress.

The time-averaged rotating cells on the shoulders are also seen to affect the in-fill of bed load through the outer box. This in-fill rate decreases as the KC -number increases because the separation bubble is washed over the shoulder thus counteracting this time-averaged motion.

It is clear from figure (8) that the typical morphological evolution is a net erosion of the trench shoulders together with a deposition in the centre of the trench. This is, however, exactly the way a diffusion process works.

The morphological development of a trench exposed to waves has been calculated using both flow models discussed previously. Four selected results are shown in figure (9), which clearly demonstrates the diffusion-like process.

As opposed to the steady current case, the depth-averaged model performs poorly in the pure wave case. This is not surprising since a detailed flow description is required to resolve the significant effect from the separation bubble dynamics on the backfilling process in waves. This causes the depth-averaged model to predict a faster backfill.

One interesting, but not surprising, consequence of the change in bed shape was the slow vanishing of the separation bubble as the trench slope becomes gentler. This involves a similar decrease in the vortex mechanism. One would immediately guess that this would lead to an increase in the backfilling rate. However, the trench widens and with this a decrease in the effective KC -number was found. After $T = tU_{1m}/D=1000$ the change in bed form was extremely weak.

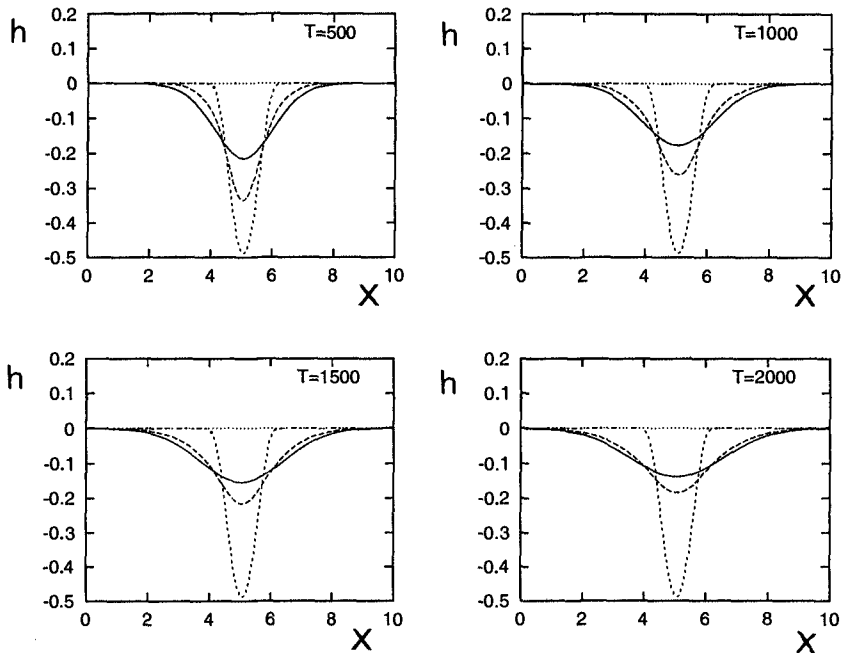

Figure 9: Shape of trench at four stages of its morphological evolution, for $k_N/D = 0.001$, $w_s/U_{1m} = 0.02$, $\theta = 0.25$ and $KC = 0.2$. $k-\epsilon$ model: - - -, Depth-averaged model: —, Initial trench shape: - - - -.

Conclusion

The dynamics of vortices originally born as separation bubbles seem to dominate the backfilling process in waves whenever they are present. This is because the separation bubble traps incoming sediment particles on the upstream slope and keeps some of these 'alive' by the massive level of turbulent kinetic energy found in separating regions. When it detaches from the surface at flow reversal, a cloud of sediment will be advected out of the trench with the vortex.

It has been shown that the vortex mechanism is important and that models which neglect this process may over-predict the backfilling rate.

The optimal backfilling rate in waves was found to be $KC \sim 0.2$.

Furthermore, depth-averaged steady state flow models give good results when applied in morphological calculations particularly in shallow waters which include navigation channels etc.. However, these simple flow models fail to describe more complicated KC -effects found in waves as the effect of separation and vortex shedding is not taken into account.

CHAPTER 251

A CLOSED-FORM SOLUTION FOR TURBULENT WAVE BOUNDARY LAYERS

Magnus Larson¹

ABSTRACT: A general, closed-form solution is presented to the linearized equation describing the velocity in a turbulent boundary layer. The solution is valid for any type of time-varying free-stream velocity, although the focus of the paper is on oscillatory flows generated by surface waves propagating over the sea bottom. A primary objective is to employ the solution for waves with an asymmetric velocity field, where nonlinear effects are small enough to be neglected in the linearized turbulent boundary layer equation. The general solution is developed to more convenient forms for a few special cases, including a sinusoidally varying free-stream velocity and a velocity given by stream function theory. The solution is tested against two different data sets from oscillatory tunnels; one set involves a sinusoidal and the other set a cnoidal free-stream velocity.

INTRODUCTION

The oscillatory boundary layer that develops when surface waves propagate over the sea bottom has many important implications for flow-dependent phenomena in the coastal zone. Examples of such phenomena are wave energy dissipation due to bottom friction and the initiation and transport of sediment (Grant and Madsen 1986). The velocity changes with elevation at a high rate in the wave boundary layer, which typically causes large shear stresses, high dissipation rates, and strong turbulence intensities. An oscillatory free-stream velocity generates a boundary layer with a characteristic thickness that is much smaller than the corresponding boundary layer under a uni-directional current. Thus, the near-bottom velocity gradients and the associated shear stresses are much larger under oscillatory waves than under a uni-directional current, which suggests that the waves dominate the flow close to the

¹ Associate Professor, Department of Water Resources Engineering, University of Lund, Box 118, S-221 00 Lund, SWEDEN. (Email: magnus.larson@tvrl.lth.se)

bottom in many cases. However, because the oscillatory wave motion often does not give rise to any net transport of for example sediment, but primarily has a stirring effect, a superimposed current may have a marked influence on the net transport rate, although the current itself may be too weak to mobilize and transport the sediment on its own.

In nature the boundary layer under waves will almost always be turbulent (Nielsen 1992). Most simple approaches to calculate the velocity in the wave boundary layer employ the eddy viscosity concept to model the turbulence, where the viscosity is taken to be a function of the elevation above the bottom (Kajiura 1968, Grant and Madsen 1979, Brevik 1981, Myrhaug 1982). These models mainly differ in the formulation of how the eddy viscosity ν varies with the elevation z ; the most simple models are based on a linear variation in ν with z (Grant and Madsen 1979), whereas more complex models assume several different layers, each having a separate equation to relate ν and z (Kajiura 1968). In reality, ν should also depend on time and Trowbridge and Madsen (1984a) developed a model where a time-varying eddy viscosity was employed. However, in most models the prediction of the velocity in the wave boundary layer is not overly sensitive to the formulation of ν , and a simple model such as the one suggested by Grant and Madsen (1979) often yields satisfactory results. This is especially true if the velocity calculations are performed with the aim of computing sediment transport rates; existing equations for calculating the sediment transport rate include large uncertainties that do not warrant excessively detailed flow computations (Madsen and Wikramanayake 1991).

The main objective of the present study is to develop a simple, analytical model of the flow in an oscillatory boundary layer under rough turbulent conditions that may be employed for situations where the free-stream velocity is not purely sinusoidal. Such velocity fields are generated by nonlinear shoaling waves, which could produce a net transport of sediment due to the asymmetry in the wave velocity. In deriving the analytical model, it will be assumed that the effects of the nonlinear terms in the momentum equations are negligible, implying that the linearized boundary layer equation may be used (Nielsen 1992). A simple eddy viscosity formulation in accordance with Grant and Madsen (1979) is employed to model the turbulent stresses. The proposed model is tested with data from Jonsson (1980) for a sinusoidal free-stream velocity and with data from Nadaoka et al. (1994) for an asymmetrical free-stream velocity of cnoidal type.

The present study focusses on boundary layer development under oscillatory waves, but the general solution presented for the velocity profile in the boundary layer is valid for any time-varying free-stream velocity. A first-order approach is taken (Grant and Madsen 1979) where the governing equation is linearized in order to obtain a closed-form solution. Thus, for cases where the free-stream velocity is generated by nonlinear waves second-order effects, such as the mass transport in the boundary layer (Trowbridge and Madsen 1984b), are not included in the solution.

Even though the mass transport may be small it could still be of significance for calculating the sediment transport.

THEORETICAL CONSIDERATIONS

General Solution

Employing the simple eddy viscosity model by Grant and Madsen (1979), the linearized turbulent boundary layer (TBL) equation may be written (Nielsen 1992),

$$\frac{\partial}{\partial t}(u_w - u_b) = \frac{\partial}{\partial z} \left\{ \kappa u_{*m} z \frac{\partial}{\partial z} (u_w - u_b) \right\} \quad (1)$$

where $u_w(z, t)$ is the velocity in the TBL, $u_b(t)$ the free-stream (wave) velocity, t time, z a vertical coordinate, κ von Karman's constant ($=0.40$), and u_{*m} a constant, representative bottom shear velocity. With the boundary conditions $u_w = 0$ for $z = z_o$, where z_o is the characteristic height of the bottom roughness, and $u_w = u_b$ for $z \rightarrow \infty$, Equation 1 has the following general solution,

$$u_w = \int_0^t \frac{\partial}{\partial t} (u_b(t - \xi)) I_u(\xi, z) d\xi + u_{bo} I_u(t, z) \quad (2)$$

where u_{bo} denotes u_b at $t=0$ and,

$$I_u(t, z) = \frac{2}{\pi} \int_0^\infty e^{-\frac{1}{4} y^2 \kappa u_{*m} t} \frac{J_0(y\sqrt{z_o}) Y_0(y\sqrt{z}) - J_0(y\sqrt{z}) Y_0(y\sqrt{z_o})}{J_0^2(y\sqrt{z_o}) + Y_0^2(y\sqrt{z_o})} \frac{dy}{y} \quad (3)$$

in which J_0 and Y_0 are zero-order Bessel functions of the first and second kind, respectively, and y is a dummy integration variable. Equation 3 corresponds to the solution for a time-independent free-stream velocity employed at $t=0$ (that is, $u_b(t) = u_{bo} = \text{constant}$); thus, the solution for any $u_b(t)$ is obtained through the superposition of the response from an infinite number of temporal changes in u_b , as expressed by the convolution integral in Equation 2. Figure 1 illustrates I_u in non-dimensional form, and the curves may be interpreted as velocity profiles at different times indicating the TBL growth through the water column.

The shear stress at any elevation z may be derived from,

$$\frac{\tau}{\rho} = \kappa u_{*m} z \frac{\partial u_w}{\partial z} = \kappa u_{*m} z \left\{ \int_0^t \frac{\partial}{\partial t} (u_b(t - \xi)) I_s(\xi, z) d\xi + u_{bo} I_s(t, z) \right\} \quad (4)$$

where,

$$I_s(t,z) = \frac{1}{\pi\sqrt{z}} \int_0^\infty e^{-\frac{1}{4}y^2\kappa u_* t} \frac{-J_0(y\sqrt{z_0})Y_1(y\sqrt{z}) + J_1(y\sqrt{z})Y_0(y\sqrt{z_0})}{J_0^2(y\sqrt{z_0}) + Y_0^2(y\sqrt{z_0})} dy \quad (5)$$

in which J_1 and Y_1 are first-order Bessel functions of the first and second kind, respectively. The integral $I_s \rightarrow \infty$ as $t \rightarrow 0$, but the approach towards infinity is slow and the singularity is easy to handle within the convolution integral in Equation 4. However, if $u_{b0} \neq 0$ an infinite shear stress will be obtained at $t=0$, because $u_w=0$ at $z=z_0$ simultaneously as $u_w=u_{b0}$ an infinitesimal distance above. The integrals in Equations 3 and 5 are time-consuming to evaluate, so in order to speed up the calculation of u_w and τ in Equations 2 and 4, respectively, it is convenient to derive look-up tables for I_u and I_s .

Figure 1. The integral I_u as a function of non-dimensional distance and time.

Equation 2 is a general solution of Equation 1 for any type of free-stream velocity, although from a physical point of view the solution only makes sense for a wave boundary layer where the assumptions behind Equation 1 are applicable. There is only one free parameter in the solution, namely the roughness length scale z_0 , which in the case of rough turbulent flow over a flat bed is typically set to $k_n/30$, where k_n is the equivalent Nikuradse sand grain roughness (Grant and Madsen 1979). After it has been defined, the representative shear velocity u_{*m} may be obtained implicitly from the solution. Grant and Madsen (1979) studied the TBL under a sinusoidal free-stream velocity and used the maximum bottom shear stress τ_{bmax} during a wave period to define $u_{*m} = (\tau_{bmax}/\rho)^{1/2}$, where ρ is the water density. For

more complex variations in the free-stream velocity other choices to define u_{*m} may be more appropriate, such as the mean absolute value of the bottom shear stress during a cycle (τ_{bav}).

Sinusoidal Free-Stream Velocity

Equation 2 was derived using Laplace transform technique and for elementary $u_b(t)$ more convenient forms than Equation 2 may be obtained. If the free-stream velocity is sinusoidal and described by $u_b = u_o \cos \omega t$, where u_o is the velocity amplitude at the bottom and ω is the angular frequency, the following solution satisfies Equation 1 and the boundary conditions,

$$u_w = u_o \cos \omega t - u_o \frac{N_o(2\sqrt{\frac{fz}{z_o}})}{N_o(2\sqrt{f})} \cos \left(\omega t + \Phi_o(2\sqrt{\frac{fz}{z_o}}) - \Phi_o(2\sqrt{f}) \right) - \frac{2u_o}{\pi} \int_0^{\infty} e^{-\frac{1}{4}\frac{\omega t}{f}y^2} \frac{y^3}{y^4 + (4f)^2} \frac{J_o(y\sqrt{\frac{z}{z_o}})Y_o(y) - Y_o(y\sqrt{\frac{z}{z_o}})J_o(y)}{J_o^2(y) + Y_o^2(y)} dy \quad (6)$$

where N_o and Φ_o is the modulus and phase, respectively, of the zero-order Kelvin function $ker_{\sigma}x + i kei_{\sigma}x$, and $f = \omega z_o / \kappa u_{*m}$. The second term in Equation 6 is a transient that is dampened out quickly for small values on f ; in most cases this term is negligible already after a wave period. The shear stress at steady-state conditions is given by (see first part of Equation 4),

$$\frac{\tau}{\rho} = -\kappa u_o u_{*m} \sqrt{\frac{fz}{z_o}} \frac{N_1(2\sqrt{\frac{fz}{z_o}})}{N_o(2\sqrt{f})} \cos \left(\omega t - \frac{\pi}{4} + \Phi_1(2\sqrt{\frac{fz}{z_o}}) - \Phi_o(2\sqrt{f}) \right) \quad (7)$$

where N_1 and Φ_1 is the modulus and phase, respectively, of the first-order Kelvin function. Grant and Madsen (1979) previously derived the steady-state part of the solution for a sinusoidal free-stream velocity (see also Kajjura 1968).

To permit rapid evaluation of the maximum bottom shear stress it is convenient to define a wave friction factor f_w from $\tau_{bmax} = 0.5 \rho f_w \mu_o^2$ (Jonsson 1966, 1980). In accordance with Grant and Madsen (1979), who defined u_{*m} based on τ_{bmax} , f_w may be obtained through the expression for τ_{bmax} given by Equation 7. An alternative approach would be to use τ_{bav} in u_{*m} instead. This would yield a smaller τ_{bmax} , because the turbulent mixing is less if τ_{bav} is used to define u_{*m} , also implying that f_w is smaller than if the conventional definition of u_{*m} is employed. Figure 2 displays f_w as a function of the bottom excursion amplitude A_b ($= u_o / \omega$) over the grain size k_n for a u_{*m} defined based on τ_{bmax} and τ_{bav} .

Figure 2. Friction factors for a sinusoidal wave velocity, where the friction velocity is defined based on τ_{bmax} respective τ_{bav} .

Free-Stream Velocity from Stream Function Theory

Stream function theory (Dean 1965) is convenient for describing nonlinear wave properties, because the theory is valid from deep water up to wave breaking. The bottom orbital velocity at a point under a wave described by stream function theory may be expressed as,

$$u_b = -\frac{2\pi}{L} \sum_{n=1}^N nX(n) \cos(n\omega t) \tag{8}$$

where L is the wavelength, $X(n)$ stream function coefficients, and N the order of the theory employed. The velocity given by Equation 8 is a sum of sinusoidal components and the steady-state solution to Equation 1 with this u_b is,

$$u_w = \sum_{n=1}^N u_n \left\{ \frac{N_o(2\sqrt{\frac{nfz}{z_o}})}{N_o(2\sqrt{nf})} \cos\left(n\omega t + \Phi_o(2\sqrt{\frac{nfz}{z_o}}) - \Phi_o(2\sqrt{nf})\right) - \cos(n\omega t) \right\} \tag{9}$$

where $u_n = 2\pi nX(n)/L$. The corresponding shear stress is given by,

$$\frac{\tau}{\rho} = \kappa u_{*m} \sqrt{\frac{f_w z}{z_o}} \sum_{n=1}^N u_n \sqrt{n} \frac{N_1(2\sqrt{\frac{nf_w z}{z_o}})}{N_o(2\sqrt{nf_w})} \cos\left(n\omega t - \frac{\pi}{4} + \Phi_1(2\sqrt{\frac{nf_w z}{z_o}}) - \Phi_o(2\sqrt{nf_w})\right) \quad (10)$$

A wave described by stream function theory is uniquely defined by the two ratios h/L_o and H/L_o (Dean 1990), where h is water depth, H wave height, and the subscript o denotes deepwater conditions. Waves with identical values on h/L_o and H/L_o yield the same dimensionless velocity $u_b/(H/T)$; thus, the quantity H/T appears as a normalizing "velocity". A friction factor derived for a stream function wave will depend not only on the normalized roughness k_n/H , but also on h/L_o and H/L_o . The friction velocity may be computed by using τ_{bav} , which is obtained from time integration of the absolute shear stress over a wave period T .

RESULTS

Data From Jonsson (1980)

Measurements by Jonsson (1980) of u_w in a water tunnel for a sinusoidally varying u_b with the amplitude u_o was employed as a first step to validate Equation 1 for describing the velocity in the TBL. It was verified that Equation 2 produced identical results to Equation 6, and the steady-state portion of the solution was used for the comparison with the data. Jonsson (1980) presented data for two cases: 1) $u_o = 2.11$ m/s, $T = 8.39$ s, $k_n = 2.3$ cm, and 2) $u_o = 1.53$ m/s, $T = 7.20$ s, $k_n = 6.3$ cm. Comparison between the analytical solution and the measurements was performed for the phases $t/T = 1/2, 5/8, 3/4, 7/8$, and 1 . The Reynolds number Re for Cases 1 and 2 were $6.0 \cdot 10^6$ and $2.7 \cdot 10^6$, respectively, based on A_b and u_o . The roughness values given by Jonsson were employed and there were no free calibration parameters. Two different definitions of u_{*m} were used in the comparison, namely $u_{*m} = (\tau_{bmax}/\rho)^{1/2}$ and $u_{*m} = (\tau_{bav}/\rho)^{1/2}$.

Figures 3 and 4 display the comparison between the analytical solution and the measurements for Cases 1 and 2, respectively. In general, the difference between the two formulations for u_{*m} is small, although using τ_{bav} seems to consistently produce somewhat better agreement with the data. Some of the overshoot effect in the data is not entirely captured by the analytical solution, especially for Case 2. The computed wave friction factors f_w for Cases 1 and 2 were 0.019 and 0.033, respectively, when τ_{bmax} was employed, and 0.014 and 0.025 when τ_{bav} was used. Using different formulations for u_{*m} will not change u_w as much as it will affect the calculation of the shear stress.

Figure 3. Calculated and measured velocity in the turbulent boundary layer for Case 1 from the data by Jonsson (1980).

Figure 4. Calculated and measured velocity in the turbulent boundary layer for Case 2 from the data by Jonsson (1980).

Data From Nadaoka et al. (1994)

Nadaoka et al. (1994) measured u_w in an oscillatory tunnel using air for a free-stream velocity that was asymmetric. The measurements used here to evaluate the TBL model involved a velocity u_b that was of cnoidal type with a positive peak velocity of 2.50 m/s, a negative peak velocity of 1.05 m/s, and a period of 5 s. A cnoidal wave producing a non-dimensional time variation in u_b corresponding to the experimental conditions implies an Ursell number of $U_r=57.8$, although during the experiment u_b was generated to agree with the velocity induced by a hyperbolic wave. In general, such a strongly nonlinear wave provides a severe test for the linearized TBL equation; neglecting the nonlinear terms in the governing equation assumes that the particle velocity is small compared to the wave phase speed (Madsen and Wikramanayake 1991), which may not be the case for strongly nonlinear waves. However, for data obtained in oscillatory tunnels the spatial gradients should be small enough to permit that the nonlinear terms are neglected.

Instead of using a cnoidal or hyperbolic wave to describe u_b in the solution given by Equation 2, u_b was approximated using a wave described by 20-order stream function theory ($H=5.26$ m, $T=10.3$ sec, and $h=8.22$ m; the resulting velocity as a function of non-dimensional time is shown in Figure 5 together with the generated hyperbolic velocity variation during the experiment). Stream function, cnoidal, and hyperbolic theory produced essentially identical variation in u_b with time, but the former theory allows direct calculation of u_w from Equation 9 for steady-state conditions without having to compute for the transient phase, which is necessary if the general solution in Equation 2 is employed. The bed consisted of spray-painted aluminum and was judged to be hydraulically smooth during the experiments. Thus, the length scale z_o is independent of the boundary roughness and may be calculated from $z_o=(3.3\nu_a/u_{*m})/30$ (Madsen and Wikramanayake 1991), where ν_a is the kinematic viscosity for air. The air temperature was about 10 deg during the experiment and the corresponding Reynolds number was $Re=2.8 \cdot 10^5$. The origin of the vertical axis in the measurements was assumed to approximately coincide with z_o .

Since smooth turbulent flow prevailed during the experiment, z_o could be obtained from ν and u_{*m} and no calibration was needed to estimate the bed roughness. The representative shear velocity was based on τ_{bav} , which was determined through time integration over T . A value of $u_{*m}=0.065$ m/s was thus calculated implying $z_o=0.024$ mm. Figure 6 displays measured and calculated velocity profiles for selected phase values of t/T . The maximum positive peak in u_b occurred at about $0.18t/T$, the maximum negative peak at $0.68t/T$, and zero velocity at $0.36t/T$. The model captures the overall features of the velocity variation in the boundary layer, but the overshoot effect is not well predicted by the model, especially during the phase of flow reversal in the boundary layer in connection with large gradients in the wave velocity. The simple eddy viscosity model employed in the linearized TBL equation is most likely the reason for the disagreement between

the model and the measurements (Sleath 1987), although lack of detailed information on z_o and the use of stream function theory to describe u_b may also contribute to the discrepancy.

Figure 5. Hyperbolic wave velocity generated by Nadaoka et al. (1994) in their experiment on turbulent boundary layers and the velocity from a stream function wave that approximates the hyperbolic wave.

Figure 7 shows the computed normalized shear stress as a function of time at selected elevations based on the experimental conditions from Nadaoka et al. (1994). The time variation in the shear stress differs significantly from u_b and τ is completely asymmetric. This feature of the shear stress under nonlinear waves is important to include in for example detailed sediment transport calculations that employ the instantaneous shear stress to compute the transport rate.

CONCLUDING REMARKS

The analytical solution presented in Equation 2 is valid for any time-varying free-stream velocity, although from a physical point of view the solution is only interesting when the conditions underlying the linearized TBL equation are fulfilled. For example, the solution will describe the temporal growth of a TBL under a unidirectional current (compare Figure 1); however, the boundary layer will grow infinitely large and at some time the assumption that the layer thickness is small compared to the water depth will be violated and the solution lacks physical meaning. Also, for strongly nonlinear waves where the convective terms in the momentum equations are significant, the linearized TBL equation will yield results that are not

Figure 6. Calculated and measured velocity in the turbulent boundary layer using the asymmetric velocity case from Nadaoka et al. (1994).

Figure 7. Calculated time variation in the shear stress at selected elevations for the experimental conditions given by Nadaoka et al. (1994).

reliable. For the case tested from the data by Nadaoka et al. (1994) the linearized equation failed to produce accurate predictions, especially during the phase of flow reversal in the boundary layer in connection with large gradients in the wave velocity. This is mainly attributed to the simple eddy viscosity model approach employed which fails to realistically capture the variation in the turbulence during a wave cycle (Sleath 1987). A time-varying eddy viscosity would most likely improve the agreement with the data, but such a formulation would not permit an analytical solution of the governing equations.

However, the simple eddy viscosity model of Grant and Madsen (1979) seemed to produce acceptable results for a sinusoidal wave velocity, even if ν increases without limit with distance from the boundary. This observation pertains mainly to the velocity profile, whereas the shear stress is more sensitive to the eddy viscosity formulation because of the dependence on the velocity gradient. Similarly, the velocity profile is not overly sensitive to the choice of representative friction velocity, in contrast to τ which is more affected by the u_{*m} used. It was found in the present study that a u_{*m} based on the mean absolute shear stress during a wave cycle produced somewhat better agreement with data for a sinusoidal wave than using the maximum absolute shear stress.

ACKNOWLEDGEMENTS

The author is grateful to Professor Akira Watanabe, University of Tokyo, for valuable comments on the paper. Professor Masahiko Isobe, University of Tokyo, developed the program for calculating waves by stream function theory. Professor Kazuo Nadaoka and his coworkers at Tokyo Institute of Technology kindly provided the data from their experiments. The support from the Japan Society for the Promotion of Science for the research visit of the author to the University of Tokyo is gratefully acknowledged, as well as the assistance from all members of the Coastal Engineering Laboratory during his stay.

The research presented in this paper was partly conducted under the SAFE Project of the Marine Science and Technology Program (Contract No. MAS3-CT95-0004) funded by the Commission of the European Communities, Directorate for Science, Research, and Development.

Abstract

High resolution synchronous measurements of turbulence, waves and vertical suspended sediment (S_{sed}) concentration profiles have been obtained during a storm above a rippled bed comprising coarse/medium sand located close to the end of a large offshore sand bank in a water depth of approximately 20m. These data are utilised to study the temporal characteristics of sediments in suspension. Sediment resuspension 'events', exhibiting vertical coherence up to approximately 30cm above the sea bed, are observed to span a range of temporal scales encompassing half wave, wave and wave group periods. The vertical concentration of S_{sed} is shown to be enhanced significantly by wave groups. Average S_{sed} profiles are described using a simple Rouse-type and an new 'convective' model.

Introduction

At the most fundamental level, a fluid motion directed away from the bed with a velocity exceeding the *in situ* grain settling velocity is the basic requirement for the suspension of sediments. In marine situations, such fluid motion can arise in three ways (Pykhov *et al.*, 1995): (a) turbulent fluid 'bursting' (Kline *et al.*, 1967; Hino *et al.*, 1983; Sleath, 1987); (b) vortices formed by interactions between waves, currents and the bed (Mogridge & Kamphuis, 1972; Kaneko, 1981); and (c) vortices formed under breaking waves which penetrate to the bed (Nadaoka & Kondoh, 1989). Spatial and temporal scales determined by the hydrodynamics and the physical properties of the sediment makes simple descriptions of the instantaneous physical characteristics of suspended sediment difficult and most approaches consider only time-average conditions. Further, in field situations, waves at angles to tidal currents frequently lead to the generation of complex and interacting bedform assemblages (Sleath, 1984) adding further complexity to the modelling of sediment dynamics.

Recently, the use of acoustic instruments has enabled acquisition of high temporal resolution data pertaining to the vertical distribution of suspended sediment in marine conditions (e.g. *Thorne et al., 1993*; *Lee & Hanes, 1996*) and progress has been made in understanding and modelling of sediment resuspension and suspension dynamics. However, the majority of experiments examining sediment processes in marine situations have been conducted just outside the breaker zone in moderate conditions (e.g. *Osborne et al., 1994*) and few field data relate to the mobilisation of sediments during storm conditions at offshore locations (e.g. *Green et al., 1995*). As a consequence, data necessary for validation of numerical models of sediment transport in extreme conditions remains scarce. The present paper presents field observations of suspended sediments and hydrodynamic conditions in the first metre of the water column above a rippled coarse/medium sandy bed in a water depth of 20m during a moderate storm.

Field site and measurements

The study site was located close to the northern end of Middelkerke Bank in the Flemish sand banks, southern North Sea, Europe (*Figure 1a*). Middelkerke Bank is approximately 10km long, 1-2km wide and is located approximately 10km offshore. Bottom sediments consisted of medium/coarse sand ($D_{50} = 450\mu\text{m}$). Approximately 15% of the sediment by weight was composed of platy angular shell fragments ($D_{50} = 650\mu\text{m}$). Data relating to hydrodynamic conditions (turbulence and waves) and vertical suspended sediment concentration (S_{sed}) profiles have been obtained using the autonomous benthic lander *STABLE* (*Figure 1b, Humphery & Moores, 1994*).

Figure 1. (a) Location of the field site at Middelkerke Bank, Belgium; (b) *STABLE* (Sediment Transport And Boundary Layer Equipment).

Instantaneous near-bed flow in orthogonal vertical planes (x - z , y - z) was measured using pairs of electromagnetic current meters (*ECM*, diameter 10cm) at heights (z) of approximately 36cm and 76cm above the sea bed (*Figure 1b*). A pressure sensor at $z = 1.63$ m was used to measure waves. *ECM* and wave data were sampled at 8Hz for approximately 19 minutes every hour in 'burst' mode. The analysis methods used to obtain hydrodynamic parameters referred to below are described by *Hannay et al., (1994)*. A vertical profile of S_{sed} perpendicular to the *ECM*'s over the range $1\text{cm} < z < 100\text{cm}$ with a vertical resolution of 1cm was derived from two acoustic backscatter sensors (*ABS*) operating at 1.0MHz (*ABS1*) and 2.5MHz (*ABS2*), (*Thorne et al., 1993*). These sensors were separated horizontally by a distance of 10cm along a line normal to the *ECM* axis (*Figure 1b*) and were synchronised precisely with *ECM* and pressure sensor data. *ABS* data were recorded independently in burst mode at 4Hz for approximately 9 minutes every hour. *ABS* data were calibrated in the laboratory using samples of the bed sediments from the *STABLE* deployment site (*Wylie et al., 1994*). For the range of instantaneous and average S_{sed} values observed in the present study ($\approx 10^{-4} - 10^1 \text{g/l}$), close agreement was found between *ABS1* and *ABS2*. Estimates of ripple wavelength ($\lambda \approx 50\text{cm}$) were obtained in the field using the *ABS* instruments and ripple height (a) was estimated using an empirical relationship between ripple steepness and grain Shields number (*Nielsen, 1981*) and approximated to 7cm. The physical roughness (k_s) of the ripples was calculated using $k_s = 8a^2/\lambda$, (*Nielsen, 1992*).

Experimental conditions

In total 50 burst records encompassing calm and storm conditions were obtained. A detailed description of the hydrodynamic conditions occurring during the periods preceding and following the storm is given by *Williams et al., (1996)*. In the present paper attention is focused upon a period of 5 hours spanning the peak of storm activity (*bursts* 34-39) when the average S_{sed} value reached a maximum. *Burst* average hydrodynamic conditions and S_{sed} values observed during this period are summarised in *Figure 2*.

During *bursts* 34-39, wave direction ($\psi_w \approx 330^\circ$) and current direction ($\psi_c \approx 200^\circ$) remained approximately constant and *burst* average S_{sed} values increased in response to increasing tidal current speed and wave orbital speed (*Figure 2*). Following *burst* 38, S_{sed} values decreased as the storm subsided. During the storm, waves were observed to be long-crested and groupy in nature and the vertical position of the bed was observed to change relative to *ABS* sensors. Since the motion sensors on *STABLE* indicated that the rig remained static during the experiment it is considered likely that the observed changes in bed elevation are attributable to the migration of bedforms beneath *STABLE*.

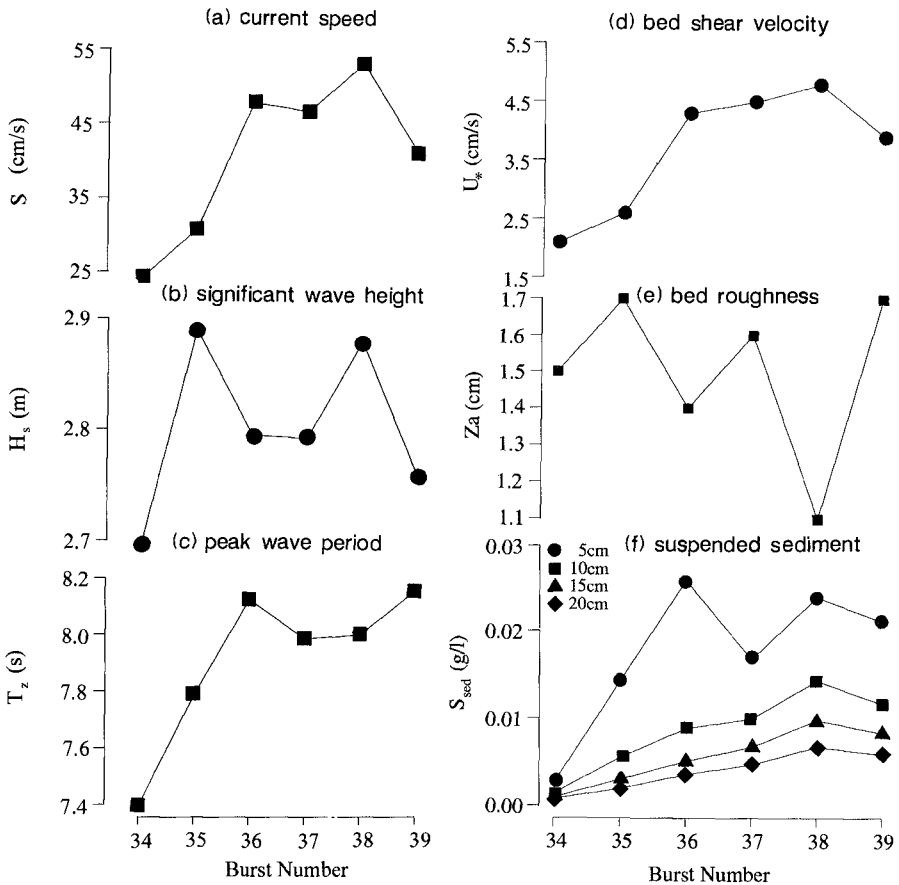

Figure 2. (a) burst average current speed (S) at $z = 76\text{cm}$; (b) significant wave height (H_s); (c) peak wave period (T_p); (d) burst average bed shear velocity (currents) obtained using the turbulent kinetic energy (t.k.e.) method (cf. Hannay et al., 1994); (e) apparent bed roughness (z_a); and (f) S_{sed} at $z = 5\text{-}20\text{ cm}$.

Results and discussion

Observed temporal and spatial structure of sediment resuspension events

Typical time series measurements of S_{sed} at $z = 4\text{cm}$, 6cm , 10cm and 40cm and surface wave amplitude are shown in Figure 3. S_{sed} time series in this figure comprise a 'background' population of suspended material ($\approx 0.02\text{g/l}$ at $z = 4\text{cm}$) and

discrete resuspension *events* in which instantaneous S_{sed} peaks frequently exceed 1.0g/l. Whilst *Figure 3* shows strong visual correlation between waves and S_{sed} *events* and marked vertical coherence in S_{sed} , coherent vertical fluid motion necessary to suspend sediment was not detected by the *ECM* sensors. This is attributed to the dissipation of coherent vertical fluid motion by $z = 40$ cm and to the physical size of the *ECM* measuring volume.

When examining *Figure 3* it is important to remember that during the storm, long-crested waves were approximately normal to the tidal currents and that the location of the *ABS* sensors changed in relation to ripple crests through time as ripples migrated. However, if it is assumed that resuspension *events* occurred along a significant length of the rippled bed parallel to the wave crests, (i.e. vortices formed by wave action are also long-crested), then material in suspension will be advected past the *ABS* sensors by the combined action of waves and the tidal current as coherent clouds approximately in phase with the waves.

Figure 3. Time series of observed suspended sediments and waves.

Surprisingly, given the strong visual correlation between waves and resuspension *events* illustrated in *Figure 3*, periodic components at wave frequencies were not identified in power spectra of S_{sed} time series irrespective of the observation height above the sea bed. This is attributed to two problems: (i) the S_{sed} time series are 'spiky' in nature; and (ii) the temporal changes in spatial location between *ABS*

sensors and resuspension *event* sources (i.e. ripple crestlines) and spatial variation in horizontal S_{sed} values combine with advected populations of suspended material to results in complex phase relationships between observed surface waves and S_{sed} time series. However, velocity²-sediment cospectra (Figure 4) show statistically significant correlation's between the horizontal flow components squared (u^2 and v^2) and S_{sed} .

Figure 4. Velocity²-sediment cospectra, burst 38.

Figure 4 shows correlation's between u^2 and S_{sed} and between v^2 and S_{sed} at half wave ($\approx 0.25\text{Hz}$), wave ($\approx 0.125\text{Hz}$), wave group ($\approx 0.01\text{Hz}$) and lower frequencies (in the range $0.01 - 0.003\text{Hz}$). In all cases examined during the storm, wave groups dominate the cospectra. This is also illustrated visually in Figure 3. Although low frequency fluid motion is recorded by *ECM* sensors, it is unclear whether or not the low frequency peak in the velocity²-sediment cospectra is a real phenomenon or simply an artefact of the analysis method. If shown to be real, further work is then required to quantify the role of this low frequency component in suspended sediment transport.

Waves recorded during *bursts* 34-39 exhibited well developed groupy structure (Figure 3). Initial visual inspection of correlation's between the wave groups and modulation in suspended sediment concentration indicated strongly that successive waves in a group resulted in a progressive increase in average S_{sed} values up to $z \approx 30\text{ cm}$ consistent with the idea of *wave pumping*. It was also determined that average

S_{sed} values associated with the last wave in a given group of more than 6 waves were a factor of approximately 2 times larger than values associated with the first wave in the same group. Following passage of a group, average S_{sed} values were observed quickly to decline to their former value.

In order to investigate further the wave-by-wave ‘pumping’ effect, the Goda run-length was utilised (Goda, 1985). Here, the start of a wave group was defined by the passage of a wave of height (h_j) that was observed to mobilise bottom sediments. For the group to continue, successive waves must be equal to or exceed h_j . In all cases an observed linear increase in average S_{sed} values with j demonstrated the enhancement of the sediment resuspension process by the passage of a successive series of larger than average waves (Figure 5). At present suspended sediment transport formulae do not include explicitly this important effect and thus are likely to underestimate the sediment transport rate in combined wave-current situations.

Figure 5. Goda wave group run length (j) versus observed suspended sediments.

Burst average suspended sediment concentration profiles

Burst average suspended sediment concentration profiles observed over the range $1\text{cm} < z < 50\text{cm}$ are shown in Figure 6. Since ripples are observed to migrate beneath the ABS sensors during a burst measurement period, these profiles also represent horizontally spatially averaged S_{sed} values in the direction of ripple migration. The observed profiles show a progressive increase in the burst average

suspended sediment concentration over the range $1\text{cm} < z < 50\text{cm}$ from a minimum during *burst* 34 to a maximum during *burst* 38. At $z > 50\text{cm}$, S_{sed} values are small (0.001g/l to 0.005g/l) and slowly decay with height above the bed. In all cases the profiles are smooth, continuous and are Rouse-like above $z \approx 20\text{cm}$. In the bottom 10cm , S_{sed} profiles for *bursts* 37-39 exhibits a significant concave curvature which develops through the storm.

Figure 6. Suspended sediment concentration profiles, *bursts* 34-39.

During the period of increasing wave height preceding the peak storm activity, S_{sed} profiles in the range $3\text{cm} < z < 40\text{cm}$ for *bursts* 34-36 were found to follow approximately Rouse-type profiles defined by *Smith (1977)* as

$$C(z) = C(a)(z/a)^{-\alpha} \quad (1)$$

where α is the Rouse parameter (i.e. $\alpha = w_s / \beta \kappa U_{*wc-max}$), $C(z)$ and $C(a)$ are S_{sed} values at heights z and a , respectively, above the sea bed, w_s is the settling velocity (estimated to be 3.5 cm/s , *van Rijn, 1989*), β is the ratio of the eddy diffusion coefficients for the fluid and the sediment (assumed to be 1.0), κ is the von Kármán coefficient (0.4) and $U_{*wc-max}$ is the maximum wave-current bed shear velocity.

Using a least squares fit to the straight line portion of the observed S_{sed} profiles, values for α were obtained from the gradient of the straight line fit, (Table 1).

Burst	S (cm/s)	σ_w (cm/s)	α	$U_{*wc-max}$ (cm/s)
34	24.2	15.5	1.27	-
35	30.9	20.7	1.32	6.6
36	47.8	22.7	1.33	6.6

Table 1. S , RMS wave orbital speed σ_w , α and $U_{*wc-max}$, values derived from observed S_{sed} profiles (Eq. 1), bursts 34-36.

Utilisation of the observed α values in Eq. 1 gave predicted S_{sed} values that matched well observed S_{sed} values for bursts 34-36 ($R^2 > 0.95$). $U_{*wc-max}$ values for bursts 35 and 36 agree broadly with values predicted by a number of wave-current models (e.g. Soulsby, 1994). Although S and σ_w values measured during burst 34 are significantly lower than those pertaining during bursts 35 and 36, a larger than expected value for $U_{*wc-max}$ was obtained from the burst 34 S_{sed} profile data (6.8cm/s). This may imply that the assumed settling velocity of 3.5 cm/s is incorrect for this burst and for this reason the value for $U_{*wc-max}$ for burst 34 is not included in Table 1.

In the case of bursts 37, 38 and 39 a new expression is required to simulate the concave curvature in the bottom 10cm of the observed profiles (Figure 6). In these cases it was found that the whole S_{sed} profile for $1\text{ cm} < z < 40\text{ cm}$ could be matched closely to the "convective" empirical profile proposed by Nielsen (1992) for natural sand ripples composed of coarse grains in oscillatory flows. Thus

$$C(z) = C(0) \left(\frac{z}{L} + 1 \right)^{-\alpha'} \quad (2)$$

where L is a characteristic length scale. Nielsen (1992) suggests a value of 2 for α' . In contrast to Eq. 1, Eq. 2 tends towards a Rouse-type profile when $z/L \gg 1$ and also tends toward $C(0)$ at the bed. The gradients of S_{sed} profiles depart from the form of Eq. 2 at $z > 30\text{-}40\text{cm}$ where finer material in suspension might be anticipated. Present data indicates that the vertical distribution of S_{sed} in the range $35\text{cm} < z < 100\text{cm}$ can be modelled well using a second Rouse-type profile with a smaller α value. However, for $z > 50\text{cm}$, S_{sed} values are observed to be 3-4 orders of magnitude

less than those observed at $z < 10\text{cm}$ and can therefore be neglected for practical purposes when estimating rates of sediment transport.

In the present study, *Eq. 2* was obtained using a semi-analytical approach by assuming that the total wave-current sediment diffusivity is the sum of the Rouse-type diffusivity defined in *Smith (1977)* and a constant diffusivity (ϵ_c) found in oscillatory only flow over ripples (*Nielsen, 1992*). This gives

$$-w_s C = (\kappa U_{*wc-max} z + \epsilon_c) \frac{\partial C}{\partial z} \quad (3)$$

and hence

$$C(z) = C(a) \left(\frac{z+L}{a+L} \right)^{-\alpha'} \quad (4)$$

where α' is a Rouse-type parameter and $L = \epsilon_c / \kappa U_{*wc-max}$. When $a = 0$, this profile is identical to *Eq. 2*.

The values of the parameters used in *Eq. 4* to obtain the best fit between observed and predicted S_{sed} profiles for *bursts 37-39* are shown in *Table 2*. These were obtained by firstly estimating the gradient of the straight line portion of a given S_{sed} profile (α') on log-log axes (typically this fell within the range $15\text{cm} < z < 25\text{cm}$). Using the suspended sediment concentration values at $z = 4\text{cm}$ as a 'reference' concentration, values of L were obtained using $C(z)$ values up to $z = 25\text{cm}$. Finally, taking the average value of L (*Table 2*), $C(0)$ was calculated using observed concentration values at $z = 4\text{cm}$ and $U_{*wc-max}$ values were derived from α' assuming $w_s = 3.5\text{cm/s}$ (*van Rijn, 1989*). A comparison between computed and observed S_{sed} profiles is illustrated in *Figure 7*. In all cases the fit between observed and predicted S_{sed} profiles is statistically significant ($R^2 > 0.97$).

<i>Burst</i>	S (cm/s)	σ_w (cm/s)	$C(0)$ (g/l)	α' -	L (cm)	k_s (cm)	$U_{*wc-max}$ (cm/s)
37	46.6	21.8	0.058	1.27	4.2	7.3	6.9
38	53.1	22.1	0.090	1.48	5.6	10.1	5.9
39	41.0	23.5	0.079	1.29	3.7	13.3	6.8

Table 2. S , σ_w and *Eq. 4* parameter values derived from observed hydrodynamics and S_{sed} profile data, *bursts 37-39*.

Table 2 shows that values for α' are lower than the value suggested by Nielsen (1992) and are similar to the α values shown in Table 1 suggesting α' may be the same parameter. Values of the parameter L in the range 3.7-5.6 are only a factor of two to four times lower than k_s values. A relationship between these two parameters is therefore suggested. Work to improve the fit between observed and predicted S_{sed} profiles for these and other field observations of suspended sediment profiles in marine situations is currently being undertaken by the authors.

Figure 7. Comparison between and computed S_{sed} profiles, bursts 37-39.

Conclusions

- (i) Field data have been obtained in the bottom 1m of the water column during a storm.
- (ii) Present analysis has examined the temporal response of medium/coarse sandy sediments to waves and tidal currents.
- (iii) Sediment resuspension has been shown to be enhanced significantly by the passage of groups of waves.
- (iv) Average S_{sed} profiles observed during storm conditions have been represented using a 'simple' Rouse-type profile (Smith, 1977) and a new wave-current profile based upon the "convective" empirical profile proposed by Nielsen (1992). The new profile allows accurate determination of $C(0)$.

CHAPTER 253

EBB TIDAL DELTA EVOLUTION OF COASTAL INLETS

Michael R. Dombrowski¹, Associate Member, ASCE
Ashish J. Mehta, Ph.D², Member, ASCE

ABSTRACT

Previous investigations have established the dependence of ebb delta volumes on wave energy and tidal energy at sandy inlets. In this study, this dependence was examined with respect to the rate of delta growth and the final equilibrium delta volume starting with the opening of a new inlet when no delta is present. A diagnostic model was developed for examining the influence of the ratio of wave energy to tidal energy on delta growth. Model sensitivity tests showed that increasing the suspended sediment concentration in the littoral zone caused the delta to approach equilibrium faster, but did not affect the equilibrium volume. Increasing the wave height increased the time of approach to equilibrium but decreased the volume. Finally, increasing the sand size increased the growth rate as well as the equilibrium volume. The model was applied to five Florida inlets. It was shown that the delta may never attain a true equilibrium volume, and the actual volume may fluctuate about a "quasi"-equilibrium volume consistent a wave energy to tidal energy ratio representative of the long-term wave and tidal conditions at the entrance.

INTRODUCTION

At the seafloor in the immediate vicinity of a coastal inlet the interrupted littoral sediment tends to accumulate and raise the floor, leading to the formation of an ebb delta. The ebb tidal delta grows due to the supply of littoral sediment and ultimately reaches an equilibrium volume when the condition of no net deposition is attained. At new inlets, or ones which have been closed for a period of time, the rate at which the seafloor is modified by deltaic formation depends on the prevailing physical

conditions, availability of littoral sediment, and geologic setting. Previous investigations have established the dependence of the delta volume on wave energy and tidal energy at sandy inlets. In this study, this dependence was examined with respect to the rate of delta growth and final equilibrium delta volume starting with the opening of a new inlet when no delta is present. The aim of this study was therefore to examine the inter-dependence between significant physical parameters governing sediment transport and the rate of delta formation at coastal inlets.

PROCEDURE

To examine the influence of the effects of current and waves on the growth rate of ebb deltas, a diagnostic approach is developed. The growth process of the delta will have an initial condition of a new inlet with no delta present (Figure I.A). The opening of an inlet the ebb delta volume increases as the inlet tidal current deposits material derived from the littoral system and ultimately reaches an equilibrium volume when the condition of no net deposition is attained. Delta accumulation height will be simulated by modeling tidal currents and superimposed waves to determine the combined shear stress, τ_b (Pa). The seafloor will continue to rise on the condition that the combined shear stress is smaller than the critical shear stress, τ_{cr} (Pa), for deposition (Figure I.B). The model must then determine the delta volume when the seafloor reaches an equilibrium elevation (Figure I.C) due to a balance of shear stresses (ie. $\tau_b = \tau_{cr}$), and the estimate the time for the equilibrium to occur.

Figure I. Idealized ebb delta growth: A) initial condition; B) growth period; and, C) equilibrium condition

DIAGNOSTIC EXAMINATION OF SEAFLOOR EVOLUTION

The net decrease of suspended sediment mass per unit delta bed area, m , with respect to time, t (s), is related to sediment settling flux by

$$\frac{dm}{dt} = F_s \quad (1)$$

Substituting $F_s = -pW_sC_s$, where W_s = particle settling velocity (m/s), C_s = depth-averaged suspended sediment concentration (kg/m³), and p = probability of deposition which is given as $p = (1 - \tau_b/\tau_{cr})$ (Krone, 1962) which can range between 1 (total deposition) and 0 (no deposition). The settling velocity can be expressed as $W_s = [(4gd_{50}/3C_D)(\rho_s - \rho_w/\rho_w)]^{1/2}$, where ρ_s = particle density (kg/m³), ρ_w = seawater density (kg/m³), d_{50} = median particle size (mm), g = acceleration due to gravity (m/s²), and C_D = drag coefficient (Schiller and Naumann, 1933). The value of C_D outside the Stokes range (Reynolds number < 1) decreases rapidly then levels off and becomes nearly constant (e.g., 0.43 for spheres) in the fully turbulent flow regime considered.

Equation 1 can thus be expressed as

$$\frac{dm}{dt} = -H_f \left(1 - \frac{\tau_b}{\tau_{cr}} \right) W_s C_s \quad (2)$$

where $H_f[x]$ = heavyside function such that $H_f[x > 0] = x$, and $H_f[x \leq 0] = 0$. Next, $\rho_d = A_D m/V$, where ρ_d = dry bed density, A_D = ebb delta deposition area (m²), m = mass (kg), and V = delta volume (m³). Furthermore, $dV = dhA_D = d(d)A_D$, where dh = change in water depth and $d(d)$ = change in ebb delta height. Substituting these relations into Equation 1 results in an expression for the change of ebb delta height over time:

$$\frac{d(d)}{dt} = -H_f \left(1 - \frac{\tau_b}{\tau_{cr}} \right) \frac{W_s C_s}{\rho_d} \quad (3)$$

Given W_s , C_s , and ρ_d , Equation 3 can be solved provided τ_b and τ_{cr} are determined. Komar and Miller (1974) found that data for sediment threshold under oscillatory flows closely agreed with Shields' (1936) relationship for incipient grain motion under unidirectional flows. Thus, $\tau_{cr} = 0.058(\rho_s - \rho_w)gd_{50}$, can be used to determine the critical shear stress for waves and currents. Grant and Madsen (1978) prescribed the following relationship for shear stress due to both current and waves, $\tau_b = 0.5\rho_w f_{cw} U_i^2$, where f_{cw} is the wave-current friction factor, and the combined wave-current velocity near the bottom, $U_i = (U_{wb}^2 + U_{cb}^2 + 2U_{cb}U_{wb}\cos\phi)^{1/2}$. The quantity, U_{cb} , is the near-bed current velocity over the bottom, U_{wb} = near-bed orbital velocity due to waves (m/s), and ϕ = angle between the current and wave direction. During flood flow, when $\phi = 0$, the waves are able to penetrate over the shoal and into the

inlet channel thereby causing more bottom scour at the delta during flood flow than ebb. Therefore, $\phi = 0$ will be assumed for this study.

For calculating the bottom stress, τ_b , the friction factor due to the combined current and waves is given by $f_{cw} = (|U_{cb}| f_c + |U_{wb}| f_w) / (|U_{cb}| + |U_{wb}|)$, where f_c = friction factor due to current, and f_w = friction factor due to waves. The near-bed orbital velocity due to waves can be obtained from linear wave theory, $U_{wb} = [H\pi \cosh(kh)/T \sinh(kh)]$ (Dean and Dalrymple, 1984), where k = wave number equal to $2\pi/L$ (1/m), L = wave length (m), T = wave period (s), and h = water depth at the delta (m). As a wave train propagates from offshore into shallower water, the wave height changes as the depth changes. According to linear wave theory, the shoaled wave height (m), $H = [H_o(C_o/2C)^{1/2}(b_o/b_s)^{1/2}]$, where b_o = distance between two adjacent deep water wave rays (m), b_s = distance between two adjacent nearshore wave rays (m), C_o = deep water wave celerity (m/s) equal to $gT/2\pi$, C = shallow water wave velocity (m/s) equal to $(gh)^{1/2}$, and H_o = deep water wave height (m). The model assumes the contours are to remain straight and parallel. Thus, the refraction coefficient, $(b_o/b_s)^{1/2} = 1$.

The initial step to determine the near-bed current velocity over the delta, U_{cb} , is to obtain the maximum velocity (m/s) through the inlet for a spring tide is given by $U_{max} = (0.86\pi P / T_i A_c)$, where P = spring tidal prism (m^3), T_i = tidal period (s), and A_c = throat cross-sectional area of the inlet (m^2) (O'Brien, 1969). The average inlet velocity at the mouth of the inlet channel over one-half tidal cycle (m/s), $U_I = (2U_{max}/\pi)$. As the flow exits the inlet channel it is considered to spread out from the inlet mouth. To obtain a characteristic velocity (m/s), U_o , at the shoreward end of the deposition area, this velocity is assumed to occur along an arc, one-half the distance (m), r_e (Figure I.B), from the entrance mouth to the outer edge of the tidal prism based ebb delta area (m^2), A_p , where $r_e = (2A_p/\pi)^{1/2}$ is obtained from continuity. Thus, $U_o = (2U_I w / \pi r_e)$, where w = width of the entrance (m).

As the seafloor rises, the water depth decreases with respect to the initial water depth (m), h_o , whereby to maintain the continuity of flow, the current velocity over the delta (m/s), U_c , must increase. The current velocity, U_c , decreases with distance from the entrance as the flow spreads out over the delta from its inner to outer limit. For this study, U_c will be defined as its value at the inner limit of the delta. It should also be noted that the velocity profile of U_c is vertically uniform, it is therefore necessary to apply a correction factor to obtain the near-bed velocity (m/s), U_{cb} .

From the logarithmic velocity profile (Mehta, 1978), the ratio of the near-bed velocity to the depth averaged current velocity, $U_{cb}/U_c = \ln(z_b/z_o)/\ln(h/z_o) - 1$, in which z_o = theoretical origin of the logarithmic profile (m), and z_b = distance above profile origin (m) and is set here equal to 0.05 m. The virtual origin of the profile is obtained from the Manning-Strickler formula, $z_o = 10^7 n^6$.

Mehta and Özsoy (1978) noted that a representative Manning's n value of 0.028 can be used for sandy inlets with a typical initial water depth of 4.0 m. Thus, the current velocity obtained by continuity is multiplied by a correction factor of 0.40, $U_{cb} = 0.40U_o(h_o/h)$. Note that when the equilibrium delta volume is attained, $U_c = U_{cr}$, hence $U_{cb} = U_{cr} = 0.40U_o(h_o/h_e)$, where h_e = equilibrium water depth (m).

Inserting equations above into Equation 3 results in the governing equation for ebb delta height variation with time, and is expressed as

$$\frac{d(d)}{dt} = -\frac{W_s C_s}{\rho_d} \left[1 - \frac{\rho_w f_{cw}}{2\tau_{cr}} \left[\frac{(H\sigma)^2 \cosh^2 kh}{4 \sinh^2 kh} + 0.16 \left[\frac{U_o h_o}{h} \right]^2 + \frac{H\sigma \cosh kh}{2.5 \sinh kh} \frac{U_o h_o}{h} \right] \right] \quad (4)$$

In the finite difference form, the left hand side of Equation 4 becomes $\Delta d/\Delta t$, and was solved using the fourth order Runge-Kutta iteration method for the incremental change in delta accumulation, Δd , for $\Delta t = T_t$ (tidal period). The incremental change in delta accumulation, Δd , can then be multiplied by the depositional area, A_D , to obtain the incremental ebb delta volume, ΔV . The cumulative volume change is then plotted to illustrate the effects of waves and currents on ebb delta growth rate and estimate the duration to achieve an equilibrium volume.

MODEL PARAMETERS

Ebb delta area, A_D . It is necessary to identify the ebb delta depositional area, A_D , over which deposition occurs. This was achieved by empirically correlating the tidal prism based ebb delta area, A_p , with A_D using measurements of 21 ebb delta areas of Florida's lower Gulf Coast inlets (Davis and Gibeau, 1990). The equation of the regression line relating the tidal prism based delta surface area and the delta depositional area, $A_D = 2.34A_p^{0.81}$, corresponds to the coefficient of regression of $r^2 = 0.65$ which shows an acceptable relationship. The surface area, $A_p = P/2a_{os}$, is characterized by spring tidal prism, P and spring sea tidal amplitude (m), a_{os} .

Suspended sediment concentration, C_s . Downing (1984) presented a time-series of sediment concentrations at three locations across the surf zone at Twin Harbor Beach, Washington. The investigator found two distinct types of vertical concentration profiles. The first occurred between resuspension events ranged from 0.0002 to 0.0004 kg/m³, when the sediment concentration had vertical uniformity. While during resuspension events a concentration gradient, 0.0015 to 0.0100 kg/m³, occurred within 0.10 m above the bed in a total column water depth of 0.25 m. These concentration ranges will be assumed to apply for this study.

Sediment grain size diameter, d_{50} . Mehta and Özsoy (1978) noted that for sandy inlets the median grain size at most inlets range between 0.2 and 0.4 mm. This range will be considered in the present study.

Deep water wave height and period, H_o . The deep water wave height has a significant effect on the growth rate of the ebb delta and its equilibrium volume. By adjusting the wave height, the model generated delta volume-time curve can be made to pass through the appropriate smallest and largest measured delta volumes at a given inlet. A characteristic wave period of 8 seconds will be used for all model runs.

Friction factors, f_w, f_c . The friction factor due to current, $f_c = 8gn^2/h^{1/3}$, where Manning's n and h = water depth (Mehta, 1978). Mehta and Özsoy (1978) noted that a typical mean Manning's n value of 0.028 can be used for sandy inlets. The initial water depth used to model the evolution of the ebb deltas averaged 4 m (Dombrowski, 1994), resulted in a characteristic friction factor due to current of 0.039. It should be noted that Mehta (1978) determined friction factors for three inlets on the Gulf Coast of Florida ranging between 0.021 to 0.050.

The friction factor due to waves, f_w , was obtained from the wave friction factor diagram developed by Jonsson (1965) which plots the friction factor against the wave Reynolds number. Given, $h = 4$ m, $H_o = 0.4$ m, and wave period of 8 seconds, $R_e = 1.7 \times 10^4$, corresponds to the fully turbulent flow range (Figure 6 in Jonsson, 1965). Given the typical variation of R_e in the present study, a representative value of $f_w = 0.005$ in the fully turbulent flow range was chosen.

Tidal inlet characteristics. The tidal inlet characteristics used in the analysis are derived from the database found in Dombrowski (1994). The characteristics include: inlet throat width, throat depth, tidal prism, and spring tidal range.

EFFECTS OF IMPORTANT PARAMETERS ON DELTA GROWTH

The effects of important parameters on the rate of delta formation at coastal inlets is examined. The three selected parameters are 1) suspended sediment concentration, C_s ; 2) median sediment grain size, d_{50} ; and 3) deep water wave height, H_o . The influence of varying these parameters on the volume growth curves are shown in plots of ebb delta volume versus time, beginning with a new inlet with no delta. The range of values of these three parameters are found in Dombrowski (1994).

Suspended sediment concentration, C_s . In the Equation 4 for the change rate of ebb delta height, $d(d)/dt$, is proportional to the suspended sediment concentration, C_s . Figure II plots the ebb delta volume, $V = A_D(h_o-h)$, versus time (years) for three suspended sediment concentrations. A characteristic that is evident from the growth curves is that the equilibrium ebb delta volumes are the equal (1.4×10^6 m³) for the three concentrations. However, it is evident that as C_s increases the rate of deposition becomes more rapid.

Sediment grain size diameter, d_{50} . Two physical parameters are dependent on the median grain size diameter, d_{50} , the settling velocity, W_s , and the critical shear stress

Figure II. An illustration of the influence of suspended sediment concentrations on calculated delta growth rate.

for sediment transport, τ_{cr} . The ebb delta volume versus time plot for varying sediment diameters (Figure III) is characterized by three different growth rates and equilibrium volumes. The increase in the sediment diameter increases the rate of deposition, due to the dependence of particle fall velocity on sediment size. An increase in the sediment size also increases the critical shear stress, allowing the sediment bed to remain more stable as compared to a bed composed of smaller grain size under the same flow conditions. This effect results in an increase in the equilibrium volume for increasing grain diameters.

Figure III. An illustration of the influence of sediment grain size diameters on calculated delta growth rate.

Deep water wave height, H_o . As the waves approach the shoreline, its height increases as the water depth decreases. This increase in wave height in turn increases the near-bed orbital velocity, U_{wb} , hence reduces the rate of deposition. Figure IV plots the ebb delta volume versus time illustrating delta growth due to current alone, 0.0 m wave height, and two additional deep water wave heights of 0.4 and 0.8 m. During sea conditions when the deep water wave height is equal to 0.0 m, the rate of deposition is observed to be relatively rapid compared to the other two wave conditions. Note the drastic decrease in the equilibrium volume with increasing H_o .

Figure IV. An illustration of the influence of deep water waves on calculated delta growth rate.

Model sensitivity tests showed that increasing the suspended sediment concentration in the littoral zone caused the delta to approach equilibrium at a greater rate, but did not affect the equilibrium volume. Increasing the wave height increased the time the delta approached equilibrium but decreased the equilibrium volume. Finally, increasing the sand size increased the growth rate as well as the equilibrium volume.

TIME-EVOLUTION OF DELTA VOLUMES

The time-evolution of sand volumes of five selected deltas along the east coast of Florida including those at 1) Jupiter Inlet; 2) South Lake Worth Inlet; 3) Boca Raton Inlet; 4) Bakers Haulover Inlet; and 5) Sebastian Inlet were analyzed. These inlets were chosen because 1) the date when each inlet was opened was available, and 2) four or more data points were available per inlet to represent the time-variation of ebb delta volumes. A plot of the measured delta volumes versus date of survey with the corresponding volume ranges for Jupiter Inlet obtained from the model is presented. The theoretical volume curves were derived from the model using the specific characteristics of the respective inlet. These data including 1) spring tidal prism, P ; 2) inlet throat width, w ; 3) inlet depth, h_o ; and 4) spring tidal range, $2a_{os}$

are summarized in Dombrowski (1994). By adjusting the deep water wave height, H_o , and the suspended sediment concentration, C_s , the delta volume-time curves were made to pass through the appropriate smallest and largest measured delta volumes.

Wave energy to tidal energy ratio, α . The inlet stability parameter, α , was introduced by O'Brien (1971) and was later expanded by Mehta and Hou (1974) to provide an indicator of the stability of inlets. An inlet in equilibrium is due to a balance between the wave energy which tends to close an inlet and the tidal energy which maintains the opening. For the present study, the (non-dimensional) stability coefficient, α , defined as the ratio of longshore wave energy to the tidal energy is used to provide an indication of the relative effect of waves and tidal current in governing the rate of growth of the ebb delta. In a reduced form for a representative deep water wave height H_o , the relationship can be expressed as:

$$\alpha = \frac{H_o^2 T_w T_t}{64 \pi a_{os} P} \quad (5)$$

where T = wave period (s), T_t = tidal period, a_{os} = spring tidal range, and P = spring tidal prism).

As the deep water wave height is increased at a given inlet, α increases and reflects a tendency to drive material toward the inlet and the nearshore area, thus limiting the delta volume. Conversely, if the deep water wave was set to zero, the corresponding α would equal zero indicating a current-determined delta. This condition results in a larger ebb delta volume as compared to a higher α -value for the same inlet when waves are present.

Jupiter Inlet. Nine delta volumes were available for Jupiter Inlet since this entrance was re-opened for navigation in 1947 (Figure V). The near linear delta growth rate from 1947 to 1967 is characteristic of the high initial growth of the delta following the opening of the inlet. This high growth rate is consistent with the occurrence of a deep sea floor at the time of the entrance opening when the incipient influence of wave action is low. The non-zero delta volumes range between $0.23 \times 10^6 \text{ m}^3$ and $0.77 \times 10^6 \text{ m}^3$, for the years 1981 and 1993, respectively. This variability may, in part, be due to the method used in estimating the volumes which could be on the order of 15% for Jupiter Inlet. We infer that this variability is primarily influenced by wave action and its seasonal as well as year-to-year variation.

The model was used to simulate the growth curves matching the volume range. The α -value of 0.17 resulting from a $H_o = 0.54 \text{ m}$ yielded a volume of $0.77 \times 10^6 \text{ m}^3$ in 1993. The higher α -value of 0.27 was calculated for a $H_o = 0.68 \text{ m}$ to modify the growth curve to achieve a volume of $0.23 \times 10^6 \text{ m}^3$ in 1981. It is therefore surmised that the relative wide range in the delta volumes between the two curves is the result of waves relative to current. Larger delta volumes correspond to lower values of α and vice versa. The maximum range of α being 0.17 to 0.27 for this inlet.

Figure V. Ebb delta volume versus year with model-calculated volume ranges for Jupiter Inlet.

INFLUENCE OF α ON DELTA GROWTH

A comparison of the ebb delta volume ranges and the corresponding wave to tidal energy ratio, α , for each of the five inlets is illustrated in Figure VI.

Figure VI. Ebb delta volume against wave to tidal energy ratio, α

As α increases, the ebb delta volume has a tendency to decrease, and vice versa. Although there is data scatter and a r^2 -value of 0.58, which is low, the regression line does show that there is an inverse relationship between the delta volume to α .

The equation of the regression line relating α and V is

$$V = 0.15\alpha^{-0.58} \quad (6)$$

Note that V (delta volume) in this case may not represent the actual equilibrium value, but may be close to it, given the manner in which the curve fitting was conducted.

DELTA VOLUME VERSUS MAXIMUM WAVE HEIGHT

Devine (1996) related historical ebb delta volumes with episodic extreme sea conditions. The calculated delta volumes for three inlets were plotted against the corresponding maximum WIS (Hubertz *et al.*, 1993) wave height of the preceding year which showed an inverse relationship between the volumes and wave heights. For one inlet, there was no distinct relationship presumably because the ebb delta has not reached a equilibrium condition.

For this study, 13 surveys performed between 1974 and 1995 of Sebastian Inlet ebb delta were estimated and plotted versus the maximum WIS (Hubertz *et al.*, 1993 and Brooks, unpublished) wave height of the preceding year (Figure VII). A "best-fit" line through the data shows an inverse relationship of wave conditions on the ebb delta volumes. The average ebb delta volume for this time period, based on the available data, is $1.48 \times 10^6 \text{ m}^3$. The inlet has not undergone any major modification since before 1974, therefore the only one parameter controlling the delta volume is the changing sea conditions. The fluctuation of data about the average may be indicative of the ebb delta being in a "quasi"-equilibrium condition due to: 1) the variation of sea conditions; and, 2) the sink not available to accumulate more sand.

Figure VII. Ebb delta volume versus maximum WIS wave height for Sebastian Inlet.

CONCLUSIONS

Effects of Significant Physical Parameters on Delta Growth. Three parameters, namely the suspended sediment concentration, sediment grain size, and the deep water wave height, were varied in the diagnostic model developed for delta growth to determine their effects on the rate of delta formation at coastal inlets. It was found that an increase in the suspended sediment concentration increases the rate of approach to equilibrium, but does not result in a change in the equilibrium volume. On the other hand, a change in the sediment grain size and the deep water wave height effect both the rate of growth and the equilibrium volume. Thus, an increase in the sediment diameter increases the rate of growth due to the dependence of the particle fall velocity on sediment size, and increases the critical shear stress resulting in an increase in the equilibrium volume. An increase in the deep water wave height increases the near-bed orbital velocity at the site of the delta, hence decreases the rate of growth. The equilibrium delta volume likewise decreases.

Effects of α on Equilibrium Delta Volumes. It was shown through the application of the model to five Florida inlets that there is a dependence between the ebb delta volume and the wave to tidal energy ratio, α . The growth of the delta is determined by the rate at which the sand, supplied by the littoral system, is deposited by the ebb tidal flow. As wave action increases, thus increasing α -value, the delta growth rate decreases as wave and current induced bottom shear stresses scour sand deposited on the delta.

The dependence of delta volume on α partly explains the observed fluctuations in the delta volume at many inlets, since α tends to vary seasonally as well as annually. This relationship was further illustrated by plotting the ebb delta volume of Sebastian Inlet versus the maximum wave height of the preceding year. Another cause of variation of the delta volume at a given inlet is that even under constant sea conditions, the equilibrium volume often occurs after several decades following the opening of an inlet. Thus the delta volumes measured during the early years of evolution will be lower than the equilibrium volume. It was shown that the delta may never attain a true equilibrium volume, and the actual volume may fluctuate about a "quasi"-equilibrium condition. This would be consistent with a value of the wave energy to tidal energy ratio representative of the long-term wave and tidal conditions at the entrance.

ACKNOWLEDGMENTS

The authors would like to extend their appreciation to Rebecca Brooks of CERC for processing the additional wave information and to Ray LaRoux and Kathy FitzPatrick of the Sebastian Inlet Taxing District for providing the historic survey data of the inlet.

CHAPTER 254

Adjustments toward Equilibrium of a Large Flood-Tidal Delta after a Major Dredging Program, Tauranga Harbour, New Zealand

Terry Healy, Joseph Mathew, Willem de Lange, and Kerry Black*

Abstract

The Port of Tauranga is located within a tidal inlet estuarine lagoon system which has been dredged to improve navigation for shipping since 1968. In 1992 a major dredging program deepened the entrance navigation channel through the ebb-tidal delta from 10 to 14 m, and the inner harbor channels to ~13 m. As a condition of the consent to dredge a detailed monitoring program was required which included annual hydrographic surveys over the flood and ebb-tidal delta as well as recording current meter records from morphodynamically sensitive locations to compare with records taken before the dredging. Results of the hydrographic surveys showed significant morphodynamic change of the flood-tidal delta had occurred essentially by the time the 6 month dredging program was completed. Comparison of the S4 current meter recordings showed current changes consistent with expectations of the EIA. Changes on the ebb-tidal delta were not expected but have occurred although not as rapidly, and seem to be ongoing.

Introduction: The Pre-dredging Assessment of Impacts

The Port of Tauranga was established last century within a meso-tidal estuarine lagoon enclosed by a Holocene barrier island and tombolo system (Fig.1). The inlet exhibits many morphological features typical of a meso-tidal inlet as presented by Boothroyd (1985), including a flood and ebb-tidal delta system and a narrow inlet gorge. Prior to dredging, channel depths reached 7-8 m through the delta systems with the narrow inlet gorge attaining 30 m.

Fig. 1. Location map of Tauranga Harbour flood and ebb-tidal deltas and dredged shipping channels.

The port was expanded in the 1950s, and in the 1960s Wallingford Hydraulics Laboratory of the UK was commissioned to undertake a study investigating improvements for navigation approaches to the port. To improve port operations for ocean-going vessels, dredging of a navigation channel to depths of 10 m through both the flood and ebb-tidal deltas was carried out in the late 1960s. As was to be expected in a high current flow sandy tidal inlet located on a littoral drift shoreline, the navigation channels required significant maintenance dredging. Since the initial navigation channel construction through the tidal delta system, the average maintenance dredging has been $\sim 70,000 \text{ m}^3$ per year, which was taken primarily from specific zones of channel deposition located either side of the inlet gorge, i.e., in the Entrance Channel through the ebb-tidal delta, and in the Cutter Channel which transects the flood-tidal delta.

In 1992, as part of further port expansion, a major shipping channel deepening and widening program was undertaken to deepen the channels from 10 to 13 m within the harbor, and to 14 m outside of the entrance. This involved dredging some 5.5 million m³ of predominantly sandy material with some shell gravel (Healy et al., 1991).

A condition of the consent permitting the development, required the port company *"to monitor all aspects of the dredging programme and its impact upon the environment, and take such action as necessary to mitigate adverse effects that the dredging shall have."* Accordingly, monitoring included annual full hydrographic surveys over the flood-tidal delta and adjacent channels, pre- and post-dredging measurement of current flows using RCMs, and surveys of barrier island shoreline change, in conjunction with biological monitoring. The monitoring continued until the end of 1995, some 4 years after the dredging.

The aims of this paper are to report on the morphodynamic changes that occurred after the dredging in this large tidal inlet and delta system, and make an assessment of the time it took for the inlet-tidal delta system to readjust to changed hydraulic conditions.

Morphodynamic Change

Morphodynamic change refers to change in bathymetry or landform created by the actions of the formative processes, in this case the currents and waves. Changing the conditions of the tidal inlet dynamic equilibrium, such as by inducing current flow hydraulic change will likely change the sediment transport pathways, and therefore lead to morphological change. The most sensitive areas are the ebb and flood-tidal deltas and the associated channels.

The projected impact on morpho- and hydrodynamics was studied at the EIA stage using 2-dimensional hydrodynamic modelling (Bell, 1991). The modelling indicated a substantial alteration to the current flow regime over the flood-tidal delta and shipping channel (the Cutter Channel), but no detectable impact on tidal currents over the ebb-tidal delta. Within the harbor the major impact predicted was that the shipping channel of ~13 m depth (c.f. original natural pre-dredged depths of 5-6 m) would act as a tidal "sink" on the ebb flow which would substantially alter the tidal cycle residual flow vectors over the flood-tidal delta (Fig.2). Accordingly, Healy et al. (1991; 1993) predicted as a result of the dredging that parts of the flood-tidal delta sediment transport pathways would be subject to change which would likely induce some morphodynamic change. What was not known was how long it would take for the flood-tidal delta to come to equilibrium after the dredging.

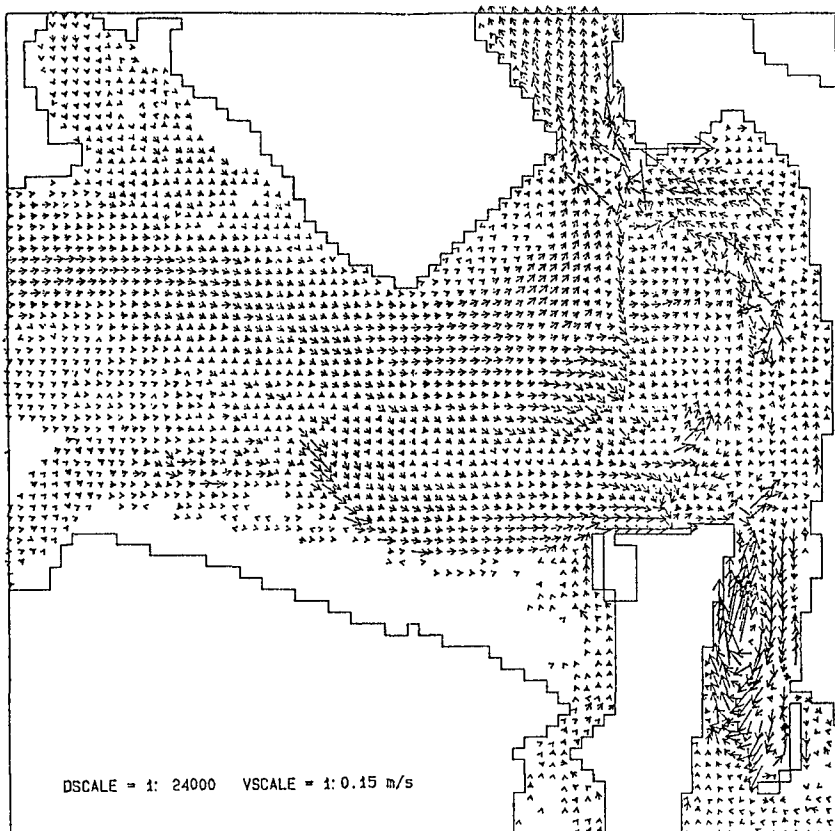

Fig. 2. Residual velocity vector differences showing the changes due solely to the deepened shipping channel in a spring tide (after Bell, 1991).

Sedimentation Within The Dredged Channels

Deepening an entrance channel to an inlet creates a greater hindrance to littoral drift and a more effective sediment trap. The long term effectiveness of the sediment trap is measured by the maintenance dredging requirement. For this case, since the channel deepening of 1992, the maintenance dredging has increased from a long term average of $\sim 70,000 \text{ m}^3$ per year to $\sim 110,000 \text{ m}^3$ per year for each of 1993, 1994, and 1995. An increase of this magnitude was expected, and to date has been remarkably uniform in amount per year. The sediment has accumulated on both the seaward and the harbor side of the inlet gorge.

The Flood-Tidal Delta (Centre Bank)

The flood-tidal delta is perhaps the most sensitive to morphodynamic change because it is formed largely as an interplay between the tidal current hydraulics and

sediment supply, whereas the ebb-tidal delta may also be influenced by wave action. Centre Bank shows some features typical of the Boothroyd (1985) "horseshoe crab" morphological model of flood-tidal delta, but is distorted by alignment of the harbour in relation to the inlet entrance, and the consequent predominant ebb-tidal discharge flowing laterally across the feature rather than being diverted by the ebb shield around the delta. For Centre Bank the EIA showed that deepening of the shipping channels within the harbor would be expected to induce a much greater west-to-east component of flow across Centre Bank, and this would likely have an impact on the sediment transport pathways.

The availability of earlier hydrographic surveys over Centre Bank, and the regular soundings since 1989, allow a close monitoring of the changes. The changes in tidal channel and bank outline bathymetry for the 1 m and 5 m depths relative to chart datum (extreme low water spring tide level) are presented in Fig.3. The plots show that between 1982 and 1989 the Lower Western Channel where it crossed the flood-tidal delta, markedly reduced in depth with a greater proportion of the tidal flow being diverted around and to the south of Centre Bank, at which time the disparate, shallower small southern shoals were scoured away. In July 1992 the major dredging program was just being completed, and as a result of the greater west-to-east tidal flows across Centre Bank, the Lower Western Channel was already opening up again. By September 1993, the Lower Western Channel had re-established itself, coincident with shallow shoals also redeveloping on the southeastern margins, and increased area of shoaling on the eastern margin adjacent to the shipping channel. Since 1993 the flood-tidal delta morphology has not changed in broad outline (Mathew et al., 1995).

The net bathymetric differences exceeding 0.5 m between April 1990 and April 1994 are presented in Fig. 4. A broad zone of scour is evident along the Lower Western Channel, resultant upon the deepening of the channel. A zone of minor scour occurred along the outer ebb shield, with a parallel band of minor accretion, indicating a relocation of the distal ebb shield. Minor scour also occurred along the southeastern flank of Matakana barrier island. Accretion was marked on the flood ramp due to channel realignment, as well as an additional capping on the highest part of the inner ebb shield, and along the northeastern rim of the Centre Bank adjacent to the shipping channel.

J. Mathew (in prep.) has undertaken detailed analysis of the sounding data including detailed cross sections. The profiles showing the most change are presented in Fig 5. The sounding sections show post-dredging infilling and scour of parts of the Lower Western Channel, with only minor change on the other parts of the Centre Bank. In particular the shallowing of the ebb shield, interpreted as a strong possibility in the EIA (Healy et al., 1991), has partly occurred, but only up to 0.5 m vertical accretion over an area of $\sim 600 \times 300 \text{ m}^2$, and this change likewise occurred rapidly after the 1992 dredging.

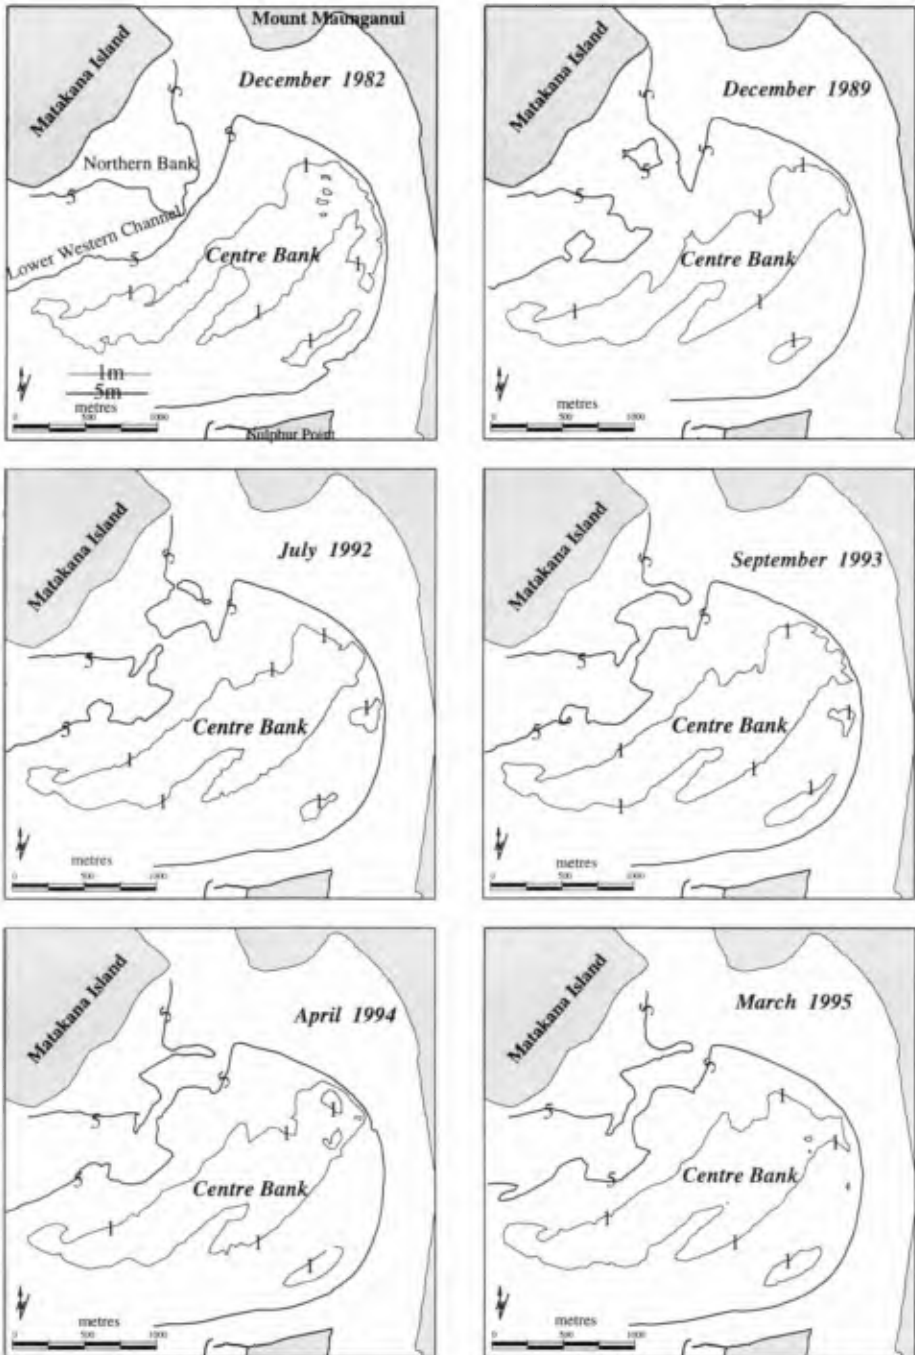

Fig. 3. Bathymetric changes in the Lower Western Channel between December 1982 and March 1995.

Fig. 4. Bathymetric differences on the flood tidal delta exceeding 0.5 m vertical extent between April 1990 and April 1994.

Air Photo Record

The annual vertical air photos flown since the major dredging have shown realignment of the direction of the sand waves which cap the topographical high of Centre Bank, geomorphically the ebb shield. Noticeable on the eastern sector of the ebb shield the sand wave bedforms have shown an easterly movement. The air photos also show a response of the flood ramp to the dredging and removal of part of a rocky shelf which had been protruding into the inlet gorge and was considered a hazard to navigation. This resulted in an expanded flood jet onto the flood ramp, and created a new area of scoured shell-gravel lag. Expansion of the flood jet was consistent with the higher current flows recorded after dredging by the S4 current meters, discussed below.

Fig. 5. Cross-sections across Western Channel showing deposition of up to 3 m in Lower Western Channel (EF) and up to 6 m in the blind flood channel (GH) between 1983 and 1994.

Changes in Current Flows Near Panepane Point

Current flows were monitored at 3 locations adjacent to the barrier island side of the inlet using S4 electromagnetic current meters. These were located in the Lower Western Channel, Pilot Bay Channel and on the edge of the Cutter Channel. The resulting data (Figs 6a-b) show some changes in velocities for the Cutter Channel site with greater flood tide dominance rising from 0.85 m/s to 1.20 m/s after the 1992 major dredging. In the Lower Western Channel near Panepane Point there was an increase in current magnitude from 1.00 m/s peak flood flow and 0.75 m/s peak ebb flow before the dredging to 1.25 m/s peak flood flow and 1.10 m/s peak ebb coincident with a directional change after the dredging. However a later deployment at the same site in 1994 showed that the current direction had resumed its pre - 1992 dredging alignment.

The observed increase in current speed at points measured is consistent with a re-aligned and laterally extended tidal jet as a result of removal of the Tanea Shelf from the inlet gorge. That, as expected, has induced some change in the affected sea floor, in particular the Lower Western Channel and flood ramp area.

Fig. 6. Current velocities at 1 m above the bed before and after dredging at: (a) the edge of Cutter Channel and (b) at Lower Western Channel near Panepane Point.

The Ebb-Tidal Delta

Annual bathymetric surveys were also carried out over the ebb-tidal delta since 1989. Comparison of the surveys indicates that the ebb delta has been largely stable in terms of its gross morphology, for example the terminal lobe has not changed in location between 1989 and 1995 (Fig.7). The major identifiable change has been that a proximal (inner) blind ebb channel northwest of Mount Maunganui has tended to infill from about 13 m depth in 1989 to 10 m depth in 1995. A distal (outer) blind ebb channel has increased in size.

Overall there has been no sudden or substantial change to the ebb delta morphology which can obviously be linked to the entrance shipping channel deepening in 1992. This is consistent with the numerical model residual vector patterns carried out in the EIA which showed that there was unlikely to be identifiable difference from deepening the Entrance navigation channel from 11 m to 14 m.

Fig. 7. Bathymetric differences on the ebb-tidal delta between March 1989 and September 1995.

Conclusions

Since the 1992 major channel dredging, the hydrographic surveys have shown that some areas of the flood ramp have accreted by up to 3 m in vertical extent while up to 2.5 m of scour associated with increased currents have occurred in the non-dredged semi-major Western Channel. Alignment of large 'dune' bedforms on the topographic high of the flood delta, morphologically the ebb shield, has changed significantly, but the depths have changed only by about 0.5 m, and overall the broadscale morphology of the flood-tidal delta has retained its coherency.

In terms of how rapidly the tidal inlet and delta system has adjusted to new conditions after the substantial hydraulic change to the tidal delta system consequent upon the 1992 dredging, it is clear that major readjustment for the flood-tidal delta was very rapid, and essentially occurred by the time the dredging was completed - over a 6 month period. On the other hand, the ebb-tidal delta adjustment has been much slower and seems to be ongoing.

CHAPTER 255

LABORATORY MOBILE BED MODEL STUDIES ON EBB TIDAL SHOAL EVOLUTION

Xu Wang¹, Lihwa Lin² and Hsiang Wang³

Abstract

Laboratory mobile bed experiments were conducted to study the ebb tidal shoal evolution process under storm wave conditions. An idealized inlet configuration was chosen for the experiment representing a typical median-sized inlet on the east coast of Florida, USA. Six different cases were tested including a natural inlet and a jettied inlet with different jetty length and jetty type. Formation of ebb tidal shoal was observed in all cases; the rate of growth and location of ebb tidal shoal were different for the cases. Inlet channel shoaling and beach erosion next to the inlet are far more severe in the case of natural inlet than that in the case of jettied inlet. In general, the established tidal shoal tends to grow during the ebb cycles and deteriorate during flood cycles. And partial removal of ebb tidal shoal has shown to increase downdrift beach erosion and reduce the rate of ebb shoal growth, though the rate of change of the mined case rapidly approached that of the case without mining.

1. Introduction

Ebb tidal shoal is a common feature associated with tidal inlets in coastal area. It is created by the combined deposition of littoral material diverted from adjacent beaches together with the alluvial material carried out from inlet by the tidal current. When inlets are stabilized with training structures, ebb tidal shoal can become more prominent as littoral material is diverted further offshore into deeper water. As a consequence, the ebb shoal volume also increases. This causes additional disruption of the normal longshore sediment transport and often results in severe downdrift shoreline recession. In Florida, over 85% of the shoreline erosion is considered to be related to inlets, particularly to those with training structures.

¹Engineer I, Division of Natural Resources Management of Lee County, FL 33902,
²Research Scientist, ³Professor, Coastal and Oceanographic Engineering Department,
Univeristy of Florida, Gainesville, FL 32611,USA.

Since ebb tidal shoal is formed mainly by material diverted from the updrift beach it is a tempting source, and reasonably so, to tap for downdrift beach nourishment. However, such practice is not common because the formation of ebb tidal shoal is part of the natural process and disturbing an ebb tidal shoal environment so close to shoreline without knowing clearly its effects is unsettling.

This paper is aimed at investigating the evolution process of ebb tidal shoal on one hand and finding the possibility of utilizing the sand from ebb tidal shoal on beach nourishment on the other by means of movable-bed physical modeling in the laboratory. To achieve this goal, an inlet model testing is designed and carried out to investigate ebb tidal shoal evolution process and corresponding shoreline responses for a natural and unimproved inlet, an inlet with jetty structures and with the ebb tidal shoal partial removal.

2. Design Of Inlet Model Experiments

The inlet-beach physical model was designed with considerations on experimental constraints and modeling laws. The model was tested under simulated storm wave conditions to insure turbulent flow and suspended sediment transport mode. The modeling law adopted in the present study is shown in Table 1, which is for an inlet-beach system based on the analyses of the experimental results of a series of 2-D and 3-D laboratory model study (Wang, *et al.*, 1994; Wang, *et al.*, 1995).

Table 1: Modeling Law

Geometric Distortion*	Wave Height Distortion	Hydrodynamic Time Scale	Morphological Time Scale
$N_\delta = N_w^{0.4} N_\lambda^{0.8}$	$N_H = \sqrt{N_\lambda}$	$N_T = \sqrt{N_\lambda}$	$N_t = \sqrt{N_\lambda}$

* N_w, N_δ, N_λ are fall velocity, vertical and horizontal length ratios, respectively.

The model experiments were carried out in a wave basin located in Coastal and Oceanographic Engineering Laboratory at the University of Florida. The wave basin has a physical size of 25m wide, 30m long, and 1m deep as shown on Figure 1. The inlet-beach model and a wave maker were located at two long ends of the basin. An ideal inlet, of straight, rectangular channel, with uniform width and depth of 1.75m and 0.2m, respectively, was constructed cutting through a plane beach made of a natural quartz sand ($D_{50}=0.19\text{mm}$). The overall length of the beach from updrift to downdrift ends is 19m. The model is laterally bounded on two wave guides formed by concrete blocks. The wave guides are perforated to allow flows in and out of the test section. The downdrift wave guide is open at the beach end to allow downdrift littoral transport to leave the test section and to be collected in the catch channel. The plane beach consists of a flat back shore segment, a steep-slope

foreshore segment, and a mild-slope offshore profile which extends seaward to about 7m from the shoreline beach face before merging with the concrete floor. The beach profile approximates an equilibrium shape of $h = Ax^{0.8}$, which h is water depth, x is seaward distance from shoreline, A is a scale factor.

A schematic of experiment setup

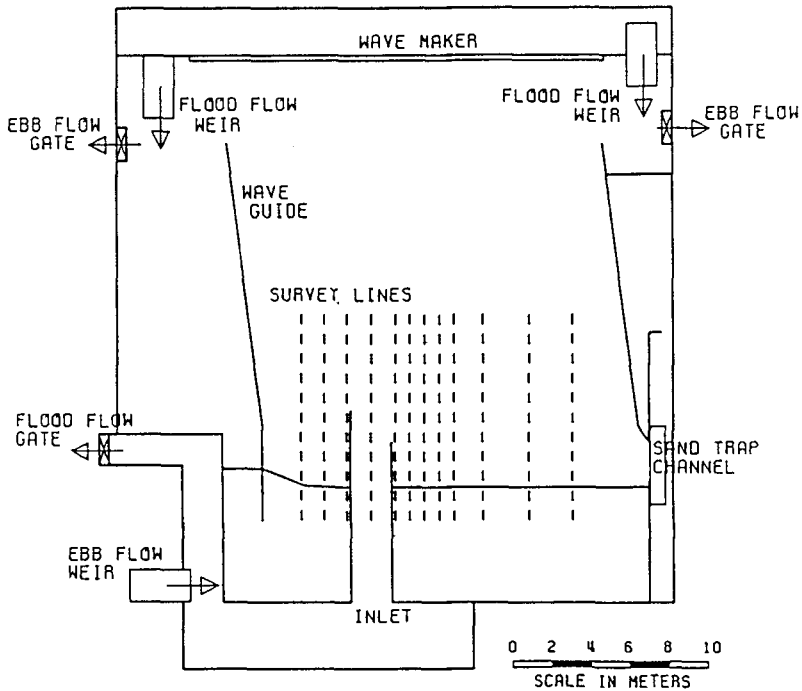

Figure 1: The Schematic Setup for Movable-Bed Inlet Physical Model.

The inlet is offset from the center towards the updrift with the updrift beach length of 5m and downdrift beach length of 12m. The wave generator is located about 27m from the shoreline based on an average water depth about 0.35m. Tidal currents are generated by recirculating water through the circulation channels connected with the wave basin. The flow discharge is controlled by the flood and ebb flow weir boxes. Water is supplied from the upper basin weir boxes (flood flow weirs) for flood current and from the lower basin weir box (ebb flow weir) for ebb current. A curved feeder beach section at the updrift end allows for continuous and

more uniform sediment supply to the downdrift which is purely due to wave-induced transport.

3. Experimental Conditions

Six different experimental cases and associated conditions are summarized in Table 2. Tidal currents are simulated in the experiment by alternating ebb and flood cycles at equal interval of 40 minutes, which is equivalent to a semi-diurnal tidal period at 1:80 geometrical scale ratio according to Froud number criterion. A constant discharge of $0.04 \text{ m}^3/\text{sec}$ is used for both ebb and flood cycles. The cross-sectional averaged currents in the inlet are maintained to be 0.12 m/s and 0.14 m/s for the flood and ebb cycles, respectively. The tidal range is 3 cm in the experiment.

Table 2: Test Conditions of Inlet-Beach System Experiment.

Case	Wave height	Incident wave condition (Wave period: 1sec) Wave angle	Beach slope		Jetties (type) e: even length u:uneven length	Model time (min)
			Foreshore	Offshore		
C1	8 cm	15 deg	1:2.4	1:14.5	none	480
C2	8 cm	15 deg	1:2.9	1:14.5	Riprap(u)	1600
C3	8 cm	7.5 deg	1:2.9	1:14.5	Caisson (u)	3200
C4	7 cm	7.5 deg	1:2.9	1:14.5	Caisson (e)	3200
EC1	7 cm	7.5 deg	1:2.9	1:14.5	Caisson (e)	3200
EC2	7 cm	7.5 deg	1:2.9	1:14.5	ebb shoal mining	3200

Experiment C1 is to simulate a natural inlet; C2 is to simulate a jettied inlet with riprap type jetties; C3 and C4 are to simulate a jettied inlet with caisson type jetties. In Case C2 and C3, the inlet consists of an updrift jetty of 1.5m and a downdrift jetty of 0.7m, both straight and perpendicular to initial shoreline. The uneven updrift and downdrift jetty geometry of an inlet is common in Florida. In C4, the updrift and downdrift jetty jetties have the same length of 1m. Experiment EC1 and EC2 were conducted to investigate the effects of ebb tidal shoal removal. Experiment EC1 is the case without removal of ebb tidal shoal and EC2 is the case with removal of ebb tidal shoal. Both experiments have the same test conditions as that of C4, except C4 has a slight larger width of the inlet. The jetty elevation is about 5cm above the flood tide water surface and jetty width is 20cm. Figure 2 shows the initial bathymetry for natural inlet case. Also, the major difference between riprap and caisson type jetties is that the riprap is porous and not sand tight whereas the caisson is impervious.

4. Experimental Procedures

The model experiments is conducted according to the following procedures: (1) Prepare initial inlet model bathymetry, (2) Conduct initial profile survey at selected cross-sections as shown in Figure 1, (3) Adjust water level and discharge to

the specified ebb conditions, (4) Start wave maker to generate storm waves, (5) Run the ebb cycle experiment for 40 minutes, (6) Readjust water level and tidal flow for the flood condition, (7) Start wave generator and run the flood cycle for 40 minutes, (8) Repeat steps from (3) to (7) until an prominent ebb tidal shoal is established, and (9) Reshape the model to its initial bathymetry for the next experiment. Eleven bottom profile surveys were conducted at irregular time intervals, shorter in the early stage and longer later in the experiment. Sediment accumulated inside the inlet and outside of the downdrift boundary was collected at the same time when bottom surveys were conducted. Both dye and sand tracer studies were conducted from time to time. The dye study was for current pattern observation and was documented by video recordings. Sand tracers were used for visual examination on sediment transport pattern. No quantitative measure of sand tracer movement was attempted.

Figure 2: Initial Topographic Contours for Natural Inlet Experiment

The initial topography of Case EC2 was prepared by modifying the final topography (3200 min) of EC1, which included mining of ebb tidal shoal and downdrift beach nourishment. Sand was removed from the ebb shoal and inlet channel areas which is indicated by the dashed rectangle in Figure ?. This sand was used in all for the downdrift beach nourishment in the preparation of initial topography of EC2.

5. Experimental Results

Formation of ebb tidal shoal was observed in all cases; the location of ebb tidal shoal and the rate of growth were different. In the laboratory, + 2cm above the initial bottom profile was chosen as the reference plane to present the results of ebb tidal shoal growth.

In the natural inlet experiment, a small shoal formed immediately near the entrance in the first ebb and flood cycles as the beach material was rapidly carried seaward to form nearshore breaking bars. Inside the breaking line, sediment from the updrift beach was seen to move towards the inlet by strong wave action. Outside the breaking line, sediment was carried across the channel and deposited at downdrift side of the channel outside the surf zone. Beach erosion was severe at both sides of the inlet from the beginning of the experiment. In the following ebb and flood cycles, the initial shoal built near the inlet entrance continued to grow and expand to form channel shoal and ebb tidal shoal. The experiment was stopped at 480 minutes or six complete tidal cycles as both channel shoaling and beach erosion became excessively severe. The shoreline erosion pattern was nearly symmetrical with respect to the inlet center. The generation and growth of the ebb tidal shoal and also the shoreline patterns in Experiment C1 using the net +2cm as the base contour are exhibited in Figure 3. It is seen that shoaling began at the channel entrance and grew in both directions towards offshore and into the channel. At 120 minutes, channel shoal and ebb tidal shoal can be separately identified. The ebb shoal began to shift towards downdrift after 120 minutes. At the end of 480 minutes, a drastic ebb tidal shoal was established while the channel shoaling was seen to extend and reconnect with the ebb shoal.

In the jettied inlet experiments, general sediment transport patterns were similar in the beginning ebb and flood cycles. Accretion of sediment occurred at the tips of both updrift and downdrift jetties. Generation of ebb shoal was not evident in this early stage. In subsequent time, the sediment transport patterns became different, which then influenced the development of the ebb tidal shoal. In C2, the updrift jetty tended to attract sediment owing to the structural porosity. Accordingly, sediment was heavily deposited on both sides of the updrift jetty around its tip. In C3 and C4, on the other hand, more updrift sediment was seen to bypass the jetty. In these jettied inlet experiments, beach erosion was significant only at the downdrift side, particularly in C2 owing to the larger incident wave angle. In C4, the ebb tidal shoal was generated more closer to the inlet than in C2 and C3 due to the small incident wave height. Compared with C4, EC1 had more centered ebb tidal shoal and much less channel shoaling because of the smaller width of the inlet which tended to transport more sediment bypassing the jetties.

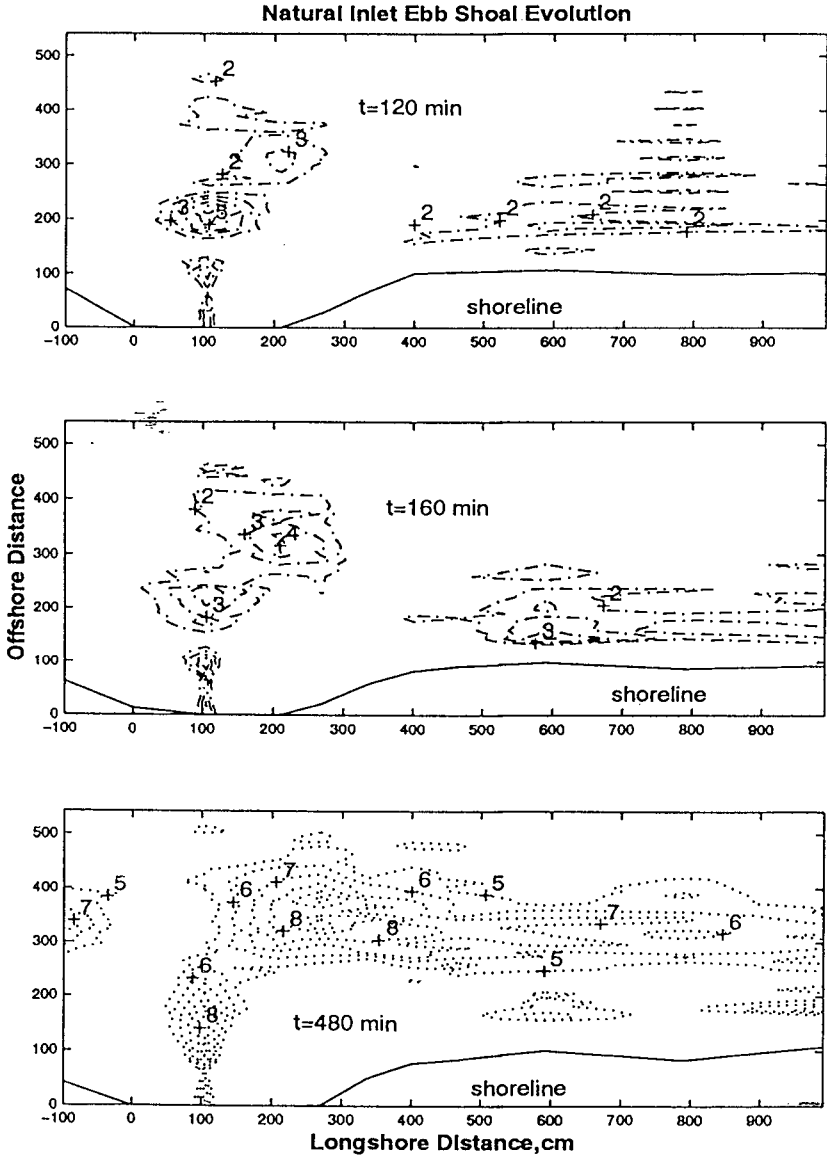

Figure 3: Ebb Tidal Shoal Evolution in Experiment C1.

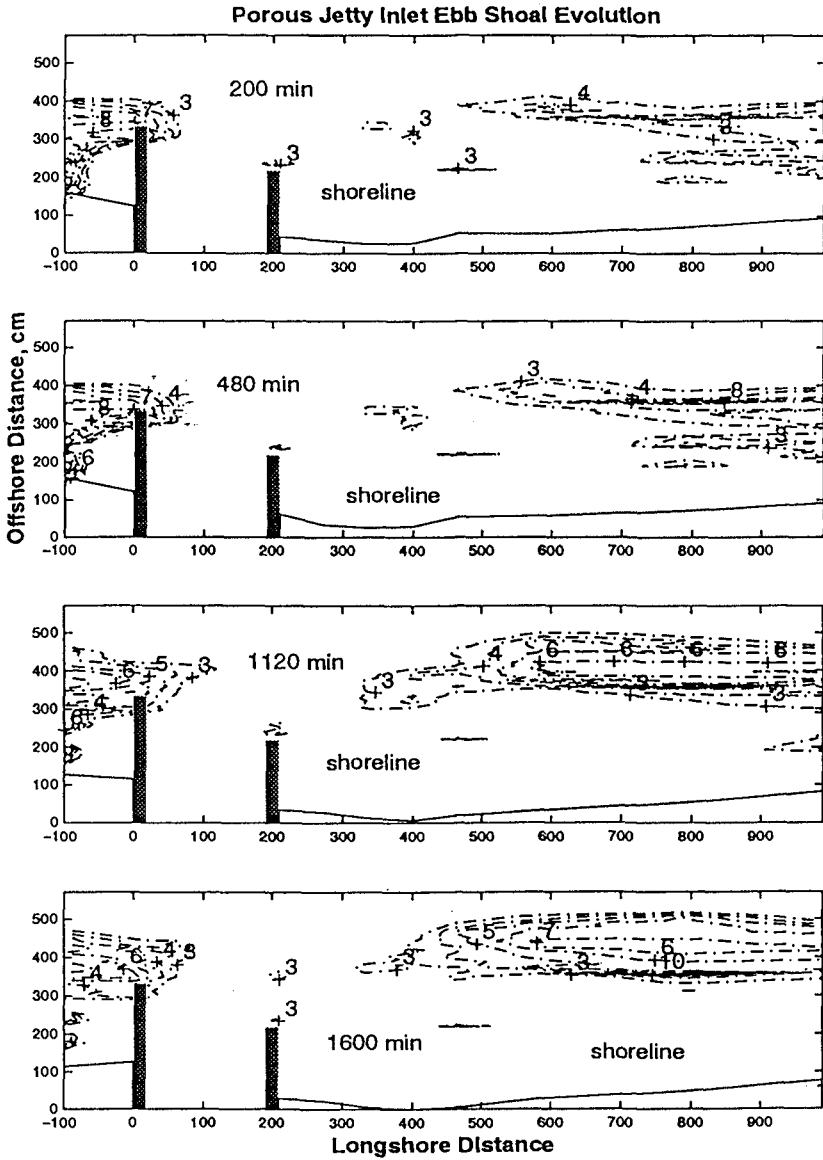

Figure 4: Ebb Tidal Shoal Evolution in Experiment C2.

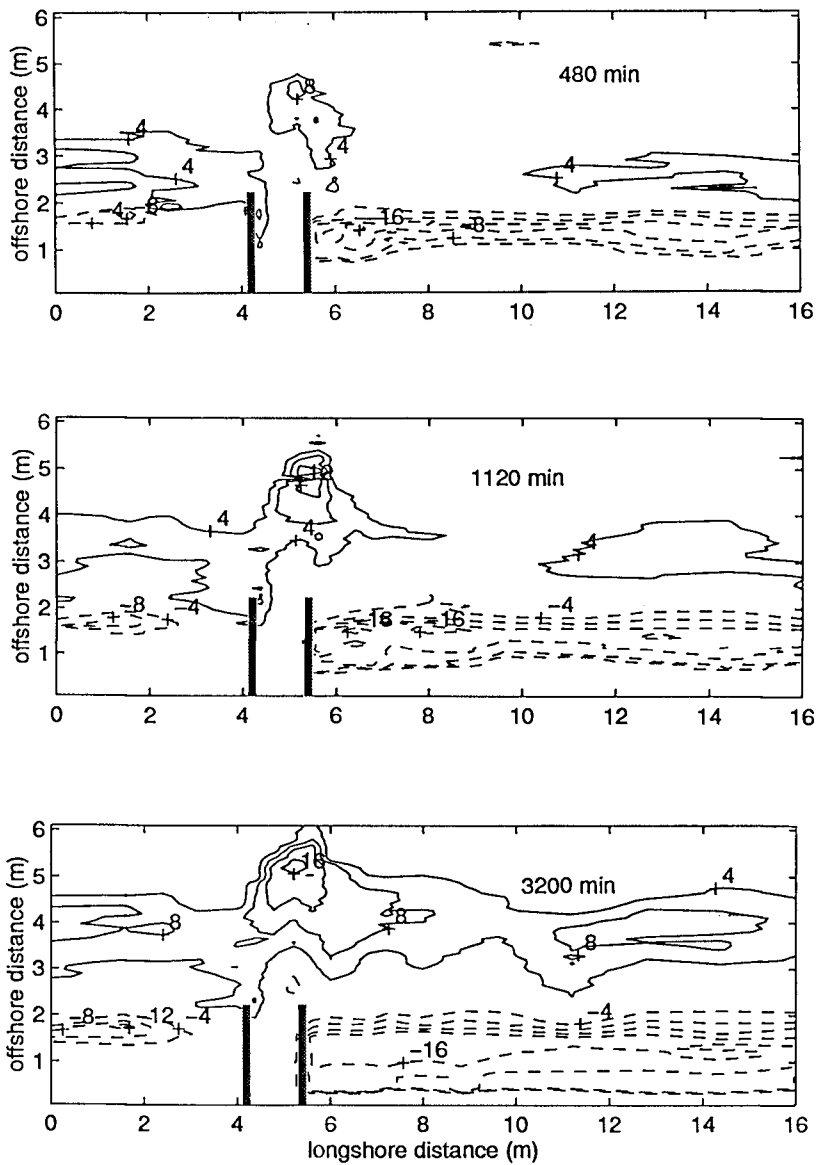

Figure 5: Ebb Tidal Shoal Evolution in Experiment EC1.

Figure 4 to 5 present the evolution pattern of ebb tidal shoal in C2 and C3 , respectively. Figure 6 compares the ebb tidal shoal volume for C1,C2, C3 and EC1. It is seen that the growth of ebb tidal shoal was unsteady in the early stage in these cases. The ebb shoal simply grew during ebb cycles but shrunk during flood cycles. After the first few cycles, the ebb tidal shoal began to grow steadily, almost in a linear fashion. The process was much rapid in the case of the natural inlet than the jettied inlet. The rate of growth apparently slowed down at a later stage of the experiment.

Figure 6: Comparison of Ebb Tidal Shoal Volume Changes for C1, C2, C3 and EC1

Experiments EC1 and EC2 were conducted to study the effect of the partial ebb tidal shoal removal. Figure 7 shows the ebb tidal shoal evolution process after part of the ebb tidal shoal sand was removed and used as the downdrift beach nourishment in EC2.

The effects of ebb tidal shoal removal on downdrift beach were evaluated by comparing the total volume of sand eroded from the beach between the downdrift

jetty and downdrift boundary in experiments EC1 and EC2. This comparison of downdrift beach erosion and erosion rate versus the elapsed time is shown in Figure 8. It is seen that the downdrift beach erosion is overall significant in EC1 and EC2, with a greater erosive rate in EC2 than in EC1, though at the later stage, this difference became much smaller.

The degree of restoration of the ebb tidal shoal was evaluated by comparing the volumes of the ebb shoal in EC1 and EC2 as shown in Figure 9. At 800 min, the ebb tidal shoal in EC2 has less volume than the shoal in EC1 implying a slower rate of growth in EC2. However, from 800 min to 1600 min, the ebb shoal growth approaches a steady rate in both experiments. The rate of growth fluctuates greatly in the first 160 min reflecting the effects of the short time intervals corresponding to individual ebb and flood tides.

6. Conclusion

Based on the experimental results, inlet channel shoaling and beach erosion in the cases of jettied inlet experiment were not as severe as compared to the case of the natural inlet. Apparently, the presence of jetties slows down the inlet shoaling and beach erosion near the inlet. It is evident that jetty structures are necessary for tidal inlets under strong wave environment.

Formation and growth of ebb tidal shoal were observed in all the inlet experiments. The location and rate of growth of ebb shoal were different, though. The ebb tidal shoal were created and expanded during ebb cycles but deteriorated and diffused during flood cycles. The porous jetty tended to attract sediment deposition near the inlet entrance whereas impervious jetty caused more sediment by passing the inlet.

Mining an ebb tidal shoal has shown to increase downdrift beach erosion and reduce the rate of ebb shoal growth at certain degree. However, the rate of change of the mined case rapidly approached that of the case without mining, which implies the feasibility of using sediment from ebb tidal shoal in downdrift beach nourishment. The experiment was successful in reproducing ebb tidal shoals observed in nature.

However, more research work is needed to gain the insight of dynamics of the system.

CHAPTER 256

INTERACTION OF THE COLORADO RIVER PROJECT, TEXAS, WITH LONGSHORE SEDIMENT TRANSPORT

Daniel J. Heilman¹, M. ASCE and Billy L. Edge², M. ASCE

ABSTRACT

In 1985, a weir jetty system was constructed at the mouth of the Colorado River, Texas, and river discharge was diverted from this mouth in 1992. An evaluation of project impacts on longshore sediment transport was performed to determine the effectiveness of the project at preserving an open, navigable channel while preventing excessive erosion along adjacent beaches. This evaluation included both physical and numerical analysis of pre- and post-project conditions at the Colorado River mouth. Analysis of site data revealed that under the dredging and mechanical bypassing schedule followed during the first 8 years after jetty construction, the project resulted in significant trapping and sorting of sediment transported alongshore. Numerical modeling of the design maintenance dredging plan confirmed the plan to be sufficient for achieving project objectives. However, the entrance channel has continued to shoal considerably more rapidly than was anticipated during the project design.

INTRODUCTION

General Setting

The Colorado River discharges into the Gulf of Mexico through Matagorda Peninsula on the Texas Gulf Coast about midway between Galveston and Corpus Christi (Fig. 1). With a generally linear WSW-ENE orientation, the Matagorda Peninsula outer shoreline is dominated primarily by Gulf waves from the northeast (Fig. 2), and it is subjected to a resulting longshore current that transports sediment in a southwestward direction (McGowen and Brewton 1975). The peninsula ranges in width from about 1.2 to 1.6 km with an average elevation of approximately 2 m and faces the Gulf with a moderately wide sandy beach. The tide is diurnal with a range on the order of 0.6 m (U.S. Army Corps of Engineers (USACE) 1977). As reported by Morton *et al.* (1976), the beach varies in composition and texture from fine sand to shell and rock-fragment gravel.

The Colorado River Mouth

Originally discharging into a large estuary shared with the nearby Brazos River, the Colorado River began discharging into Matagorda Bay near the mainland shore at Matagorda, Texas, around 1,000 years ago (McGowen and Brewton 1975). Sediment transported by the river to the bay was restricted in the mid and late 1800s by a jam consisting of tangled masses of logs and brush embedded in silt, which was characteristic of the Lower Colorado River (Morton *et al.* 1976). By 1926, the log mass backed up in the river 74 km above Matagorda and created a lake, further restricting river sediment discharge by impounding coarse sediment. As shown in Fig. 3, which is a digitized rendering of a survey map prepared in January, 1839, the lake and log mass effectively prevented the river from creating a delta in the bay. In the late 1920s, a channel was dredged through the log mass, resulting in the release of trapped sediment and the rapid growth of the Colorado River delta into Matagorda Bay (Fig. 4) (Bouma and Bryant 1969). By 1935, the delta extended across Matagorda Bay to Matagorda Peninsula. In search of a direct path connecting the river to the Gulf, the Matagorda County and Reclamation District dredged a straight channel from one of the river outlets in the delta, across the bay, and through Matagorda Peninsula to the Gulf of Mexico (Morton *et al.* 1976, Ralston 1987).

The Colorado River Project

The Gulf entrance of the Colorado River has historically been subject to heavy shoaling, primarily due to longshore transport, and was often restricted enough to prevent the passage of small boats or flood flows. The major portion of the bed load material transported by the river was deposited above the GIWW in a silting basin (USACE 1977). The inlet was occasionally re-opened by high river discharges and by periodic maintenance dredging (Ralston 1987).

The shoaling which occurred at the Gulf entrance of the river continued to interrupt the capability of the river to serve as a dependable small-craft channel. In 1968, federal authorization was given for the USACE Mouth of the Colorado River Project in response to a need for a dependable, navigable channel connecting the Gulf Intracoastal Waterway (GIWW) to the Gulf of Mexico near the town of Matagorda, Texas. The project included a jettied entrance at the Gulf of Mexico, a navigation channel along the existing Colorado River through the delta, a harbor and turning basin, recreational facilities, and full, uncontrolled diversion of the Colorado River into Matagorda Bay (Fig. 5) (USACE 1977). The primary benefit from the project was dependable navigation between the Gulf and the GIWW.

The jetty system for the project was completed in 1985 and included a weir jetty on the northeast side of the inlet and an impoundment basin adjacent to the weir to accumulate southwesterly moving longshore sediment. The river diversion was completed in 1992, and construction of a 4.6-m deep and 61-m wide entrance channel and a 3.7-m deep and 30.5-m wide navigation channel extending to the GIWW

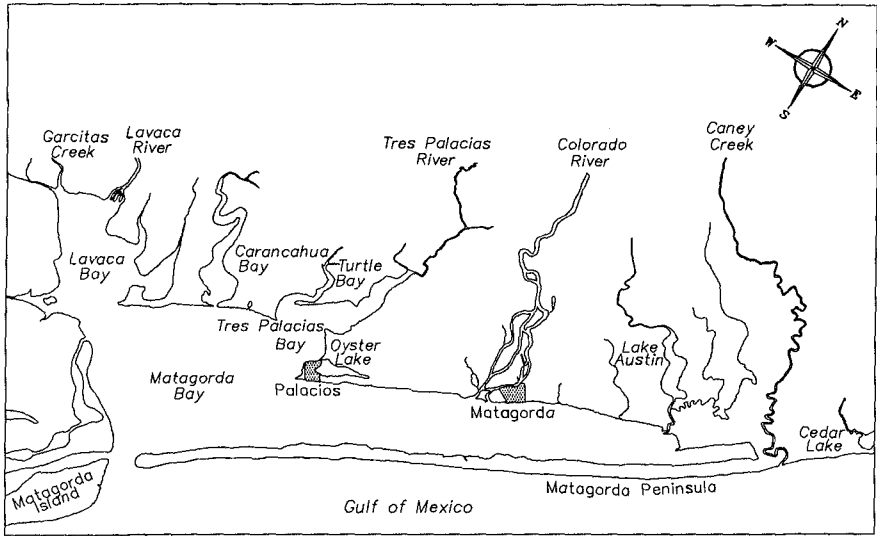

Figure 3. Survey map of Matagorda Bay, dated January 16, 1839 (original map archived by the Texas General Land Office).

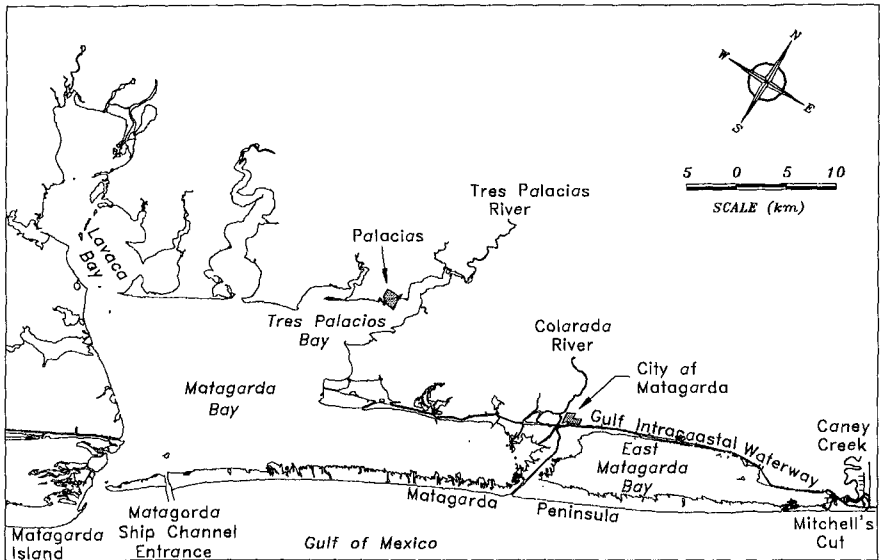

Figure 4. Map showing Colorado River delta which extended across Matagorda Bay to Matagorda Peninsula by 1935.

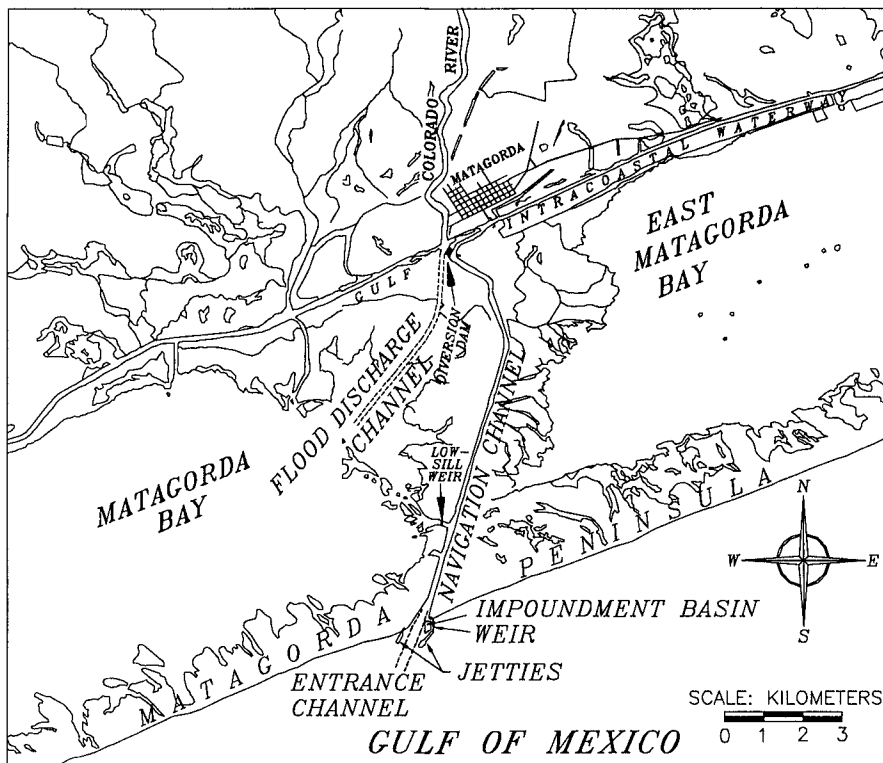

Figure 5. Features of the USACE Colorado River Project.

near Matagorda was completed by 1990 (USACE 1977). The jetties and entrance channel were aligned along the pre-existing flood discharge channel into the Gulf, with the seaward ends of the jetties spaced about 400-m apart. The weir section in the northeast jetty extended 305-m seaward from the shoreline at a crown elevation of 0 mean low tide (MLT). Past the weir section the jetty extended to the 3.7-m depth contour and was aligned to serve as a breakwater for the impoundment basin and entrance channel. The southwest jetty extended seaward to the 1.5-m depth contour.

The impoundment basin was initially designed to hold approximately 460,000 m³ of littoral sediment (USACE 1977). Based on estimated rates of longshore sediment transport, it was assumed the basin would require dredging on average once every two years. Material dredged from the basin was to be mechanically bypassed by pipeline and discharged in the surf zone approximately 610 m downdrift of the southwest jetty (Fig. 6).

STUDY OBJECTIVES

Because the entrance to the navigation channel and the impoundment basin have accumulated sediment more rapidly than was anticipated, assumptions made about the

Figure 6. Colorado River mouth, December 12, 1992.

sediment transport rate at the mouth of the Colorado River have been in question since completion of the jetties (Rozsypal 1994). The frequent maintenance that has been required to retain an open, navigable channel has suggested the need for modification of the jetties or bypassing system. However, improvements cannot be made without accurate understanding of the interaction between the project and sediment transport processes.

To evaluate the influence of the project on longshore sediment transport, a coastal processes analysis was conducted using historical and recent data, and numerical analysis was conducted using the GENESIS shoreline change model (Hanson and Kraus 1989). The updrift and downdrift limits of inlet impact on shoreline migration were estimated, a summary of predicted longshore sediment transport rates was developed, and pre- and post-project beach profiles were used along with dredging records to quantify sediment trapping. Present and future project impacts on shoreline stability and longshore sediment transport were estimated through the use of GENESIS. Future project effectiveness was tested based on the anticipated pre-project maintenance dredging plan.

PROCEDURE

Historic Inlet Impact on Adjacent Shorelines

An evaluation of historical volumetric shoreline changes along Matagorda Peninsula was conducted using shoreline position data obtained from the University of Texas, Bureau of Economic Geology (Morton *et al.* 1976, Paine and Morton 1989). The data were compiled from topographic charts and aerial photographs and cover the period from 1855 to 1982. Based on these data, Morton *et al.* (1976) and Paine and Morton (1989) concluded that the Matagorda Peninsula Gulf shoreline is historically erosional.

Beach volume change trends were estimated by application of the equilibrium beach profile concept as presented by Moore (1982) and Dean (1991). The beach volume change trends were evaluated to a distance of 33.6 km downdrift and 11.5 km updrift. Using methods developed by Bodge (1995), whereby shoreline change data representing pre- and post-introduction of a potential sediment sink are compared, the differences between the average of the pre- and post-inlet beach volume change rates were considered to identify the net effects of the inlet (which was cut in 1935) on the adjacent beaches. In the method, all beach volume change updrift and downdrift of the inlet is attributed to the interruption of the longshore sediment transport by the inlet (i.e., the effects of hurricanes, cross-shore transport, wind-blown sand transport, etc., are neglected). Based on this assumption, the maxima in a curve plotting the difference between the averages of the pre- and post inlet volume change rates, calculated cumulatively as a function of the distance from the inlet, represents the alongshore terminus of the beach segment within which the inlet influences beach volume change. As plotted in Figs. 7 and 8, the un-jettied Colorado River mouth (as existed from 1935 to 1982) may have impacted shoreline stability as far downdrift as 18.4 km and as far updrift as 5.4 km along the Gulf-facing shoreline of Matagorda Peninsula.

Figure 7. Cumulative annualized volume changes downdrift of the un-jettied Colorado River mouth. The pre-inlet average is based on 1855 to 1937 shoreline position data, and the post-inlet average is based on 1937 to 1982 shoreline position data.

Figure 8. Cumulative annualized volume changes updrift of the un-jetticed Colorado River mouth. The pre-inlet average is based on 1855 to 1937 shoreline position data, and the post-inlet average is based on 1937 to 1982 shoreline position data.

Sediment Transport

As outlined by USACE (1984), four methods of estimating longshore sediment transport exist, including (in order of decreasing preference) calculations based on: (1) A known rate at a nearby site; (2) Measured historical changes in bathymetry or topography; (3) Wave height and direction data; (4) Only wave height data. These prediction methods can be combined to compare estimated rates or to supplement a lack of data that precludes the complete application of any one method. The traditional methods outlined by the USACE were applied to the study area, and the results are summarized in Table 1.

Calculated net longshore transport rates for the Texas Gulf Coast which are in excess of 200,000 m³/yr appear to the authors to represent over-estimates, particularly if comparison is made to other calculations of net transport documented for harsher wave climates. For example, Bodge (1995) determined the net average longshore transport rate to be about 184,000 m³/yr for a beach on the north Florida coast facing the Atlantic Ocean; the transport rate along Texas beaches should be less because the average wave climate is less severe. Heilman and Kraus (1995) calculated the net average transport rate along South Padre Island, Texas, to be 115,000 m³/yr based on a sediment budget, and Kraus *et al.* (1996) calculated the net rate along Mustang and north Padre Islands to be 34,000 m³/yr and the gross rate to be 150,000 m³/yr based on 8 years of wave hindcast data. Also, as noted by Mason (1971), Mason and Sorensen (1971), and Kraus and Militello (1996), small cuts have historically existed near the eastern end of East Matagorda Bay. These cuts, which are not subjected to strong tidal flows, would be expected to rapidly close under a strong longshore transport rate.

Method	Rate (m³/yr)
1. Estimate based on hindcast wave data, spit growth, and beach erosion at Brown Cedar Cut, Matagorda Peninsula (Mason and Sorensen 1971).	38,000 <i>net</i> 460,000 <i>gross</i>
2. Estimation derived from sediment budget developed for nearby Sargent Beach (Seelig and Sorensen 1973).	31,000 <i>net</i>
3. Average rate based on 47 years of historical shoreline position data (Heilman 1995).	152,000 <i>net</i>
4. Estimation derived from evaluation of sediment impoundment at nearby Matagorda Ship Channel jetties (USACE 1977).	150,000 <i>net</i>
5. Estimation based on inspection of historic data at the project site, including survey data, aerial photography, and dredging records (USACE 1977).	170,000 <i>net</i>
6. Design rate used for the project based on combination of methods 2 and 3 above (USACE 1977).	230,000 <i>net</i>
7. Post-project rate based on inspection of beach profile survey data and dredging records (revised after Heilman 1995) (data obtained from USACE).	250,000 <i>net</i> 420,000 <i>gross</i>
8. Potential rate calculated from a 22-month time series of directional wave data using $K = 0.77$ (Heilman 1995) (data obtained from USACE, CERC).	310,000 <i>net</i> 580,000 <i>gross</i>

Over-prediction of sediment transport rates based on bathymetric changes at the study site may be due to use of the assumption that sediments are predominantly introduced to the system from alongshore. A significant volume of sand may be transported onshore as the historic Colorado River ebb delta (if it exists) is eroded by waves (Kraus 1995). The cause of the suspected over-prediction of the longshore transport rate based on collected directional wave data is unknown, but may have occurred if the sampling period (May, 1990 to August, 1992) was not representative of the typical, long-term wave climate. A comparison between wave and wind data for the study site indicated that the measured wave directions were accurate, with the predominant direction being from the southeast and sediment transport reversals occurring only 20% of the year. The average mean wave height at a depth of 5.2 m was 0.77 m, the average wave period was 5.3 sec, and the average incident wave angle was 84 deg measured clockwise from the local shoreline orientation.

Inspection of aerial photographs and observations made at the site indicate that wind-blown sand also plays a significant role in channel infilling, as sand along the beach is transported across and around the jetties to constrict the channel opening.

This process has been noted to play an important role at other jettied Texas inlets (Kieslich 1977, Kraus and Heilman 1996).

Sediment Sorting and Trapping

Sediment grain-size data collected in August, 1994, and October, 1995, by the USACE, Galveston District, were examined to determine that finer sand (0.02 to 0.04 mm) collects in the impoundment basin than in the portion of the entrance channel adjacent to the basin (0.14 to 0.18 mm). The existence of finer sand in the impoundment basin is probably a result of: 1) the sorting of suspended-load sediments from bed-load sediments by the weir; 2) the lack of sediment sorting by currents in the deep (low-energy) basin; and 3) the transport of fluvial silts and clays to the inlet from the navigation channel during ebb flows (these fine sediments may be trapped in the basin). Analysis of survey data collected by the USACE revealed that the channel and impoundment basin fill from the weir side in a southwestward direction and that the heaviest shoaling occurs close to the shoreline.

As shown in Table 2, a comparison was made between pre- and post-project beach volume change rates near the jetties. The change from pre-project beach erosion to post-project beach accretion was considered to represent a reduction in the net longshore transport of sand past the inlet. The comparison indicated an average increase in the beach volume change rate of about 53,700 m³/yr (the difference between -9,700 m³/yr and +44,000 m³/yr) between 1984 and 1992 along 3.9 km of shoreline updrift and downdrift of the channel. Based on a longshore transport rate of approximately 230,000 m³/yr, this impoundment of sand at the inlet is equivalent to a 23% reduction in the transport of sand to beaches downdrift of the inlet.

Period (Years)	Rate of Beach Volume Change (m ³ /yr)		
	Uprift Beach (from 0.8 to 3.6 km from inlet)	Downdrift Beach (from 1.6 to 2.7 km from inlet)	Total (along 3.9 km of shoreline)
1857-1935 (Pre-Inlet)	6,700	-2,800	3,900
1935-1956	13,800	22,000	35,800
1956-1965	-58,000	60,400	2,400
1965-1974	-15,400	-109,000	-124,400
1974-1982	8,100	-13,000	-4,900
1935-1982 (Average)	-7,100	-2,600	-9,700
1984-1992	31,000	13,000	44,000

Numerical Simulation of Shoreline Change

As a means of supplementing knowledge gained through evaluation of field data collected at the project site, numerical modeling was conducted to simulate shoreline change based on theory and approximation. The GENESIS model, developed by the USACE, Coastal Engineering Research Center (CERC) (Hanson and Kraus 1989) was applied to the study site to test the effectiveness of the design maintenance dredging schedule at preventing channel shoaling. Shoreline reaches updrift and downdrift of the jettied inlet were modeled separately. Details of the model setup, input, and calibration are presented in Heilman (1995).

Model results indicated that the design maintenance dredging volume of 460,000 m³ consistently bypassed every other year is sufficient for preserving the transport of sand past the inlet and for minimizing channel shoaling. However, the model results also suggested that accelerated shoreline erosion will occur updrift of the weir due to the unidirectional transport of sediment over the weir. Based on inspection of aerial photography and visits to the site, this shoreline recession has not distinctly occurred updrift of the weir, although a series of beach profile surveys conducted by the USACE, CERC indicate beach erosion occurred within about 500 m updrift of the weir between 1984 and 1992 (Liang 1995). Model results also revealed a tendency for sediments to be temporarily stockpiled in the dredged material discharge zone (approximately 600 m downdrift) due to wave sheltering by the jetties. The sediment stockpiling process may increase rates of channel shoaling as the effective length of the downdrift jetty is reduced and northeastward-flowing sand enters the channel.

CONCLUSIONS

The Colorado River Project was a response to the need for a dependable, navigable channel connecting the GIWW to the Gulf of Mexico. Jetties were constructed in 1985 including provisions for the mechanical bypassing of littoral sediments past the entrance from an impoundment basin filled by functioning of an innovative weir. Through utilization of the bypassing system, whereby sediments are regularly dredged from the impoundment basin and discharged into the surf along the downdrift beach, the potential for accelerated beach erosion has been reduced. However, the efficiency of the system has been decreased by the unexpectedly-high infilling of the impoundment basin and resulting excessive channel shoaling, and by the sorting of littoral sediments.

Possible causes for the rapid shoaling which occurs at the Colorado River mouth include:

1. A higher than anticipated net longshore transport rate.
2. The breakup of an assumed historic Colorado River shoal.
3. The reduction in effective length of the downdrift jetty (which originally extended only to the 1.5-m depth contour) by the growth of a shoreline fillet; this process results in a nearly unimpeded transport of sediment around the jetty during longshore transport reversals.

4. The diversion of river discharge to Matagorda Bay and associated reduction in flushing of channel sediments from the channel entrance.
5. The growth of shoals across the channel adjacent to open, unvegetated areas of the beach by wind-blown sand.

Main results of this study are:

1. Historical records indicate that the un-jettied Colorado River inlet influenced migration of the Matagorda Peninsula Gulf shoreline as far updrift as 5.4 km and as far downdrift as 18.4 km. The Colorado River jetties and channel are expected to exert control on long-term shoreline migration at least as far as these extents.
2. The Colorado River jetties trap sediment despite mechanical bypassing. Some sorting occurs as the weir separates suspended and bed-load sediments.
3. A varying degree of sediment is lost from the mechanical bypassing process when more sediment reaches the impoundment basin than can be stored. Overflowing sediment may be either lost to shoals (causing navigation hazards) or transported farther downshore (starving the local beach). Numerical simulation indicates that this sediment overflow can be reduced with a consistent bypassing schedule.
4. Numerical simulation predicts that a unidirectional transport of sediment occurs across the weir, resulting in a sediment deficit directly northeast of the weir during periods when waves arrive from the southwest. The effects of this process have not been observed at the study site.

ACKNOWLEDGEMENTS

Special thanks is given to Dr. Nicholas Kraus of the Coastal Engineering Research Center (CERC) for providing technical review of this report. The authors also give thanks to Mr. T. Neil McLellan at the U.S. Army Corps of Engineers, Galveston District and to Dr. David King and Dr. Tom White, both of CERC, for providing technical assistance and data. Recognition is given to Dr. Robert Morton at the University of Texas, Bureau of Economic Geology, and Dr. Richard Seymour at Texas A&M, College Station, for their patience and cooperation in providing other needed information.

CHAPTER 257

A Comprehensive Field Study of Tidal Inlet Processes at Ponce de Leon Inlet, Florida

Gary L. Howell¹

1 Introduction

Traditional coastal engineering concerns at tidal inlets include navigation and channel maintenance. Today coastal engineers are faced with new concerns such as adjacent shoreline impacts, water quality, and wetlands preservation. The development of new engineering tools to address these problems depends on improved understanding of tidal inlet processes. A necessary component of this research is comprehensive field measurement of the complex hydrodynamic and sedimentation processes at tidal inlets (Mehta, 1995).

The field measurement work unit of the Coastal Inlets Research Program (CIRP) of the US Army Corps of Engineers is a coordinated effort to acquire a comprehensive data set of physical inlet processes. The measurements will be used to evaluate and refine existing process models and motivate new predictive methods. A wide range of approaches must be served by common measurements. These include physical, numerical, analytical, empirical, semi-empirical, and hybrid models. Field data are required for development, calibration, and validation.

This paper describes the planning, site selection, and design of the study. Preliminary results from the first year of data collection are presented. It is intended as a reference for investigators using the data. Problems as well as successes are described so that future studies will hopefully improve on the efforts described here.

2 Planning

2.1 Measurements

The Ponce study is the first major long term field study of a tidal inlet since the General Investigations of Tidal Inlets program (G.I.T.I.) of the 1970s. It is also the first to benefit from the major improvements in instrumentation and computer technology since that time. However a tidal inlet remains a difficult environment for field studies. The same conditions that cause hazardous navigation impact the installation and survivability of instrumentation. Rapid changes in bedforms

¹Research Engineer, US Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, Mississippi 39180-6199 USA.

make siting of in-situ gages difficult and mandate frequent surveys. The variety of measurements required to describe all of the interacting processes still exceeds today's measurement capabilities.

Careful planning of field experiments is required to match limited resources with conflicting needs. Approaches to field experiments are affected by the technical discipline and research interests of various investigators. For example, there is not a consensus on whether it's best to study a single inlet intensively or study several inlets with limited measurements. The planning of the Ponce experiment reflects the evolution of research from traditional tidal hydraulics problems to problems of decadal or longer time scales such as impacts on adjacent shorelines from dredging and other engineering activities. Today there is more emphasis on these longterm geomorphologic responses and the sediment transport processes that drive them. Measurement technology has improved in the areas of hydrodynamics but unfortunately, progress in sediment transport measurements has been much slower.

The approach which led to the Ponce study was based on applying an engineering design method to the field studies. Study proposals and measurement requirements documents were developed by each investigator. The requirements focussed on the end use of the data, rather than specific gages or surveys. Based on requirements, experiment plans were developed which attempted to meet as many requirements as possible. Gages and surveys were prioritized by the number and technical value of requirements they satisfied. The decision to initially concentrate on comprehensive measurements at a single inlet was based on cost/benefit analysis. There remains a need to examine variability between different types of inlets, but this will be left to future studies. The planning resulted in the following types of measurements:

- Water levels at the open coast, outer throat, inner throat, and back bay open boundaries.
- Directional wave measurements in the offshore, ebb shoal, and throat areas.
- Current measurements in the throat and on the ebb shoal.
- Wind velocity and barometric pressure.
- Bathymetry
- Beach profiles on the ocean side
- Sediment samples
- Long term monitoring of shoreline, breaker lines, and the shoals.
- Regular and post-storm aerial photography.

2.2 Site selection

Since the CIRP is a national program, there were many possible field study sites. The selection was based on technical merit by using a formal analysis that matched technical and operational requirements with the characteristics of candidate inlet field sites. Each investigator developed requirements for hydrodynamic and sedimentary characteristics of the study inlet. Operational and cost factors were also considered for each inlet.

The set of all U.S. inlets was reduced to 12 candidate inlets by establishing minimum requirements. From the research viewpoint, availability of historical data was a major factor. Relevance as demonstrated by real world problems representative of those faced by the Corps was important. Finally the inlet should have a manageable physical size for field operations.

A weighted requirements matrix analysis was employed to compute separate metrics for technical and operational characteristics of the candidate inlets. In the case of the technical requirements, the field study requirements were used to compute the weights. For operational and cost factors, weights were assigned based on a consensus of senior field technicians and project engineers.

The candidate inlets were ranked by operational score, technical score, and a combined score which was normalized to provide equal weight to the operational and technical factors. Separately each candidate inlet was evaluated to determine its suitability for physical modeling. The major factor in this evaluation was the scale factor necessary to represent the inlet in available facilities. For some inlets, factors such as tide range and wave generation requirements were also important.

The results of the formal analysis ranked Ponce de Leon Inlet, Fl. highest. The recommendation was reviewed and accepted by all investigators, program managers, and sponsors. Experience during the first year of the field study has supported the selection. Ponce is a tidal inlet typical of the east coast of the U.S. It has a jettied entrance with a visible north jetty and a south jetty covered with sand. The design channel is 5m deep and 70m wide. Historically, the inlet has undergone significant evolution due to engineering activity and natural response. A substantial set of historic data is available (USAE Jacksonville District, 1993). Present engineering problems include dangerous navigation, potential breach locations, severe scour along the inside of the north jetty, inner bank erosion, and jetty sand bypassing problems. Many unique operational advantages at Ponce have been important in achieving a successful monitoring effort. These include undeveloped land south of the inlet, the Coast Guard Station close by, and a single tall condominium building near the inlet which was ideally sited for video monitoring. Ponce is a dynamic inlet which can be expected to undergo measureable changes during the lifetime of the study.

Figure 1: Ponce Inlet long term field measurements.

3 Instrumentation

3.1 Hydronamic gages

Figure 1 shows the layout of the long term instrumentation at Ponce. There are directional wave gages at three sites on the ocean side of the inlet. The site **DWG1INT1** is intended as a reference for incident waves. The gage is located in 14m of water north of the inlet in an area where the bottom contours are relatively parallel. The site **DWG1EBB1** is located on the face of the ebb shoal in approximately 7m of water. The site in the outer throat of the inlet is **DWG1OTH1**. Each of these sites has a DWG-1 (Howell, 1992) directional wave gage. The DWG-1 is a short-baseline pressure gage array. The pressure gages are Paros Digiquartz which provide accurate water level information. *PUV* type directional wave gages using electro-magnetic current meters were not used because of the high cost and difficulty of the regular cleaning. The Ponce area is regularly visited by shrimp trawlers, making the trawler resistant design of the

DWG-1 advantageous.

The ebb shoal site and the inlet throat site also have RDI ² broadband 1200kHz Acoustic Doppler Current Profilers (ADCP) located on the same mounting pod as the DWG-1. Figure 2 shows the right angle upward looking style ADCP used. The ADCP is configured for continuous real time output at a 1Hz sample rate and 1m vertical bins. The combined DWG-1 and ADCP share the same cable for both power and data output. All data recording is continuous, real-time via the cable. The internal recording modes of the instruments are not used.

Water level data in the inner bay is provided by Paros Digiquartz pressure sensors. The sensors are mounted in a steel protective sleeve are attached to a fixed length pipe which is used to mount the sensors to a pile. The top of the pipe has a reference mark which can be surveyed to establish the datum for the water levels. Both the offshore water levels (from the DWG-1) and the inner bay water levels use absolute pressure sensors which require compensation for barometric pressure. Another Paros sensor is used as the principle barometric pressure measurement and is recorded simultaneously with the water level sensors. A backup barometric measurement is available from the meteorological station installed on the north beach³The meteorological station is provided by the Battelle institute. A standard stilling well tide gage is located at the Coast Guard Station (**VITLBAY3** in Figure 1). This gage uses an air acoustic sensor and provides a check on the air pressure corrections and datums for the pressure water level sensors.

Datums for the offshore water levels obtained from the DWG-1 wave gages were not surveyed like the inner bay gages. Instead data analysis of six months of data was used to estimate the datums. The technique is based on an iterative minimization of the residuals between the Coast Guard Station tide gage (**VITLBAY3**) and the offshore water levels. The technique selects data windows at slack water when the inner and outer water levels approach equality. The method produces accuracies comparable to that obtained with conventional surveys. Details of the method will be provided in a future publication.

Table 1 lists the locations of the principle measurement sites.

3.2 Time series data acquisition

Table 2 gives the sample rates and resolution of the measurements. All data are acquired continuously. However some of the routine analysis use shorter record lengths. For example directional wave spectra are computed using 34 minute records windowed from the available 59 minute records.⁴ All data analyses are performed at least hourly. Data from all of the time series gages are logged by a single computer located in a leased trailer at the Coast Guard Station. The trailer is connected to the Internet via a 56k Band leased line to the Jacksonville COE District office in Jacksonville. Figure 3 shows the layout of the connections from the gages to the central logging computer. Most of the connections are through

⁴A variety of analysis products are produced from the Ponce data. Users should check the analyses parameters used for the particular product rather than relying on the general description here.

cable installed for the experiment or local leased telephone lines. This design was used instead of radio telemetry because experience in previous projects has shown that wireline installations provide higher data return at a lower maintenance cost than telemetry. Another reason for use of a central computer facility was the desire to preposition the infrastructure that would be required for a larger short term experiment. Without this requirement a design based on several outdoor Remote Transmission Units (RTUs) could have been used.

All of the data logged by the central computer are acquired through serial ports. The computer is a standard industrial rackmount PC computer. A multiport serial card is installed to provide extra ports. There are three identical computers installed. Two of the computers are operational all of the time and have the serial data arriving continuously. Logged data from one of the computers is transferred over the Internet link to a computer in Vicksburg which is configured with a standard data acquisition, analysis and storage system known internally as PMAS (McKinney and Howell, 1996). Should a failure of the principal computer occur, data are automatically acquired from the backup computer. The third computer is installed and tested, but disconnected from power, network, and serial lines. It can be manually configured to replace either of the two operating computers. This mode is used to protect this machine from lightning surges which overpower the surge protection devices.

The software for the PC compatible computers logs the data from each serial port to files. The Posix compliant Linux⁵ operating system provided most of the building blocks for the system. Customized code was implemented primarily with shell scripts. Procedures too complex for shell scripts were implemented as Ada programs using the freely available GNAT Ada compiler⁶. The software is configured to operate completely unattended. Status information is available at any time on-site or remotely using the *finger* command. Automated email messages are sent to advise of any unusual situation or error. A status monitor implemented as a shell script runs continuously on the computer in Vicksburg. It uses a combination of the *finger* and *traceroute* commands to detect problems at the site and network outages. Automated email messages are also sent by the Vicksburg monitor computer to warn of problems.

3.3 Problems and performance

The general performance of the hydrodynamic monitoring system has been very good. The data acquisition system has achieved over 99% reliability. The ebb shoal directional wave gage and ADCP experienced a cable failure during the March 1996 storm. The failure was caused by incomplete disassembly of the instrument by unauthorized divers. The instrument located in the throat of the

inlet has experienced periodic burial by sand. The directional wave gage continued to yield useful data. However the sand cover which ranged from 1-2m rendered the ADCP data unuseable. Relocation of these instruments is under consideration. Some problems have been encountered with the Vitel tide gage in setting its range to accomodate the extreme highs and lows of the water levels. These problems have been easily corrected but compromise the peak tide data until correction. After an initial period of working with the telephone company to debug the leased telephone lines, the bay pressure tide gages have been very reliable.

Data analysis of the wave and water level gages has been generally routine. However the Ponce system is our first experience with continuous time series data from multiple ADCPs. Automated analysis and quality control software was not available at the beginning of the study. Development of this software is underway, but will require extensive effort before its performance is comparable with existing wave and tide measurement software. ADCPs have the potential to provide details of both mean and orbital velocities, as well as suspended sediment concentrations. As better analysis tools become available these measurements should become feasible.

4 Spatial monitoring and surveys

4.1 Bathymetry

The Ponce study is fortunate to have available a powerful new tool for coastal engineering work, the helicopter Lidar bathymetric system. The system developed by the Corps of Engineers is known as SHOALS. Irish *et al.*(1996) in this Proceedings provides a detailed description of the SHOALS system and its use for monitoring volume changes at inlets. Figure 1 shows bathymetry obtained from the SHOALS system. The detailed and rapid coverage provided by the laser system allow the details of the complex bottom topography of the inlet system.

A Lidar system operates by measuring the time difference between the reflection of a laser light pulse from the water surface and the bottom. Scanning the laser allows coverage of a 100m swath as the helicopter moves across the survey area. Figure 4 shows a photograph of the SHOALS system mounted on the survey helicopter. The accuracy of SHOALS is continually being evaluated and improved. Experience at Ponce shows that accuracies are already comparable with that of traditional fathometer surveys. Improved GPS technology now allows SHOALS to survey the above water portions of the beach profile. The accuracies of this capability are currently under evaluation.

The main limitation of Lidar technology is dependence on water clarity. At Ponce there have been periods where surveys could not be performed because the water was too turbid. Turbidity problems were most severe near the throat and in the back bay. Turbidity can be caused by a variety of weather conditions. These include storms which suspend large quantities of sediment. The rapid survey capability of SHOALS makes it ideal as a post-storm survey tool, however turbidity will prevent its use during the storm and the recovery period immediately afterwards.

4.2 Shoreline response

Monitoring of the long term shoreline response is performed using previously developed techniques. Data are acquired from

- Color digital aerial photography
- Wading beach profiles
- Continuous video monitoring

The aerial photography and beach profiles are combined with the SHOALS bathymetry in a Geographic Information System (GIS) database. Once in the GIS, standard tools such as differencing and volume change mapping are applied. As longer records become available, the GIS will be used as a tool to help manage the spatial data and facilitate correlations with the hydrodynamic forcing.

Figure 5: Video photo looking out from the top of the condominium toward the inlet channel and jetties. The photo is a result of a timed exposure which causes the breaker lines to appear as white streaks.

Potential development of inlet response models require long term data of shoreline position that is sampled more frequently than annual or semiannual beach surveys. One approach that has been applied to beaches on the open coast is video monitoring. Konicki and Holman (1996) describe the technique in a paper in this Proceedings. For the Ponce experiment, five video cameras were mounted on top of a condominium on the south side of the inlet. The cameras provide views of the up and down coast beach, the throat, ebb shoal, and flood shoal. Figure 5 shows an unrectified view from one camera of the channel and jetties. The photo is the result of a six minute time averaged exposure. Averaging highlights wave breaking zones as white bands. By processing many such photos, shoreline, bar, and shoal positions may be tracked.

The usefulness of the video data has not yet been demonstrated. Long term records and substantial efforts in data analysis are required. If successful, results from this monitoring will appear in future publications.

5 Sample storm data

Figure 6 shows waves from both the offshore gage and the wave gage in the throat of the inlet. This storm occurred in March 1996 and was unusual in that the wind

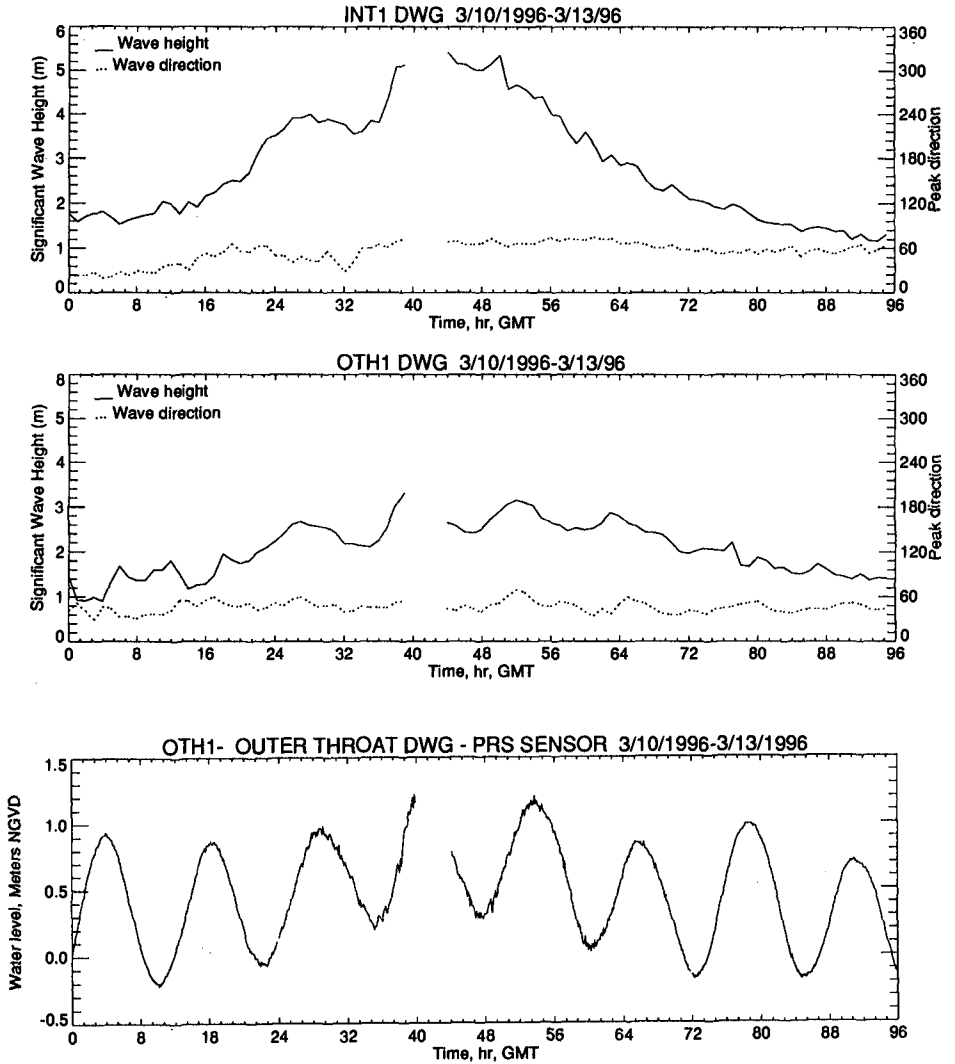

Figure 6: Inlet wave shoaling during a large storm. Note the modulation of wave height by water level in the throat (OTH1).

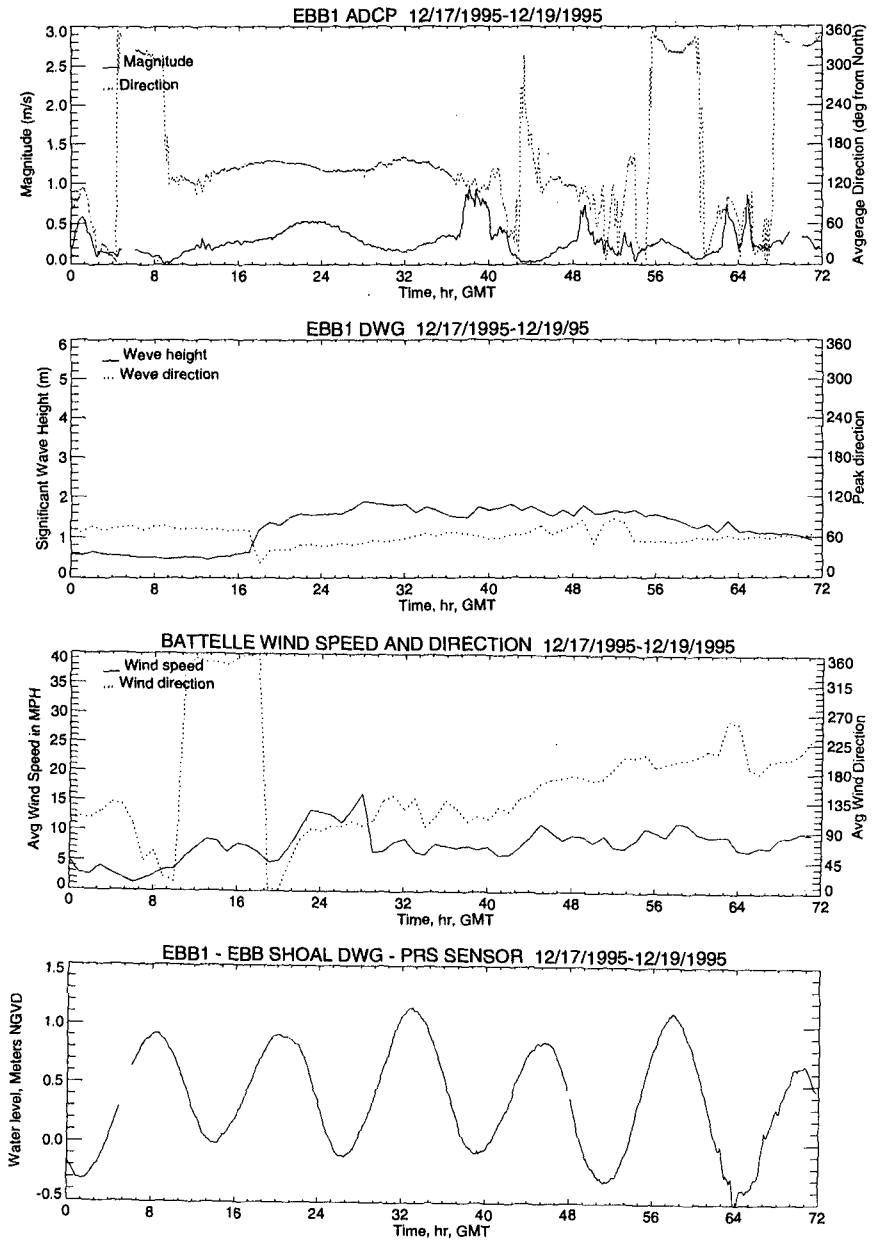

Figure 7: Ebb shoal waves and currents. Note the wind and waves driven currents as well as tidal currents.

direction stayed fairly constant as can be seen by the wave direction. The throat waves show both the effects of shoaling and the sheltering of the north jetty. The modulation of the wave height by the tide confirms the importance of water levels and tidal currents in predicting waves in inlets.

Figure 7 shows vertically averaged mean currents on the ebb shoal during a moderate Nor'easter. The beginning and end of the record show tidal currents dominant as is the ambient condition. As the wind and wave directions change, the tidal component of the mean current is strongly influenced.

Additional data analysis is currently underway and will be reported by the program investigators. The data already acquired provide confirmation of the complexity of the hydrodynamic and sedimentary processes at Ponce inlet.

6 Acknowledgements

Many people made important contributions to this study. Bill Grogg, Trap Puckette, Sam Corson, Pat McKinney, Rhonda Lofton, Kent Hathaway, Jeff Lillycrop, and Tom Martin all played key roles. The U.S. Coast Guard Station, the Inlet Condominium, the Battelle Paint testing facility, and many other public and private land owners made their property and facilities available. This work was supported by the Coastal Inlets Research Program of the US Army Corps of Engineers. Permission for publication was granted by the Chief of Engineers.

Transport of Fluid Mud generated by Waves on Inclined Beds

Thijs van Kessel*, C. Kranenburg† and J.A. Battjes‡

Abstract

Liquefaction of a freshly deposited mud bed may occur if shear stresses in the bed, generated by wave-induced pressure gradients, locally exceed the yield strength. In this way fluid mud is generated, which has a concentration close to the original bed concentration (generally a few hundreds kg m^{-3}). If fluid mud is displaced, very high transport rates are to be expected. This may be an explanation for rapid mud accumulations often observed in navigation channels after storm periods. In this paper wave-induced liquefaction of a sloping mud bed is investigated with laboratory experiments. A yield strength profile of the bed is obtained with a small-scale sounding test. Rheological properties of the mud after liquefaction are determined with independent rheological experiments. It is shown that calculated shear stresses in the bed at the onset of liquefaction just exceed the measured yield strength. The combination of waves and a slope turns out to be very effective for the transport of fluid mud.

1 Introduction

Harbours and coastal areas are affected by the accumulation of mud in several respects. Resulting bathymetric changes often hamper navigation and make expensive dredging operations unavoidable in order to maintain navigable depth. Moreover, mud is often heavily polluted as it easily adsorbs many pollutants such as heavy metals and pesticides because of its high specific area and surface properties. This negatively affects water and sea bed quality and makes disposal of dredged material expensive. In order to prevent the undesired accumulation of mud, the relevant transport mechanisms have to be identified, thus providing a tool for coastal management.

Mud may accumulate gradually by sedimentation from the water column during slack tide. This is a slow process, as the sediment concentration in the water column generally does not exceed 1 g l^{-1} , and the settling velocity of the mud particles is low. The freshly deposited sediments may also be resuspended during ebb and flood tides, which reduces the net accumulation rate during a tidal cycle.

Another transport mechanism is the transport of concentrated, near-bottom mud layers—often referred to as 'fluid mud'—under the influence of waves and gravity. This may result in very high transport rates during a short period of time, as sediment concentrations in fluid mud may be up to a few hundreds kg m^{-3} . This transport mechanism may be an explanation for the rapid, event-like mud accumulations often observed after storm periods.

In this paper the latter mechanism is studied by means of laboratory experiments. In §2 the theory underlying the generation and transport of concentrated mud layers is discussed in greater detail; in §3 the experimental results are presented and discussed. Conclusions are drawn in §4.

2 Theory

2.1 Generation of fluid mud

Several erosion mechanisms of mud are possible. Surface erosion will occur if the bed shear stress exerted by the orbital motion of water under waves or by current, exceeds the critical shear strength for erosion (Mehta et al. 1989). Bulk erosion will occur if the shear stress inside the bed generated by wave-induced pressure gradients on the bed surface, exceeds the yield strength of the bed. For the experiments reported in this paper the latter mechanism prevailed, as the frictional bed shear stress remained small because of the absence of current.

Because of the very low permeability of a mud bed, water flow inside the bed caused by wave-induced pressure gradients is negligible (undrained conditions). Erosion caused by fluidisation or swell will not occur in this case. The behaviour during and after undrained failure of a mud layer will depend on its state of consolidation. Freshly deposited and consolidated beds tend to decrease in volume when subjected to shear, as they are loosely packed. A (positive) excess pore water pressure is generated, resulting in decreases in effective stress and strength. As the bed liquifies without the flow of water, sediment particles become mainly supported by the pore water instead of the grain skeleton. A liquified bed is easily transported if net forces are acting on it (De Wit 1995).

However, if the bed is closely packed because it has been exposed to high effective stresses in the past—by burial and subsequent exposure, for example—it tends to expand under shear, resulting in the generation of negative pore pressures. No liquefaction occurs in this case; on the contrary, the bed 'breaks'. Shear stresses needed for this type of failure to occur are generally much higher

than those for the liquefaction of loosely packed mud beds.

The sediment beds used in the experiments described in the present paper were freshly consolidated and loosely packed. Therefore, a positive excess pore water pressure generated upon failure, and liquefaction of the bed are to be expected.

The yield stress of the sediment bed is the key parameter for possible bed failure for the present experiments. It is essential that yield strength is measured *in situ*, as remoulded yield strength tends to be much lower than *in situ* strength. Measurements with a rheometer using a standard geometry in which a bed sample is injected gives erroneous results. A better option would be to use a vane geometry that inserted into the undisturbed bed, as the shear surface during insertion is different from the shear surface when measuring yield strength.

Another technique, which has been applied to the beds used in this study, is a sounding test, during which the force exerted on a small geometry slowly penetrating into the sediment bed is measured with a sensitive balance. With bearing capacity theory (Terzaghi 1943) the yield strength profile can be calculated from the force as a function of vertical position (Van Kessel 1996b).

As was remarked before, undrained failure occurs if the wave-induced shear stresses inside the mud bed exceed the local yield strength. Shear stresses in the bed generated by the pressure gradients caused by waves can be calculated from prescribed boundary conditions assuming a certain constitutive behaviour of the bed. For stresses well below the yield stress the bed will behave as an elastic material, whereas for stresses close to the yield stress the bed will behave as a visco-elastic material. Stresses beyond the yield stress result in liquefaction and concurrently viscous behaviour. If the constitutive behaviour of the bed is purely elastic, then the applied shear stress and the resulting strain are in phase. If the behaviour is purely viscous, then the shear stress and shear rate are in phase.

The wave-induced shear stresses in the bed during the present experiments were calculated assuming an elastic constitutive behaviour, which is in accordance with the concept of a yield strength as long as it is not exceeded. Horizontal and vertical displacements at the interface between sediment bed and fixed bottom were assumed to be zero (no-slip condition), whereas at the interface between sediment bed and overlying water the shear stress was assumed to be zero. The latter boundary condition can be justified if the stresses inside the bed caused by the pressure gradients are much larger than the frictional shear stress on the bed surface caused by the orbital motion of water under waves, which is shown to be true in §3.2. The final boundary condition needed to obtain a closed set of equations is the wave-induced pressure gradient exerted on the bed surface, which can be calculated from linear surface wave theory, for example. Details of the calculations are not presented herein for reasons of brevity. An analytical solution can be obtained (Van Kessel et al. 1997), which is a special case of the Yamamoto et al. (1978) model.

2.2 Transport of fluid mud

After the yield strength has been exceeded, the liquified bed starts to flow if subjected to a net force, which is the gravity force in the present study. As failure of the bed is undrained, the sediment concentration in the liquified layer equals the original bed concentration, which generally is a few hundreds kg m^{-3} . Because of the high viscosity, the flow of these layers tends to be laminar. Mixing with overlying water hardly occurs, because of the large density gradient stabilizing the interface.

In order to predict the flow of fluid mud layers, it is essential to know their rheological behaviour. The rheology of concentrated suspensions of cohesive sediment particles is quite complex; for a detailed discussion the reader is referred to Van Kessel (1996a), Toorman (1993), James et al. (1987) and Williams (1984). Fluid mud subjected to simple shear flow can be rheologically characterized by a (residual) yield strength and a shear rate dependent viscosity (non-Newtonian behaviour). A complication is that the viscosity is a function of the shear rate history rather than the actual shear rate, because structural changes that take place within fluid mud if the shear rate is changed, need time to reach an equilibrium situation. The constitutive model used to describe the fluid mud flow in the present experiments includes thixotropic behaviour (Toorman 1997):

$$\tau_{xz} = \lambda \tau_y + \left(\eta_\infty + \frac{c_1}{1 + \beta |\dot{\gamma}|} \right) \dot{\gamma} \quad (\tau_{xz} > \lambda \tau_y) \quad (1)$$

where τ_{xz} is the shear stress parallel to the bed, $\dot{\gamma}$ is the shear rate, τ_y is the yield stress, η_∞ is the viscosity as infinite shear rate and c_1 and β are coefficients incorporating shear-thinning behaviour. The structure parameter λ decreases with time from 1 to 0 as a result of structural break-up of the sediment caused by wave action (Moore 1959):

$$\frac{d\lambda}{dt} = -c_2 \lambda |\dot{\gamma}| \quad (2)$$

Structural recovery is not taken into account for the present experiments, because the time scale of recovery is much larger than that of the experiments. In §3.3 the calibration of the model coefficients τ_y , η_∞ , c_1 , β and c_2 for the sediment type and concentration used is discussed.

The equation of motion for the fluid mud layer can be solved together with the rheological model and boundary conditions. The equation of motion can be simplified into:

$$\rho \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} + \frac{\partial \tau_{xz}}{\partial z} + (\rho - \rho_w) g \sin \theta \quad (3)$$

where ρ is the density of fluid mud, ρ_w is the density of water, u the local velocity, t is time, $\partial p / \partial x$ is the the wave-induced pressure gradient, z the coordinate normal to the bed, g is the acceleration of gravity and θ is the angle of the slope

to the horizontal. The convective terms that should appear in (3) have been neglected, as for the present experiments they are very small compared to the other terms. Additionally, it has been assumed that the motion of the overlying water layer is not influenced by the mud layer, and that the slope is small. The pressure gradient at the bed caused by wave action is expressed by:

$$-\frac{\partial p}{\partial x} = -k \frac{\rho_w g a}{\cosh kh} \cos(\omega t - kx) \quad (4)$$

where k is the wave number, a is the wave amplitude, h is the water depth, ω is the circular wave frequency and x the coordinate parallel to the water surface.

Boundary conditions are:

$$\left. \begin{array}{l} z = D_1 : u = 0 \\ z = 0 : \dot{\gamma} = 0 \end{array} \right\} \quad (5)$$

Here $z = D_1$ is the elevation of the interface between non-liquified and liquified mud determined from observations and $z = 0$ is the interface between liquified mud and water. Initial conditions are:

$$t = 0 : u = 0 \text{ for all } z \quad (6)$$

These equations, which describe the motion of the mud layer after liquefaction, were solved numerically.

3 Experimental results and discussion

3.1 Experimental methods

An experimental setup was built to study wave-induced liquefaction and transport on a slope experimentally (Figure 1). Sediment beds were prepared by sedimentation and consolidation of a suspension of China clay in tap water in which 0.5% NaCl was dissolved. The initial sediment concentration was 275 kg m^{-3} . The suspension was mixed for 2 weeks in order to reach physicochemical equilibrium. China clay—mainly consisting of kaolinite—was used as an artificial mud because of its reproducible properties and easy handling. After 1 week of consolidation the bed height remained constant and the bed was tilted to its desired angle (0.05 rad). The bed height after consolidation was 0.12 m, its width 0.65 and its length 4.67 m.

At $z = 0, 0.02, 0.06$ and 0.10 m from the bed surface pore pressure transducers were mounted to observe the liquefaction behaviour. These transducers were located at measuring station 3. The sediment concentration profile in the bed was measured with a conductivity probe. Velocities both in the bed (after liquefaction) and above the bed were measured with two electromagnetic flow meters (EMF) mounted on traversing units to obtain vertical profiles. These traversing units were located at measuring stations 1, 2 and 3. Sediment concentrations in

Figure 1: Experimental set-up (not to scale); measuring stations 1, 2 and 3 are indicated; lengths in m

the water column were measured with turbidity meters in order to estimate the importance of interfacial mixing. Also three wave height meters were installed. The signals of these instruments were logged onto a PC.

3.2 Wave-induced liquefaction

The experiments were started by generating sinusoidal waves with a period of 1.65 s and an initial wave amplitude of 0.005 m. During the experiments the wave amplitude was increased in steps to 0.008, 0.010, 0.013, 0.016, 0.021, 0.027, 0.036 and finally 0.042 m and the pore pressure response was measured (Figure 2). Initially no changes in the wave-averaged pore pressure were observed. However, after an increase in wave-height from $a = 0.005$ to $a = 0.008$ m, suddenly excess pore pressures were generated and the bed started to liquefy. Bed flow does not yet occur at this wave-height, as is illustrated in Figure 3, where the velocity histories at several levels inside and above the bed are shown.

The bed did flow if the wave amplitude was increased to 0.010 m. This can be derived from Figure 2, where a sudden drop in pore pressure can be attributed to the removal of the liquified mud layer. The thickness of this layer can be calculated from the observed pore pressure drop (approximately 150 Pa at $z = 0.06$ m), as the initial sediment concentration is known from the conductivity probe measurements ($\rho = 1340 \text{ kg m}^{-3}$). The thickness thus estimated is 0.045 m. This result is consistent with Figure 4, where the velocity histories shown indicate that the bed is eroded up to the level $z = 0.065$ m.

A comparison of the wave-induced stresses in the bed—calculated from the elastic model—with the yield strength profile obtained with the sounding test (§2) is shown in Figure 5. At $a = 0.005$ m, when no liquefaction is observed, wave-induced shear stresses just remain below the yield strength. At $a = 0.008$ m, however, onset of liquefaction was observed, which is consistent with Figure 5, where, for this wave amplitude, the shear stress exceeds the yield strength in the

Figure 2: Changes in wave-averaged pore pressure $\Delta\bar{p}$; wave amplitudes in mm

Figure 3: Velocities versus time for $a = 5$ mm; z in mm; station 3

Figure 4: Velocities versus time for $a = 26$ mm; z in mm; station 3

upper 8 cm of the bed. The onset of liquefaction can therefore be well predicted if the yield strength profile of the bed is known. The yield strength of the bed increased with depth in a similar fashion as the effective stress, which was also observed by Bowden (1988).

3.3 Fluid mud flow

After liquefaction the fluid mud starts to flow. Rheological properties of China clay have been investigated independently to calibrate the rheological model applied (§2). In Figure 6 the equilibrium flow curve of China clay with $C = 467$ kg m^{-3} suspended in tap water with 0.5% NaCl is shown. It was measured with a Carrimed controlled stress rheometer equipped with a cone-plate geometry. This flow curve has been used to calibrate the Toorman (1997) model. In addition to measuring the flow curve, also thixotropic experiments have to be performed to measure the time-scales of structural break-up. These measurements are not discussed herein, the reader is referred to Van Kessel (1996a). Values for the model parameters used are listed in Table 1.

With the rheological model and the equation of motion presented in §2 fluid mud flow can be calculated numerically. Results of these calculations are shown in Figure 7. Peak velocities are approximately 0.02 m s^{-1} and increase in time because of structural break-up of fluid mud. Plug flow can be explained by the residual yield strength of the bed; negative velocities do not occur for the conditions during the experiments because of the finite yield stress. The model shows that the combination of wave-loading and the shear-thinning behaviour of mud results in a decrease in its effective viscosity, which markedly enhances

Figure 5: Yield strength, deviator stress and concentration profiles of a bed of China clay, obtained from sedimentation of a suspension of 275 kg m^{-3}

transport under the influence of net forces, such as gravity.

A displacement of 5 m (approximately the length of the test section) is reached within a few minutes, therefore fluid mud flow can be observed only for a short period of time, which is confirmed by visual observations. However, quantitative comparison between the flow model and measured velocities proved difficult. The accuracy of the flow meters in the velocity range of 0.01 m s^{-1} is low, too.

After removal of the fluid mud layer, a new non-liquefied layer became exposed, which would only liquefy if the wave amplitude was increased. At $a = 0.027 \text{ m}$, when the bed is clearly completely eroded at $z = 0.06 \text{ m}$, a pore pressure increase at $z = 0.10 \text{ m}$ was observed. Erosion of this layer occurred at $a = 0.027$ and 0.036 m .

Even at the largest wave amplitude, $a = 0.042 \text{ m}$, not all sediment was liquefied. After the experiments a layer of $0.02\text{--}0.03 \text{ m}$ was still present in the upper part of the tilting flume, which is not influenced by the sill at the lower end. This can be explained by two factors. First, the yield strength close to to the fixed bottom is the highest as the mud has been most compacted by the weight of the overlying sediment, and secondly, the (high) pressure gradients at the end of the experiments are much less effective, as the bed becomes thinner and thinner, which leads to lower shear stresses inside the bed.

4 Conclusions

Undrained failure of freshly deposited mud layers may be caused by pressure gradients on the bed surface, if the resulting shear stresses inside the layer locally exceed the yield strength. If the yield strength profile is known, failure can be well predicted using an elastic model to calculated shear stresses in the mud layer. For loosely packed layers, which have not yet been subjected to higher effective stresses than the actual effective stress, positive excess pore pressure are generated upon failure and liquefaction occurs. The strength of the layer is then much reduced, and a transition from predominantly elastic to predominantly viscous behaviour takes place.

Figure 7: Velocity profile $u(z, t)$ resulting from wave-induced liquefaction on a slope. $D_1 = 0.04$ m, $\rho = 1346$ kg m $^{-3}$, $\theta = 0.05$ rad, $h = 0.30$ m, $a = 10$ mm, $k = 2.49$ m $^{-1}$, $\omega = 3.93$ s $^{-1}$; rheological coefficients used are listed in Table 1

If the fluid mud layer generated by liquefaction starts to flow under the influence of a net force, e.g. gravity, very high transport rates in a short period of time are possible, as the concentration of the liquified mud equals the original bed concentration (generally a few hundreds kg m $^{-3}$). This may partly explain the large mud accumulations often observed in the field after a storm period. In order to model fluid mud flow, its rheological properties have to be studied first, taking into account shear rate dependent and thixotropic behaviour.

The transport mechanism described in this paper may be important for the redistribution of cohesive sediments in depositional areas, where layers of freshly deposited, still consolidating mud are present. In erosional areas, however, the surface layer has generally been buried in the past and is therefore more compacted. Also ageing effects will contribute to the strength which tends to be much higher than for surface layers in depositional areas. Liquefaction of these old layers is therefore unlikely.

CHAPTER 259

Wave on pebble beach and deformation of pebble beach

Ichiro Deguchi¹⁾, Masanobu ONO¹⁾ and Toru SAWARAGI²⁾

Abstract

Hydraulic function of pebble are investigated by carrying out 2-D experiments in laboratory. Numerical model for predicting wave height and wave run-up are developed by applying a Boussinesq type equation and a non-linear unsteady Darcy's law for the fluid motion on the pebble beach and in the pebble layer. The applicability of the model are examined using experimental results. Deformation of pebble beach are also measured in the field and laboratory to investigate the applicability of Dean's profile and to examine the shoreline change by a single-line theory.

Introduction

Urban coastal region in Japan have been developed in various ways for various purposes. Especially, after the World War II, through the post-war industrial reconstruction, Japan experienced a rapid and high economic growth. During that period, a large part of natural shoreline around big cities in Japan disappeared by the reclamation for heavy industries. As a result, public access to the shoreline decreased and natural coastal environment was lost. Recently, there are strong demands for restraining lost natural coastal environment and creating new pro-water front structures to increase public access to the coast and coastal amenity.

Target structure of this study is the pebble beach constructed as a permeable gentle slope seawall to increase public access and improve coastal view. It is usually permitted for such kind of pebble beaches to deform their profiles until they lose their originally expected function. The aims of this study are to examine hydraulic function of pebble beach and to establish numerical model for predicting wave transformation and run-up on pebble beach through carrying out two dimensional experiments. Characteristics of deformation of pebble beach is also investigated by using experimental results and field data.

2-D experiments on the hydraulic function of pebble beach

Experimental set-up and conditions:

Hydraulic function of pebble beach was examined by carrying out two-dimensional experiments in a laboratory. Figure 1 shows a rough sketch of the experimental set-up.

-
- 1) Department of Civil Engineering, Osaka University, Suita-city, Osaka 565, Japan
 - 2) Department of Civil Engineering, Osaka Sangyo University, Daito-city Osaka, Japan

We examined two slopes 1/10 and 1/5 constructed by pebbles of different sizes in a wave tank of 27m long, 1,9m high and 1,5m wide. To investigate the effect of permeability of the slope on incident wave, wave run-up, reflection, we also conducted the same measurements on the impermeable slope. The mean diameter D of the larger one was about 4.1cm and that of smaller one was 1.8cm. Table 1 shows the permeability k_p , turbulent drag coefficient C_f , added mass coefficient C_m and void ratio λ of these two pebbles obtained from the unsteady permeability tests. Depth at the horizontal bottom was varied from 25cm to 55cm and incident wave height was in the region of 6cm to 14cm with the period of 1.2s to 2.0s.

Surface displacement was measured between 0.5m landward from the shoreline and horizontal bottom. When deformation of pebble beach took place, we recorded the profile.

Figure 1 Experimental set-up

Table 1 Characteristics of pebbles

D (cm)	k_p (cm ²)	C_f	C_m	λ
4.08	0.0038	0.151	1.0	0.47
1.76	0.0015	0.255	1.0	0.46

Wave height distribution on pebble beach:

Figures 2 and 3 show measured cross-shore distribution of wave height on pebble beach and on impermeable slope of the slope 1/5 and 1/10. Incident wave period and height on horizontal bottom in both figure are 1.6s and 14cm and water depth at horizontal bottom was 50cm. Closed and open circles are the wave height and set-up measured on the impermeable slope and another symbols are the results obtained on the pebble beaches.

Wave height on pebble beach decreases significantly when compared with that on the impermeable slope. Especially the decay of wave height on the slope of 1/10 is large because incident waves have to travel for long distance on the permeable layer when compared with the case of the slope 1/5. On the other hand, there is little difference between the wave height measured on the pebble beaches of different sizes.

Figure 2 Wave height distribution on 1/5 slope

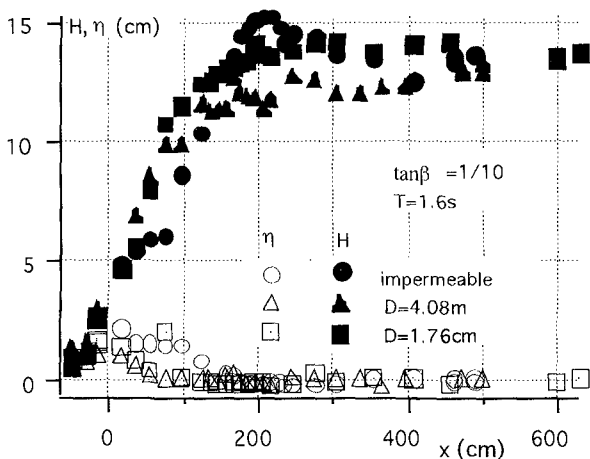

Figure 3 Wave height distribution of 1/10 slope

Wave run-up and reflection coefficient:

Figure 4 shows the non-dimensional run-up height normalized by the incident wave height R/H . The horizontal axis is the surf similarity parameter. Measured run-up height on pebble beaches shown by closed triangle and rectangle are 40 to 50% smaller than that measured on impermeable slope shown by the closed circles. Solid line in the figure show the relation $R/H = \xi$ that is usually applied to the run-up height on impermeable slope. Broken line in the figure is the empirical result for the non-dimensional run-up height on rubble mound breakwater obtained by Losada and Kurto(1981).

Figure 4 Wave run-up height

Figure 5 illustrates measured reflection coefficient K_r by Goda's method using two time series of measured surface displacements on the horizontal bottom. Horizontal axis is the incident wave steepness. The value of K_r in all cases are less than 30% and significant difference between the value of K_r measured on impermeable slope and pebble beaches can not be seen. K_r plotted in the region of wave steepness smaller than 0.005 is the result of long wave generated by a bichromatic waves.

Figure 5 Reflection coefficient

Solid and broken line in the figure are the reflection coefficient on the impermeable slope of 1/5 and 1/10 evaluated by the Mich's formulae.

Numerical model for predicting wave height distribution on pebble beach

We have already proposed a simple model for estimating wave height on the permeable slope (Deguchi et al., 1995). Definition of variables and coordinate system used in the model is illustrated in Fig.6. h is the depth on pebble beach and d is the thickness of the pebble layer. For evaluating wave height on the sloping beach, we apply nonlinear shoaling model proposed by Shuto(1974) with the energy dissipation

after wave breaking E_b , energy loss in the permeable layer E_p and surface drag on the pebble beach E_{fb} . These expressions are shown below:

Figure 6 Definition of variables

In the calculation, wave height on the sloping beach was firstly calculated from Eq.(1) by giving incident wave height at offshore. When the wave height became greater than wave breaking height, wave height was reduced according to the energy loss by wave breaking that is given by Eq.(2) (Sawaragi, et al., 1984).

$$\begin{aligned}
 gHT^2/h^2 \leq 30: & \text{small amplitude wave theory} \\
 30 \leq gHT^2/h^2 \leq 50: & Hh^{2.7} = \text{const.} \\
 50 \leq gHT^2/h^2: & Hh^{5/2}(\sqrt{gHT^2/h^2} - 2\sqrt{3}) = \text{const.}
 \end{aligned}
 \tag{1}$$

$$E_b = \alpha_1 \left(5.3 - 3.3 I_r - \frac{0.07}{\tan \beta} \right) \left(\frac{(\rho g H^2 / 8)^3}{\rho h^3} \right)^{1/2}
 \tag{2}$$

where ρ is the density of water, g is the gravitational acceleration, β is the slope, ξ is the surf similarity parameter and α_1 is the empirical constant of the order of one.

When waves propagate on pebble beach, wave height is also reduced by energy dissipation on the permeability and the surface drag that are expressed by Eqs.(3) and (4) (Sawaragi et al., 1992).

$$E_p = \frac{\rho g H^2}{4} C_g k_i
 \tag{3}$$

$$E_{fb} = \frac{2}{3} \pi^2 \frac{\rho f_w H^3}{T^3 \sinh^3 kh} (1 - \lambda)
 \tag{4}$$

where C_g is the group velocity, f is Jonsson's friction factor, and k_i is the imaginary wave number determined by the following dispersion relation on the permeable layer:

$$\sigma^2 = gk \frac{(S/f_e + i) \sinh kh \cosh kd + (1/f_e) \cosh kh \sinh kd}{(S/f_e + i) \cosh kh \cosh kd + (1/f_e) \sinh kh \sinh kd}
 \tag{5}$$

in which k is the complex wavenumber and f_e is the equivalent drag coefficient defined by using equivalent permeability k_{pe} as follow:

$$1/f_e = K_{pe} \sigma / \nu, f_e = 0.1 + 1.8(u/\sigma D_m)
 \tag{6}$$

Figure 7 is the comparisons of measured and calculated wave height and set-up on permeable and impermeable slope of 1/10. The mean diameter of the pebble on the permeable slope was $D=1.76\text{cm}$. Shift of the location of breaking point and decrease in wave height are reproduced well by the model.

Figure 7 Comparison of measured and calculated wave height

Numerical model for predicting wave run-up on pebble beach

Some numerical model have already developed to predict wave run-up on the permeable slope (for example, Kobayashi and Wurjanto, 1990). However, it is not sufficient to explain various non-linear phenomena including wave breaking, wave propagation into the permeable layer, wave run-up on the slope and so on. Here, we developed a numerical procedure for predicting surface displacement on the slope in a coordinate system shown in Fig.8. To construct numerical model, we neglected a vertical water particle velocity and applied Boussinesq type equation and a non-linear unsteady Darcy's law for the fluid motion on and in the pebble beach. Driving force of the fluid motion on and in the pebble beach is the pressure gradient. Although pressure on the pebble beach calculated from the Boussinesq equation is not hydrostatic, driving force on fluid motion in the pebble layer is assumed to be determined by the gradient of surface displacement. Definition of variables are shown in Fig.8.

Figure 8 Coordinate system and definition of variables

Equation of motion of water particles on and in the pebble beach are expressed as follows:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial \eta}{\partial x} = \frac{h}{2} \frac{\partial}{\partial x} \left[\frac{\partial}{\partial x} \left(h \frac{\partial u}{\partial t} \right) \right] - \frac{h^2}{6} \frac{\partial}{\partial x} \left[\frac{\partial}{\partial x} \frac{\partial u}{\partial t} \right] - D_1 \quad (7)$$

$$D_1 = \alpha_2 \frac{\partial}{\partial x} \left[\kappa g (h + \eta) \left(\frac{u}{h} \right)^2 \right] + \frac{\alpha_3}{h + \eta} f u |u| \quad (8)$$

$$S \frac{\partial u_d}{\partial t} + u_d \frac{\partial u_d}{\partial x} + g \frac{\partial \eta}{\partial x} = - \frac{\nu}{K_p} u_d - \frac{C_f}{\sqrt{K_p}} u_d |u_d| \quad (9)$$

$$S = \{1 + (1 - \lambda) C_m\} / \lambda$$

where u and u_d are the water particle velocity on the pebble beach and in the pebble layer, ρD_1 is the momentum dissipation, κ is Karman's constant, α_2 and α_3 are the empirical constants.

Equation of continuity of the fluid motion on the horizontal bottom and on the pebble beach are expressed by the following two equations.

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} [(\eta + h)u] = 0 \quad (10)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} [(\eta + h)u + h_d u_d] = 0 \quad (11)$$

In the region shoreward of the wave front on pebble beach, h in Eq(11) becomes zero.

These equations are transformed into finite difference equations and are solved by giving time variations of surface displacement and water particle velocity at the offshore boundary. Continuity condition of surface displacement inside and on the pebble beach is imposed. A so-called moving boundary condition is used to determine the location of wave front on the pebble beach.

Figure 9 illustrates a comparison of calculated and measured surface displacements in the breaker zone on the pebble beach of the slope 1/5 of large grain size.

Figure 9 Comparison of calculated and measured time variation of surface displacement

In the figure, $\eta(-50)$, $\eta(15)$ and $\eta(50)$ are the surface displacements at -50m , 15m and 50m from the initial shoreline, solid and broken lines are the calculated and measured surface displacement. Calculated and measured surface displacements in front of the pebble beach, $\eta(15)$ and $\eta(50)$, coincide well with each other. Calculated amplitude of the surface displacement in pebble beach, $\eta(-50)$, also reproduces the measured one. However, the time variation of measured surface displacement is smooth when compared with the calculated result and there is a small phase lag between them. Until now, we can not explain the reason of these discrepancy.

Figure 10 is an example of calculated surface profiles drawn at time interval of 0.2s on impermeable slope of $1/5$. Incident wave period is 2.0s .

Figure 10 Surface profile in front of impermeable slope and pebble beach

Figure(a) is the result on the impermeable slope and Figures(b) and (c) are the results on the pebble beach of different materials. The maximum run-up height on the impermeable slope is almost the same as the incident wave height. Run-up height on the pebble beach of large materials under the same wave conditions shown in Fig.(b) is smaller than the incident wave height and even in the permeable layer, surface displacement of the amplitude of more than 1cm exists. Run-up height on the pebble beach of small materials shown in Fig.(c) is almost the same as that in the former case but the amplitude of the surface displacement in the permeable layer is smaller than the former case.

Open symbols in Fig.4 are the run-up height determined from the calculated surface profiles examples of which are shown in Fig.10. Although the predicted run-up height on both pebble beach and impermeable slope are a little bit smaller than those of the measured results, the decrease in the run-up height on a pebble beach is expressed by the numerical model.

Characteristics of topography change of pebble beach

Field and laboratory experiments:

We examined the characteristics of the deformation of the pebble beach based on the bottom topographies measured in two dimensional experiments and field measurements. In the experiments, significant deformation took place only in the case of pebble beach of small materials of the slope of 1/5. Field measurement were carried out on the artificial pebble beach constructed as a gentle slope seawall of the reclamation just landward of the Kansai International Airport in Osaka Bay as shown in Fig.11. The total length of the beach is about 3km and we measured bottom topography in one section of the beach surrounded by two groins. The length of the section is 300m. Construction of the beach finished in March 1992. In this paper, characteristics of the deformation are discussed based on the measured results on October 1995 about 3.5years after the construction of the beach.

Figure 11 Location of field measurement

The representative planned cross-section of the beach is shown in Fig. 12. Average depth at the toe is about 5m and the slope of the beach is 1/15. The surface of the beach is covered by pebbles of marble of the diameter 4-10cm. The thickness of the cover layer is 1m. We call this beach as Marble Beach.

Figure 12 Representative cross-section of the Marble beach

Bottom topography was measured along 15 measuring lines set at an interval of 20m. Figure 13 illustrates the bottom topography when we see the beach from the land. There are groins at both side of this section.

Figure 13 Measured topography of Marble Beach

Characteristics of topography change took place on Marble Beach:

In Fig.13, two berm crests can be seen at the north side of the beach and it is easy to imagine that pebbles were transported landward to form landward berm at first stage of the deformation and then they were transported from south to north to form the

second berm. According to the empirical eigenfunction analysis, it is found that about 60% of the total deformation was caused by the longshore pebble transport and about 30% was caused by the net onshore pebble transport. Measuring line #15 is the north end of the beach and #8 is almost the neutral section for the topography change due to longshore transport.

Applicability of 2/3-power law:

Figures 14 and 15 are the representative cross-sections measured on the Marble Beach and in the laboratory.

Figure 14 Representative measured cross-sections of Marble Beach

Figure 15 Measured cross-sections in experiments

Both sections shown in the figure, as well as those shown in Fig.14, are the typical accretion-type profile. We examined the applicability of the 2/3-power-law to these sections. Bruun(1962) and Dean(1991) proposed the equilibrium beach profile that is expressed by Eq.(12).

$$h = Ax^{2/3} \tag{12}$$

where h is the depth of the equilibrium beach profile, x is the cross-shore distance and A is the empirical constant.

Dean (1991) gave physical meaning to Eq.(12) from the view point of energy dissipation in the surf zone and proposed the following empirical expression for the value of A as a function of settling velocity of the bed material W_f .

$$A = 0.067W_f^{0.44} \quad (13)$$

We examined the applicability of the expression of Eq.(12) to the measured profile of pebble beach in the laboratory and in the Marble Beach. Figures 16 and 17 are the results. Profiles of both laboratory and field roughly coincide with the predicted profiles with the value of A 0.34 and 0.4, respectively.

Figure 16 Comparison of Dean's profile and that measured on Marble Beach

Figure 17 Comparison of Dean's profile and that measured in experiments

Shoreline change:

To evaluate total energy flux to the beach, we used wave records measured at observation station near the Kansai International Airport where various quantities concerning with the sea state are measured at one hour interval.

The total incident wave energy flux are evaluated from south to north and from north to south separately. The result is shown in Table 2. Energy flux from south to north is larger than that from north to south. Using this result together with the calculated volume of pebbles that were transported from south to north, we determined

the longshore pebble transport rate and one representative wave to calculate location of contour line by a so-called one line theory.

Table 2 Incident wave energy flux in longshore direction (ton)

	1992	1993	1994	1995	total
from south to north	107280	178740	136656	68076	490752
from north to south	45720	61128	56988	32580	196416

It is found that the total longshore pebble transport rate Q_y is related to the longshore energy flux of incident waves in deep water by the following relation:

$$Q_y (m^3 / day) = 0.036(EC_g)_o \sin \theta \cos \theta (t / m / day) \tag{14}$$

where $(EC_g)_o$ is the incident wave energy flux in deep water and θ is the incident wave direction.

Figure 18 is the comparison of the calculated shift of the -4m contour line and measured location of the same contour line. As can be seen from the figure, -4m contour line almost becomes equilibrium 4 years after the construction and the measured location coincides calculated location fairly well. The measured contour line locates a little shoreward than the location of the calculated contour line. This is because the advancement of the contour line caused by the net onshore pebble transport is not taken into account in the calculated location of the -4m contour line.

Figure 18 Comparison of measured and calculated deformation of -4m contour line

Conclusions

In this paper, numerical models for predicting wave height and run-up on pebble beach are proposed and the applicability of the model are examined through the laboratory experiments. Although the proposed model is too simple to reproduce the phenomena perfectly, we can predict rough figure of the wave tun -up on pebble beach.

Characteristics of the deformation of the pebble beach are also investigated using measured bottom topography in the field and laboratory. It is found that we can apply a so-called $2/3$ -power law and a single line theory for the cross-sectional profile and shoreline change of pebble beach.

CHAPTER 260

Wind-Induced Waves and Currents in a Nearshore Zone

Nobuhiro Matsunaga¹, Misao Hashida² and Hiroshi Kawakami³

Abstract

Characteristics of waves and currents induced when a strong wind blows shoreward in a nearshore zone have been investigated experimentally. The drag coefficient of wavy surface has been related to the ratio u_{*a}/c_p , where u_{*a} is the air friction velocity on the water surface and c_p the phase velocity of the predominant wind waves. Though the relation between the frequencies of the predominant waves and fetch is very similar to that for deep water, the fetch-relation of the wave energy is a little complicated because of the wave shoaling and the wave breaking. The dependence of the energy spectra on the frequency f changes from f^{-5} to f^{-3} in the high frequency region with increase of the wind velocity. A strong onshore drift current forms along a thin layer near the water surface and the compensating offshore current is induced under this layer. As the wind velocity increases, the offshore current velocity increases and becomes much larger than the wave-induced mass transport velocity which is calculated from Longuet-Higgins' theoretical solution.

1. Introduction

When a nearshore zone is under swell weather conditions, the

3 Graduate student, Department of Earth System Science and Technology, Kyushu University, Kasuga 816, Japan.

Fig.1 Sketch of sediment transport process in a nearshore zone under a storm.

sediment transport process depends strongly on the wave-induced mass transport velocity. The process is relatively slow. On the other hand, a large amount of sediment is suspended and transported under a storm. The transport process under storm weather conditions is very different from that under swell weather conditions. Shepard (1950) observed the change of beach profiles along Scripps Pier, La Jolla, California. He revealed that a beach profile with longshore bars forms under storm weather conditions and a profile with pronounced berms develops under swell weather conditions. The former has been referred to as the winter profile, and the latter as the summer profile. Komer (1976) claims the use of terms 'storm profile' and 'swell profile' to be preferable.

Many researchers (e.g., Johnson (1949), Rector (1954), Iwagaki and Noda (1963)) investigated seasonal variations of beach profiles and obtained a critical wave steepness at which they change from the storm profile to the swell one. In their studies, the steepness of storm waves was regarded as the most important factor to determine the beach profile. However, it seems to be difficult to explain the sediment transport process under storm weather conditions without considering the wind effect. In the case when a strong wind blows shoreward, a strong onshore wind-driven current forms along a thin layer near the water surface, and the compensating offshore current along the bed (see figure 1). The offshore current may transport a large amount of sediment seaward because the concentration of suspended sediment increases to the seabed. After a storm, in fact, we can often see a beach being eroded remarkably and floating matters such as seaweeds and pieces of wood being cast ashore.

In this study, waves and currents formed in a nearshore zone under storm weather conditions have been investigated experimentally in order to understand the wind effect on the onshore-offshore sediment transport.

Fig.2 Experimental apparatus.

2. Experimental set-up

Experiments were carried out by using a water tank equipped with an inhalation-type wind tunnel. Figure 2 shows a schematic diagram of the experimental apparatus. The tank was 32 m long, 0.6 m wide and 0.94 m high. A sloping bed was attached to the end of the tank as a beach model. Its gradient was fixed at 1/30. The mean water depth was 0.3 m at the horizontal bed section. Wind waves were generated by the shoreward wind. Measurements of the wind velocity, wave height and wind-induced current velocity were made at positions 1 to 5. The distance from the intake of the wind to Position 1 was 11 m. The intervals between the adjacent measuring positions were 2.0 m. Positions 1 and 2 were in the horizontal bed section and positions 3 to 5 on the sloping bed. The wind velocity was measured by using a propeller-type current meter. In the wave height measurements, two capacitance-type wave gauges were used in order to obtain the phase velocity. They were set 28 cm away. The wave signals were digitized at the intervals of 1/50 s and 16,384 data were sampled. Horizontal and vertical components of the wind-induced currents were obtained by using an electromagnetic current meter. The sampling rate of the velocity signals was 1/20 s and the number of sampled data was 2,048.

Table 1 shows the wind parameters and the wave ones. Five tests in all were carried out by varying the wind velocity. The cross-sectionally averaged wind velocity U_m was varied from 7.60 m/s to 21.8 m/s. F is the fetch and h the mean water depth. The air friction velocity on the wavy surface is denoted by u_{*a} and the mean wind velocity at a 10 m height by U_{10} . H is the mean wave height. The periods, lengths and phase velocities of predominant waves are

Table 1 Experimental parameters.

represented by T_p , L_p and c_p , respectively. E denotes the total wave energy. The drag coefficient C_D is defined by $(u_{*a}/U_{10})^2$, and U_r is an Ursell parameter defined by HL_p^2/h^3 .

3. Experimental results and discussion

3.1 Drag coefficient of wavy surface

Vertical profiles of the mean wind velocity U in the case of $U_m = 15.5$ m/s are shown in figure 3, where z is the vertical coordinate taken upward from the mean water level. Though the wind velocity near the ceiling of the wind tunnel decreases due to the boundary layer, a logarithmic profile is formed near the water surface. The wind set-up increases the wind velocity and the velocity gradient near the water surface in the leeward direction. The values of u_{*a} were calculated by

Fig.3 Vertical profiles of mean wind velocity.

fitting the logarithmic law

$$U = \frac{u_* a}{\kappa} \ln \frac{z}{z_0} \quad (1)$$

to the wind velocity profiles, where κ ($= 0.4$) is von Karman's constant. It is read from table 1 that the values of $u_* a$ increase with increase of U_m and with increase of F . The drag coefficient C_D is defined by

$$C_D = \left(\frac{u_* a}{U_{10}} \right)^2 \quad (2)$$

The relation between C_D and U_{10} has been investigated until now by many researchers. Some of the empirical expressions and our experimental data are shown in figure 4. The data include ones obtained through other experiments in which the wind blew on swells made by a wavemaker. Though the U_{10} -dependence for the wind waves is different from that for the swell and wind waves, the data approach gradually to Kondo's empirical curve when $U_{10} \geq 25$ m/s. Some of our data are under the values to which the empirical curves

Fig.4 U_{10} -dependence of C_D .

Fig.5 Relation between C_D and u_{*a}/c_p .

approach with increase of U_{10} . The validity of these data remains to be proved.

The relation of C_D and U_{10} has been investigated from the standpoint of practicality. However, if we try to obtain a universal form for C_D , relations between C_D and dimensionless parameters should be examined. Figure 5 shows a relation between C_D and u_{*a}/c_p . The solid line is drawn by the least-square fit method. The discrepancy between the data for the wind waves and ones for the swell and wind waves becomes much smaller than that shown in figure 4. Increasing linearly with u_{*a}/c_p when $u_{*a}/c_p \leq 1$, C_D becomes constant for a large value of u_{*a}/c_p .

3.2 Wind waves in shallow water

It is well-known that the energy of wind waves in deep water and the periods of the predominant wind waves increase with increase of u_{*a} and F . The empirical fetch-relations proposed by Mitsuyasu (1968) are

$$\frac{gE^{1/2}}{u_{*a}^2} = 1.31 \times 10^{-2} \left(\frac{gF}{u_{*a}^2} \right)^{0.504} \quad (3)$$

and

$$\frac{u_{*a} f_p}{g} = 1.00 \left(\frac{gF}{u_{*a}^2} \right)^{-0.330} \quad (4)$$

where $f_p = 2\pi/T_p$. As read from table 1, the values of T_p in shallow water increase with increase of F but the values of E do not increase monotonically with F because of the wave breaking. We can also read that the increase of F corresponds to that of U_r . It means that the wind waves progress into a shallow region with increase of F . If equations (3) and (4) are rewritten by using the wave energy E_0 and the frequency f_{p0} at a standard point,

$$\frac{E}{E_0} = \left(\frac{F}{F_0} \right)^{1.008} \quad (5)$$

and

$$\frac{f_p}{f_{p0}} = \left(\frac{F}{F_0} \right)^{-0.330} \quad (6)$$

are obtained, where F_0 is fetch at the standard point. Equations (5) and (6) give the increasing rate of the wave energy to E_0 and the decreasing rate of the predominant wave frequency to f_{p0} , respectively. The

Fig.6 Comparison of fetch relation of E in shallow water with that in deep water.

Fig.7 Comparison of fetch relation of f_p in shallow water with that in deep water.

Fig.8 Variation of energy spectra of wind waves with increase of U_m .

Fig.9 Comparison between energy spectra before and behind breaking point.

values of E/E_0 are plotted against F/F_0 in figure 6, where the fetch to the breaking point is selected as F_0 . The breaking point of the wind waves is defined as a position at which E becomes maximum. The solid line expresses the relation given by equation (5). The dashed line is the best fit curve based on the data. In the offshore side from the breaking point ($F/F_0 < 1$), the increasing rate of E is a little larger than that in deep water. It may be caused by the wave shoaling. On the other hand, in the onshore side ($F/F_0 > 1$), the increasing rate decreases rapidly with fetch because of the wave breaking. Figure 7 shows the relation between f_p/f_{p0} and F/F_0 . The data collapse well onto the curve given by equation (6). It means that the decreasing rate of f_p in shallow water agrees well with that in deep water.

Figure 8 shows energy spectra $\phi(f)$ of wind waves measured at Position 2. The total energy increases with increase of U_m because no wave breaking occurs at Position 2. The values of $\phi(f_p)$ become large with the U_m -increase and the values of f_p become small. These are the same features as in deep water waves. The f -dependence of $\phi(f)$ in the high frequency region changes from f^{-5} to f^{-3} as the wind velocity increases. The spectral form in an equilibrium region is given by

$$\phi(f) \propto g^\alpha u_* a^{2-\alpha} f^{-3-\alpha} \quad (7)$$

with the aid of a dimensional analysis, where g is the gravity acceleration and α an arbitrary constant. In the case when the effect of the gravity is much larger than the wind effect, α takes 2. At that time, $\phi(f)$ is proportional to f^{-5} in the high frequency region. On the other hand, as the wind velocity increases, it can be guessed that the effect of the gravity becomes small and $\phi(f) \propto f^{-3}$ in the limit. These dimensional considerations are supported by the results shown in figure 8.

Figure 9 shows the energy spectra of wind waves at positions 1 to 5. It is seen that the energy of the predominant waves decays remarkably due to the wave breaking.

3.3 Wind-induced currents

Figures 10 (a) to (e) show vertical profiles of wind-induced currents. Here, u is the horizontal component of the current velocity and the negative value indicates that the current is offshore. The vertical axis z is normalized using the local water depth h . Offshore wind-induced currents are formed in the range of $-1.0 \leq z/h \leq -0.1$. This suggests that an onshore strong current is generated in a thin layer near the water surface. As a natural result, the offshore currents

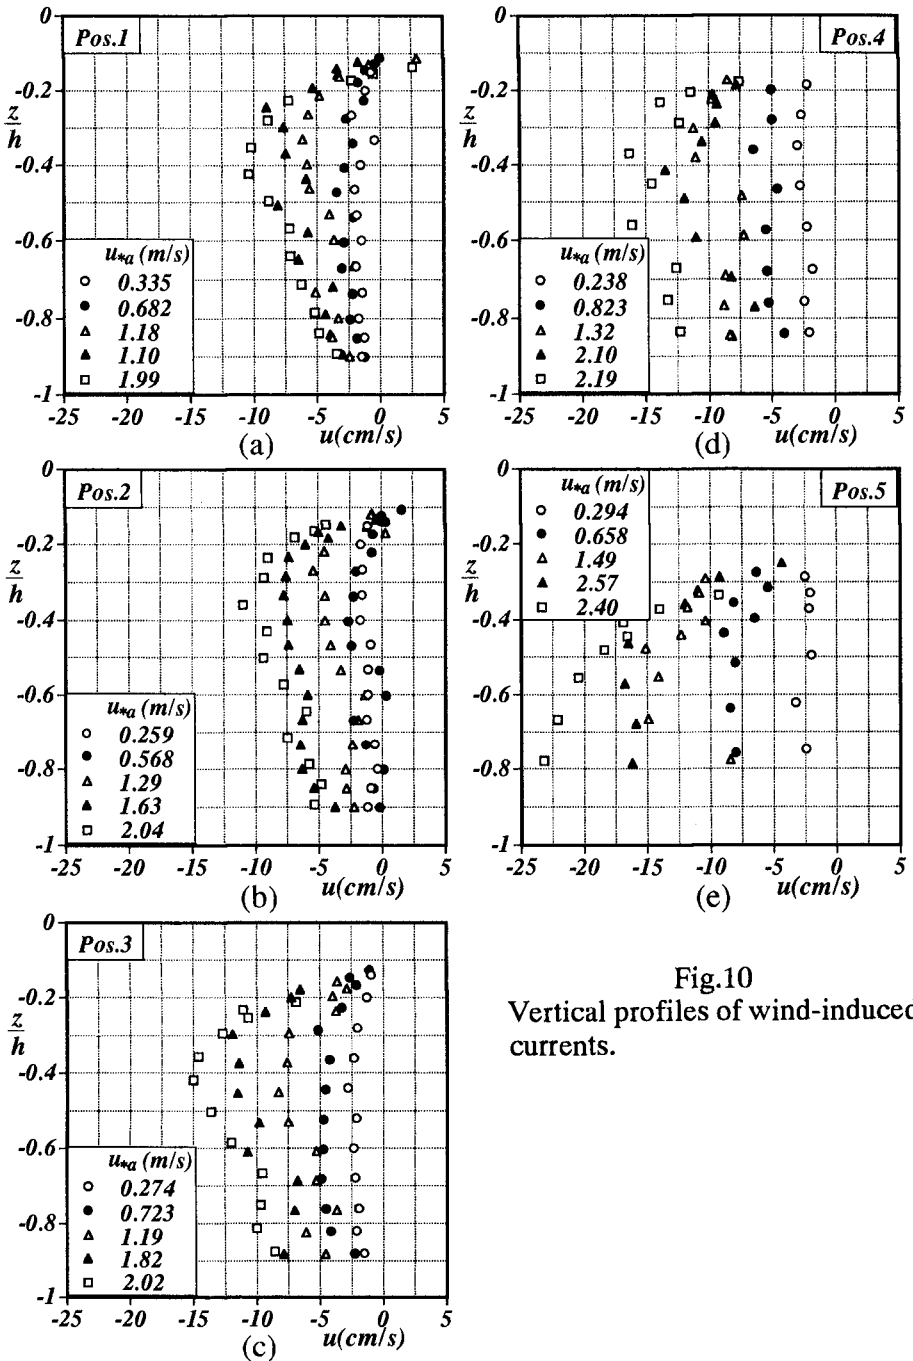

Fig.10
Vertical profiles of wind-induced currents.

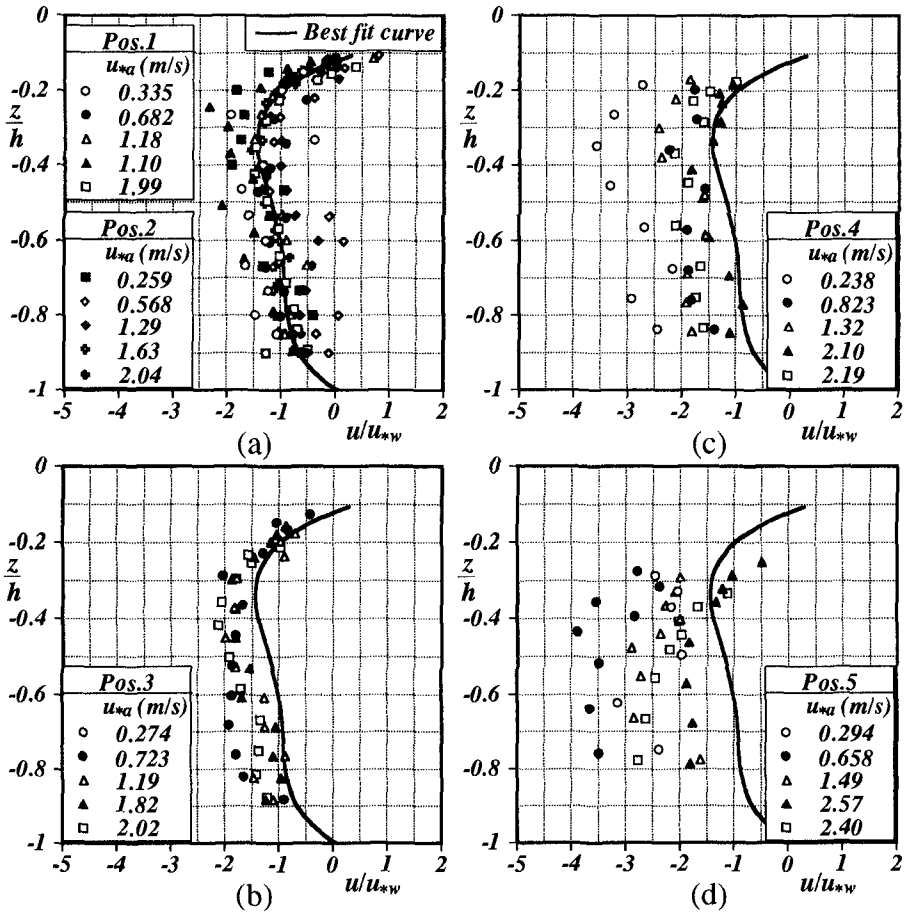

Fig.11 Normalized vertical profiles of wind-induced currents.

become stronger as u_{*a} increases and as the water depth decreases.

In figures 11 (a) to (d), the values of u are normalized by using the water friction velocity u_{*w} calculated from $(\rho_a/\rho_w)^{1/2}u_{*a}$. Here ρ_a and ρ_w are the densities of air and water, respectively. The values of u/u_{*w} at positions 1 and 2 are expressed approximately by the solid line (see figure 11 (a)). It may be due to that the wind-induced currents on a horizontal bed are uniform in the flow direction and the current velocity increases in proportion to u_{*a} . The maximum velocity of the offshore currents takes about $1.5u_{*w}$ at $z/h = -0.3$. Figures 11 (b) to (d) show the normalized vertical profiles for positions 3 to 5, respectively. The solid lines in these figures are the one drawn in figure 11 (a). It is

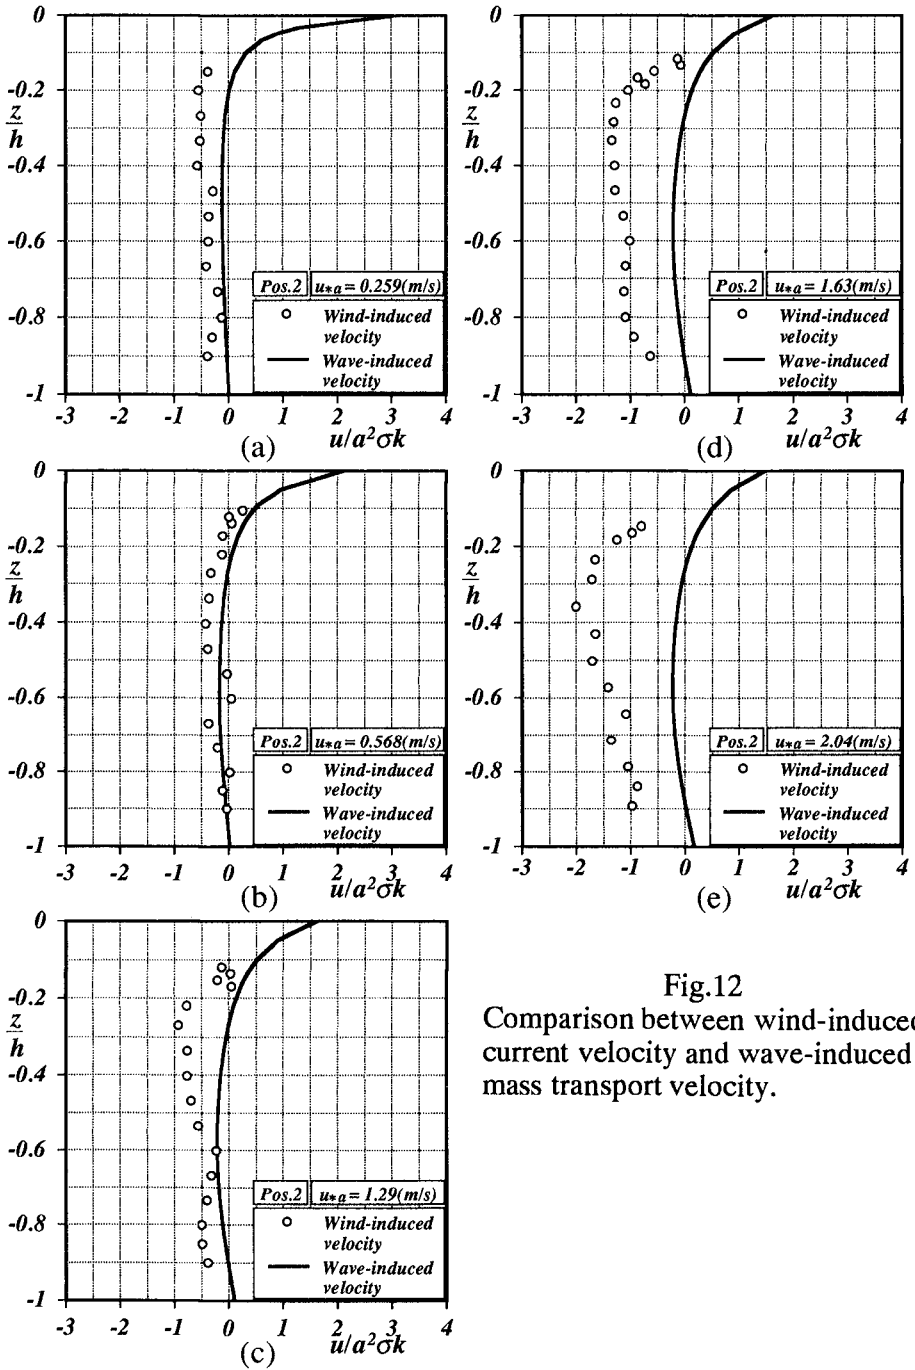

Fig.12
Comparison between wind-induced current velocity and wave-induced mass transport velocity.

difficult to express universally the vertical profiles on the sloping bed by using u_{*w} and h , because even if u_{*w} is uniform in the leeward direction, the water depth variation makes the offshore currents accelerate. In fact, the values of u/u_{*w} increase in the leeward direction.

Dimensionless velocity profiles of the wind-induced currents at Position 2 and the wave-induced currents are compared in figures 12 (a) to (e). The wave-induced velocity is estimated by using Longuet-Higgins' theoretical solution (Longuet-Higgins (1953)) and the measured values at Position 2. The theoretical results are drawn by the solid lines. The wave amplitude a , frequency σ and wave number k are given by $H/2$, $2\pi/T_p$ and $2\pi/L_p$, respectively. From these figures, it is seen that the wind-induced currents become much larger than the wave-induced currents as the values of u_{*w} increase. This suggests that the wind effect on the sediment transport under storm weather conditions is very important rather than the increase of wave steepness.

4. Conclusions

In this study, the characteristics of waves and currents formed in a nearshore zone under storm weather conditions have been investigated experimentally. The obtained main results are as follows.

- 1) The drag coefficient of wavy surface C_D is related to u_{*a}/c_p . The values of C_D increase monotonically with increase of u_{*a}/c_p but become constant for a large value of u_{*a}/c_p .
- 2) In the offshore side from the breaking point, the increasing rate of the total wave energy in shallow water is a little larger than that in deep water because of the wave shoaling. However, the increasing rate reduces remarkably in the onshore side from the breaking point due to the wave breaking. The decreasing rate of the predominant wave frequency in shallow water agree well with that in deep water.
- 3) The wind-induced current velocity increases with the wind velocity and becomes much larger than the wave-induced current velocity. Therefore, the wind effect is very important in the sediment transport process under storm weather conditions.

The authors are grateful for a grant from the Ministry of Education, Science and Culture.

CHAPTER 261

PREDICTING LARGE-SCALE, CROSS-SHORE SEDIMENT MOVEMENT FROM ORBITAL SPEEDS

Edward B. Hands¹, John P. Ahrens², and Donald T. Resio³

ABSTRACT: The ratio U of near-bed peak orbital speed to grain threshold speed should express the competence of coastal waves to agitate loose seafloor sediments. Using Stream Function Wave Theory, U can be evaluated separately under the wave crest U_C and trough U_T to produce a pair of parameters whose relative magnitudes indicate the direction of the displacing force. The authors tested this simple parametrization in two distinctly different, large-scale coastal transport situations. One situation involved relative stabilities and displacements of submerged dredged-material mounds outside the normal surf zone. These mounds contained 10s to 100s of thousands of cubic meters of sandy material. Predicted wave responses match well with measurements made over months and years at 11 such mounds widely scattered around the United States. The second situation involved predicting whether beaches accrete or erode during single storms. Comparison between U -based predictions and 99 beach responses, compiled from the published literature, provided good confirmation in the second situation.

Critical values of U are surprisingly skillful in predicting both types of cross-shore movement. Where extreme U_C 's exceeded U_T 's by more than about 5, mounds migrated shoreward; where waves were more linear, mounds remained stationary. Beaches eroded significantly where $U_T < -2$; and accreted otherwise regardless of the degree of wave linearity.

INTRODUCTION

Purpose

Two very simple critical conditions “explain” different types of coastal sediment dispersion. Either the tested large-scale laboratory and field studies fail to capture some significant class of conditions or the relative speed of bottom wave oscillations and sediment thresholds is the dominant factor controlling coastal profile response from the shoreline to well offshore. Broad-scale predictors, even if not precise, are useful to engineers who must often work with limited input data. Accordingly, the profile adjustment predictors developed here depend on the height and period of the wave, size and density of the sediment, and depth and density of the water.

Background

Artificial beach nourishment is a widely popular form of storm damage reduction. Good uses for dredged sands that improve cost-to-benefit ratios of inlet channel maintenance are of keen interest to coastal managers. Much of the sand dredged continually to maintain navigation can be used to reduce coastal storm damages. Several new uses involve designing submerged mounds to either shelter adjacent shorelines from erosive waves or cost-effectively augment the natural sediment supply to the coast (Bodge 1994 a 1994b; Foster, Healy, and de Lange 1996; Hands and Resio 1994; Landin, Davis, and Hands 1995; Stive et al. 1992). Motivated by the need for an easy method to determine which conditions move sand onshore and offshore, we found two velocity parameters to be effective predictors in widely disparate transport situations.

DEFINITION OF PARAMETERS

Both parameters are ratios of near-bed oscillatory peak speeds (NOPS) to the sediment threshold speed, i.e., $U \equiv u_{d \max} \div u_{\text{crit}}$, where $u_{d \max}$ is the NOPS and u_{crit} is the threshold speed required to initiate motion of selected grain sizes. As waves approach shore, orbital speeds increase under narrowing crests while decreasing under widening troughs. A pair of parameters results if a nonlinear theory is used to evaluate U separately under the wave crest (U_c) and trough (U_T). Differences ($U_c - U_T$) may be crucial especially in contrasting nearshore transport effects of steep storm waves versus gentle swell.

METHODS OF APPLICATION

NOPS were determined from Dean's (1974) Stream Function Wave Theory (SFWT). SFWT contains the crucial nonlinearities and is easy to apply because extremely accurate regression equations were developed in this study for a suitably wide range of conditions ($0.002 \leq d/L_0 \leq 0.20$ and $H_b/4 \leq H \leq H_b$, where d is water depth, L_0 is the deepwater wave length, H is local wave height, and H_b is the breaking wave height).

Under the wave crest,

$$u_{-d \max c} = \left(\frac{H}{T} \right) \left(\frac{d}{L} \right)^{-0.579} e^{0.289 - 0.491(H/d) - 2.97(d/L_o)} \quad (1)$$

where T is the wave period and L is the local wave length. Under the trough,

$$u_{-d \max t} = - \left(\frac{H}{T} \right) e^{1.996 - 1.73(H/d) - 8.70(d/L_o) + 5.58(H/L_o)} \quad (2)$$

More information on fitting near-bed speeds to Stream Function Wave Theory will be provided in Ahrens and Hands 1997.

If the representative grain size $d_{50} \leq 2 \text{ mm}$, threshold speeds come from Hallermeier (1980)

$$u_{crit} = \sqrt{8 \gamma g d_{50}} \quad (3)$$

where γg is the grain to fluid ratio of unit submerged weights. If $d_{50} > 2 \text{ mm}$, threshold speeds come from Komar and Miller (1974)

$$u_{crit} = \left[0.47 \gamma g T^{1/4} (\pi d_{50})^{3/4} \right]^{4/7} \quad (4)$$

For application to long-term fates of submerged mounds, where wave conditions fluctuated over a wide range, NOPS were calculated for an arbitrary, but common representation for wave extremes: the 12-hr/year exceedance value. Threshold speeds were calculated based on median grain sizes as sampled soon after mound placements.

For discrimination between beach erosion and accretion, the threshold speeds were calculated for the reported typical beach grain sizes. The breaker depth was selected as a reasonable standard location at which threshold ratios (U_c and U_T) are compared. This reference depth was obtained by fitting a breaker depth index to the SFWT data to obtain

$$d_b = 0.68 \left(\frac{L_o}{2\pi} \right) \ln \left(\frac{1+s}{1-s} \right) \quad (5)$$

where $s = H_b / 0.171 L_o$ and H_b comes from Kaminski and Kraus's (1993) expression for the breaker height index

$$\frac{H_b}{H_o} = 0.46 \left(\frac{H_o}{L_o} \right)^{-0.26} \quad (6)$$

RESULTS

The skill of these new U parameters is determined by applying them to a number of published laboratory and field studies. The single parameter U_T shows considerable and unsuspected skill in predicting erosion or accretion of beaches. Surprisingly, the seaward-directed component better discriminates between eroding and accreting beaches. Combining both parameters, U_C and U_T , explains observed movement of the 11 test mounds.

Response of Shore Profiles from Large Wave Tank Tests

Larson and Kraus (1989) published results from two sets of large-scale wave tank tests. One set was run with monochromatic waves at the Coastal Engineering Research Center (CERC) (Saville 1957). The other set was run at the Central Research Institute of Electric Power Industry in Japan (CRIEPI) (Kajima et al. 1982). Deep-water wave heights were in the range of $0.30 < H_o < 1.78$ m, wave periods were in the range of $3.0 < T < 16.0$ sec., and sediment sizes were in the range of $0.22 < d_{50} < 0.47$. These laboratory conditions thus cover a wide range of prototype conditions.

Erosional profiles had no berm above uprush and at least one pronounced bar offshore; *accretional* profiles had a prominent berm and no bar formations. Kraus et al. (1991) has shown that H_o/L_o and $H_b/w_f T$, where w_f is the sediment fall velocity, correctly categorize these two types of storm profile changes. Dalrymple (1992) combined Kraus's two variables into a single profile change predictor.

Figure 1 shows *accretional* (A) and *erosional* (E) profile responses as functions of U_C and U_T . Profile transitions during the storms were *erosional* if U_T was less than a critical value near -2. In other words, if magnitude of NOPS under the trough was greater than twice the grain threshold speed, the storms ended with *erosional* profiles. Otherwise profiles became *accretional*. Even events with high U_C values remained *erosional* so long as the critical value of U_T remained less than -2.

Skill is a simple statistical measure for quantifying the performance of a categorical predictor on a given set of data (Seymour and Castel 1989). *Skill* equals the ratio of correct predictions to total observations. Using $U_T = 1.8$ as a threshold level, there is one miscategorized erosion and one miscategorized accretion in the 32 tank results, for a predictive skill of 0.94.

Figure 1 Large wave tank data

Storm Response of Shore Profiles from Field Measurements

Kraus and Mason (1991) compiled and standardized 99 cases of storm profile change from field studies published by many researchers worldwide. Seventy-two cases were *erosional*. Twenty-seven were *accretional*. To qualify as *accretional* the storm had to have resulted in a notable seaward advance of the shoreline, a buildup of the subaerial berm, or a landward movement of the longshore bar. Kraus et al. (1991) used this data set, along with the previously presented results from large wave tank tests, to develop discriminators between *erosional* and *accretional* storms. In the field data set, deepwater significant wave heights ranged from 0.08 to 7.90 m, wave periods from 2.0 to 15.3 sec, and sediment sizes from 0.17 to 3.5 mm. Wave periods were associated with either deepwater significant wave height or the spectral peak.

Accretional and *erosional* type profiles are denoted in Figure 2 as functions of U_C and U_T . U_T discriminates well between *erosional* and *accretional* profiles at a value around -2, just as for the laboratory data. And if $U_T < -2$, *erosional* profiles occur even if U_C is quite large.

Figure 2 Field beach profile data

Using $U_T = -1.90$ as the discriminator, three cases are miscategorized as *erosional* and three are miscategorized as *accretional* in this field data set of 99, for a predictive skill (0.94) similar to that of previously proposed criteria. The skill of Dalrymple's (1992) criterion on this field data is 0.94 and the favored pair one of eight criteria examined by Kraus et al. (1991) had a skill of 0.91. Largely by coincidence, the skill of U_T on field and laboratory data are identical. More importantly, the critical U_T threshold levels are essentially equal for both field and large wave tank results.

Long-Term Response of Submerged Mounds

Nearshore placement of feeder deposits is an increasingly attractive form of erosion protection offering a variety of environmental, social, and economic benefits (Bodge 1994a and b; Bruun 1988; de Lange and Healy 1994; Foster, Healy, and de Lange 1994; Foster, Healy, 1996; Mulder, van de Kreeke, and van Vessem 1995; Roelvink and Stive, 1988; Russell, Robinson, and Soward 1994; Uda, Naito, and Kanda 1991; Zenkovich and Schwartz 1987). Hands and Allison (1991) compiled results from feeder mound tests and developed criteria to distinguish between stable nearshore deposits and others that moved promptly shoreward. Those mound criteria were used to identify conditions where dredged material mounded outside the surf zone acts not only as a temporary wave dissipator, but also gets pushed shoreward to nourish the surf zone.

Eleven reference mounds monitored in the United States have been categorized as *active* or *stable* depending on whether repeated surveys indicated significant loss of material from the placement area. All but one of the *active* cases showed clear shoreward displacement of mound centroids. Evidence of change was always identifiable within months. *Stable* mounds remained stationary without evidence of dispersion or displacement for years (Hands 1991). Wave forces appear to be the dominant factor in moving mounds landward (Hands and Resio 1994, Douglass, Resio, and Hands, 1995). There has never been strong evidence of any seaward movement at the test sites.

Table 1 lists the locations of all 11 field test mounds, pre-mound water depths, median grain sizes of placed material (d_{50}), wave parameters, and indicators of which mounds were *active* (A) and which *stable* (S).

Table 1 Dredged Mound Data

Site Location	Mound Depth (m)	Smaller of $H_{99.863}$ or H_b (m)	\bar{T}_A (sec)	Grain Size d_{50} (mm)	Stable or Active	U_C	U_T
Long Island, NY	4.6	2.4	8.0	0.40	A	7.20	-3.27

* = only case with $H_b > H_{99.863}$

To test the velocity ratios, the full time series of waves were transformed to each mound from the nearest offshore Wave Information Study hindcast site. Velocity ratios were evaluated using transformed spectral peak heights and average associated peak periods, T_A , i.e., the average period of all waves having a height within 0.1 m of the 99.863 percentile nonexceedance wave height ($H_{99.863}$). This wave height was chosen

to match Hallermeier's (1980) selection of the 12-hr/ year exceedance wave height as the determinate for beach profile zonation. Use of $H_{99.863}$ to calculate the velocity ratio is also consistent with its use in the Empirical BERM model (Hands and Resio 1994). In only one case would this extreme wave have broken before passing over the mound. It seems reasonable in such a case to use the H_b estimated from SFWT. Both approaches gave identical results, however, to within the two significant figures used here.

Mound responses are denoted in Figure 3 as functions of U_C and U_T . In the mound situation, U_T alone is a poor discriminator. U_C and U_T are both needed. *Stable* mounds have smaller values of U_C than active mounds for approximately equivalent values of U_T . The $U_C = U_T$ line indicates the limiting condition for NOPS which is reached only by linear waves. Above this line a curve follows the trend between *active* and *stable* mounds.

Figure 3 Field mound response data

Bivariate classification of the reference mounds does not imply one should expect unambiguous behavior at future mounds. An ill-defined zone of uncertainty separates the two classes. Occurrence of a severe storm or extended periods of unusual calm will affect a mound's response and the accuracy of any climatological-based prediction. And the role of unusual storms should be most critical for the mounds in the transition zone separating expected *stable* and *active* regions.

Earlier Approach for Mound Predictions

Hallermeier (1977) proposed a sediment entrainment parameter to characterize fluid motion at the onset of intense bed agitation. This parameter had the form of a Froude number which Hallermeier (1980) simplified using linear wave theory to obtain his two profile zonation limits. Hands (1991) used dimensionless ratios of these profile limits to mound depths as feeder-berm citing criteria. Linear theory was also used to show that the distributions of predicted near-bed oscillatory speeds from hindcasted waves could be used to distinguish between *active* and *stable* mound sites (ibid.). The new approach, presented here, is the first attempt we know to improve mound predictions by advancing beyond linear wave theory.

Revised Approach for Evaluation of Nonlinear Oscillatory Speeds

Threshold ratios presented here are very much works in progress. The form of the threshold ratios, the theory and procedure for evaluating oscillatory speeds, and alternative methods for summarizing distributions have not been thoroughly explored. We briefly examined the impact of basing the criteria on deepwater, local, and breaking wave heights; fitting $u_{-d \max}$ instead of U to SFWT, and optimizing fit in terms of U_T instead of to both U_T and U_C because only the single criterion seems necessary for erosion prediction. These variations led to considerable differences in the spread of U_T and U_C values, yet, each of these versions support the same conclusions except for small adjustments as to the best critical values. With different versions, the critical U_T for beach erosion field data ranged from -1.8 to -2.3. Present uncertainties about sediment transport and the limited available prototype data do not support refinement of details. Fortunately threshold ratios seem to be robust with respect to tested methods of evaluation.

SUMMARY

Simple threshold ratios indicate tendencies for waves to drive cross-shore sediment fluxes. These ratios combine oscillatory peak speeds with initiation of movement criteria. The given equations are applicable over a wide range of indicated wave conditions and sediment sizes. Results from testing these ratios against known laboratory and field data produce trends consistent with present understandings of onshore and offshore sediment movement under waves.

The single parameter U_T shows considerable and unexpected skill (0.94) in distinguishing between beach erosion and accretion. Surprisingly, the speed under the trough is more diagnostic than under the crest. In fact U_C seems to be unimportant for predicting the shore profile change. Both parameters, U_T and U_C , are necessary, however, to predict responses of nearshore mounds built of sand- to silt-sized dredged material. While experiences with mounds is limited and many cases cluster close to the discrimination boundary, the present approach has an advantage over previous methods given by Hands (1991), because U captures the inherent nonlinearity of waves nearshore

and provides a logical explanation for the noted preferential shoreward movement of *active* mounds.

CONCLUSIONS

Admittedly, this presentation does not investigate the mechanics of sediment motion and thus does not offer a general solution to cross-shore coastal transport. Nevertheless, we hope our results focus more attention on what certainly seems to be the dominant effect of nonlinear wave motion in some important coastal situations. The success of U criteria over the demonstrated range of wave conditions, water depths, and grain sizes seems to justify their adoption as simple decision criteria needed now to help manage coastal sediment resources. For long-term mound movement, the option of using a more encompassing parameter to represent ranges of near-bed fluid motion seems promising as an easy improvement that should characterize the net effect of the range of waves impacting mounds over their months and years of migration. On a spatial scale, some broader measure of surf conditions may offer improvements over the simple default to breaker conditions tested first.

Obviously, however, wave effects are more complex than can be represented by peak bottom speed and many other factors affect sediment motion (e.g., bottom slope, bed forms, cohesive particle forces, and other currents). Net effects of wave groupiness, undertow, grain inertia, and intra-wave phase lags between stress and sediment concentration and a time-varying eddy viscosity are simply lumped in a single critical ratio. The fact that such a simple characterization as U , even with reduction of NOPS distributions to a default percentile, produced a more than acceptable correlation with laboratory and field data, will hopefully spark theoretically based improvements.

ACKNOWLEDGMENTS

Support from the NOAA Sea Grant Office and the U.S. Army Engineer Waterways Experiment Station is acknowledged, especially the recently concluded Dredging Research Program for collecting mound response data and the new Dredging Operations and Environmental Research Program for follow-on analyses. Comments and suggestions from Mr. Thomas W. Richardson and Drs. Nicholas C. Kraus and Andrew Morang were very helpful and are greatly appreciated. The first author received permission from Headquarters, U.S. Army Corps of Engineers, to publish this information.

CHAPTER 262

Small-scale Morphology Related to Wave and Current Parameters Over a Barred Beach

A.F. Garcez Faria¹, E.B. Thornton¹, T.P. Stanton¹

ABSTRACT: Small-scale morphology (< 5 m horizontal wavelength) was measured by combining CRAB surveys with bed elevations acquired from a 1 MHz sonic altimeter mounted on the CRAB during the DUCK94 experiment in October 1994. Bedform plan views were recorded simultaneously using a 500 KHz side-scan sonar mounted on the CRAB. Waves and currents were measured at the same time. Three cases are examined in detail: mild waves and weak longshore currents resulting in wave ripples throughout the study area; narrow-band, normally incident waves with a strong rip current resulting in a planar bed except in the throat of the rip where mega-ripples were measured; and storm waves with strong longshore currents resulting in lunate and straight-crested mega-ripples in the trough of the barred beach. During these strong current days, bed shear stresses calculated from logarithmic velocity profiles are equated to a quadratic bottom shear stress formulation. The associated bed shear stress coefficients vary by more than an order of magnitude across the surf zone (0.0006-0.012). Bottom roughness was obtained by calculating the wavenumber spectra of the bed. The bed shear stress coefficients are positively correlated with bottom roughness (linear correlation coefficient, 0.68). A higher linear correlation coefficient (0.80) is obtained by subtracting skin friction from the total bed shear stress.

INTRODUCTION

The nearshore bed on a barred beach is composed of complex bedforms caused by varying wave and current regimes. With the exception of wave ripples in deeper water, few quantitative observations of bedforms are available, especially in the nearshore, and simultaneous quantitative wave and current measurements are almost non-existent. The lack of data is due to difficulties in making measurements in the nearshore. Observations historically have been made by divers who are limited by visibility and the harsh nearshore environment, which can become unfavorable for observations even in the mildest of storms.

Earlier field measurements were reported by Dingler and Inman (1976), which profiled wave ripples using a moveable acoustic altimeter placed on a track on the bottom outside the surf zone, but were limited to a single track of approximately 2 m in length. Other methods have included using waxed combs pushed into the bed by divers to record ripple profiles. Miller and Komar (1980) found ripple wavelength to be related to the orbital diameter of the waves.

The measurements described in this paper were made in shallow water (< 8 m) where shoaling and breaking waves are typically asymmetric, resulting in asymmetric bedforms. A conceptual view of wave-induced small-scale morphology on a barred beach is summarized by Clifton (1976) based on diver observations, which describes the asymmetric transition of bedforms with increasing velocity from long-crested

¹Oceanography Department, Naval Postgraduate School, Monterey, CA, 93943-5000, USA; E-mail: faria@oc.nps.navy.mil; Tel: +1 408 656 2379; Fax: +1 408 656 2712.

ripples, to irregular ripples, to cross-ripples, to lunate mega-ripples on the seaward slope of the bar, to a planar bar crest where the waves break, and to wave ripples again in the trough where wave intensity decreases after waves cross the bar. These are the least observed nearshore bedforms owing to difficulties in obtaining quantitative measurements.

The objective of this paper is to correlate small-scale morphology measured over a barred beach with waves and currents. In the following sections, a description of the DUCK94 experiment, the methodology of the data analysis, the description of the small-scale morphology observed on Oct. 8, 12, and 20, and the relationship between measured bottom roughness and bed shear stress are presented.

DUCK94 EXPERIMENT

The measurements described here are part of the comprehensive nearshore DUCK94 experiment conducted during October 1994 at the U.S. Army Corps of Engineers Field Research Facility (FRF), Duck, North Carolina. The weather during October was climatologically characterized by three distinct phases: weak currents and winds from the north (4-9 Oct.), relatively strong currents from the north (0.6-1.0 m/s) caused by a storm with predominant winds and waves from the north (10-12 Oct.), and variable currents and winds from the north/south (13-21 Oct.).

The morphology of the bottom (bathymetry) was measured at various scales using the Coastal Research Amphibious Buggy (CRAB). The surveys were performed daily during the experiment by driving the CRAB in a series of cross-shore survey lines with alongshore separation of 25 to 30m. Large-scale variations of bathymetry were obtained by recording the CRAB position using a laser ranging/auto-tracking system approximately every meter (order 3 cm rms vertical and horizontal accuracy). Three-dimensional, large-scale morphology mapped by the CRAB during the three periods of interest (8, 12, and 20 Oct.) are shown in Fig. 1.

Small-scale vertical bottom variations relative to the CRAB, including ripples and megaripples, were measured with a 1 MHz sonic altimeter mounted on the CRAB 70 cm from the bed. The altimeter has a nominal sampling rate of 25 Hz, which resulted in a sample spacing of 2-4 cm (dependent on CRAB speed) with mm vertical resolution and accuracy less than 2 cm (Gallagher *et al.*, 1995). The decrease in accuracy relative to resolution is due to the changing reflective surface owing to the bed dialating or sediment transported along the bed as waves pass overhead. The CRAB survey and altimeter measurements were combined to obtain a high resolution description of the bottom (Thornton *et al.*, 1996).

A 500 KHz side-scan sonar suspended in the center of the CRAB approximately 1.25 m from the bed generates high-resolution plan views of the morphology. The nominal horizontal range of the sonar was approximately 10 to 15 m to each side of the sonar, which allowed overlap of sonar data from adjacent survey lines, giving a relatively complete view of the geometry and spatial representation of the ripple features.

Corroborating wave and current data were acquired using an instrumented sled. A vertical stack of eight Marsh-McBirney two-component electromagnetic

current meters (cm's, hereafter) with 2.5 cm diameter spherical probes were mounted on a 2.5 m mast to measure vertical profiles of longshore and cross-shore currents. The sled was oriented with the vertical stack of current meters placed on the up-current side to prevent the sled structure from contaminating flow measurements. Waves and mean water level were measured using an array of five pressure sensors configured in a 3 m square with sensors at the corners and one at the center. For data collection, each morning the sled was towed by the CRAB to its furthest position offshore, dependent upon wave conditions, for the first data run. A forklift on the beach pulled the sled shoreward approximately 10 to 30 m for each subsequent run. Data were acquired at each location for approximately one hour at four to eight locations. Additionally, directional wave spectra were acquired using a linear array of 10 pressure sensors in 8 m depth offshore of the survey area.

METHODOLOGY

The bottom roughness is examined by calculating wavenumber spectra of the bed. To calculate wavenumber spectra, the unevenly spaced data from the combined CRAB surveys and altimeter measurements are linearly interpolated to evenly spaced 2 cm increments of the cross-shore distance. The small-scale morphology in general shows large cross-shore variation; as a consequence, the condition of spatial homogeneity (stationarity) required for calculating averaged spectra is not met. Therefore, continuous wavenumber spectra are calculated for 20 m cross-shore segments at increments of 1 m across the surf zone. Lowest wave numbers are filtered by subtracting a third-order polynomial best-fit curve from each 20 m section. A 10 percent eosine-taper data window is applied. The spectra are summed over three wavelength bands (0.4 - 0.83 m, 0.83 - 1.67 m, and 1.67 - 5 m) plus the total band (0.4 - 5 m), resulting in 52, 24, 16, and 92 degrees of freedom for each band respectively. The wavelength bands chosen are based on examination of individual spectra that were generally broad, indicating that several ripple wavelengths coexisted as a result of newly formed ripples combining with residual ripples from the past to form a complex series of ripple patterns. The *rms* height of each band is calculated as the square root of the variance within each band. The general trend is that the bottom was smoothest offshore and over the bar where wave ripples were planed-off due to higher near-bottom velocities, with increased roughness within the trough associated with mega-ripples (see Thornton, *et al.*, 1996, for details).

Linear shear stress gradients occur in flows driven by constant hydrostatic pressure gradients, such as in steady open channel flows, are well described by a logarithmic velocity profile. Therefore it is hypothesized that a steady, uniform, turbulent boundary layer flow over a rough surface in the alongshore direction can be described by a logarithmic profile:

$$V(z) = \frac{v_*}{\kappa} \ln \left(\frac{z + h}{z_o} \right) \quad (1)$$

where z is positive upwards from the surface, h is the mean water depth, κ is the Von Karman constant (0.4), v_* is the alongshore shear stress velocity and z_o is the physical roughness height, determined by bottom topography and sediment grain size. When waves are present, nonlinear interactions between waves and currents within the bottom boundary layer increase the bottom shear stress. Following Grant and Madsen (1979), this additional stress can be modeled by an apparent roughness height z_a , that is analogous to, but larger than z_o . Logarithmic profiles are fit to the data based on a linear-regression least-squares method. The value of z_a is calculated from the z intercept of the linear-regression on a semi-log plot of z versus $V(z)$, and the shear stress velocity v_* is calculated from the slope.

Mean along shore bottom shear stress ($\overline{\tau_y(-h)}$) is related to the alongshore shear stress velocity (v_*) through (overbar indicates time averaging)

$$\overline{\tau_y(-h)} = \rho v_*^2 \quad (2)$$

where ρ is water density. In addition, the bed shear stress coefficient, C_f , can be calculated assuming a quadratic bed shear stress relationship

$$\overline{\tau_y(-h)} = \rho C_f \overline{(u^2 + v^2)^{1/2} v} \quad (3)$$

and combining with (2), gives

$$C_f = \frac{v_*^2}{\overline{(u^2 + v^2)^{1/2} v}} \quad (4)$$

C_f values are calculated using measured velocities (u, v) at the elevation of 1 m above the bed, with v_* determined by least-squares log fit (Garcez Faria *et al.*, 1996).

DISCUSSION

October 8 Morphology

The large-scale morphology on Oct. 8 at first glance appears to be relatively homogeneous. The offshore bar is nearly parallel to the shore and is located approximately 230-250 m offshore (Fig. 1). Therefore, it would be expected that the small-scale morphology would also be homogenous alongshore throughout the survey area given the same wave and current conditions. However, close examination shows that the small-scale morphology is not homogeneous and that ripple patterns vary both in the cross-shore and alongshore directions.

Two representative lines (710 and 940 m along shore coordinate) of cross-shore combined CRAB and altimeter profiles are selected to depict the differences present in the small-scale morphology for the survey area (Fig. 2). The primary differences in the ripple dimensions between the two representative lines are observed in the trough and the seaward slope of the bar. The small-scale morphology in the trough of line 940 is predominantly long wavelength mega-ripples (1.67-5 m)

with shorter wavelength wave ripples superimposed on them. The trough region of line 710 has a more homogeneous ripple pattern in which no wavelength band predominates. The seaward slope of the bar on line 940 shows the ripple wavelength bands of 0.83-1.67 m and 1.67-5 m are dominant and the rms height is on the order of 3 cm. The seaward slope of the bar on line 710 shows relatively homogeneous ripple wavelengths with rms heights of approximately 2 cm.

October 20 Morphology

The most striking observation on the 20th is the hole in the bar with the bar bowed seaward due to the rip current between 800 and 1100 m in alongshore coordinates (Fig. 1). The bar is parallel to the beach and is located approximately 210-225 m offshore north of the rip area, shifting to greater than 300 m offshore in the rip area. The narrow trough, north of the rip area, acts as a rip-feeder channel and has the same small-scale morphological features as the rip area. The dominant small-scale morphology observed in the rip area are seaward-facing lunate and straight-crested mega-ripples. The mega-ripples were generally asymmetric with the steep slope facing seaward indicating the ripples were formed primarily as a result of the rip current. However, some ripples were symmetric while others were asymmetric facing toward the beach, which may infer a more complex formation due to a combination current and wave interactions. The area immediately north and south of the rip current is void of any discernable small-scale morphology with the exception of the rip-feeder channel. Typical rms roughness values in the rip area range from 5 to 15 cm, which are an order of magnitude larger than rms roughness values away from the rip. A contour plot of rms roughness values for the survey area is shown in Fig. 3, which displays the extreme variability of roughness in the rip current area compared with that of the area away from the rip current. The rip current, as qualitatively observed with dye on the 20th, is superimposed on the accompanying contour plot of the macro-scale bathymetry. The bed is essentially smooth away from the rip current with rms roughness values being less than 2 cm, which appears to be the result of planing action of the long-period swell.

October 12 Morphology

The large-scale morphology of Oct. 12 is similar to that of Oct. 8. The offshore bar is nearly parallel to the beach, but migrated 30 m offshore to approximately 260-280 m offshore (Fig. 1). Although the large-scale morphology is similar for the two days, the small-scale morphology is dramatically different owing to differences in the wave and current conditions associated with the arrival of a storm on Oct. 10. Large amplitude mega-ripples are now present in the trough and no regular bedform patterns are observed seaward of the bar for the entire survey area. The strong longshore current that appeared on the 10th is believed to be the dominant process that formed the small-scale morphology observed in the trough on the 12th.

The small-scale morphology across the surf zone is relatively homogeneous alongshore, and therefore, the survey area is represented by the rms roughness from the combined CRAB and altimeter profile for line 940 (Fig. 4, lower panel), which

is close to the position occupied by the sled. The small-scale morphology in the trough compared with the region seaward of the bar crest are distinctly different. Seaward of the bar the bed is essentially plane, due to intense breaking associated with large waves. In the trough, the rms roughness is primarily associated with the larger ripple wavelengths of 1.67-5 m. Side scan plots showed the mega-ripples in the outer trough to be lunate, facing in the direction of the longshore current; while straight crested in the inner trough.

Bottom Roughness and Bed Shear Stress

The more energetic period (Oct 10-12) is used to relate small-scale morphology to wave and current forcing. The data are qualitatively sorted by location into the two regions of over the bar and in the trough. This sorting allows a better identification of the possible correlations among variables, as wave breaking which is a major controlling factor within the surf zone is significantly different for these regions.

All 22 vertical profiles of longshore currents obtained during these three days are analyzed. The profiles are based on the measurements by three to seven em's over the vertical. The em closest to the sea bed was not used because of malfunction. The observed and logarithmic predicted velocity profiles at successive offshore positions (runs) that the sled occupied during 12 Oct. is shown in the upper panel of Fig 4. The data agree well with the model.

A high correlation coefficient for the linear regression, is commonly accepted as an indicator of the validity of the logarithmic approach (Gross *et al.*, 1994; Li, 1994). The linear correlation coefficients for all profiles ranged from 0.95 to 0.99, with an average value of 0.98, and the largest deviations occurring over the bar, where wave breaking was strong. This can be related to the increase of turbulent mixing due to wave breaking producing a more uniform vertical profile of the current for a given shear stress, compared with profiles in the absence of breaking. Therefore, larger discrepancies between observations and logarithmic profile predictions (lower correlation coefficients) would be expected for increased turbulent mixing caused by wave breaking, as the logarithmic profile presumes no surface turbulence source.

The bottom shear stress coefficient (C_f) varied by an order of magnitude across the surf zone, with the values offshore and over the bar in the order of 10^{-3} , while the values in the trough were in the order of 10^{-2} . An attempt was made to find empirical relationships between C_f with measured physical parameters commonly used throughout the literature such as $|\vec{u}_b| / V$ (ratio of near-bottom wave velocity magnitude to mean current speed), and the rms bottom roughness (r). Surprisingly, no statistically significant correlation was found between C_f and $|\vec{u}_b| / V$. The strongest correlation was found between C_f and the bottom roughness, with C_f increasing with bottom roughness (Fig. 5, upper panel), with a linear correlation coefficient of 0.68, which is statistically significant at the 99.75 percent confidence level. Theoretically this is expected as larger roughness implies larger bottom stress due to form drag, and consequently larger C_f values.

The scatter of data observed in Fig. 5 (upper panel) may be due to correlating the non-synoptic velocity measurements with bottom roughness measured once in the

morning, prior to the positioning of the sled for the first station. Wave forcing changed during the period of observation due to both wind and tidal variations. Changes in wave forcing have a direct effect in the measured velocities and an indirect effect in bottom roughness due to modification of wave ripples associated with variations in wave height.

Another reason for scatter of data arises from C_f values being calculated from the total bottom shear stress, which has stress contributions from skin friction related to sediment grains, waves-current nonlinear interactions within the bottom boundary layer as well as form drag related to bed forms. Smith and McLean (1977) linearly partitioned the total bed shear stress into skin friction and form drag and found good agreement with the data from the Columbia River. Extending this concept to the surf zone environment requires adding a component due to non-linear interactions between waves and currents within the bottom boundary layer to the total bed shear stress. Assuming that the linear stress partition is valid within the surf zone, the skin friction contribution can be removed from the total bottom stress and a new bed shear stress coefficient C_f' is defined

$$C_f' = \frac{v_{*d}^2 + v_{*wc}^2}{(u^2 + v^2)^{1/2} \nu} \quad (5)$$

where v_{*d} and v_{*wc} are the form drag and waves-current interactions shear stress velocities. The relationship between C_f' and the total bed shear stress coefficient (C_f) can be determined from (4) and (5)

$$C_f' = \left[1 - \left(\frac{v_*}{v_*'} \right)^2 \right] C_f \quad (6)$$

where v_* is the skin friction related shear stress velocity. As skin friction was not measured during the DUCK94 experiment, an attempt is made to isolate its contribution from the total bottom shear stress by applying a stress partitioning model. The probabilistic approach used to quantify bottom roughness does not allow the adjustment of the two empirical coefficients C_D and a_1 necessary to apply the Smith and McLean (1977) model. Therefore, the empirical relationships obtained by Li (1994) are used to estimate skin friction shear stress velocity from the total shear stress velocity obtained from the logarithmic profile

$$\frac{v_*'}{v_*} = 0.125 \left(\frac{v_*}{R} \right) + 0.373 \quad \text{for} \quad \frac{v_*}{R} < 2.3 \text{ s}^{-1} \quad (7)$$

$$\frac{v_{*s}}{v_*} = 0.107 \left(\frac{v_*}{R} \right) + 0.266 \quad \text{for} \quad \frac{v_*}{R} \geq 2.3 \text{ s}^{-1} \quad (8)$$

where R is ripple height, assumed here to be equal to the measured *rms* bottom roughness ($R = r$). The recalculated bed shear stress coefficients C_f' (Equation 6) are also positively correlated with bottom roughness (Fig. 5, lower panel), but show a higher linear correlation coefficient (0.80). Theoretically this is expected as the removal of the skin friction component from the total stress should enhance the form drag contribution, and consequently increase the correlation between bed shear stress and bottom roughness.

CONCLUSIONS

Quantitative measurements of small-scale morphology on a barred beach were acquired during the DUCK94 experiment. Three separate sequences are examined in which distinctly different ripple dimensions and bedform types were observed owing to varying wave and current regimes.

The measurements of small-scale morphology on Oct. 8, when mild waves and weak longshore currents prevailed, shows surprising differences within the survey area. The absence of significant variation associated with wave and current forcing suggests that the mega-ripples in the trough of line 940 may be residual from some earlier time of formation, such as on Oct. 3 when a strong longshore current was present.

Oct. 20 is characterized by a rip current with two distinct areas of small-scale morphology. In the throat of the rip current, straight-crested and lunate mega-ripples were observed. The area away from the rip current was void of any ripple patterns as a result of the planing action of the long-period swell.

Oct. 12 is characterized by the occurrence of a strong longshore current. The small-scale morphology of the inner trough region is characterized by relatively straight-crested mega-ripples (1.67-5 m) generated by the waves, superimposed by smaller wavelength ripples $O(1 \text{ m})$. In the outer trough, lunate mega-ripples in the direction of the longshore current predominated. Seaward of the bar, the bed was essentially void of ripples.

The wavenumber spectral results infer a spatial and temporal variability of ripple dimensions in both the cross-shore and alongshore directions. The wavenumber spectra were generally broad, indicating that several ripple wavelengths coexisted as a result of newly formed ripples combined possibly with residual ripples from the past to form a complex series of ripple patterns. This broadening is also due to non-cross-shore (cross-track) orientation of the morphological features.

The vertical structure of mean longshore currents on a barred beach is well described by a logarithmic profile for the three strong longshore current days examined. This hypothesis works better in the trough where turbulent bottom boundary layer processes are more dominant than over the bar, where breaking-wave induced turbulence generated at the surface modifies the profile.

A relationship between bed shear stress coefficients (C_f) and bottom roughness was found. While the relatively small amount of data used (three days) are not enough to establish a definitive empirical relation from the available data, it can be concluded that C_f is directly proportional to bottom roughness, and therefore, the latter is an important parameter to characterize the bottom boundary layer. Surprisingly, only poor correlations of C_f and z_a were found with wave parameters.

The empirical relationships obtained by Li (1994) were used to remove the skin friction contribution from the total bottom shear stress. The improved correlation between bottom shear stress and bottom roughness obtained, although not conclusive to validate these simple expressions, indicates that the linear stress partition concept introduced by Smith and McLean (1977) can be extended to the surf zone environment.

ACKNOWLEDGMENTS

This research was funded by the Office of Naval Research, Coastal Sciences Program, under contract N00114-95-AF-002. The authors wish to express their appreciation to all those who participated in DUCK94 experiment, particularly the staff of the U.S. Army Field Research Facility. In addition, special appreciation is expressed to R. Wyland, Jim Stockel, and Mary Bristow, Naval Postgraduate School, for their role in the acquisition and processing of wave and current data.

CHAPTER 263

PREDICTION OF SHORELINE CHANGE CONSIDERING CROSS-SHORE SEDIMENT TRANSPORT

Yoshimichi Yamamoto¹, Kiyoshi Horikawa², Katsutoshi Tanimoto³

ABSTRACT

Relations of cross-shore sediment transport rate with the grain size of sediment, the sea bottom slope in a surf zone and others were investigated by using data of field observation and large scale model experiments. The results are as follows :

- (1) the coefficient of a cross-shore sediment transport rate varies inversely as the 1.31th power of the grain size. Then, the steeper a initial bottom slope is, the faster a beach profile reaches a state of equilibrium.
- (2) The amount of a shoreline change is roughly proportional to the square root of the cross-shore sediment transport rate.
- (3) The stabilized bottom slope in the surf zone increases with the grain size and the wave period, and it decreases as the breaking wave height increases.

Then, new equations to predict a beach profile change induced by cross-shore sediment transport were introduced from this investigation. Moreover, the adequate applicability of these equations to actual coasts was confirmed.

1. INTRODUCTION

As practical models for predicting long-term transformation of long beaches, a shoreline change model and Uda et al.'s contour change model (1991, 1996) were proposed. However, these numerical models do not take cross-shore sediment transport rate into consideration.

In designing measures to control coastal erosion and wave overtopping, it is necessary to take account of short-term beach transformation under stormy weather condition in addition to the long-term transformation as shown in Figure 1. The short-term transformation, which cannot be

Figure 1 Transformation of a beach with time.

² Dr.-Eng., President, Saitama University, 255 Shimo-okubo, Urawa, 338, Japan.

³ Dr.-Eng., Professor, Ditto.

determined without considering the cross-shore sediment transport, can be predicted by means of 2 or 3 - dimensional beach transformation models combined with the computation of waves and currents (e.g., Horikawa, 1988; Sato, 1994; Shibayama et al., 1994). However, it is difficult to apply these models to long-term prediction of long beaches, because long computational time is required and numerous coefficients introduced in sand transport rate formulas have not yet been generalized.

In this study, an attempt was made to generalize the coefficient of cross-shore sediment transport rate formulas. Moreover, a convenient beach evolution model using this result was proposed and applied to actual coasts.

2. CROSS-SHORE SEDIMENT TRANSPORT NEAR SHORELINE

Sunamura (1984) proposed the following formula for calculating cross-shore sediment transport rate, Q near the shoreline per unit time and unit beach width :

$$Q = K U_r^{0.2} \phi (\phi - 0.13 U_r) w \bar{d} \tag{1}$$

where K : a coefficient of sediment transport rate, U_r : Ursell parameter $[= g H T^2 / h^3]$, ϕ : Hallermeier parameter $[= H^2 / s h \bar{d}]$, w : the settling velocity of sediment, \bar{d} : the median grain size of sediment, g : the acceleration of gravity, h : the wave setup height at shoreline against the still water level $[= (1.63 \tan \alpha + 0.048) H_b]$, Sasaki and Saeki (1974), H : the wave height at shoreline against the still water level $[= 2.4 (\tan \alpha)^{0.3} h]$ Yamamoto(1988), T : the wave period, s : the specific gravity of sediment in water, $\tan \alpha$: the initial bottom slope in the surf zone, H_b : the breaker height.

Now, let us generalize the coefficient K of Eq. (1). As long as external forces remain constant, the rate of cross-shore sediment transport decreases with the lapse of time, and the beach profile approaches the equilibrium state. Therefore the coefficient K can be expressed by the following equation with the elapsed time t :

$$K = A \cdot e^{-Bt/T} \tag{2}$$

where A and B are coefficients. Then, we assume that the coefficients A and B are dominated by $\tan \alpha$ and \bar{d}/H_b (H_b is the wave height in deep water), and investigate relations of these coefficients with $\tan \alpha$

Figure 2 Relationship of the coefficient K with t/T .

and d/H_0 by using data of field observation and large scale model experiments given in Tables 1 ~ 4 in the appendix.

Figure 2 is a semilogarithmic graph of the relationship between K and t/T based on these data. Symbols with a vertical segment mean field data and other symbols mean experimental data. Then, average values of significant waves are used for the wave height and the wave period of irregular waves, because data of significant waves are used in many countries. However, experimental data of regular waves are used in order to supplement lack of data. Each straight line in this figure shows a tendency of data of each group. When t/T is 0, $K (= A)$ varies greatly depending on the value of d/H_0 , but changes very little by d/H_0 . Moreover, the slope of the straight lines in this figure varies widely depending on the value of $\tan\alpha$, while it is little affected by the value of d/H_0 . This means that the coefficient B is strongly dominated by $\tan\alpha$.

$\tan\alpha$ \ d/H_0	$6 \times 10^{-5} \sim 10 \times 10^{-5}$	$11 \times 10^{-5} \sim 34 \times 10^{-5}$	$42 \times 10^{-5} \sim 102 \times 10^{-5}$

0.045~0.068		○	□
0.075~0.125		△	

Figure 3 Relationship of A with d/H_0 .

Figure 4 Relationship of B with $\tan\alpha$.

Figure 3 illustrates the relationship of the coefficient A with d/H_0 and Figure 4 shows the relationship of the coefficient B with $\tan\alpha$. As these figures indicate clearly that the coefficient A increases as d/H_0 falls and the coefficient B increases with $\tan\alpha$. Namely, the smaller the grain size of sediment is the larger the coefficient A is and the steeper the sea bottom slope is the faster the beach profile reaches the equilibrium state. These relations can be expressed by the following equations :

$$\left. \begin{aligned} A &= 3.61 \times 10^{-10} (d/H_0)^{-1.31}, & B &= 4.20 \times 10^{-3} (\tan\alpha)^{1.57} \\ &[\tan\alpha = 0.017 \sim 0.125, & d/H_0 &= 0.00006 \sim 0.00102] \end{aligned} \right\} \quad (3)$$

The rate of cross-shore sediment transport near the shoreline can be obtained from Eqs. (1), (2), and (3). Figure 5 shows the comparison between

measured values and calculated values obtained from data shown in Tables 2 and 4. This figure shows that the calculated values agree fairly well with the measured values.

3. SHORELINE CHANGE DUE TO CROSS-SHORE SEDIMENT TRANSPORT

Let us consider a simplified pattern of beach profile change, as shown in Figure 6, due to cross-shore sediment transport. Transforming slightly the continuity equation of cross-shore sediment transport, we can obtain the shoreline displacement as $\Delta y \propto (\int_0^t Q dt)^{0.5}$. Moreover, by using the data shown in Tables 2 and 4, the following equation can be obtained:

$$\Delta y = 2.7 (\int_0^t Q dt)^{0.5} \quad (4)$$

Therefore, the shoreline displacement due to cross-shore sediment transport can be calculated by using Eq. (4).

Figure 7 compares the measured values shown in Tables 2 and 4 with the calculated values given by Eq. (4). The data marked with + mean cases that initial bottom slopes above the still water level are steep by cliffs or steps. This figure shows that the calculated values agree well with the measured values. However, since Eq. (4) is intended for the simple beach profile change due to cross-shore sediment transport, Application of Eq. (4) to shores undergone complex beach changes should be preceded by careful study.

By combining the above equations with a formula for calculating the stable slopes of sea bottoms, the beach pro-

Figure 5 Measured vs. calculated values of cross-shore sediment transport rate.

Figure 6 Patterns of beach change due to cross-shore sediment transport.

Figure 7 Measured vs. calculated values of Δy .

files after transformation can be determined.

From Eq. (1), when the beach profile reaches the equilibrium state, the following relation can be obtained:

$$\phi = 0.13 U_r \quad (5)$$

Figure 8 Image of $\tan \beta$ (sea bottom slope under equilibrium state in the surf zone).

Substituting Hallermeier parameter, Ursell parameter and Eq. (6) (Yamamoto, 1988) to Eq. (5), and transforming slightly, we can obtain Eq. (7).

$$H = 2.4(\tan \beta)^{0.3} h = 1.9(\tan \beta)^{0.3} H_b \quad (6)$$

$$\tan \beta = \left(\frac{0.0864 s g d T^2}{H_b^2} \right)^{2/3} \quad (7)$$

where $\tan \beta$ is the sea bottom slope under the equilibrium state in the surf zone, and H_b is the breaking wave height.

Then, assuming that the rate of time change of the sea bottom slope equals $e^{-Bt/T}$, the sea bottom slope of the arbitrary elapsed time t in the surf zone, $\tan \theta$, can be expressed by the following equation:

$$\tan \theta = \tan \beta + \frac{\tan \alpha - \tan \beta}{e^{-Bt/T}} \quad (8)$$

Moreover, substituting the data shown in Tables 5 and 6 in the appendix, we can obtain Figure 9. The figure indicates that the calculated values agree well with the measured values.

Figure 9 Measured vs. calculated values of $\tan \theta$.

4. APPLICATION OF THE PROPOSED

EQUATIONS TO ACTUAL COASTS

We performed the following two beach change simulations.

(1) SHORELINE CHANGE AT HAZAKI COAST

The first one is the time series hindcast for 18 days at Hazaki coast in Ibaragi Prefecture, Japan, based on the data given in Katoh and Yanagishima's paper (1988). In their paper, time series data of the daily mean wave energy flux, and limited data of the maximum significant wave height $[(H_{1/3})_{max}]$ and period on stormy days were given. Therefore, time series data of the significant wave height $(H_{1/3})$ from the data of the square root of the daily mean wave energy flux $(E^{1/2})$ were calculated by using the following empirical relations:

$$H_{1/3} = (H_{1/3})_{\max} / 1.5 \quad (9), \quad E^{1/2} = (H_{1/3})_{\max} \quad (10)$$

Equation (10) can be obtained from Figure 10 drawn by limited data under stormy weather. However, as the offshore bars exist and the mean water depth at the bar crown is about 2.9 m, the significant wave height of waves acting on the shoreline is less than approximately 2.2 m due to wave breaking. Therefore, the breaking wave height higher than 2.2 m is reduced to 2.1 m. Then, the time series data of the wave period are calculated by using Eq. (11) obtained empirically in their paper.

$$H_{1/3} / L^{1/3} = 0.25 \times E^{0.37} \quad (11)$$

where L is the wavelength.

However, as larger waves are diminished in this case, the breaking wave height is cut down, the wave period in this case should be shortened by using the following equation based on Bretschneider's formula [$T = 3.86 (H_{1/3})^{0.5}$]:

$$T_a / T_b = C (2.1 / H_{1/3b})^{0.5} \quad (12)$$

where the suffix a means the values after wave breaking, while the suffix b means the values before wave breaking, and C is a proportional coefficient ($= 1.1$ from a few field observation data).

Because the shoreline of Hazaki coast is straight and no coastal structure like a groin exists along this coast, the shoreline change due to longshore sediment transport can be neglected. Therefore, the shoreline change on this coast can be simulated by using Eqs. (1) ~ (4), (7), and (8). The calculated result of shoreline change agrees well with the measured result as shown in Figure 11.

Figure 10 Relation between maximum significant wave height and square root of daily mean wave energy flux.

Figure 11 On-offshore changes of shoreline position (D.L. + 1.4 m).

(2) SHORELINE CHANGE AT MISAWA PORT COAST

Another example is the simulation for one year at Misawa Port coast in Aomori Prefecture, Japan, based on data of Hashimoto and Uda's paper (1979).

A remarkable shoreline change occurred during the period of one year from 1976 to 1977, when the off-shore breakwater at Misawa Port became long enough to bring about remarkable diffraction effect (refer to Figure 12).

It is likely that the diffraction effect of the breakwater made the wave height small in the water area sheltered by the breakwater, thereby the rate of onshore sediment transport increased in this area as shown in Figure 13. Hashimoto and Uda applied an empirical eigenfunction expansion method to predict shore transformation at and around Misawa Port and pointed out the existence of cross-shore sediment transport.

Thus, the probable mechanism of this shoreline change was that alongshore transport sediment entered the port area due to influence of the diffraction effect of the breakwater, then the waves in the port transported the sediment onshore, therefore the shoreline advancement occurred.

The hindcast of the shoreline change in this area was performed by combining Eqs. (1) ~ (4) with the shoreline change model.

First, the shoreline change model was applied under the following conditions on the basis of the Hashimoto and Uda's paper :

- (a) The height of the longshore sediment transport zone was 11 m.
- (b) Ozasa and Brampton's formula (1979) was used to calculate the longshore sediment transport rate, and the figure 0.2 was selected as a coefficient in

Figure 12 Configuration of breakwaters at Misawa port.

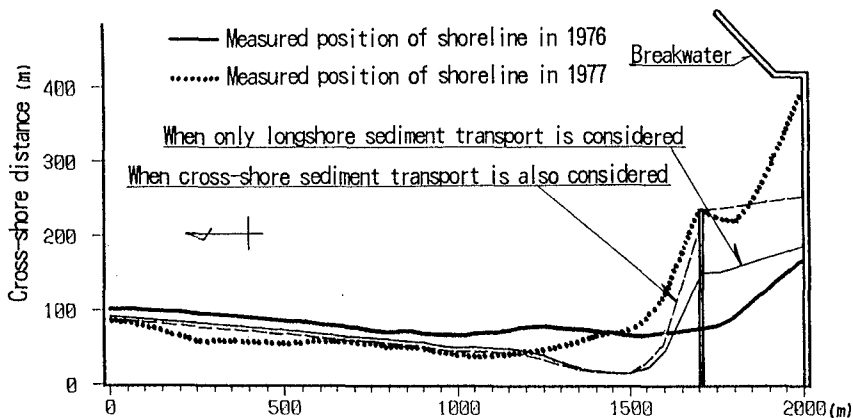

Figure 13 Result of shoreline change simulation.

the formula.

- (c) The wave height, period and direction are shown in Table 7 in the appendix.
- (d) The sea bottom slope was $1/50$.

The result of this simulation was plotted in Figure 13 by a solid line. This result, which was the same as that calculated by Hashimoto and Uda, did not agree with the measured result shown as a dotted line.

Then, the shoreline change due to the cross-shore sediment transport was taken into account by using Eqs. (1) ~ (4). The influence of the wave hysteresis on the shore transformation seems to be great. However, the available data were not the time series data of waves but the statistical data shown in Table 7. Therefore, we adjusted the median grain size of sediment so as to obtain reasonable shoreline displacement. Because the natural beach change after one year induced by cross-shore sediment transport is regarded as small, the shoreline change due to the cross-shore sediment transport near the 0 m point, which is far from the breakwater, can be deemed small. Namely, the median grain size of sediment must be selected so as to obtain a small shoreline change due to the cross-shore sediment transport near the 0 m point. When the figure 0.43 mm was selected as the median grain size from usual grain size at Misawa Port coast, the shoreline displacement near the 0 m point became small as shown in Table 7. Therefore, the calculation by Eqs. (1) ~ (4) was performed under the condition of the median grain size 0.43 mm. By combining this result with the result obtained by the shoreline change model, the significantly improved shoreline displacement was obtained as shown in Figure 13 by a broken line.

5. CONCLUSIONS

Main conclusions are as follows :

- (1) The relations among $\tan\alpha$, d/H_0 and the coefficient K of cross-shore sediment transport rate (in Sunamura's formula) can be expressed by Eqs. (2), (3) based on the analyses of data obtained by field observation and large scale experiments.
- (2) The formulas [Eqs. (4), (7) and (8)] were proposed for calculating the shoreline displacement and the bottom slope change in the surf zone due to the cross-shore sediment transport. Then the effectiveness of these formulas against actual coasts was demonstrated by the simulation results of shoreline change on two actual coasts.

Wave heights of Saville's, Simizu et al's, Dette et al's, Kraus et al's, and Southgate's data are not significant values but mean values, because of experiments carried out by using regular waves.

CHAPTER 264

THE INFLUENCE OF ROLLERS ON LONGSHORE CURRENTS

Daniel A. Osiecki¹ and William R. Dally²

Abstract

A computational model is developed for depth-averaged cross-shore and longshore currents which includes the effects of the surface roller generated by wave breaking. The creation and evolution of the roller itself is modeled explicitly (Dally and Brown, 1995), and convective acceleration terms are included in both the cross-shore and longshore momentum equations. Lateral mixing is parameterized in terms of the local cross-shore current and a turbulent eddy viscosity, as proposed by Svendsen and Putrevu (1994); however, a new model for eddy viscosity is proposed which contains contributions from both the roller-induced and bed-induced turbulence. The laboratory measurements of quasi-uniform longshore currents reported by Visser (1991) are used to calibrate and verify the model. For driving the model, it is shown that using stream function wave theory produces significantly better results than linear wave theory. Also, comparisons of longshore current distributions with and without the roller terms included show that the roller plays an essential role in faithfully modeling the longshore current. The calibrated model also produces accurate results for the set-up/set-down using stream function theory, for the limited data available from Visser (1991).

Introduction

Recent investigations of the roller have demonstrated its importance in mean cross-shore currents (undertow); e.g., see Svendsen (1984b), Okayasu et al. (1988), Deigaard et al. (1991), and Dally and Brown (1995). We now focus attention on

¹ Research Engineer and ²Associate Professor, Ocean Engineering Program, Florida Institute of Technology, 150 W. University Blvd., Melbourne FL 32901, USA.

the potentially important influence of the aerated roller on longshore currents, both in driving longshore flows as well as in cross-shore mixing.

For shore normal waves, Dally and Brown (1995) showed that the roller momentum flux (R_{xx}) was comparable to the Radiation Stress (S_{xx}) associated with the organized wave motion, and that their gradients tend to balance in the outer surf zone. This balance is responsible for the landward shift in the initiation of setup, as well as the landward shift in the location of the peak of the undertow, that have been observed in laboratory data (Bowen, et al., 1968; Nadaoka and Kondoh, 1982). In the present study it will be shown that with obliquely incident waves, the gradients of the cross-product momentum terms (R_{xy} and S_{xy}) also tend to balance in the outer surf zone. This results in a landward shift in the peak of the longshore current, which is also evident in laboratory data (Visser, 1991).

Although lateral mixing of the longshore current has been an important modeling issue since the 1970's, it was not until recently that a physically realistic mechanism for observed cross-shore mixing, i.e. residual convective acceleration induced by the vertical structure of the cross-shore and longshore currents, was proposed by Svendsen and Putrevu (1994). In the present study the influence of the roller, which enhances vertical mixing and consequently *reduces* lateral mixing, will also be modeled and explored.

General Governing Equations for Longshore and Cross-shore Currents

Assuming steady currents, longshore uniformity, and no flow through the shoreline, a simple equation for the mean, depth-integrated, period-averaged, cross-shore current below the mean water level (U) is developed by integrating the conservation of mass equation. This relation is given by

$$U = \frac{-(Q_{wx} + Q_{rx})}{(h + \bar{\eta})} \quad (1)$$

The Stokes Drift term (Q_{wx}) is provided by the wave theory selected to drive the model, the roller volume flux (Q_{rx}) is provided by an energy-based roller model, and the still water depth (h) is known. The elevation of the mean water level ($\bar{\eta}$) is as yet unknown.

Again, assuming steady state conditions, applying longshore uniformity, and neglecting wind stress, the period-averaged, depth-averaged momentum equations for the cross-shore and longshore directions are

$$-\frac{\partial}{\partial x} [U^2(h + \bar{\eta})] + \frac{1}{\rho} \left(\frac{\partial}{\partial x} S_{xx} + \frac{\partial}{\partial x} R_{xx} \right) + g(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} = \frac{1}{\rho} \left(\overline{\tau_{zx}} \Big|_{-h} \right) \quad (2)$$

and

$$\frac{\partial}{\partial x} \left(D_c h \frac{\partial V}{\partial x} \right) - \frac{1}{\rho} \left(\frac{\partial}{\partial x} S_{xy} + \frac{\partial}{\partial x} R_{xy} \right) = \frac{1}{\rho} \left(\overline{\tau_{zy}} \Big|_{-h} \right) \tag{3}$$

where S is the Radiation Stress, R is the roller momentum flux, D_c characterizes a horizontal mixing mechanism, τ is the time-averaged bed stress, and V is the depth-averaged longshore current. The first term in Eq. 3 represents a lateral mixing mechanism due to the vertical structure of the cross-shore and longshore currents (Svendsen and Putrevu, 1994) with D_c approximated by,

$$D_c = \frac{0.5 h^2 U^2}{\nu_t} \tag{4}$$

where ν_t is a turbulent eddy viscosity. The eddy viscosity model developed herein contains vertical mixing introduced by both the aerated surface roller and the bottom, as described below.

A quadratic bed stress model is adopted:

$$\overline{\tau_{zx}} \Big|_{-h} = \rho \frac{c_f}{8} \overline{u_b (u_b^2 + v_b^2)^{\frac{1}{2}}} \tag{5}$$

$$\overline{\tau_{zy}} \Big|_{-h} = \rho \frac{c_f}{8} \overline{v_b (u_b^2 + v_b^2)^{\frac{1}{2}}} \tag{6}$$

where u_b and v_b are the total instantaneous velocities at the bed. Following Smith et al. (1993) c_f is the Darcy-Weisbach friction factor, related to Manning's n_m and the total water depth by

$$c_f = \frac{8 g n_m^2}{(h + \overline{\eta})^{\frac{1}{3}}} \tag{7}$$

Manning's resistance coefficient has units of ($s \cdot m^{-1/3}$) and was determined experimentally by Chow (1959) for a wide variety of channels.

To solve the system of equations, the initial conditions of wave height, wave angle, and bottom topography must be specified. The selected wave theory is then used to determine the mass and momentum fluxes while shoaling and refracting the wave to the next grid. The cross-shore mass and momentum equations are next solved for the undertow and the wave induced set-up/set-down. By iterating between the mass equation, the cross-shore momentum equation, and the roller model, the undertow and the set-up/set-down are determined across the entire transect. The present model employs the wave height decay model of Dally, Dean, and Dalrymple (1985), hereafter referred to as the D^3 model.

Once the cross-shore hydrodynamics are computed, the longshore momentum equation is solved with a forward difference scheme. The longshore momentum equation is solved from onshore to offshore because the boundary condition of $V=0$ must be applied at the shoreline. Equation (3) is solved across the entire transect using an implicit tridiagonal solution method. Because there is a quadratic dependence on V in the longshore mean bed stress, the longshore momentum equation is iterated until V converges to a selected tolerance for all points across the

transect. The solution method outlined in this section is the same regardless of the wave theory used to drive the model.

The Roller Model

The roller model recently developed by Dally and Brown (1995) is used to predict the development and decay of the aerated surface roller in the surf zone, and is based on a depth-integrated and period-averaged energy balance equation. For obliquely incident waves, the roller model, under the condition of longshore uniformity, is expressed by

$$\frac{\partial \overline{F}_w \cos \theta}{\partial x} + \frac{\partial}{\partial x} \left(\frac{1}{2} M_R c^2 \cos^2 \theta \right) = -M_R g \beta_d \cos \theta \quad (8)$$

where \overline{F}_w is the depth-integrated, time-averaged, wave-induced energy flux, x is the cross-shore coordinate positive in the shoreward direction, M_R is the roller mass flux, θ is the local wave angle (computed from Snell's law), g is gravity, and β_d is the roller dissipation coefficient. β_d was calibrated by Dally and Brown (1995) using a number of laboratory data sets, and a value of 0.1 yields good agreement when stream function theory is used to compute the driving terms. The volume flux of the roller, used in the conservation of mass equation (Eq. 1), is calculated from

$$Q_{rx} = \frac{M_R}{\rho} \cos \theta \quad (9a)$$

$$Q_{ry} = \frac{M_R}{\rho} \sin \theta \quad (9b)$$

The momentum flux terms for the roller in used in Eqs. 2 and 3 are calculated from

$$R_{xx} = \rho Q_{rx} c \cos \theta \quad (10a)$$

$$R_{xy} = \rho Q_{rx} c \sin \theta = \rho Q_{ry} c \cos \theta \quad (10b)$$

The Eddy Viscosity Model

It is suggested that two sources of turbulence, i.e. roller-induced turbulence and bottom-induced turbulence, should be accounted for in the eddy viscosity model. The measurements of Battjes and Sakai (1981) and Nadaoka and Kondoh (1982) suggest that as a wave dissipates across the surf zone, the turbulence it creates and leaves behind is similar to a turbulent wake. Consequently, an analogy is made that the turbulent wake produced by the roller of a breaking wave is similar to the turbulent wake produced by a cylinder submerged in a moving fluid. From the

theory of turbulent wakes, the eddy viscosity in a turbulent wake (v_T) can be described by (Tennekes and Lumley, 1977)

$$v_T = \frac{\kappa}{R_T} U_o \Theta \tag{11}$$

where κ is Von Karman's constant (equal to 0.4), R_T is the turbulent Reynolds number (equal to 12.5 based on experimental observations), U_o is the free stream velocity, and Θ is the momentum thickness of the wake. For a coordinate system moving with the breaking wave, it would seem that the wave celerity (c) is analogous to U_o . Tennekes and Lumley (1977) show that the momentum thickness for a circular cylinder is approximately half the frontal height of the cylinder, for Reynolds numbers between 10^3 and 3×10^5 . Thus, if the roller is equated to a cylinder, a logical estimate of the momentum thickness, or 'radius', of the roller (Θ_R) is given by

$$\Theta_R = \frac{1}{\sqrt{\pi}} \sqrt{M_R \frac{T}{\rho}} \tag{12}$$

Completing the cylinder analogy, the roller contribution to the eddy viscosity is given by

$$v_R = \frac{0.4}{12.5} c \Theta_R \tag{13}$$

where v_R is uniform over depth, which also follows from turbulent wake theory.

With the upper layer turbulence represented, the bottom-induced turbulent eddy viscosity is now developed. Nielsen (1985) suggests that the length scale of the near-bed eddies should be that of the oscillatory water particle excursion, whereas the velocity scale should be that of a friction velocity. We also suggest that the friction velocity is well-represented by the maximum water particle velocity multiplied by a friction factor. Consequently, it appears that the turbulent eddy viscosity contribution from the bed might be modeled by

$$v_B = \sqrt{\frac{c_f}{2}} |u_{max}| \xi_{max} \tag{14}$$

$$u_{max} = \frac{H\sigma}{2 \sinh kh} \tag{15}$$

$$\xi_{max} = \frac{H}{2} \frac{1}{\sinh kh} \tag{16}$$

where, c_f is the friction factor discussed in the previous section, u_{max} is the maximum orbital velocity given by linear wave theory in equation (15), ξ_{max} is the maximum water particle displacement given by linear wave theory in equation (16), H is wave height, σ is angular frequency, and k is wave number. With the bottom-induced eddy viscosity component modeled, the combination of mixing induced by the roller of the breaking wave and mixing induced by bottom turbulence is given by

$$v_T = \left(v_R^2 + v_B^2 \right)^{\frac{1}{2}} \tag{17}$$

A comparison of the new eddy viscosity model with the eddy viscosity model proposed by Svendsen and Putrevu (1994) (Figure 1) shows an order of magnitude agreement. The new eddy viscosity model does provide a better behaved transition across the breakpoint, with the point of maximum turbulence located inside the surf zone, whereas the Svendsen and Putrevu (1994) eddy viscosity model has a maximum at the breakpoint.

Figure 1 Comparison of the new eddy viscosity model to Svendsen and Putrevu's (1994) eddy viscosity model for Visser's (1991) Case 4 conditions.

Calibration

The numerical model presented here is compared to the laboratory data set of Visser (1991) for calibration and verification. This data set is unique because it is the only experiment to minimize the recirculation present in enclosed basins by utilizing a longshore pumping method, to develop a uniform longshore current. Calibration of the longshore current model entailed the selection of a Manning's friction factor from a range of values presented by Chow (1959) for open channel flow conditions. The empirical decay coefficient (κ) and the stable wave height coefficient (Γ), in the D^3 wave decay model are also calibrated to minimize the error in wave height prediction. Manning's friction factor and the D^3 coefficients are

selected based on their relative least squares error to the measured data defined by equation (18) where B represents the variable in question:

$$E_v = \left(\frac{\sum (B_{meas} - B_{calc})^2}{\sum (B_{meas})^2} \right)^{\frac{1}{2}} \tag{18}$$

Calibration results for the longshore current model are presented for two wave theories in tables 1 and 2. The numerical model results with stream function theory are presented in contrast to the model results for linear wave theory.

7	59.32 %	43.89 %	25.75 %
<i>Linear Theory</i>			
7	43.27 %	31.35 %	17.01 %

Table 2 Least squares percent error for the range of Manning’s friction coefficients (n_m) from Chow (1959) for Visser’s (1991) cases 4 through 7.

Because Visser did not measure the cross-shore current distribution, it is impossible to assess the validity of the cross-shore velocity predictions. However, based on the work of Dally and Brown (1995), the cross-shore current is expected to be reasonably represented. Sensitivity testing of the longshore current model shows that the magnitude of the longshore current is not overly dependent on Manning's friction factor. For the smooth bottom, cases 4-6, the normal friction factor value provides accurate results; however, for the gravel bottom in case 7 a value larger than Chow's (1959) suggested maximum provides better results.

Visser's experiments 1-3 were performed on a beach with a slope of 1/10. Because stream function theory is limited by the breaker height to water depth ratio of 0.78, cases 1-3 were not investigated because the breaking waves in these experiments exceeded this ratio. Because case 8 was reported without wave height measurements, this case was also discarded.

Results and Discussion

The most obvious way to assess the effect of the roller on the longshore current is to contrast the results to a model without the roller term. Figure 2 shows the calibrated longshore current model results for Case 4, with and without the roller term in the cross-shore and longshore momentum equations. It is noted that the roller contribution to turbulence is still included. The model that neglects the roller term in the momentum equations shows a dramatic decrease in the longshore current velocity inside the surf zone and the location of the maximum current is shifted offshore. A similar effect occurs in the model predictions for all the cases studied.

To assess the importance of the roller contribution to turbulence in the surf zone, results are presented that neglect the roller contribution to the eddy viscosity model. It is noted that the roller contribution to the longshore momentum equation is included in this comparison so that the effect of the roller turbulence on lateral mixing may be examined exclusively. Figure 3 clearly shows that the roller-induced turbulence has a significant effect on the overall longshore current distribution. The absence of the roller turbulence in the eddy viscosity model decreases the maximum velocity in the longshore current and shifts this point landward. Also, outside the breakpoint, a slight increase in the longshore current is produced without the roller-induced turbulence included.

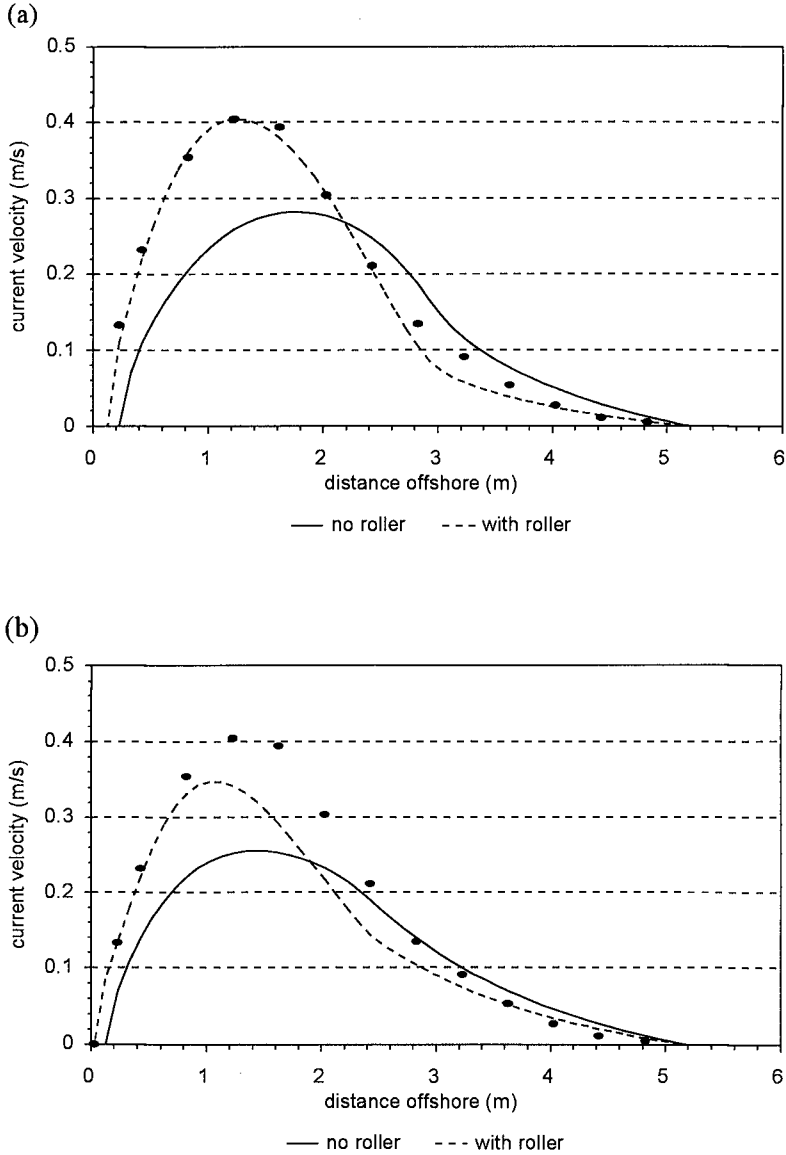

Figure 2 Visser's (1991) Case 4 model comparisons with and without the roller contribution to the longshore momentum equation for (a) Stream Function theory and (b) Linear Wave theory.

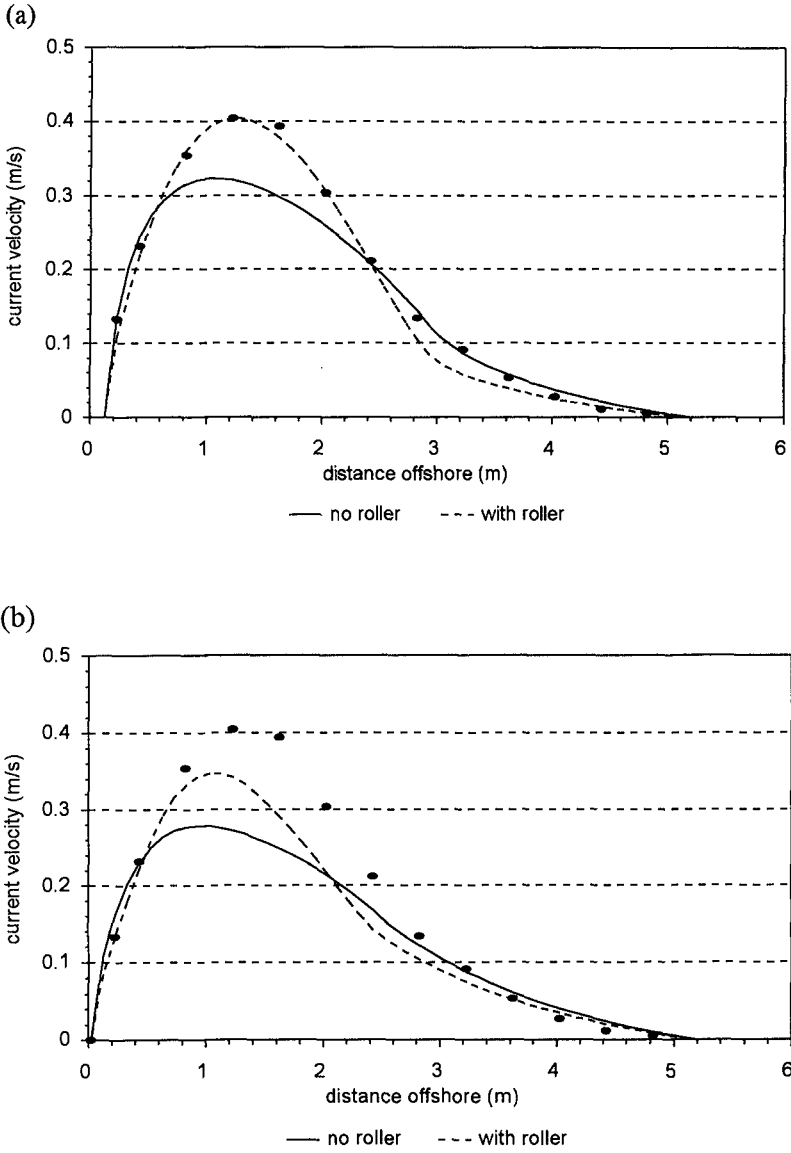

Figure 3 Visser's (1991) Case 4 model comparisons with and without the roller contribution to the eddy viscosity model for (a) Stream Function theory and (b) Linear Wave theory.

It is important to note that the predicted cross-shore current driven by linear wave theory is much greater than the stream function theory cross-shore current. According to Dally and Brown (1995) linear theory in general overpredicts the Stokes drift, whereas stream function theory provides a better prediction of this wave-induced mass transport. Although Visser (1991) did not measure the cross-shore velocity component, it is reasonable to conclude that the hydrodynamic model that uses stream function theory is the better model for calculating the cross-shore and longshore currents.

Conclusions

The major findings of this investigation are as follows: (1) The nonlinear mixing term described by Svendsen and Putrevu (1994) provides an adequate amount of lateral mixing, with realistic eddy viscosity values, in comparison to the laboratory data for longshore currents collected by Visser (1991). (2) The addition of roller momentum to the longshore equation of motion is necessary for accurate longshore velocity predictions. (3) The contribution of turbulence from the roller is an important aspect of realistically modeling the turbulent eddy viscosity. These findings affirm the premise that the roller plays a significant role in driving the longshore current and in shifting the maximum longshore velocity inside the breakpoint.

CHAPTER 265

Velocity Field Measurements in a "Coastal Buffer Zone"

Hiroshi Yagi¹, Hirofumi Hinata¹ and Kazuo Nadaoka²

Abstract

To investigate the characteristics of flow field in the coastal buffer zone (C.B.Z.), velocity measurements in a field were performed both in non-stratified and stratified conditions. The results of the data analysis have shown that in the non-stratified condition wind action, together with tidal motion, may induce unexpectedly large velocity even near the bottom with the magnitude beyond the threshold of the sediment movement, suggesting that the appreciable sediment transport may be caused by these wind-driven currents in C.B.Z.. In the stratified condition, it is revealed that internal tides with baroclinic velocity fluctuation may dominate the cross-shore exchanging motion of water mass.

INTRODUCTION

In coastal current system, the surf zone and the far-offshore region may be regarded as two extremes in a sense that the former is dominated exclusively by nearshore currents, while the latter is governed mostly by the ocean currents (Fig.1). The intermediate-depth zone, on the other hand, may be affected by both the factors as well as tidal currents, wind-driven currents, density currents, river flow, and hence may be called "coastal buffer zone (C.B.Z.)". Therefore for developing a reliable tool to describe the flow field in this zone, more integrated knowledge on these factors and, if any, the interactions among them are necessary. However, still limited parts

¹ Department of Civil Engineering, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro-ku, Tokyo 152, Japan.

² Department of Mechanical and Environmental Informatics, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro-ku, Tokyo 152, Japan.

of the actual physical process of these factors are known for this purpose (Sato,1995; Yasuda et al.,1995). Hence, in the present study, field measurements in a C.B.Z. have been performed to clarify the fundamental characteristics of its velocity field.

OUTLINE OF FIELD OBSERVATION

The observation was carried out in the Kashima coast, as a typical open coast in Japan, which has a straight sandy beach facing the Pacific Ocean (Fig.2(a)). To clarify the characteristics of the current system in the C.B.Z. both in the non-stratified and stratified conditions, field observations were performed in the periods from Nov. 6 to 28 in 1994 and from July 19 to Aug. 20 in 1995.

In the field measurements, three observation stations (St.1-3) were set to be aligned in the cross-shore direction as shown in Fig.2(b). At these stations electromagnetic current meters, pressure-type wave gauges and thermometer were installed. The location of observation stations and the arrangement of measuring instruments were slightly changed between the observations in the non-stratified and stratified conditions as shown in Fig.2(b).

RESULTS AND DISCUSSTION

Non-stratified condition

Figure 3 shows the time histories, at the three stations, of the mean water surface elevation and the shore-parallel component of the mean velocity close to the bottom (0.7-1.7m above the bottom). These mean values were obtained by a moving time averaging over one hour. The regular diurnal tidal fluctuations appear in the mean surface elevation. On the other hand, the shore-parallel bottom velocity shows appreciable irregularity and its maximum magnitude attains almost 40cm/s at St.1. This is an unexpectedly large value, and such a large near-bottom velocity is observed also by Sato (1995) at the Ishikawa coast facing the Sea of Japan. The velocity of 40cm/s is beyond the threshold for the sediment movement, which is estimated as about 25cm/s by the Shields experimental curve for the sand with the mean diameter of 0.2mm. This fact suggests that in C.B.Z. appreciable sediment transport may be caused by these currents, although conventionally significant sediment transport has been believed to occur mostly in the surf zone and its vicinities.

To find the causes of the large velocities near the bottom, the non-tidal irregular components were extracted from the near bottom velocity data by a moving time average over 24 hours. The results are shown in Fig.4, in which the long-period fluctuations with the period of 6 or 7 days appear at each station. Although the velocity amplitude at St.1 in the shallower region is larger than that at St.3 in the deeper region, their fluctuation patterns are very similar each other. This fact suggests that there exists a common mechanism to cause these long-period velocity fluctuations in the C.B.Z.. To find the mechanism, the wind speed, which is indicated with a thick line in Fig.4 (wind-speed data are partly lacked because of trouble in the measurement), is compared with these long-period velocities.

Obviously there is a close correlation among them. Hence, it is suggested that the wind may induce the long-period fluctuating currents with an appreciable magnitude even near the bottom.

To obtain more quantitative understanding of the wind-driven currents in the C.B.Z., its numerical simulation has been done. The governing equations of the computations are 2-DV momentum equations with the coriolis force and the continuity equation. The k - ε model described below has been employed to evaluate the vertical eddy viscosity ν_t .

$$\frac{\partial k}{\partial t} + u \frac{\partial k}{\partial x} + w \frac{\partial k}{\partial z} = \frac{\partial}{\partial z} \left(\frac{\nu_t}{\sigma_k} \frac{\partial k}{\partial z} \right) + P_k - \varepsilon, \quad (1)$$

$$\frac{\partial \varepsilon}{\partial t} + u \frac{\partial \varepsilon}{\partial x} + w \frac{\partial \varepsilon}{\partial z} = \frac{\partial}{\partial z} \left(\frac{\nu_t}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial z} \right) + C_{\varepsilon 1} \frac{\varepsilon}{k} P_k - C_{\varepsilon 2} \frac{\varepsilon^2}{k}, \quad (2)$$

$$\nu_t = C_\mu \frac{k^2}{\varepsilon}, \quad (3)$$

where x and z represent the cross-shore and vertical coordinate, u and w the velocity components in the x - and z -direction, k the kinetic energy of turbulence, ε the dissipation rate of the turbulence kinetic energy, and P_k the production rate of k . C_μ , $C_{\varepsilon 1}$, $C_{\varepsilon 2}$, σ_k and σ_ε are the turbulence model parameters, for which the standard values ($C_\mu=0.09$, $C_{\varepsilon 1}=1.44$, $C_{\varepsilon 2}=1.92$ and $\sigma_k=\sigma_\varepsilon=1.0$) are adopted here. In the present computation, the shore-parallel uniformity is assumed and the topography of the computational area is simplified as shown in Fig.5. The spatially uniform wind shear stress at the water surface was given, being based on the wind data obtained at the nearshore observation station (as shown in Fig.4) and the friction factor at the water surface ($C_d=0.002$).

Figure 6 shows the computed vertical profiles of the shore-parallel velocity for the three cases of the water depth; i.e. $h=20, 60, 100$ m. The indicated results are those after 9.5 days from the beginning of the computation. In the case of $h=100$ m, the vertical gradient is relatively large in the surface layer, while it becomes small beneath it. This fact suggests that the effect of wind shear stress is limited to the surface boundary layer, and the geostrophic current under the balance between the coriolis force and the cross-shore gradient of the water surface elevation is formed beneath the surface layer. On the other hand, in the case of $h=20$ m, the influence of wind shear stress reaches the bottom so that the large vertical gradient of velocity is induced through the entire depth. This means that in the present observation area, because of its shallow water depth less than 20m, the large bottom velocity may be induced by the wind shear stress. These facts indicate that the ratio between the surface Ekman boundary layer width δ_E and the local water depth h , δ_E/h , is one of

the principal factors for the overall understanding of the velocity field of a C.B.Z..

Figure 7 represents the computed time histories of shore-parallel bottom velocities at St.1 to 3, which show the long-period fluctuation similar to those found in Fig.4. However, the magnitude of the computed velocity, except for St.3, is smaller than that of the measured, and the velocity differences among the three stations are not well reproduced. One of the possible causes of these discrepancies is the difference between actual and simulated turbulence structure of the wind-driven currents. Besides the offshore wave breaking due to wind may act to augment the bottom velocity (Yasuda et al., 1995).

Stratified condition

Figure 8 (a) and (b) show respectively the shore-parallel and cross-shore components of the bottom velocity fluctuation in the case of the stratified condition at St.2, where the water depth is 13m and the distance from the shoreline is 1.5km. The long-period fluctuation as found in the non-stratified condition does not appear in this case. However, more conspicuous feature in the time variation characteristics can be found; namely, as compared with those in the non-stratified condition, these velocity data show high frequency fluctuation with appreciable irregularity, especially in the cross-shore component. To examine the frequency characteristics of these velocity fluctuations, the frequency spectra have been computed as shown in Fig.9, which indicate that in the shore-parallel component the diurnal tidal fluctuation has dominant contribution to the spectrum both in the surface and bottom velocities. In the cross-shore velocity component, on the other hand, the diurnal tidal fluctuation prevails in the surface velocity, while in the bottom velocity the semi-diurnal fluctuation arises with appreciable magnitude.

These diurnal and semi-diurnal velocity fluctuations were further examined with the water surface tidal fluctuation by extracting them from the raw data by applying a band-pass filtering. The results are shown in Fig.10 and indicate that the diurnal components of the shore-parallel velocity in the surface and bottom layer are nearly in phase. This means that the shore-parallel velocity is governed mainly by the *barotropic* tidal motion. On the other hand, the semi-diurnal components of the cross-shore velocity in the surface and bottom layer are mutually 180 degrees out of phase. These facts suggest that the *baroclinic* tidal motion is dominant in the cross-shore direction.

To examine the cross-shore barotropic motion in more detail, the water temperature variations both in time and space has been investigated. The field data for this purpose was obtained with the vertical arrays of several thermometers at the three stations. Figure 11 represents a typical example of the time sequence of the spatial distribution of the water temperature. It can be seen that the bottom water body with relatively low temperature runs up and down on the sloping sea bottom with the excursion length of about 1 km for the front movement. Corresponding to this bottom water motion, the upper water body with higher temperature shows cross-shore oscillating motion in the opposite phase from the bottom water motion.

From these results, the velocity field of the C.B.Z. in the stratified condition may

be summarized as follows; i.e., in the shore-parallel direction, the barotropic tidal motion is dominant, while in the cross-shore direction the baroclinic tidal fluctuation is significant. This difference may be explained by the role of the shore boundary; i.e. it prevents the barotropic tidal motion exclusively in the cross-shore direction. However, the baroclinic cross-shore tidal motion appears as running up and down motion near the shore with large excursion length. Since this baroclinic tidal motion results in appreciable cross-shore exchange of water mass, it may have a dominant role in the cross-shore mass transfer in C.B.Z..

CONCLUSIONS

The major conclusions obtained in the present study for C.B.Z. are summarized as follows:

1. In the non-stratified condition, wind action may induce unexpectedly large velocity even near the bottom with the magnitude beyond the threshold of the sediment movement. This fact suggests that the wind-driven current may cause appreciable sediment transport in the C.B.Z..
2. The ratio between the surface Ekman boundary layer width δ_E and the local water depth h is one of the principal factors for overall understanding of the velocity field in C.B.Z..
3. In the stratified condition, internal tide with baroclinic velocity fluctuation may dominate the cross-shore exchanging motion of water mass.

CHAPTER 266

DEVELOPMENT OF UNDERWATER BEACH PROFILE BY MONOCHROMATIC AND RANDOM WAVES

Karsten Peters¹, Jürgen Neue¹ and Hans-H. Dette², M.ASCE

ABSTRACT: Central to all problems involving alluvial coasts is the response of the underwater profile to given wave conditions. It has been demonstrated in laboratory tests that a constant wave pattern leads to an equilibrium profile. BRUUN (1954) defined this profile by a parabolic equation and various refinements have been proposed since. Applications to field data show, however, that the fit is frequently less than satisfactory. Noteworthy is also that profiles generated in the large wave flumes tend to have significantly narrower surf zones than similar sand beaches in the nature. To answer this and other questions a series of experiments were carried out in the Large Wave Flume (LWF) in Hannover.

INTRODUCTION

The Large Wave Flume in Hannover is 324 m long, 5 m wide and has a depth of 7 m and is capable of generating waves up to 2 m height. These waves are generated by an electronically controlled hydraulic system, which drives a piston-type wave board. A wave absorption device allows the minimization of wave reflections during the tests.

The main objective in the 1993 experiments was the investigation of beach profile response under erosional and accretional wave conditions. The experiments included tests with monochromatic waves and spectral waves at constant water level and spectral waves with superimposed tidal simulation with 1m tidal range.

¹) Research Assistant ²) Academic Director, Department of Hydrodynamics and Coastal Engineering, Leichtweiss-Institute for Hydraulics, Technical University Braunschweig, Beethovenstr. 51a, 38106 Braunschweig, Germany.

EXPERIMENTAL SET-UP

The initial profile geometry consisted of a dune, a 1:30 beach slope and a 70 m long toe berm (Fig. 1). A sand volume of 1.700 m³ was necessary to build up the initial profile. The used sand had a grain diameter of $D_{50} = 330 \mu\text{m}$ with a fairly narrow grading. This is representatively for the beaches along the west coast of the high energy coast of the Island of Sylt/North Sea. Data were collected on bed profile development, water levels and waves, wave energy dissipation, velocity distributions and suspended sediment distributions, only aspects relating to profile development will be discussed here.

The experiments in the Large Wave Flume can be divided into three major parts:

- In part I monochromatic waves were used to generate an equilibrium profile under erosional conditions (Test Series 0 and 2) and accretional conditions (Test Series 1), while the water level was kept constant.
- In part II (Test series 3 and 4) random waves (TMA-Spectra) were used to investigate the profile response under erosional and accretional test conditions with a constant water level.
- In part III (Test Series 5 and 6) random waves (TMA-Spectra) were run together with water level variations in order to simulate a profile development under tidal conditions. The tide had a range of 1 m with the previous constant water depth of 4.50 m representing the high water level. The 12 hours 'sinusoidal' tide is simulated as step function in 25 cm steps of 60 minutes, except high and low water phases with 90 minutes duration.

Table 1 summarizes information on wave parameters, water level, test duration and profile response for the Test Series' 0 to 6. The final profile of each single Test Series was used as initial profile for the following series.

Figure 1. Initial profile built up in the Large Wave Flume in Hannover.

6	result of 5	S+T	1.05	10	3.5 - 4.5	39:00	Accretion

with M - monochromatic waves with H and T

S - TMA-spectrum with H_{m0} and T_p

S+T - TMA-spectrum with water level variations (tidal simulation)

RESULTS AND DISCUSSION

Profile Shape

- In part I monochromatic waves in Test Series 0 with a height of 1.2 m and a period of 5 sec. were used to generate an equilibrium profile under erosional conditions. The initial 1:30 beach slope and the dune (Fig. 2a) were transformed during 17 hours of erosion in Test Series 1 (Fig. 2b) into a typical bar-trough-profile, which can be characterized by the relatively steep and narrow bar and the following trough. The slope of the seaward bar face had a magnitude of 1:5. Arrows in Fig. 2 indicate the direction of the bar movement.

The final profile form in Test Series 0 was stabilized under 16 hours of accretional waves with a period of 10 sec. in the following Test Series 1 (Fig. 2c), where ripple structures were formed seaward and landward of the widened bar. The surf zone has been filled with sand so that the profile level inside the surf zone raised.

Additional 7 hours of erosional wave conditions in Test Series 2 (Fig. 2d) widened the surf zone and formed a steeper bar. The inner surf zone was raised again and rebuild like a foreshore terrace, while the ripple structures at the sea floor disappeared.

Figure 2. Initial and final beach profiles under monochromatic waves and constant water level (Test Series 0 - 2).

- In part II (Test series 3 and 4) irregular waves (TMA-Spectra) were used in order to investigate the profile response under erosional and accretional waves. In 15 hours of erosion the profile has smoothed inside and outside the surf zone and the seaward slope of the foreshore terrace has moved further offshore (Fig. 3a).

11 hours of accretional wave conditions formed ripple structures at the profile bottom (compare with Test Series 1) and rounded the foreshore terrace (Fig. 3b). In comparison to the monochromatic case the bar is much lower and broader.

- In part III (Test Series 5 and 6) random waves (TMA-Spectra) were run together with water level variations in order to simulate the profile development under tidal conditions. Caused by different water levels and spatially moving zones of energy dissipation an equilibrium profile developed in the surf zone area. The final profile of Test Series 5 (Fig. 3c) shows how the inner surf zone has been smoothed, while the seaward front face of the surf zone moved further offshore indicated by an arrow.

39 hours of accretional wave conditions in Test Series 6 flattened the bar profile in the surf zone area and a short terrace could develop (Fig. 3d). The wet beach remained the original shape over the whole Test Series' 5 and 6.

2D/3D Profile Development

In order to illustrate the morphological processes caused by the spectral waves and superimposed tidal simulation more in detail the single profiles of Test Series 5 have been joint together into time-dependent profile evolution diagrams. The upper diagram in Fig. 4 shows the profile evolution under erosional wave conditions over the time of $3\frac{1}{2}$ tidal cycles. Two arrows indicate the starting and the final position of the bar crest. In the lower graph (Fig. 4), which shows the top view of the profile evolution, the phases after low and high water level conditions are marked.

It is significant to see in both graphs how the bar profile changed into a smoothed foreshore terrace, while the seaward face of the terrace moved in rhythmic manner further offshore. The offshore movement of the bar, which is caused by erosional wave conditions, is overlapped by the rhythmic bar movement over the tidal cycles. This morphological rhythm, which can be observed between position 200 m and 220 m in the upper diagram with the help of the contour lines, shows the profile response on the tidal simulation.

At low water level zones of energy dissipation are spatially placed further offshore, which results in a higher erosion potential because the profile in that tidal phase is not in equilibrium with the incoming waves. At high water level the zones of energy dissipation are shifted further onshore and the waves do not break at the front face of the foreshore terrace as at low water levels. The front face of the foreshore terrace moves onshore, by which means the crest height of the bar is increased.

Figure 3. Initial and final beach profiles under spectral waves with constant water level (Test Series 3 and 4) and spectral waves with superimposed tidal simulation (Test Series 5 and 6)

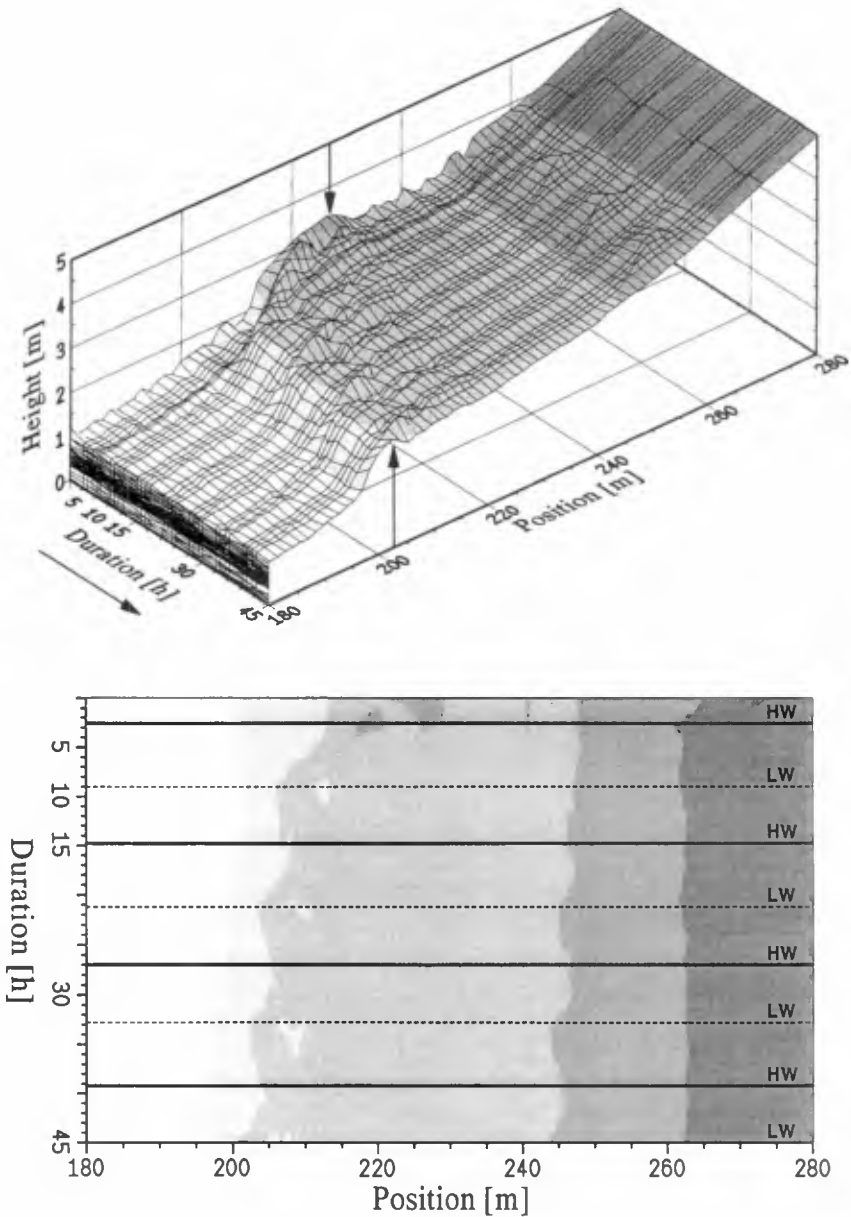

Figure 4. Profile evolution under erosional wave conditions (TMA spectra) with superimposed tide as a 3D-diagram (above) and as a top view (2D diagram below).

By tidal simulation the bar movement has been intensified. This was also observed for Test Series 6 (not illustrated here) under accretional wave conditions, where the rhythmic bar movement caused by the tide overlapped the onshore movement of the bar system.

Bar Position and Bar Height

All profile data for each wave condition can be analysed as a time history over the whole test duration. In the upper graph of Fig. 5 the definitions of the bar height, the bar position and the surf zone width are shown. The bar crest in this case is defined as crest height of the seaward shore face.

In the lower graph of Fig. 5 the surf zone and the enclosed beach with the adjacent shoreline is shown as a top view and the bar height with the corresponding water level as a side view. It can be seen how the bar position at the seaward end of the surf zone developed, and how the crest height of the bar corresponds to this. Additionally the water level is indicated. For Test Series 5 and 6 the manner of tidal simulation is illustrated.

For the Test Series' 1 to 6 it can be summarized that erosional wave conditions (marked with 'E' in the graph) widen the surf zone and lower the crest of the bar, while accretional wave conditions (marked with 'A' in the graph) cause a reduction of the surf zone width and connected with an increase of the bar crest level. The superimposed tide and the tidal range intensify the bar movement, compared to the Test Series with constant water level. These two components, the bar movement at a constant water level and the tidal cycles itself, lead to a rhythmic bar movement. After 2-3 tides the morphological changes during each tide became stable, which means that the morphological changes on the profile over one tidal cycle reached already a minimum.

Ripple Structures

Accretional monochromatic waves (see Test Series 1) have caused large bed forms at the profile bottom. This is demonstrated in Fig. 3b. As a time history the plotted profiles in Fig. 6 show a considerable ripple movement seaward of the bar. Starting with the initial profile at the bottom the intermediate profiles are plotted above in temporal order. It can be seen how the bed forms grow and develop at the seafloor and how they propagate in landward direction until they reach the toe of the bar. The bed forms were not able to propagate into the surf zone, so that they stopped at the toe of the bar and increased the width of the bar. Because the bar crest remained nearly at its position the seaward slope of the bar became flatter.

Figure 5. Definition of the surf zone (above) and position and height of bar over all Test Series' (below)

Figure 6. Development of bed forms during accretional wave conditions (Test Series 1).

CONCLUSIONS

The flume experiments in 1996 showed that beach profiles reached their equilibrium state under erosional and accretional wave conditions in small timescales. For a constant water level the profiles have been transformed into quasi-equilibrium profiles after 10 to 15 hours of test duration. In the case of a varying water level 2-3 tidal cycles were only necessary to develop a state, where the profile changes during one tidal cycle reached a minimum.

The experiments for accretional conditions were affected by a steep seaward slope, what is not naturelike. Further tests are necessary to investigate this question.

ACKNOWLEDGEMENT

This work was carried out as a part of the research project "Untersuchungen zur Ausbildung von Gleichgewichtsprofilen auf der Grundlage von Experimenten im Großen Wellenkanal" ("Investigation in the development of equilibrium profiles based on experiments in the Large Wave Flume") funded by the German Ministry of Education, Science, Research and Technology under contract no. 515-3892-MTK 0559.

CHAPTER 267

TURBULENT STRESSES IN THE SURF-ZONE: WHICH WAY IS UP?

John W. Haines¹ and Guy Gelfenbaum¹

Abstract

Velocity observations from a vertical stack of three-component Acoustic Doppler Velocimeters (ADV) within the energetic surf-zone are presented. Rapid temporal sampling and small sampling volume provide observations suitable for investigation of the role of turbulent fluctuations in surf-zone dynamics. While sensor performance was good, failure to recover reliable measures of tilt from the vertical compromise the data value.

We will present some cursory observations supporting the ADV performance, and examine the sensitivity of stress estimates to uncertainty in the sensor orientation. It is well known that turbulent stress estimates are highly sensitive to orientation relative to vertical when wave motions are dominant. Analyses presented examine the potential to use observed flow-field characteristics to constrain sensor orientation. Results show that such an approach may provide a consistent orientation to a fraction of a degree, but the inherent sensitivity of stress estimates requires a still more restrictive constraint. Regardless, the observations indicate the degree to which stress estimates are dependent on orientation, and provide some indication of the temporal variability in time-averaged stress estimates.

Introduction

Few observations of turbulent stresses in energetic surf-zone conditions exist. This observational void is in marked contrast to modeling efforts describing surf-zone circulation. Published models include details of the stress distribution which have yet to be constrained by field observations (*Svendson et al.*, 1987, *Deigaard et al.*, 1991). Moreover, investigations of nearshore circulation have suggested that simpler (constant eddy viscosity) models of the stress distribution may be inconsistent with field observations of the mean flow field (*Haines and Sallenger*, 1994).

¹U.S. Geological Survey, Center for Coastal Geology, 600 4th St. South, St. Petersburg, FL, 33701

In an attempt to better constrain modeling efforts, a field program was designed to collect data on the vertical and temporal distribution of turbulent stresses within the surf-zone. As part of the Duck94 field program a vertical array of SonTek Acoustic Doppler Velocimeters (ADV) was deployed and 24 days of nearly continuous data collected (Figure 1). The principle aim of the deployment was to return observations of the high-frequency intermittent phenomena associated with bottom and surface boundary-layer processes. The objective was to accurately describe the turbulent statistics of the flow-field adjacent to both boundaries under breaking and non-breaking wave conditions.

A critical requirement for the calculation of stress estimates is the precise definition of an appropriate coordinate system. Because of the relatively large horizontal flows associated with shallow-water incident waves, stress estimates are inherently sensitive to the choice of a vertical coordinate. Previous work has suggested that, under representative incident wave conditions, a precision of 0.03 degrees is required in definition of the tilt angle to assure stress estimates are correct within $1\text{cm}^2\text{s}^{-2}$ (Lohrmann *et al.*, 1995). The appropriate coordinate system may depend on the modeling approach taken. For example, a gravitational coordinate system may produce results significantly different than a coordinate system aligned with the local bed slope. In the absence of field observations of the magnitude and variability of the stresses, the precision required for array design is speculative. Observed variability also provides an indication of the sensitivity of results to the choice of coordinate frame.

The ADV array deployed was instrumented with a continuously recording tilt-meter. Subsequent analyses suggest that the tilt-meter lacked the required accuracy for definition of a reliable coordinate system. Given the shortcomings of the tilt measurements, and the sensitivity of stress estimates to tilt, we are investigating the potential for using the flow data itself to determine an appropriate coordinate system. Regardless of the success of this effort, the data also provides a means for investigating the sensitivity of field observations to deviations from the vertical. The observations will also provide some indication of the magnitude of the temporal and spatial variability of surf-zone stresses.

Data

As part of the Duck94 experimental program, a vertical stack of Sontek ADVs was deployed at the US Army Corps of Engineers (ACOE) Field Research Facility (FRF) in Duck, NC. The deployment consisted of 7 ADV sensors in a vertical array, with supplementary observations of water level, optical backscatterance, array tilt and rotation, and bed elevation from a sonic altimeter (Figure 1). All sensor outputs were digitized *in situ*, synchronized via GPS clock, and written to shore-based storage via a fiber optic cable. The ADVs were sampled at 25 Hz. All other sensors were sampled continuously at 64Hz. The ADV distribution was intended to span the bulk of the water column and return observations of near-bed and near-surface turbulent fluctuations.

Figure 1: Array configuration. Bed height determined from altimeter is approximately 1m from ADV position. ADV sensing volumes are 15cm below the sensor heads shown.

Figure 2: Offshore significant wave heights from the Field Research Facility pressure array in 8m water depth. Solid lines indicate period of sensor deployment, thick solid line shows period of data recovery.

The array was initially deployed in approximately 4.5m water depth, outside the primary bar normally present at the Duck site. Subsequent to deployment, an energetic storm event (October 16-18th, Figure 2) resulted in substantial bar migration, burying the lowermost ADV and obscuring the sampling volume of the next highest sensor. The following weeks saw a slow erosion of the bar, and the upper impacted sensor eventually began to return data. Figure 2 shows the off-shore wave conditions present throughout the deployment. The deployment spans 3 substantial storm events, and only data from these events, where the array was within the surf zone, are discussed in the following. Discussion is further limited to those 5 sensors which were continuously operational. The deployment was violently terminated by surf-zone debris associated with the passage of Hurricane Gordon.

Figure 3: a) Time series from ADV sensors, offset to indicate increasing height above the bed. b) Time series from uppermost ADV and pressure sensor (normalized by velocity variance).

The data quality from the ADV sensors appears to be uniformly good. Figure 3a shows representative data from the 5 operational ADV's, demonstrating extremely high coherence between sensors across the incident wave band. Independent verification of sensor performance is given by comparison to the water level data (as shown in Figure 3b.) Depth decay of the incident-band velocities are consistent with linear theory, supporting the overall data quality. Visual inspection of the data suggests that high-frequency variance "events" occur with greater frequency high in the water column. This may be suggestive of breaking-produced turbulence, and is an area for further investigation.

The data are further described in Figure 4a, showing cross-shore, u , and vertical, w , velocity spectra (Figure 4a). Above incident-band frequencies the

Figure 4: a) u (higher energy) and w spectra. b) pu (thick line) and pw squared coherences. Frequency scales are not equivalent for the two panels. Data shown are post-rotation as determined by the analysis described herein.

spectra show an $f^{-5/3}$ decay. The horizontal velocities generally show enhanced energy levels relative to the vertical velocities at all frequencies. The leveling of spectral energy at high frequencies for the horizontal velocity is due to the noise-floor of the sensor, which is substantially reduced for the vertical component. Coherences between pressure observations, p , and horizontal velocities are high across the incident band and uniformly higher than pw coherences.

Analysis

While the data appear reliable, calculation of the turbulent stresses requires accurate constraint of the coordinate frame. In the following we will attempt to determine the sensor orientation from the observed flow characteristics. In order to maximize the signal-to-noise ratio of the data, further analysis is restricted to high-energy conditions. Selected one-hour data segments, described in Table 1, were analyzed.

The underlying assumption for the following analysis is that the flow field, as described by the observations, contains information about the sensor orientation. A plausible first assumption might be that, following linear wave theory over a horizontal bed, within the incident-wave band, vertical and horizontal velocities are in quadrature. It follows that the time-averaged stress, $\langle uw \rangle$, should be zero. We might then choose to rotate the observations into a coordinate frame where this criteria is met. For a sloping bed, the result is rotation into a bed-normal

coordinate system, or more correctly, rotation into a wave-defined coordinate system. Alternative criteria for determination of the coordinate system might include rotation to zero mean vertical velocity, $\langle w \rangle = 0$, or minimization of the vertical variance, $\langle ww \rangle$. The $\langle w \rangle$ criteria would follow on assuming that mean flows were constrained to be bed-parallel. The validity of this assumption may vary with distance from the bed. In all cases the resulting coordinate frame may be expected to reflect the influence of a sloping bed. It is of interest to examine whether variations on the order of the bed slope significantly change the estimated stress quantities.

The rather simplified view outlined supports a variety of approaches for determining a best rotation. The assumption that relevant information is contained in the wave-driven flow requires application of any methodology across some subset of the entire frequency range sampled. Any of the above criteria might be applied, singularly or in a weighted combination. The assumption of uw -quadrature further supports minimization of a number of co-spectral quantities across the frequency band of interest. In fact, any of the variance properties ($\langle uw \rangle$, $\langle ww \rangle$) may be minimized as band-averaged quantities, or minimized frequency band-by-band in a least-squares sense across the entire frequency range of interest.

A number of candidate criteria were tested. The "best" criteria were determined by the consistency of the resulting coordinate system. This is based on

the necessary assumption that the array was stationary throughout the data examined. Here the deposition of approximately 50cm of sand associated with the bar migration may be viewed as a benefit. This deposition, we presume, further stabilized the array, reinforcing the stability properties provided by a deep central jetted pipe and three anchored guy wires. A further assumption is that the coordinate frame, as defined by the flow, is stationary. This assumption is invalidated by any significant change in the underlying bed topography.

Among all the criteria tested the most consistent results were achieved by constraining the mean vertical velocity to be zero ($\langle w \rangle = 0$) and minimizing the vertical variance subject to this constraint. The minimization requires selection of a frequency band of interest, and it is the band-averaged variance which is ultimately minimized. Variations arising from this selection will be discussed in the following.

The constraint of $\langle w \rangle = 0$ defines a functional relationship between the two tilt angles given by $\gamma = f(\beta)$, where γ is the tilt angle in the alongshore/vertical (yz) plane, and β is the tilt angle in the cross-shore/vertical (xz) plane. The search for $\langle ww \rangle = \min$ may then be restricted to the line in $\gamma\beta$ space defined by the $\langle w \rangle$ constraint.

The shore-normal horizontal coordinate frame chosen approaches, for the nearly shore-normal wave conditions examined here, a frame oriented with the principle component of the wave velocities. As a result, as will be shown, the tilt angle, β , in the shore-normal direction is strongly constrained by the energetic wave motions, while the γ solution, subject to less energetic wave motions, is less well defined. Conversely, small variations in β have a large (relative to γ) impact on the estimated stresses. The alongshore component of the system is dominated by the strong alongshore currents present during most of the runs analyzed. The mean currents influence the rotation through the $\langle w \rangle = 0$ constraint.

This approach to determining a coordinate frame implies a further, less obvious constraint. The minimization procedure ($\langle w \rangle = 0$, $\langle uw \rangle = \min$) is equivalent to constraining the stress terms, $\langle uw \rangle$, to be zero. We do not expect this constraint to be strictly valid, due to system noise and the influence of "non-wave" motions. Nonetheless, the results provide the greatest consistency in determination of sensor tilt. While it might be hoped that averaging the results over several data segments might reduce the effects of such contamination, it is equally (or more) likely that this procedure has a systematic bias in the tilts determined.

The minimization procedure was applied to the data subsets described in Table 1. Stable estimates resulted only when conditions were energetic, suggesting the wave signal must exceed some "noise" level in the data (where noise may include a variety of non-wave motions as well as system or random noise). Further examination indicated that the stability of the estimates was enhanced when the incident wave field was narrow-banded in direction. The stability of the tilt estimates was determined from the variance of the estimates from segmented runs. While variability in the results increased with decreasing wave height,

Figure 5: a) Resulting best γ (tilt in yz plane) values for 1 hour data runs. Values offset to indicate sensor location. Line types indicate the frequency range of the solution. b) Representative cross-shore velocity spectrum and frequency range of solutions (shown by horizontal lines).

there was no significant change in the mean values determined. The final values determined are consistent with the data from the tilt sensor, though this provides constraint within only a few degrees.

Determination of the best rotation in the following is restricted to data Runs 7 – 11 (Table 1) which are relatively continuous in time and subject to energetic incident wave conditions. In fact, all runs listed are well within the surf-zone. Only beneath breaking waves were conditions energetic enough to result in stable estimates. The impact of breaking wave conditions on the approach can not be assessed as non-breaking conditions with large waves were not observed.

Results

Results for the γ (yz plane) tilt determination are shown in Figure 5a. The minimization was applied over three separate frequency bands as shown in Figure 5b. For determination of γ the results are insensitive to the frequency band chosen. The best γ values resulting show significant variance and a marked trend with time. While the variance in γ is large, the relatively modest amounts of incident wave energy in the along-shore direction results in little effect on calculated stress quantities.

Determination of β , in the plane of maximum wave orbital motions, has a far greater impact on stress calculations. Figure 6 shows that while the overall variance in the estimated orientation is reduced relative to γ , the sensitivity to

Figure 6: a) Resulting best β (tilt in xz plane) values for 1 hour data runs. Values offset to indicate sensor location. Line types indicate frequency range of solution. b) Representative cross-shore velocity spectrum and frequency range of solutions (shown by horizontal line).

frequency band selection is increased. Stable estimates require a choice which encompasses the entire incident band, and stability is further enhanced by inclusion of the higher harmonics. This is a somewhat problematic finding. Ideally we would like to determine orientation using an approach independent of information in the higher turbulent frequencies.

The standard deviations of the β values found for the 5 runs are shown in Table 2. The variance reduction with increasing frequency range is clear. There is also an indication that the upper and lower sensors are less well constrained. This is consistent with enhanced turbulence generation at the boundaries (reducing the wave signal relative to other motions) or may suggest some deviation from linear-wave behavior near the free-surface and bed. Overall, consistent tilt estimates are found to within half a degree (2 standard deviations) for all sensors.

Discussion

The mean tilt values from the 5 runs described were applied to correct all the data. The resulting vertical velocity spectra and uw coherences are shown in Figure 4. Vertical velocity variances are substantially reduced relative to the unrotated data, as are uw coherences; suggesting a removal of wave fluctuations from the vertical component. The data still show marked spectral and coherence peaks in the incident wave band. The method applied minimizes the w -variance across the entire band. Peak removal is somewhat enhanced if the variance mini-

Sensor #	Std. deviation β (degrees)

mization is applied in a least-squares sense, band-by-band, across the frequency range selected. Results from this approach are comparable, though somewhat more variable.

The approach followed here is based on some general assumptions about the frequency contribution to the stress. Figure 7 describes this contribution, and the effect of rotation. The figure shows the cumulative stress as higher frequencies are included in the stress calculation. Shown are the results for the best orientation determined previously (averaged over 5 runs), and rotations representative of ± 0.2 and ± 0.4 degrees in γ and β . The solid horizontal line shows the frequency range for which the tilt angles are determined. The best rotation for this run (as opposed to the best average rotation) would result in the intersection of the cumulative stress curve and the high-frequency end of the frequency range. The case shown is a worst case result, serving to illustrate the sensitivity of the stress to relatively small changes in tilt.

The total stress is given by the high-frequency end of the cumulative stress curve (flat beyond the limits shown). It is clear that the resulting estimates are highly sensitive to the tilt. Furthermore, the stress is completely specified to a high degree by frequencies lower than 0.5Hz . This result is independent of uncertainties in the orientation. Also of note, the resultant stresses change in a near-linear fashion with orientation, with the rate of change fairly constant for all sensors. This implies that, though absolute values of the stress may be highly sensitive to orientation, temporal and spatial trends (between-sensor variability) may be more amenable to observation.

For the sensor and data run shown the "best" average rotation results in a flattening of the cumulative stress curve across the incident band. In contrast, the best solution specific to this run and sensor (approximated by the lowermost cumulative stress curve) shows stress contributions which cancel within the incident band. This cancellation of regions (in frequency) of opposing stress is common to all the runs examined. A more rigorous approach will require a more complete consideration of this structure and the indicated physics of incident-band motions.

Overall the message from Figure 7 is rather disheartening. The suggestion

Figure 7: Cumulative stress plots for representative time series. Results from best rotation (thick line), plus (minus) 0.2 degrees in γ and β are given by upper (lower) solid lines, plus (minus) 0.4 degrees in γ and β are given by upper (lower) dotted lines.

Figure 8: Stress estimates for all runs for uppermost (thin) and lowermost (thick) sensors. Error bounds indicated represent ± 2 standard deviations in γ and β .

Figure 9: a) Estimated stresses for all sensors. Sensor location indicated by symbols. b) Variation in alongshore mean current for uppermost (thin line) and lowermost (thick line) sensors.

is that the most consistent results require utilization of flow information across the entire frequency band responsible for the observed stresses. There is no clear indication that the wave band is, in fact, independent of some turbulence band which contributes significantly to the stress.

The stresses resulting from the top and bottom sensors are shown in Figure 8. Calculations have been extended to incorporate all the data from Table 1, applying the best rotation as found for the 5 runs (7 – 11) previously discussed. While we believe the array was stationary across the entire period, we can not demonstrate this to the level required and the data must be viewed with some skepticism. Indications are that the near surface stress is much less variable than that near the bed. The effects of significant changes in bed elevation may be contributory. Estimates show changes in sign for both sensors, and changes in relative sign between sensors. The degree of temporal variability is large near the bed and suggests that observational efforts, with orientation precision of order 0.2 degrees are feasible. Some credibility is added to these results as both the bottom two sensors show marked temporal variability relative to the uppermost sensors (Figure 9a).

The temporal variability noted may be related to both changes in bed elevation and changes in the fluid forcing. The mean alongshore flow was highly variable across the runs examined. Figure 11b shows this variability, which is qualitatively similar to that observed for the stress estimates in the lower water column. The temporal trend in γ previously shown (Figure 5) is strongly correlated with the

Figure 10: a) Instantaneous stress (uw) for uppermost and lowermost (offset by -10^{-4}). b) One and ten minute averages of stress from uppermost sensor.

variability in the alongshore current.

As a final note we leave the rotation problem behind to examine the variability of the stress estimates on short time scales. Figure 10a shows time series of stress from the uppermost and lowermost (offset by -10^{-4}) sensors. The degree of variability in the instantaneous stresses is elevated near the free surface, in contrast to the behaviour previously shown for time-averaged values. Averaged values (1 and 10 minute averages, Figure 10c) from the uppermost sensor clearly show that, over 10 minute periods, the stress estimates display substantial temporal variation.

Conclusions

First and foremost, precise sensor orientation is critical to estimating the absolute magnitude of turbulent stresses. Observed sensitivity to variations in tilt suggests that a precision of order 0.1 degrees in the vertical is required. Flow derived orientations are consistent to roughly 0.4 degrees. This level of precision appears to be sufficient for investigations of the temporal and spatial variability in stress estimates in at least some cases. The lack of a clear physical underpinning for the resulting coordinate frame limits further application of the results. The sensitivity of the results to orientation further suggests that consideration of bed slope effects may be required.

The observations demonstrate that stress estimates are highly variable across a variety of temporal scales. The bulk of the stress is generated by motions at frequencies approaching the incident band fundamental and harmonic frequencies.

The separation of motions into turbulent and wave-driven components is dubious when based solely on the frequency characteristics of the data.

CHAPTER 268

Asymmetric and Irregular Wave Effects on Bedload: Theory versus Laboratory and Field Experiments

Leszek M. Kaczmarek & Rafał Ostrowski¹

1. INTRODUCTION

To parameterise the sediment transport in terms of the wave spectrum and a few other parameters, it is necessary to start from the surface elevation spectrum which can be transformed into orbital velocities at the bed and then to bed shear stress. The bed shear stress so derived is used in a new sediment transport formula put forth by the Authors. The problem is highly non-linear and at a few points in the process it is necessary to make non-linear transformations. This route: surface elevation - sediment transport and the importance of the non-linearity are central to this study.

The theoretical model is based on the concept proposed by Kaczmarek & O'Connor (1993) who used the procedure for matching the solutions of equation of motion in the turbulent flow above the theoretical bed level and in the collision-dominated granular-fluid region. This concept, first used for regular linear waves, has recently been developed for random waves by Kaczmarek et al. (1994) and for non-linear waves by Kaczmarek (1995).

Then, on the above basis, the first attempt was made by Kaczmarek et al. (1995) to formulate bedload theory and verify it using available laboratory data and IBW PAN radio-tracer field results.

This paper presents the results of experiment carried out at IBW PAN laboratory. The verification of the theory for regular and irregular waves using own experimental data is the major goal of this study. There are few experimental data sets for ripple regime, especially in the range $\theta_{2.5}=0.1-0.4$. Therefore the laboratory survey covered this range, particularly taking account of the identification of non-linear effects. This range of small $\theta_{2.5}$ is extremely important as one can expect the equivalence of bedload and total sediment transport in this regime (small suspended load rate). Thus,

¹ both Polish Academy of Sciences' Institute of Hydro-Engineering, *IBW PAN*,
7 Kościarska, 80-953 Gdańsk, Poland

only in this regime bedload theory can be precisely verified while in more severe hydrodynamic conditions bedload is a minor part of total sediment transport.

The various aspects of the non-linearity in respect to moveable bed roughness including the asymmetry of waves (described by 2nd and 3rd Stokes theory) and the wave-current interactions as well as wave irregularity are also discussed. A methodology for predicting the bed shear stress time series for irregular waves is applied to a large number of data sets of bottom velocity, some of which are simulated from field free surface elevation spectrum and some taken from IBW PAN laboratory data. The resulting bed shear stress is used in the bedload transport formula to predict sediment transport rate series for each data set. Hence, some questions concerning the equivalent regular waves generating the same shear stress root-mean-square values and the same bedload root-mean-square values as the irregular waves are answered.

2. MOVEABLE BED BOUNDARY LAYER THEORY

2.1. FORMULATION OF THE PROBLEM

The nearbed dynamics is examined and modelled for the flow regions above and beneath the original static bed line, see Figure 1. The collision-dominated granular-fluid region I stretches below the nominal static bed while the wall-bounded turbulent fluid region II extends above it. Since both water and sand grains are assumed to move in both regions, there must be a certain transition zone between I and II, in which the velocity profiles of I and II would merge and preserve continuity of shape.

Figure 1. Definition sketch

The velocity distribution about a porous rough bed is controlled by various features of roughness and bed permeability. At first it is assumed that the velocity is determined by roughness geometry and outer flow parameters, such as the free-stream wave velocity.

The iteration procedure permits matching of velocities in the regions I and II. The velocity profile in the upper turbulent layer, which is linked with identification of roughness k_a , is determined first and then passed to the lower collision-dominated layer. The intersection of the two velocity profiles is marked as point *A* in Figure 1.

2.2. BASIC EQUATIONS

The flow in the turbulent upper region for regular waves is described by the integral momentum model based on the solution proposed by Fredsøe (1984):

$$\frac{dz_1}{d(\omega t)} = \frac{30\kappa^2 U}{k_a \omega e^{z_1} (z_1 - 1) + 1} - \frac{z_1 (e^{z_1} - z_1 - 1)}{e^{z_1} (z_1 - 1) + 1} \frac{1}{U} \frac{dU}{d(\omega t)} \quad (1)$$

$$\frac{dz_1}{d(\omega t)} = \frac{30z_1^2 \left[\left(\frac{\kappa U}{z_1} \mp u_{f0} \right) \left(\frac{\kappa U}{z_1} \pm u_{f0} \right) \pm u_{f0}^2 \right]}{k_a \omega U \left[e^{z_1} (z_1 - 1) + 1 \right]} - \frac{z_1 (e^{z_1} - z_1 - 1)}{e^{z_1} (z_1 - 1) + 1} \frac{1}{U} \frac{dU}{d(\omega t)} \quad (2)$$

for pure wave motion and wave with/against current, respectively.

The solutions of Equations (1) and (2) are achieved by the Runge-Kutta second-order method. As a result for a particular case, the function $z_1(t)$ is obtained and the time distributions of the friction velocity $u_f(t)$ and boundary layer thickness $\delta(t)$ are calculated thereafter using the following equations:

$$z_1 = \frac{U\kappa}{u_f \mp u_{f0}} \quad (3)$$

$$\delta = \frac{k_a}{30} (e^{z_1} - 1) \quad (4)$$

It should be emphasised that the free stream velocity $U(t)$ can be described as linear or nonlinear, thus Fredsøe's model can be adapted to nonlinear (asymmetric) wave motion, cf. Kaczmarek & Ostrowski (1992).

The solutions of Equations (1) and (2) enable the values of $u_{f\max}$ to be determined, if the quantities k_a are specified. To evaluate the roughness parameter k_a an iterative procedure is proposed for finding the matching point *A*.

The approach for irregular waves incorporates a time-invariant, two-layer eddy viscosity and bottom boundary layer thickness. Bed roughness is calculated using the iteration procedure taking account of the reduction of this parameter due to irregularity of wave motion. More detailed discussion on modelling of bed roughness is given in section 3.1.

In the sub-bed flow region, the sediment concentration is high and chaotic collisions of grains are the predominant mechanism. Particle interactions are assumed to produce two distinct types of behaviour. The Coulomb friction between particles give rise to rate-independent stresses (of the plastic type) and the particle collisions bring

about stresses that are rate-dependent (of the viscous type). The use of the mathematical description by Sayed & Savage (1983) for determination of the stress tensor was made and the balance of linear momentum according to Kaczmarek & O'Connor (1993) leads to the following equations:

$$\alpha^0 \left(\frac{c - c_0}{c_m - c} \right) \sin \varphi \sin 2\psi + \mu_1 \left(\frac{\partial u}{\partial z'} \right)^2 = \rho u_f^2 \quad (5)$$

$$\alpha^0 \left(\frac{c - c_0}{c_m - c} \right) (1 - \sin \varphi \sin 2\psi) + (\mu_0 + \mu_2) \left(\frac{\partial u}{\partial z'} \right)^2 = \left(\frac{\mu_0 + \mu_2}{\mu_1} \right) \Big|_{c=c_0} \rho u_f^2 + (\rho_s - \rho) g \int_0^{z'} c dz' \quad (6)$$

in which:

ρ_s and ρ are the densities of the solid and fluid, respectively;

α^0 is a constant;

c_0 and c_m are the solid concentrations corresponding to fluidity and the closest packing, respectively;

μ_0 , μ_1 and μ_2 are functions of the solid concentration c :

$$\frac{\mu_1}{\rho_s d^2} = \frac{0.03}{(c_m - c)^{1.5}} \quad (7)$$

$$\frac{\mu_0 + \mu_2}{\rho_s d^2} = \frac{0.02}{(c_m - c)^{1.75}} \quad (8)$$

The value φ in Equations (5) and (6) is the quasi-static angle of internal friction, while the quantity ψ is equal to:

$$\psi = \frac{\pi}{4} - \frac{\varphi}{2} \quad (9)$$

For the calculations the following numerical values are recommended:

$$\frac{\alpha^0}{\rho_s g d} = 1 \quad c_0 = 0.32 \quad c_m = 0.32 \quad \varphi = 24.4^\circ \quad (10)$$

where d denotes the diameter of grains.

3. MODELLING OF BEDLOAD UNDER IRREGULAR WAVES

3.1. BED ROUGHNESS

The apparent bed roughness parameter k_a is a central quantity in the theoretical model. Both the turbulent and sub-bed velocity profiles depend on k_a , which is not known a priori. Therefore an iteration procedure is proposed for finding the matching point A between these profiles. The matching is assumed to take place at the phase of maximum shear stress, although at any other phase of oscillatory motion there must be some transition between the two profiles. Under monochromatic waves the maximum shear stress is the maximum value of shear stress during a wave period, while for spectral waves it becomes the maximum value of the random shear stress

time series. To calculate this value it is proposed to use, the following simple relation, Kaczmarek et al. (1994):

$$\tau_{\max} = \frac{3\tau_{rms}}{\sqrt{2}} = 3\delta_{\tau} \quad (11)$$

The choice is fairly arbitrary, however, as it was shown by Kaczmarek et al. (1994), it yields the best agreement of the calculations of wave friction using Madsen et al.'s (1990) data.

For engineering purposes it is useful to approximate the theoretical results by a curve expressed in terms of skin friction. To determine the skin friction one can follow Nielsen's (1992) description:

$$\theta_{2.5} = \frac{1}{2} f_{2.5} \psi_1 = \frac{1}{2} f_{2.5} \frac{(a_{1m}\omega)^2}{(s-1)gd} \quad (12)$$

$$f_{2.5} = \exp \left[5.213 \left(\frac{2.5d_{50}}{a_{1m}} \right)^{0.194} - 5.977 \right] \quad (13)$$

in which $s = \rho_s/\rho$.

The iteration procedure proposed for finding the matching point A between the velocity profiles (Fig. 1) was run for a wide range of small and large scale conditions and for a few diameters of sandy bed. Then the results were approximated yielding the following formulae for regular and irregular waves, respectively:

$$\frac{k_a}{d} = 47.03\theta_{2.5}^{-0.66} \quad (14)$$

$$\frac{k_a}{d} = 26.64\theta_{2.5}^{-0.71} \quad (15)$$

For irregular waves k_a is calculated using Eq. (15) taking root-mean-square wave height (or free-stream velocity) and peak period for determination of $\theta_{2.5}$.

The moveable bed roughness under sinusoidal and asymmetric waves with/versus a steady current has also been considered. The numerical solution of Eq. (2) is used with the free stream velocity $U(\omega, t)$ expressed using linear or nonlinear approximation. The considerations on nonlinearity have been limited to the 2nd Stokes wave propagating without current and with/against weak and strong currents. For wave-current motion the ratio U_{mean}/U_{1m} was kept constant and amounted to 0.2 and 0.5 for weak and strong current, respectively. The quantity U_{mean} is the steady current, known as an input, averaged over water depth in the outer region (outside the bed boundary layer). The mean slip velocity (at the top of the bed boundary layer) is calculated from U_{mean} with the assumption of the logarithmic velocity profile in the outer region, using the model of Kaczmarek & Ostrowski (1992). This model also provides the value of shear stress $u_{\tau 0}$ resulting from the presence of steady current.

Figure 2 depicts the relative differences in roughness computed for regular waves (linear and nonlinear) and currents, as well as irregular wave motion, with respect to pure sinusoidal cases. The results imply that the greatest reduction of the roughness

parameter k_a (about 40%) is observed when the waves are irregular and in a certain range of Shields parameter - when the nonlinear waves are accompanied by a steady current. Smaller reductions of k_a occur for sinusoidal waves superimposed on currents. It can be seen that for nonlinear cases the reduction of k_a is more distinct for waves propagating with the current than for waves versus the current.

Figure 2. Relative differences (smoothed values) in k_a with respect to sinusoidal case Hence, the irregularity of waves is the most important factor causing the reduction of moveable bed roughness.

3.2. SHEAR STRESS AND BEDLOAD

It is convenient to introduce complex notation which determines the dependence of velocity on time and will ensure the analytical solution of the equation of motion. The free stream velocity will be written as $U(t)=U\exp(i\omega t)$, in which U = real velocity amplitude. Similarly, one may write:

$$u(z,t) = u(z)e^{i\omega t} \quad \text{and} \quad u_d(z,t) = u_d(z)e^{i\omega t} \tag{16}$$

in which $u(z)$ and $u_d(z)$ are in general complex due to the phase shift relative to the free stream velocity. The equation of motion may now be written as:

$$\frac{d}{dz} \left[\nu_t(z) \frac{du_d(z)}{dz} \right] - i\omega u_d(z) = 0 \tag{17}$$

It is fortunate that this equation is explicitly solvable both when $\nu_t(z)$ varies linearly with z and when it is a constant. Thus, following Brevik (1981), the two-layer eddy viscosity model is proposed:

$$\nu_t(z) = \kappa u_{fr} z \quad \text{for} \quad \frac{k_a}{30} < z \leq \frac{\delta_r}{4} + \frac{k_a}{30} \tag{18}$$

$$\nu_t(z) = \kappa u_{fr} \left(\frac{\delta_r}{4} + \frac{k_a}{30} \right) \quad \text{for} \quad z > \frac{\delta_r}{4} + \frac{k_a}{30} \tag{19}$$

where $u_{fr} = \sqrt{\tau_r / \rho}$ and δ_r are the representative friction velocity and representative bottom boundary layer thickness, respectively.

To solve the Eq. (17) the free stream velocity is specified as that associated with a wave spectrum, i.e.:

$$U(t) = \sum_n U_n e^{i\omega_n t} \quad (20)$$

in which the index n denotes summation over frequencies. With such a representation of $U(t)$ the velocity amplitudes U_n are related to the near-bottom orbital velocity spectrum and to the surface amplitude spectrum through:

$$U_n = \sqrt{2S_U(\omega_n)d\omega} = \frac{\omega_n}{\sinh(k_n h)} \sqrt{2S_\eta(\omega_n)d\omega} \quad (21)$$

in which ω_n and k_n are related to each other by linear dispersion relationship.

The linearity of Eq. (17) combined with the assumed time-invariant eddy viscosity concept (Equations (18) and (19)) suggests a solution in the form of:

$$u(z, t) = \sum_n u_n(z) e^{i\omega_n t} \quad (22)$$

in which $u_n(z)$ represents the complex velocity component amplitudes and only the real part of Eq. (22) constitutes the solution sought.

Introducing Equations (18) and (19) into Equation (17), one can obtain the equation for each velocity component n . Introducing the dimensionless variable:

$$\xi_n = \left(4\omega_n \frac{z}{\kappa u_{fr}} \right)^{\frac{1}{2}} \quad (23)$$

Eq. (17) reduces to the standard differential equation for the Kelvin functions of zeroth order, with ξ_n as the independent variable.

On the basis of the velocity solution one can obtain the shear stress at $z=z_0$ (complex value) which can be expressed as:

$$\tau(t) = \tau_n \exp[i(\omega_n t + \varphi_{\tau_n})] \quad (24)$$

where τ_n and φ_n are the bed shear stress amplitude and phase, respectively, corresponding to n th harmonic component U_n of the input free stream velocity random series $U(t)$.

The solution obtained for the turbulent flow in the wave boundary layer involves the representative friction velocity u_{fr} and the representative thickness of the boundary layer δ_r , which are yet to be specified. Although each harmonic component of wave motion is described by the same equation, i.e. Equation (17), there is a coupling between the components incorporated in the eddy viscosity. This appears in the modelling of the representative values u_{fr} and δ_r by iterative procedure which is schematically shown in Figure 3. The quantities u_{fr} and δ_r are determined by using Eq. (1) and specified as:

$$u_{fr} = u_{f \max} \quad (25)$$

$$\delta_r = \delta_m = \max(\delta_1, \delta_2) \quad (26)$$

where u_{fmax} is the maximum value of bed shear velocity during the wave period, that is $\max[u_f(\omega t)]$ and δ_1 and δ_2 the boundary layer thicknesses at the moments corresponding to maximum and minimum velocity at the top of the turbulent boundary layer. For a given by free stream irregular series the iterative procedure of Fig. 3 is used to determine the representative period T_r , friction velocity u_{fr} and the boundary layer thickness δ . The exemplary shear stress results vs. Gdańsk lab data, collected by Ostrowski (1993), are shown in Figure 4.

Figure 3. Computation of bed shear stress and bedload under irregular waves

Once the bed shear stress is determined the velocity distributions can be computed for the regions I and II (Fig. 1), as well as the concentration of grains in bedload layer. Basing on Bagnold's (1956) definition, according to which the bedload is a part of sediment transport subject to inter-granular forces, the bedload layer can be

represented as the region II. Knowing the instantaneous shear stress one can calculate the instantaneous bedload rate from velocity and concentration profiles in this layer:

$$Q_B = \int_0^{\delta_s} u(z', t) \cdot c(z', t) dz' \quad (27)$$

and the dimensionless bedload rate defined as:

$$\phi_B = \frac{Q_B}{d\sqrt{(s-1)gd}} \quad (28)$$

Figure 4. Theoretical and experimental irregular shear stress

The methodology for predicting the bedload time series for irregular waves was applied to a number of laboratory data sets. These results are discussed in the next section. The presented concept was also used for modelling of the bedload series for the field free surface elevation series taken at IBW PAN Coastal Research Facility in Lubiato. The exemplary results of the bedload simulation are given in Figures 5 and 6.

Figure 5. Time series of shear stress and bedload simulated for field wave input

Figure 6. Spectra of shear stress and bedload simulated for field wave input

4. LABORATORY BEDLOAD SURVEY

4.1. EXPERIMENTAL SETUP

The measurements were carried out in the IBW PAN wave flume. The wave flume, 0.5 m wide and 22.5 m long, is equipped with a programmable wave maker and can be filled with water up to 0.7 m. Reinforced concrete slabs 8 cm thick were placed on the bottom with a sandy measuring section (also 8 cm thick) 7 m long situated about the middle of the flume. Natural sand was used in the experiments with a grain diameter $d_{50}=0.22$ mm.

For each test, free surface elevation was registered at three points along the flume. The horizontal component of free stream velocity was measured at one point in the measuring section, using a micro-propeller, together with one of the wave gauges which was located above the sand trap. The other two wave gauges were spaced $1/4*L$ from each other (L being a wave length) to estimate the reflection effects in the flume. Experimental setup, together with the sand trap, is shown in Figure 7.

The sand trap was covered by a lid and buried in the sandy section before each test. Then the waves were generated until bed ripples were fully formed, which took 25-60 minutes. The lid, suspended on four strings, was removed thereafter, together with a thin layer of sand on it. Then the wave action was continued for 1.2-15 minutes and

sediment grains were being accumulated in the sand trap. Finally, the grains were siphoned from the trap and weighed to determine the sedimentation quantity.

The sand trap had two cells to ensure the determination of onshore and offshore bedload components.

Together with the sedimentation, bed forms geometry was measured and their shape was assessed after each test.

Figure 7. Experimental setup

A constant water depth of $h = 0.5$ m above the measuring section was maintained during each test. The experiments were carried out for six sets of parameters for regular waves (Tests 1, 2, 3, 4, 11 and 12) and for six irregular wave series (Tests 5, 7, 8 for JONSWAP and Tests 6, 9, 10 for Pierson-Moskowitz spectrum generated by the wave maker). As a total, 141 series were run, among which 103 ones were regular.

The conditions expressed in terms of $\theta_{2.5}$ varied roughly from 0.1 in Test 3 to 0.4 in Test 12. This range of rippled bed (cf. Fig. 4b) is extremely important as one can expect the equivalence of bedload and total sediment transport in this regime (small suspended load rate). Thus, only in this regime bedload theory can be precisely verified while in more severe hydrodynamic conditions bedload is a minor part of total sediment transport.

4.2. RESULTS OF MEASUREMENTS VS. PRESENT THEORY

The experimental bedload data in comparison with theoretical results obtained by using present theoretical linear approach are shown in Figure 8.

The waves registered in the flume had a slightly asymmetric shape. Therefore, for better representation of actual laboratory conditions, the theoretical results have been produced using present approach adapted for non-linear waves. The free stream velocity in Equation (1) was described using 2nd order Stokes theory, as indicated by Kaczmarek & Ostrowski (1992). Then, for known distributions of u_f in time, the instantaneous bedload transport rate has been found from Equations (5) and (6) for

the entire wave period, integrated over time and averaged over wave period. These results are also shown in Figure 8.

The conformity of theoretical evaluations and experimental data can be seen in Figure 8, especially while using non-linear approach (except for Test 2). It should be pointed out that for long and highly asymmetric waves, represented by Test 11 (Ursell parameter of 40), the experimental data fit the present non-linear theory while they differ significantly from the linear approach. The most severe shear stress conditions generated in the flume without wave breaking had a $\theta_{2.5}=0.4$ and were achieved in Test 12. However, the Ursell number (equalled to 31) was less than in Test 11. In Test 12, a very distinct concentration of suspended sediment was observed which could result in increased accumulation in the sand trap, bigger than theoretically modelled, using both linear and non-linear theory.

Figure 8. Regular bedload IBW PAN lab data vs. present linear and non-linear theory

The laboratory bedload data for irregular waves in comparison with theoretical results are depicted in Figure 9. Computed values have been modelled using the present computational procedure (Fig. 3) for the full-time (15 minutes) water surface elevation series registered at the measuring section. The agreement between theoretical and experimental results appears to be very good.

Figure 9. Bedload IBW PAN lab data vs. present theory for irregular waves

For the sake of full comparison the laboratory bedload data for regular and irregular waves are plotted together in Figure 10, against linear theory. Additionally, the bedload results simulated for field-recorded waves are included in Fig. 10. All results for irregular waves are presented as a function of dimensionless stress $\theta_{2.5}$, calculated using root-mean-square wave height and representative wave period T_r .

Figure 10. Bedload under regular and irregular waves vs. present linear theory

Figure 10 implies that the bedload rate for irregular cases can be successfully modelled with the use of present linear theory taking root-mean-square wave height

H_{rms} and representative wave period T_r as an input. It should be noted that in analysed cases the computed values of T_r are close to those of peak period, thus the peak period (T_p) can be used as representative. However, further studies are necessary to find out whether this conclusion is valid for all types of spectra.

It can also be seen from Figure 10 that for weak and moderate shear stress conditions the regular laboratory bedload data lie slightly above the results obtained using linear theory, thus for precise determination of bedload rate under regular-asymmetric waves the non-linear approach should be used. Finally, it can be concluded that for high shear stresses the present linear theory underestimates bedload rate, most probably - due to significant concentration of suspended sediment.

CHAPTER 269

KINEMATICS AND SHEAR STRESSES FROM COMBINED WAVES AND LONGSHORE CURRENTS IN THE UK COASTAL RESEARCH FACILITY

Richard R.Simons¹, Ruairi D.MacIver², Wameidh M.Saleh²

Abstract

The paper describes a series of experiments involving regular and random waves propagating over an orthogonal longshore current in the UK Coastal Research Facility at Wallingford. Mean and wave-induced velocities have been measured above a horizontal fixed rough bed using three acoustic velocimeters, and simultaneous measurements of mean and oscillatory bottom shear stress have been made with a UCL shear cell. Wave-induced shear stresses have been expressed as friction factors and compared with widely used empirical formulae. Other results have been compared with predictions for shear stress and apparent bed roughness from eight wave-current theories. The predicted enhancement of these parameters is judged against the relative strengths of the waves and currents tested, and against the practical range of conditions achievable in such laboratory basins.

Introduction

In trying to understand the effects of waves and currents on the coastal environment it is important to be able to predict the forces exerted on the seabed by the fluid motion and, conversely, what effect the seabed has on that motion. Such boundary layer processes are included in the wave-current interaction elements of the new generation of coastal numerical models, but there remains insufficient reliable data against which predictions from these models can be validated. Researchers at UCL are involved in a number of projects aimed at filling this gap.

In an earlier series of tests performed by the UCL group [Simons *et al.* (1992), (1994)], bottom shear stresses were measured directly using a novel shear cell device under conditions including regular and random waves propagating across an orthogonal current. This work suggested that waves have a significant effect on the current-induced mean shear stresses but that an additional current makes little difference to the wave-induced stresses. However, the relatively small basin used for those tests meant that the flows were not all fully rough turbulent. To produce

results which can be applied to field-scale conditions and provide a valid test for the models, the experiments reported here have been carried out in the UK Coastal Research Facility (UKCRF) at Reynolds numbers well beyond transition and over a large fixed bed roughness.

The number of models in the literature which offer possible solutions to the problem of wave-current interaction in a turbulent coastal flow field is too extensive for detailed consideration here. All such models require empirical assumptions about the physical structure of the combined flow, and many also lead to difficult calculations in achieving a solution. In their review of the subject, Soulsby *et al.* (1993) put forward a simplified method for applying these theories using a set of standard formulae to relate the significant parameters. Each model is characterised by a unique set of 26 coefficients - found by fitting curves through model solutions for a wide range of input parameters - and these are used in the standard formulae to determine mean and maximum shear stresses. These "parameterised" versions of certain models are compared with the present experimental data later in this paper, both in terms of the enhanced bottom shear stress and also the apparent increase in bed roughness when waves are superimposed.

UK Coastal Research Facility

The UKCRF has been designed to provide a controlled environment in which various coastal processes can be simulated at relatively large scale. It measures 54m by 27m overall, with a central test region 20m by 15m (**fig.1**), and is designed for

water depths between 0.3m and 0.8m - although the present tests have been performed with 0.5m depth. The wave generation system consists of 72 individually controlled wave boards (each 0.5m wide) mounted along one wall of the basin. This can produce orthogonal or oblique-incidence regular or random waves up to 30° from shore-normal, with periods between 0.8s and 3.5s and heights up to 0.25 metres.

Currents are circulated by 4 independent reversible flow pumps and are introduced into the basin through 40 inlet flumes, each controlled by its own undershoot weir, with a matching set of flumes at the outlet end. One of the novelties of the UKCRF is that this system allows wave-driven currents to be circulated and at the same time allows for simulated wind- or tidally-driven longshore currents to be superimposed. Another is that the pumps act under programmable control, thus allowing time-varying (tidal) longshore currents with a user-defined period to be superimposed onto a controlled sequence of waves.

The facility is equipped with a wide range of instrumentation. For the present tests, a UCL shear cell was used to make direct measurements of the wave- and current-induced bottom shear stresses on the horizontal region of the basin. Briefly, the shear cell consists of a thin 250mm diameter plate supported level with the bed on four thin needles and deflecting laterally under the action of any horizontally applied shear stress at the bed. The movement (less than 0.5 mm) is recorded by two orthogonal eddy-current sensors and converted into an analogue voltage - as described in Grass *et al.* (1995).

A 3-d fibre-optic laser Doppler velocimeter (restricted here to 2-d operation only) provided detailed information within the bottom boundary layer; three Sontek 3-d acoustic Doppler velocimeters (ADV) were mounted, one above the other (**fig.2**), on the z-axis of the instrument deployment bridge, thereby speeding up the process of measuring full vertical profiles of mean and wave-induced velocities; and 4 wave probes were deployed close to the shear cell to provide measurements of wave height and period.

To control the ADV's when they are operating near the centre of the basin, it is necessary to deploy a dedicated computer on the instrument carriage. The system is then operated from the control room via long cables linking the keyboard, screen and data logger to the remote processor.

For the present set of tests, the bed was roughened with nominal 10mm diameter granite chippings stuck to the concrete base of the basin and also to the surface of the UCL shear cell (**fig.3**). The bottom roughness was stuck as a single layer, with a thin coating of adhesive painted onto the bed, the chippings rolled into it and left to set, and the surplus swept off some time later. The observed Nikuradse roughness was 18.7 mm.

Long-crested waves were generated in the offshore region and propagated across

Figure 2 **Photograph of the three Sontek acoustic velocimeter probes**

Figure 3 Granite roughness on the surface of the UCL shear cell

the horizontal bed before moving on to a 1-in-20 sloping plane beach. The general design and capabilities of the basin are described by Simons *et al.* (1995).

Experiments

The experiments reported here were performed with waves propagating orthogonally across a turbulent current above a fixed bed roughness. They involved:

- a) 2 wave sequences generated from Jonswap spectra with peak frequencies of 0.4 Hz and significant wave heights of 0.15m and 0.18m; and
- b) 5 regular wave conditions, with periods in the range 1.7s to 3s and heights between 0.18m and 0.26m.

Each test condition was repeated with the velocity measuring system positioned at different heights above the bed to allow vertical velocity profiles to be determined. For the tests on regular waves, between 150 and 200 wave cycles were recorded at each position - from which ensemble averages were processed; for the random waves, the sequences lasted 20 minutes.

Figure 4 Graph showing the distribution of longshore current across the beach in the central test region of the basin.

The longshore current superimposed on the waves had a maximum velocity in the deep water region of approximately 0.14 m/s, reducing parabolically up the plane beach - see **fig.4**. At each position on the basin centreline, the vertical profile was logarithmic and demonstrated that the boundary layer was fully developed. This particular current setting is one of the standard reproducible conditions for the UKCRF established during initial evaluation work on the Facility. Test conditions and results are listed in **Table 1**.

Figure 5 Longshore current mean velocity profiles: $u \ v \ \log z$
Current alone and with waves superimposed.

Results

Analysis of the logarithmic mean velocity profiles for the current alone suggested a bed roughness, k_s , of 18.7mm. When orthogonal (or oblique) waves were superimposed, the logarithmic profiles (**fig.5**) showed the expected increases in mean shear stress and apparent bed roughness from their values for current alone. It was also noted that the average-over-depth flow rate was slightly higher at the offshore measuring position when the waves were present. This was attributed to the non-linear wave-current enhancement of mean shear stress being greater in shallow water than in the deep water region, thereby producing a greater resistance to the longshore current inshore on the 1-in-20 beach and thus redirecting the flow out towards the deeper water - where the present measurements were made.

Table 2 shows a comparison between the observed mean longshore shear

stresses τ_{wc} deduced from the logarithmic velocity profiles and predictions from a number of wave-current models. τ_c was measured for the current on its own. The values from Davies *et al.* (1988), Fredsoe (1984), Huynh-Thanh & Temperville (1991), Myrhaug & Slaattelid (1990), and O'Connor & Yoo (1988) were all deduced from the parameterised versions of those models presented by Soulsby *et al.* (1993) and discussed above; this was particularly helpful for the fully numerical models which would otherwise have been inaccessible. The values from Coffey & Nielsen (1986), Sleath (1991), and Nielsen (1992) were calculated (more-or-less) directly.

Table 3: Apparent bed roughness k_s : comparison of measurements from regular wave tests with predictions from 8 theories.

However, these three models are intended primarily to predict the enhanced bed roughness assuming an appropriate value for wave-current shear stress. To deduce the predicted shear stress in these cases, it has been assumed that the mean-over-depth velocity is as measured for the wave-current tests, and also that the velocity profile remains logarithmic across the full flow depth. Then, starting with an initial guess for shear stress, it is possible to calculate a first estimate for apparent bed roughness from an integrated form of the logarithmic boundary layer equation. An improved estimate for shear stress can then be found, and repeated iteration used to produce solutions both for apparent roughness and for mean shear stress.

Table 3 gives a similar comparison to that described above, but now looking at the apparent bed roughness. The predictions have been calculated, again assuming fully logarithmic velocity profiles and also that the mean-over-depth velocity is as measured in the combined wave-current flow. This was done to allow flows to be compared "like-for-like" and to overcome the problem of the local flow rate having been altered by the redirection of the longshore current (as discussed above). In order to obtain these data for each case, it was necessary to integrate the velocity profiles manually - taking into account the additional Eulerian mean flow taking place above Still Water Level through the wave crest. A typical example, showing a curve-fit through the scattered ADV data from which the mean-over-depth velocity was calculated, is shown in **fig.6**.

The first thing to note from these two tables is that the apparent bed roughness and mean shear stress have, as the models all predict, both increased when the waves are superimposed. That there is not a steady increase with relative wave strength can be attributed to the observation that the longer period waves have become non-linear with significant secondary crests. However, even when looking at the 1.7s and 2.1s period tests, it can be seen that there is a wide range of predictions and that no single model stands out as ideal.

Turning to the wave-induced stresses, friction factors for the regular wave tests calculated from ensemble averaged wave-induced velocities and shear stresses showed no visible change when the current was superimposed, so confirming UCL's earlier results.

Continuous time-series of velocities and shear stresses from the random wave tests were analysed half a wave cycle at a time to produce some hundreds of independent values of friction factor through each sequence of irregular waves (**fig.7**). Values were calculated for a specific half-wave period, determining the amplitude between consecutive trough and crest - of wave-induced shear stress from the shear cell, and of velocity from ADV measurements outside the wave boundary layer.

Again, these showed that for the range of test conditions possible in the UKCRF

Figure 6 Mean velocity profiles for:
 a) current alone, b) current + wave ($T=2.5s, H=0.2m$)

Figure 7 Friction factor calculated from each half wave cycle:
 Random wave sequence: $T_p=2.5s$, $H_s=0.15m$

there is no discernable increase in friction factor (and hence no effect on the wave-induced bottom shear stress) when a current is superimposed. However, they did confirm that Swart's (1974) formula for friction factor gives a good estimate, for waves alone or with an orthogonal current added, even at very low a/k where a constant value has sometimes been proposed. Comparison with the power law approximation proposed in Ockenden and Soulsby (1994) is also encouraging for the practical range $5 < a/k < 100$ although this appears less accurate at low values of a/k and cannot be correct at high a/k where the friction factor should tend to a constant value for a quasi-steady current.

If we now consider what enhancement of wave-induced shear stress (or friction factor) is to be expected when a current is superimposed, it seems that none of the models actually predicts any significant enhancement under the conditions being investigated. This is because the wave boundary layer only starts to be modified when the current-induced mean shear stress is of a similar magnitude to the wave-induced stress, and this can only be achieved in the laboratory if mean flow velocities are impractically high or the waves are so small as to be dominated by viscosity and surface tension. So the consistent behaviour of the waves whether with and without the longshore current is indicating that this aspect of wave-current theory is valid.

Conclusions

For a longshore current, mean shear stress and apparent bed roughness are both increased significantly by the addition of relatively strong orthogonal waves. Predictions from the wave-current models vary significantly, although the Davies *et al.* (1988) and Fredsoe (1984) theories appear most consistent with the present data.

Swart's (1974) formula for wave friction factor gives excellent agreement with the values measured by the shear cell for both regular and irregular waves.

The addition of a relatively weak longshore current has no effect on the bottom shear stress generated by waves on a rough bed.

The UCL shear cell is capable of measuring mean and oscillatory bottom shear stresses in a large-scale three-dimensional flow field.

CHAPTER 270

Movable Bed Roughness in the Flow of Irregular Waves and Currents over Movable Beds

Zai-Jin You¹ Peter Nielsen²

Abstract

The bed roughness k_s in the flow of irregular waves and currents over a movable bed is studied on the basis of measured current profiles and the model of You (1994). It is found that the movable bed roughness k_s is affected by both waves and currents and that the existing formulae derived in purely oscillatory flow generally fail to predict k_s in the flow of waves and currents. A new formula is proposed to calculate k_s in the flow of irregular waves and currents over a movable bed. The present bed roughness formula together with You's (1994) model gives better prediction of current shear velocity \bar{u}_{cw}^* and especially apparent roughness z_1 than the existing formulae derived in purely oscillatory flow.

Introduction

The bed roughness k_s is an important input parameter in the modelling of coastal processes, but usually unknown in the coastal zone where the seabed is often movable owing to irregular waves and currents. The movable bed roughness k_s in purely oscillatory flow has been studied by many investigators (Van Rijn, 1982, Grant and Madsen, 1982; Nielsen, 1983; Raudkivi, 1988), but little investigated in the flow of irregular waves and currents. Consequently, the formulae derived in purely oscillatory flow have been often applied to estimate the movable bed roughness k_s in

¹Victorian Institute of Marine Sciences, Locked Bag 7, Collins Street East Post Office, Melbourne 8003, AUSTRALIA.

²Department of Civil Engineering, University of Queensland, Brisbane 4072, AUSTRALIA.

in the flow of irregular waves and currents. For example, Coffey (1987) used the formulae of Nielsen (1983), Van Rijn (1982), and Grant and Madsen (1982) to calculate k_s at $\theta = 0^\circ$, 90° and 180° , but did not explain why the different formulae were applied for the different angles, where θ is the angle between the wave propagation and a current.

Van Kampen and Nap (1988) found that the movable bed roughness k_s , estimated at $\theta = 0^\circ$ or 180° from their experimental data was very large and could not be predicted by the existing formulae. In the sequential experiment of Havinga (1992), however, k_s estimated at $\theta = 60^\circ$ or 120° was found to be very small and could not be predicted by the existing formulae either.

Drake *et al.* (1992) used the model of Grant and Madsen (1979) to study the movable bed roughness k_s in the flow of irregular waves and currents on the basis of measured current profiles. A simple empirical formula was suggested to be $k_s = 28\eta^2 / \lambda - 0.14\theta$, where $0 \leq \theta \leq 90^\circ$. Unfortunately, the model of Grant and Madsen (1979) together with the empirical formula still failed to predict the apparent roughness z_1 as shown in Figure 4 of Drake *et al.* (1992).

More recently, Mathisen and Madsen (1996) studied the fixed bed roughness in steady flow, oscillatory flow and combined wave-current flow, respectively. It was found that k_s experienced by a pure current was equal to that by waves alone or by waves and currents. However, this is not valid for a movable bed simply because the movable bed form, which is suggested to a main contributor to k_s , is found to be quite different in steady flow compared to that in a combined wave-current flow (Arnot and Southard, 1990; Havinga, 1992).

In the present study, the movable bed roughness k_s in the flow of irregular waves and currents over a movable bed is studied on the basis of measured current profiles and the calibrated model of You (1994). A practical application is also given to calculate k_s in the coastal zone.

Model of Wave-Current Flows over Fixed Beds

In steady flow over a fully rough fixed bed, the current profile is logarithmic

$$\bar{u} = \frac{\bar{u}_c^*}{\kappa} \ln \frac{z}{z_0} \quad (1)$$

in which \bar{u}_c^* is the current shear velocity, κ is the von Karman constant, $k_s = 30z_0$ and k_s is the bed roughness. When waves are superimposed on a current, a logarithmic current profile near the bed can still be found and similarly expressed as

$$\bar{u} = \frac{\bar{u}_{cw}^*}{\kappa} \ln \frac{z}{z_1} \quad (2)$$

but with $\bar{u}_{cw}^* > \bar{u}_c^*$ and $z_1 > z_o$ as first studied experimentally by Bijker (1967) and recently by Havinga (1992) and Klopman (1994).

Many models of combined wave-current flows over fixed beds have been developed to calculate the current shear velocity \bar{u}_{cw}^* and the apparent roughness z_1 in Eq.(2). A review of existing models of combined wave-current flows refers to You (1992). You (1994, 95a) compared the four analytical models of Christoffersen and Jonsson (1985), Coffey and Nielsen (1986), Sleath (1991) and You (1994) with the laboratory measurements of van Doorn (1991, 82) and Kemp and Simons (1982). It was concluded that the model of You (1994) was simpler and gave better agreement with the experimental data than the others. In the present study, the model of You (1994) is chosen to study the movable bed roughness k_s in the flow of irregular waves and currents.

In the model of You (1994), the input parameters were chosen to be the wave parameters (A , ω), a reference current velocity \bar{u}_r at an arbitrary level, and the bed roughness k_s . For irregular waves, significant wave height H_s and period T_s were suggested to calculate A and ω using linear wave theory. The current shear velocity \bar{u}_{cw}^* in Eq.(2) was explicitly calculated by

$$\bar{u}_{cw}^* = 0.5u_w^* \left\{ \log_a^b + \left[(\log_a^b)^2 + 1.6 \frac{\bar{u}_r}{u_w^*} \log_a^a \right]^{0.5} \right\} \quad (3)$$

in which the wave shear velocity u_w^* was evaluated as

$$u_w^* = \sqrt{0.5f_w} A \omega \quad \text{and} \quad f_w = 0.108 \left(\frac{k_s}{A} \right)^{0.343} \quad (4)$$

and the parameters a and b were defined by

$$a = \frac{30e\delta_1}{k_s}, \quad b = \frac{2\delta_1}{z_r} \quad \text{and} \quad \delta_1 = \frac{0.5\kappa u_w^*}{\omega} + 0.2z_o. \quad (5)$$

The apparent roughness z_1 in Eq.(2) was also calculated explicitly by

$$z_1 = 2\delta_1 \left(\frac{30e\delta_1}{k_s} \right)^{\frac{\bar{u}_{cw}^*}{u_w^*}}. \quad (6)$$

The derivations of Eqs.(3)-(6) refer to You (1994). Alternatively, when the current shear velocity \bar{u}_{cw}^* and the apparent roughness z_1 are measured, the movable bed roughness k_s in the flow of waves and currents can be determined by the model.

Movable Bed Roughness

The formulae derived in purely oscillatory flow have been often used to calculate the movable bed roughness k_s in the flow of waves and currents (Grant Williams, 1984; Coffey, 1987; Drake et al, 1992)

$$k_s = C \eta^2 / \lambda + f(\Theta) \quad (7)$$

in which η and λ are the ripple height and length, $f(\Theta)$ is an additional bed roughness owing to the near-bed sediment transport, and C is constant and was chosen to be 8, 16 and 28 by Nielsen (1983), Raudkivi (1988) and Grant and Madsen (1982), respectively. Since no direct measurements of k_s are available in the flow of waves and currents over movable beds, a direct comparison of Eq.(7) with experimental data on k_s becomes impossible. When the current shear velocity \bar{u}_{cw}^* and apparent roughness z_1 are measured, however, Eq.(7) may be verified indirectly by using a calibrated model of combined wave-current flows. That is, if the calibrated model together with Eq.(7) can agree well with the measured \bar{u}_{cw}^* and z_1 , it may be concluded that Eq.(7) gives good estimation of k_s .

In the present study, the laboratory experimental data from Kaaij and Nieuwjaar (1987), Van Kampen and Nap (1988) and Havinga (1992) are used to study the movable bed roughness k_s in the flow of irregular waves and currents. The irregular waves in the three sequential experiments were generated by a directional wave generator. The wave spectrum was JONSWAP. The significant wave heights H_s ranged from 7.5 to 18cm, the peak wave period T_p was about 2.5s, and the depth-averaged current velocity $\langle \bar{u} \rangle$ varied from 10 to 40cm/s. The current profiles and bed forms in the absence and presence of irregular waves were measured. The movable roughness k_s calculated from Eq.(7) was found to be generally dominated by the first term in Eq.(7).

In Figure 1, the models of Sleath (1991) and You (1994) together with Grant and Madsen's (1982) formula of $k_s = 28\eta^2 / \lambda$ are used to calculate the apparent roughness z_1 and compared with the experimental data. It can be seen that the models generally underestimate z_1 at $\theta = 0^\circ$ and 180° , but overpredict z_1 at $\theta = 60^\circ$ and 120° . This indicates that the bed roughness k_s used in the models has been underestimated at $\theta = 0^\circ$ and 180° , but overcalculated at $\theta = 60^\circ$ and 120° . The models would not give better prediction of z_1 by adjusting the constant C or the second term in Eq.(7).

Figure 1. Comparison of the apparent roughness z_1 measured by Kaaij and Nieuwjaar (1987), Van Kampen and Nap (1988) and Havinga (1992) with those calculated by the models of Sleath (1991) and You (1994) with $k_s = 28\eta^2 / \lambda$. The ripple height η and length λ were directly measured in the experiments.

Figure 2. Comparison of the apparent roughness z_1 measured by Kaaij and Nieuwjaar (1987), Van Kampen and Nap (1988) and Havinga (1992) with those calculated by You's (1994) model with the input of k_s estimated from Eq.(8). The bed roughness z_0 in steady flow alone, the depth-averaged current velocity $\langle \bar{u} \rangle$ and the nearbed wave velocity amplitude $A\omega$ in Eq.(8) were measured in the experiments.

In other words, the use of the other former formulae (eg Nielsen, 1983; Raudkivi, 1988) in the models would not give better prediction of z_1 in Figure 1.

As a first approximation, the movable bed roughness k_s in the flow of irregular waves and current flow may be simply structured as

$$k_s = 30z_o \left(1 + \frac{A\omega}{\langle \bar{u} \rangle} \right) \quad (8)$$

in which A is the nearbed semi-excursion of wave orbital motion, ω is the angular frequency, $\langle \bar{u} \rangle$ is the depth-averaged current velocity, and z_o is the movable bed roughness in steady flow alone. In the field, a current velocity \bar{u}_A averaged from the bed to a level h_A is suggested to replace $\langle \bar{u} \rangle$ in Eq.(8). It can be seen from Eq.(8) that the movable bed roughness k_s in the flow of waves and currents is larger than that in steady flow alone. The increase of k_s in the presence of waves may be understood to result from the appearance of wave-generated sand ripples and the increase of the nearbed sediment transport. It is shown in Figure 2 that the model of You (1994) together with Eq.(8) gives satisfactory agreement with the measured apparent roughness z_1 . The three variables z_o , $\langle \bar{u} \rangle$ and $A\omega$ in Eq.(8) were directly measured in the experiments. It may be concluded here that the new formula expressed by Eq.(8) gives good estimation of k_s in the flow of waves and currents.

It should be mentioned here that the formula suggested by Eq.(8) is only valid for a movable bed. For a fixed bed, it is often assumed that the bed roughness in steady flow is equal to that in oscillatory flow alone or in a combined wave-current flow. This has also been studied quantitatively by Mathisen and Madsen (1996).

Practical Applications

The bed roughness in the flow of waves and currents can't be obtained from Eq.(8) unless all the variables in Eq.(8) are known. The movable bed roughness k_s in the field can be determined from Eq.(8) when \bar{u}_{cw}^* , z_1 and $A\omega$ are measured.

The current velocity \bar{u}_A , which is depth averaged from z_o to a level h_A in steady flow alone, can be calculated by

$$\bar{u}_A = \frac{\bar{u}_c^*}{\kappa} \ln \frac{h_A}{e z_o}. \quad (9)$$

In the presence of waves, \bar{u}_A can also be approximately estimated from

$$\bar{u}_A = \frac{\bar{u}_{cw}^*}{\kappa} \ln \frac{h_A}{e z_1} \quad (10)$$

in which h_A is an arbitrary level and is chosen to be about 1.0m above the seabed in the present study. On the other hand, the relationship between \bar{u}_c^* and \bar{u}_{cw}^* was derived by You (1995b) as

$$\bar{u}_{cw}^* = \bar{u}_c^* + K \times A \omega \quad (11)$$

in which K is constant and was determined to be 0.026 and 0.020 for the laboratory and field data, respectively. For irregular waves, significant wave height H_s and period T_s were suggested to calculate $A \omega$ in Eq.(11) using linear wave theory. The comparison of Eq.(11) with available experimental data is shown in Figure 3. Therefore, the movable bed roughness k_s in the coastal zone can be explicitly calculated from Eqs.(8)-(11). The depth-averaged current velocity $\langle \bar{u} \rangle$ in Eq.(8) should be replaced by \bar{u}_A in Eq.(10).

Figure 3. Comparison of Eq.(11) with the available experimental data from Bijker (1967) [$\theta = 75^\circ$ and 90° , regular waves], Kemp and Simons (1982, 1983) [$\theta = 0^\circ$ and 180° , regular waves], Visser (1986) [$\theta = 90^\circ$, regular waves], Kaaij and Nieuwjaar (1987) [$\theta = 0^\circ$ and 180° , irregular waves], Van Kampen and Nap (1988) [$\theta = 0^\circ$ and 180° , irregular waves], Simons *et al.* (1988) [$\theta = 0^\circ$, regular waves], and Havinga (1992) [$\theta = 60^\circ$, 90° and 120° , irregular waves]. After You (1995b).

Figure 4. Comparison of the current shear velocities \bar{u}_{cw}^* calculated by the models of Grant and Madsen (1979) and You (1994) with the field measurements of Grant and Williams (1984, 85). The movable bed roughness of $k_s=6.0\text{cm}$ used in the models was calculated from Grant and Madsen's (1982) formula by Grant and Williams (1984, 85).

Figure 5. Comparison of the apparent roughness z_1 calculated by the models of Grant and Madsen (1979) and You (1994) with the field measurements of Grant and Williams (1984, 85). The bed roughness of $k_s=6.0\text{cm}$ used in the modes was estimated from Grant and Madsen's (1982) formula by Grant and Williams (1984, 85).

Figure 6. Comparison of the current shear velocities calculated by the model of You (1994) with the field measurements of Grant and Williams (1984, 85). The bed roughness k_s used in the model is calculated from Eqs.(8)-(11).

Figure 7. Comparison of the apparent roughness z_1 calculated by the model of You (1994) with the field measurements of Grant and Williams (1984, 85). The bed roughness k_s used in the mode is calculated from Eqs.(8)-(11).

Grant and Williams (1984, 85) provided high-quality field measurements of current profiles of combined wave-current flows over a movable seabed. In Figures 5 and 6, the models of Grant and Madsen (1979) and You (1994) are used to calculate the current shear velocity \bar{u}_{cw}^* and apparent roughness z_1 and compared with the field measurements. The bed roughness of $k_s = 6.0\text{cm}$ used in the two models was estimated from Grant and Madsen's (1982) formula by Grant and Williams (1984, 85). It can be seen that the two models generally fail to predict the apparent roughness z_1 even though the models give good agreement with the measured current shear velocities \bar{u}_{cw}^* . In Figures 6 and 7, however, the model of You (1994) gives satisfactory agreement with the measured \bar{u}_{cw}^* and z_1 when the bed roughness k_s is calculated from Eqs.(8)-(11). The depth-averaged current velocity $\langle \bar{u} \rangle$ in Eq.(8) should be replaced by \bar{u}_A in Eq.(10), and $h_A = 1.0\text{m}$.

Conclusions

The movable bed roughness in the flow of irregular waves and currents are studied based on the simple model of You (1994) and measured current profiles. A new formula expressed by Eq.(8) is proposed to calculate k_s in the flow of irregular waves and current. The present bed roughness formula together with the model of You (1994) gives better agreement with the measured apparent roughness z_1 than the former formulae derived in purely oscillatory flow. The field measurements of current profiles in the presence of irregular waves can be also predicted well with the model of You (1994) and the new bed roughness formula.

CHAPTER 271

Seabed and Foundation Response to Wave Loading

Michael H. Davies¹

Abstract

The interactions between wave loading and soil response in both open waters and around the foundations of coastal structures are observed experimentally. Experimental results for wave action over sand beds are compared to analytical predictions based on both Sleath's porous bed model and on Biot's consolidation theory. Experiments on wave action in the vicinity of a rigid caisson, in conjunction with Mei's boundary layer theory, allow for the development of guidelines for interpreting the relative importance of drainage on the effective stress response of foundations to wave action.

Introduction

The geotechnical response of seabeds and foundations to wave loading can be a critical factor in evaluating the stability of proposed coastal and offshore structures. This paper reviews some of the techniques available for analysis of seabed response to wave action and presents a new heuristic approach for evaluating the relative importance of soil drainage in the response of coastal foundations.

Bea and Aurora (1981) and Wright and Dunham (1972) proposed total stress analysis for seabeds under wave loading. These techniques view the seabed loading as a harmonic tractive stress on the upper boundary, total stress analysis is used to calculate seabed response. Such analysis can use elastic, elasto-plastic or visco-elastic constitutive models and is commonly undertaken within a finite element framework. These approaches are particularly suitable to conditions where the soil is relatively soft and impermeable. These techniques have been successfully applied in analyzing the behaviour of soft soils such as Mississippi Delta muds in the Gulf of Mexico.

The pore pressure response within a seabed was originally explored by Putnam (1949) and later expanded by Sleath (1970). This analysis assumes that pore fluid flows are independent of soil stresses. This assumption is generally valid for stiff, permeable beds such as coarse sands and gravels. Yamamoto (1978) and Madsen (1978) independently proposed the use of 'poro-elastic' analysis for seabed response to wave action using Biot's (1941) linearized equations of consolidation. This allows the treatment of the coupled response to wave-seabed interactions, that is the porous

¹ Canadian Hydraulics Centre, Bldg.M-32, National Research Council, Ottawa, Canada, K1A 0R6 (e-mail: Michael.Davies@NRC.CA)

media response coupled with the elastic soil response. This provides a technique suitable for a wide range of soil and wave conditions ranging from soft, impermeable silts and clays through to stiff sands. Since the initial work by Madsen and Yamamoto, a wide range of papers has been written proposing expansions and adaptations of the work, e.g. Finn et al (1983) and Okusa (1985). The development of full finite element solutions of time-dependent effective stress problems has provided another analysis tool. Models such as those of Shen et al (1986) provide a finite element framework within which the coupled effective stress response of soils can be investigated.

In experimental studies of soil-wave-structure interaction, measurements of soil stress or strain are difficult. Pore pressure response is, however, readily measured and is thereby often used as the main indicator of soil behaviour. Other techniques tend to be highly intrusive and fail to provide a time history of soil response (e.g. cone penetration testing). One promising technique for measurement of soil response is measurement of the acoustic emissions from the soil mass (AE). This technique was successfully employed in this research program and was described in Davies, et al (1990). The present paper focuses on the use of pore pressure response as a measure of soil behaviour.

Pore pressure in seabeds

In a porous seabed under harmonic wave loading (wave frequency, ω) the pore pressure, U of a fluid with unit weight, γ , has three components:

$$U = \gamma z + \gamma P(\cos \omega t) + u_r \quad (1)$$

Where γz is the hydrostatic component of the pore pressure at depth z below the free surface, P is the wave-induced component of the pore pressure fluctuation (expressed as a piezometric head), and u_r is the residual component of the pore pressure (due to consolidation and or shearing action). It is important to draw the distinction between the wave-induced fluctuation in the pore pressure, P and u_r , the residual pore pressure in excess of hydrostatic. The wave-induced pore pressure fluctuation is an indicator of the steady-state harmonic fluctuations in the effective stress state of the soil caused by wave loading. The residual pore pressure, u_r is a more gradual change in the pore pressure (non-harmonic) possibly caused by shearing action of the soil which results in soil volume change and consequent changes in the residual pore pressure.

Experimental Set-up—Flat Bed Testing

A series of flume tests was conducted on a sand bed consisting of 15 m^3 of a fine Ottawa sand ($D_{50}=0.07\text{mm}$). The sand was hydraulically placed using a positive displacement slurry pump. The resulting berm had a uniform crest height of 0.91m over a 10 m width. This uniform section was flanked by 1:10 side slopes. A vertical array of pore pressure transducers had been installed in the flume prior to construction of the berm. This consisted of 14 Druck PDCR81 pore pressure transducers (7 kPa capacity) at 10 cm vertical spacing. A capacitance-type wave gauge was located directly above the pressure transducers.

Figure 1 Vertical distribution of pore pressure as per Sleath (1970) for $k_x=1.8k_z$

Sand densities were determined using a 12 cm diameter brass sampling tube. Soil relative density was determined to be 47% (soil unit weight was 15.5 kN/m^3). Constant head permeability tests yielded a coefficient of permeability of $k=5.0 \times 10^{-5} \text{ m/s}$. The experimental setup is described in detail in Davies (1992).

Steady-state harmonic response

The pore pressure response measured in these experiments was compared to Sleath's rigid, porous bed model and to that predicted by poro-elastic theory as per Yamamoto, and Finn.

In general, the Sleath formulation was seen to provide a good estimate of the vertical distribution of the magnitude of the pore pressure fluctuation if the effects of anisotropic permeability are considered (see Figure 1). Here the amplitude of the harmonic pore pressure, P is normalized by P_0 , the pressure at the top of the seabed. Since Sleath's model assumes a porous media flow within a rigid bed, this solution provides no information about the stress response of the soil. Poro-elastic analysis is required to examine the coupled response of the soil and the pore fluid.

In comparing the pore pressure response to that predicted by poro-elastic theory, initial comparisons were made to the model of Yamamoto, 1978. This formulation does not consider the effect of anisotropic permeability and it was not possible to obtain good agreement between the model and theory. To match the observed vertical attenuation of the pressure magnitude, the predicted phase lags were far too large – on the order of 30° . Measured phase lags in the model were not seen to exceed 15° . Consequently, Finn's Stabmax routine was employed since it allows for anisotropic permeability. Using Stabmax, good agreement could be obtained for both the amplitude and phase of the pore pressure response. This agreement is shown in Figures 2 and 3. It should be noted here that the poro-elastic models were seen to be extremely sensitive to the volumetric degree of soil saturation, S_r . Sensitivity tests showed that varying the soil saturation ratio from 98% to 99.8%

resulted in predicted phase lags at the bottom of the bed varying from 28° down to 3° , the trend being that phase lag reduces with reducing air content. These findings are described in more detail in Davies (1992).

Figure 2 Measured pore pressure response vs poro-elastic theory (Stabmax, Finn, 1982)

Figure 3 Phase lag of pore pressure response vs poro-elastic theory (Stabmax, Finn, 1982).

Experimental Set-up—Caisson Testing

The second experimental test program in this study was designed to examine the interactions between seabeds and rigid coastal structures under the influence of wave action. Large-scale flume tests were undertaken to study the effective stress response

of seabeds beneath caissons, and to examine the combined effective stress, pore pressure and scour response of the toes of caisson-type coastal structures. This experimental study was also used to explore the validity of the Tsai et al (1990) analytical poro-elastic approach for the prediction of foundation response.

The Coastal Wave Basin of the National Research Council in Ottawa was used for the caisson testing. This basin is 85m long and 14m wide. The maximum water depth available for testing is 1.2m (allowing 0.3m of freeboard for waves). Two parallel 2.4m wide channels were built within the basin. This layout enabled the simultaneous testing of two different caisson foundations. Berms were built in each of these channels to serve as foundations for two identical steel caissons (see Figure 4). The berms were composed of two different sands; a coarse sand with $D_{50}=0.38\text{mm}$, and a fine sand, with $D_{50}=0.10\text{mm}$. Due to the large amount of fill required to build the foundations for the caisson (roughly 25 tonnes of sand in each flume) it was not possible to rebuild the berm between tests. The test sequence employed gradually exposed the caissons to irregular waves of increasing amplitude and period in a manner simulating the building of a storm. For all tests, the hydrodynamics acting on the structure and the response of both the soil and the caisson were measured in detail.

One of the results of the test program was a series of measurements of the pore pressure response within the foundations beneath the leading edge of the caissons. The following section gives a review of some of these pore pressure measurements.

Figure 4 Schematic cross-section of caisson tests.

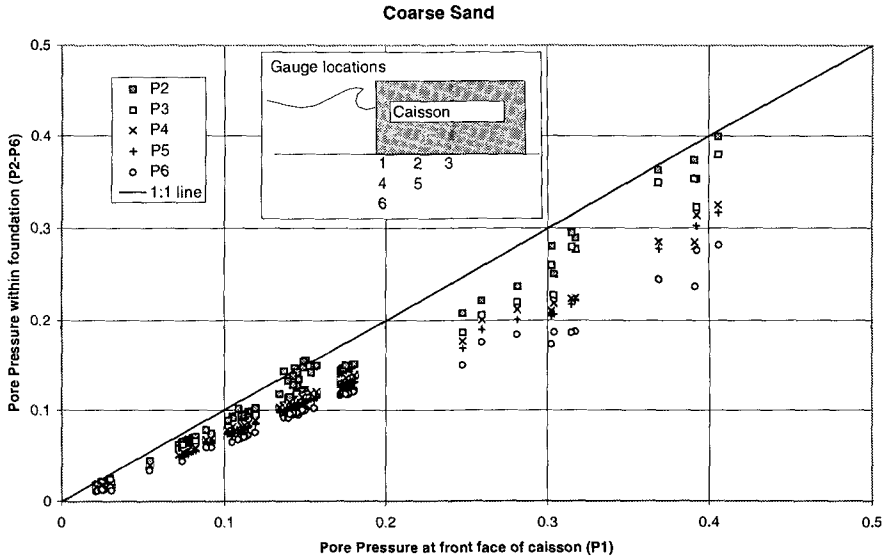

Figure 5 Pore pressure response - coarse sand.

Pore pressure response within coastal foundations

Figure 5 shows how the pore pressure response measured beneath the caisson compared to that at the outside front corner of the caisson (at the mudline) for the coarse sand foundation. This plot shows the amplitude of the pressure fluctuations measured by each of six pore pressure transducers installed beneath the caisson. These transducers are denoted as P1 through P6 and their locations are shown schematically in the inset in Figure 5. The measured pore pressure at each of gauges P2 through P6 is plotted against the pore pressure measured at the front corner (P1). There is a general trend that the pore pressure diminishes with depth into the seabed and with distance beneath the caisson, i.e. P3 and P6 are significantly lower than P1.

Figure 6 shows a similar plot for the fine sand test. The general pattern of diminishing pressure amplitude with depth and with distance from the front edge of the caisson still exists with one exception: for test conditions generating a pore pressure at the front face of the caisson (gauge P1) of around 0.1 m, the pressures along the underside of the caisson were significantly increased. This trend was not observed for the coarse sand caisson when exposed to the same wave conditions with the same caisson geometry and caisson ballast. This suggests that, under this combination of wave conditions, the finer sand caisson was experiencing complex wave-soil-structure interactions which were not observed with the coarser sand. The following sections describe a boundary layer approach to provide some insight to these interactions.

Figure 6 Pore pressure response - fine sand

The Boundary Layer Approach

The boundary layer approach of Mei and Foda (1981) shows that, in the treatment of a poro-elastic solid using Biot's linearized theory of consolidation, for the frequencies of typical ocean waves, a Stokes' type of boundary layer exists near the top of the bed. The soil and fluid move together as a single phase in the region below this boundary layer. Within the boundary layer, the effects of the free draining upper boundary are evident. This allows a greatly simplified analysis where the outer region (far below the mudline) can be treated as a single phase elastic solid for which analytical solutions to the soil's behaviour are readily found. Mei and Foda show that in the boundary layer, a one-dimensional analysis using Terzaghi's theory of consolidation can be applied (provided that the boundary layer thickness is small relative to wavelength). Solutions to a variety of poro-elastic problems using this boundary layer technique have been presented in the literature (see Mei and Foda, 1981 and Mei, 1982)

Intuitively, one would expect that for a soil of permeability, k , which is small relative to the frequency of loading, $\omega=2\pi f$, there is little fluid motion relative to the soil skeleton. For such a case the soil and fluid move together and the medium can be treated as a single phase as described by the equations of elastic dynamics. Near the seabed there will be a free-draining region extending to some depth, δ . For $\delta/L \ll 1$, where L is the wavelength, then the upper boundary region becomes essentially one-dimensional. Mei and Foda show that the first order approximation of the boundary layer is the Terzaghi equation for one-dimensional consolidation.

In the boundary layer $\partial/\partial z \gg \partial/\partial x$. The thickness of the boundary layer, δ is given by

$$\delta = \sqrt{\frac{c'_v}{\omega}} \quad (2)$$

where c'_v is the soil consolidation coefficient

$$c'_v = \frac{k \gamma}{m'_v} \quad (3)$$

Here k is the soil's coefficient of permeability, γ is the unit weight of water, and m'_v is the effective modulus of volume compressibility for soil with a partially saturated pore fluid.

$$m'_v = n\beta' + \frac{1-2\nu}{2(1-\nu)G} \quad (4)$$

Here the stiffness of the soil matrix is characterized by the bulk shear modulus, G , and Poisson's ratio, ν . The soil porosity is n and the stiffness of a partially saturated fluid is β' (as per Verruijt, 1969),

$$\beta' = \beta + \frac{1-S_r}{P_{\text{tot}}} \quad (5)$$

Here β is the compressibility of pure water ($\beta=4.3 \times 10^{-10} \text{ Pa}^{-1}$), and S_r is the volumetric degree of saturation of the soil. P_{tot} is the absolute pressure at the point of interest.

The exact total solution for dynamic stresses and pore pressures is determined through the solution of the dynamic elastic equations governing the outer region and subsequent application of a boundary layer correction:

$$()_{\text{exact}} = ()^o + ()^b \quad (6)$$

where the superscripts o and b denote outer region and boundary layer region terms, respectively.

The boundary layer formulation provides an accessible and heuristically appealing treatment of the soil-wave interaction problem. The boundary layer thickness, δ quantifies the relative depth of influence of wave action in a seabed.

Foundations - Drained vs Undrained

The problem of wave action in the vicinity of coastal structures can be considered in terms of the permeability and stiffness of the soil mass relative to the size of the structure. Wave loading on a rigid coastal structure such as a caisson causes wave stresses to be transferred from the caisson to the seabed. At the same time wave-induced pressure fluctuations at the seabed cause uplift pressures along the underside of the structure. The complex interactions between a rigid structure and the seabed under wave loading have been examined in the literature by Lee and Focht (1985), Lindenberg et al, (1982) and Tsai et al (1990). Analytic solutions of the wave-soil-structure interaction problem have been formulated by Mei (1982) as well as by Tsai et al (1990). These analytic solutions use elastic solutions for a rigid block resting on

a flexible base to solve the total stress state in the foundation. A boundary layer correction is then applied to take account of the presence of the free-draining upper boundary. These solutions rely on an assumption that the boundary layer thickness, δ is small relative to the wavelength, L and furthermore that the boundary layer thickness is small relative to the caisson size, C (for some solutions the half-width of the caisson is used as the representative caisson dimension).

These calculations are quite complex but yield some interesting insight into the behaviour of wave-soil-structure interactions. For practical problems, a finite element effective stress model is more adaptable (e.g. Shen, 1990).

One of the insights provided by boundary layer theory is the concept of relative boundary layer thickness. In assessing the appropriate analysis to be undertaken for a specific structure, simple calculations of boundary layer thickness relative to wavelength and relative to caisson geometry can allow the classification of the problem in terms of the influence of pore fluid flow on soil response.

There are two bounding conditions often considered in analysing foundation response. These are **undrained** and **drained** behaviour:

- 1) For **undrained** analysis, it is assumed that the rate of application of loading is rapid relative to the soil's permeability. Consequently the pore fluid and soil matrix move together. At a lower bound, for example, the case of a structure resting on clay, the role of pore pressures in generating uplift forces is negligible. For undrained analysis the total stress state is used, and the concept of effective stresses is not applicable.
- 2) For **drained** analysis, it is assumed that the rate of application of loading is slow relative to the soil's permeability. Consequently, the pore fluid is free to move relative to the soil matrix. At an upper bound, the Shore Protection Manual (1984) and Goda's models of wave-induced uplift pressures are reasonable, (a triangular pressure distribution acting along the underside of the structure). For drained analysis, an effective stress approach is employed.

In reality, these limiting cases rarely exist. The true soil response lies somewhere between fully undrained and fully drained. What is needed is a set of practical guidelines to evaluate the relative importance of drainage to the structure.

Foundation response guidelines

When the boundary layer thickness, δ is small, free-drainage occurs only close to the mudline. When δ is large the free-drainage zone extends further into the seabed.

The pore pressure response within the seabed in the vicinity of a caisson will be related to two dimensionless parameters:

1. f/f_n - describes the frequency response of the system and how close the loading frequency, f is to the natural frequency of the caisson, f_n . For a single degree of freedom oscillator (such as the caisson response in pure pitch motion), the natural frequency of the caisson-soil system is related

to the foundation stiffness and the polar mass moment of inertia of the caisson as follows:

$$f_n = \frac{1}{2\pi} \sqrt{\frac{E'B^3}{12I_p}} \quad (7)$$

Here, E' is the equivalent foundation stiffness, and B is the caisson width.

2. δ/C - the thickness of the boundary layer, δ relative to the caisson size gives a measure of how large the free-draining boundary is relative to the size of the caisson.

Figure 7 Illustration of boundary layer thickness concept for caissons

For a given caisson geometry (and hence given f/f_n), the pore pressure response could be expressed as a function of the ratio of boundary layer thickness to caisson width alone:

$$\frac{P}{P_0} = \phi\left(\frac{\delta}{C}\right) \quad (8)$$

Three conditions can then exist:

- 1) If $\delta \ll C$ then the boundary layer effect will be small, uplift pressures will only exist very close to the outer edge of the caisson and undrained analysis will be sufficient.
- 2) If $\delta \gg C$ then the entire caisson will lie within the boundary layer, uplift pressures will be large and drained analysis will be appropriate. Here solution of the pore pressure response (and uplift) can be 'de-coupled' from the soil stress response.
- 3) Where δ is of the order of C , the response will be partially drained – the interactions between the pore fluid and soil matrix must be considered. Figure 7 provides a schematic of these concepts.

Consider the behaviour of the two caisson test series shown in Figure 5 and Figure 6. The major differences between these two caissons were the soil's coefficients of consolidation. This is reflected in different boundary layer thicknesses for the two caisson datasets. Figure 8 shows a plot of the relative amplitude of the pore pressure response beneath the caisson (normalized by P_1) against the ratio of boundary layer

thickness to caisson size, δ/C . This figure shows that for test conditions corresponding to δ/C around 0.1, amplification of the pore pressure response beneath the caisson is observed (e.g. P3 in caisson 1). This trend is not observed for sensors mounted deep in the bed at the front face of the caisson (vis P6). For test conditions of δ/C much greater than 0.5, the amplitude of the pore pressure response starts to approach the linear distribution suggested by Goda and others for caissons resting on very coarse rubble beds.

Figure 8 Pore pressure response vs drainage ratio, δ/C (combined results for both coarse and fine sands).

Table 1 shows typical ranges of foundation conditions and wave conditions for some typical coastal structure geometries

Wave period, $T = 15$ s		$\omega = 2\pi/T = 0.42$		
Influence of foundation type	c_v (m ² /s)	δ [m]	C [m]	δ/C
Rubble fill	1000	48.86	15	3.26
Hard sand	100	15.45	15	1.03
Soft sand	10	4.89	15	0.33
Stiff clay	0.1	0.49	15	0.03
Soft clay	0.001	0.05	15	0.00
Influence of caisson size	c_v (m ² /s)	δ [m]	C [m]	δ/C
Rubble fill	1000	48.86	3	16.287
Rubble fill	1000	48.86	10	4.886
Rubble fill	1000	48.86	100	0.489
Soft clay	0.001	0.05	3	0.016
Soft clay	0.001	0.05	10	0.005
Soft clay	0.001	0.05	100	0.000

Table 1 Relative boundary layer thickness for typical field conditions

For cases where the foundation material is stiff and permeable (such as rubble fill), Table 1 shows that, except in the case of exceptionally wide structures, the ratio δ/C

is large and the free-draining condition can be expected to be observed along the entire underside of the structure. This is in accordance with the design techniques presented by Goda and the Shore Protection Manual where, for caissons resting on rubble foundations, a triangular uplift pressure distribution is assumed along the underside. For cases where either the foundation material is soft and impermeable (soft clay) or where the structure is very large (large C), the ratio δ/C can be seen to be quite small. In these cases, the uplift pressures due to wave action will be negligible and the undrained analysis is most appropriate (e.g. as described by Lee and Focht). In cases such as this, skirts are sometimes installed around the base of the structure to act as cut-off walls to further reduce the likelihood of uplift pressures existing. The structures are then designed for a no-uplift condition. The ratio δ/C serves to delineate how foundations in intermediate conditions may behave. For example if a structure rests on soft sand or stiff clay, the ratio δ/C becomes useful in combining the effects of wave period, consolidation coefficient and structure size to give a sense of the relative size of the drainage path, δ .

Conclusions

The pore pressure response of a seabed exposed to wave loading can be reasonably well described by the rigid, porous bed solution of Sleath (1970). To obtain information about the effective stress state in the soil, however, it is better to use a poro-elastic seabed response model such as that of Finn (1982).

Often the response of a coastal structure is neither fully drained nor fully undrained but somewhere in between. For engineering analysis, practical guidelines are needed to delineate the extent of influence of the free-draining boundary. Through boundary layer theory, it is possible to interpret this influence through δ , the boundary layer thickness. Preliminary analysis of test results indicates that the ratio, δ/C might be useful here. For small values of δ/C (less than 0.05, say), the soil can be treated as fully undrained and a total stress analysis can be used. As δ/C becomes large (greater than 0.3, say), soil behaviour starts to become fully drained and analysis techniques such as those proposed by Goda and the Shore Protection Manual become more appropriate. Soil conditions in the intermediate range ($0.05 < \delta/C < .3$) require particularly close attention since the response of the soil and pore fluid is closely coupled.

The idea of using the relative boundary layer thickness, δ/C as a predictor of seabed response is hypothetical at this stage. Further verification and extension of this idea requires examination of a wider range of experimental conditions. Variation of the ratio of f/f_n (the frequency of wave loading relative to the natural frequency of the system) should also be further explored.

CHAPTER 272

Interannual Shoreline Variations at Duck, NC, USA

Nathaniel Plant and Rob Holman

ABSTRACT

We have analyzed 3 years of daily observations of the shoreline position along a 2 km segment of the coast at Duck, NC. Shoreline variations were found to be dominated by length scales of order 1 kilometer, with an amplitude that was modulated by a seasonal cycle, and a spatial structure that progressed alongshore at an average rate of 1 m/day. Surprisingly, the alongshore-averaged shoreline position did not display an annual cycle. Instead, the most pronounced alongshore-averaged shoreline changes occurred over several years. The dominance of large spatial and temporal scales suggests that short scale studies at Duck (typical duration < 1 month and lengths < 500 m) seriously under-resolve an important component of shoreline variability.

INTRODUCTION

To describe general beach behavior, we have often referred to a "summer-winter" conceptual model (e.g. Komar, 1974), in which beaches erode and sand bars form or move offshore during large storms (winter), followed by beach accretion and onshore bar movement during calm periods (summer). Recently, however, observations of nearshore bathymetry have revealed interannual and decadal morphologic behavior, which are not described by a seasonal model. Examples include offshore progressive sand bars at Duck, NC, USA (Birkemeier, 1985; Lippmann and Holman, 1990; Kraus and Larson, 1992) and along the Holland Coast (Ruessink and Kroon, 1994; Wijnberg and Terwindt, 1995) over periods of several years to over a decade. In addition, there is evidence that beach response over these long time periods is not alongshore-uniform. Wijnberg and Terwindt (1995) showed examples of alongshore progressive variations at the shoreline, with an alongshore wavelength of about 2 km and periodicity matching that of the bars. It appears likely that, with increasing time scales, beach variability may be dominated by large length scales. Quantifying the contribution of various alongshore length scales to beach variability, and determining characteristic time scales associated with each length scale are clearly important to understanding (or simply describing) the long term behavior of beaches.

In this paper, we focus on the behavior of a particular beach elevation contour near the shoreline at Duck, NC. One reason to focus on the shoreline is that it

delineates the width of the subaerial beach, which is of practical significance to those who live on or visit the beach. Also, the shoreline is a morphologically active (and therefore interesting) region of the beach, which responds to variations in wave conditions, tides, and (perhaps) interannual forcing. We seek to determine the relative contribution of different length scales to shoreline variability, and to describe the relationships between length and time scales. First, we will describe observations of the cross-shore position of a particular shoreline contour, obtained from analysis of video images. Then, we will present an analysis of the spatial and temporal variability of this data set. Since the dominant variability is associated with large length scales, we quantify this variability by focusing on two scales: (1) the alongshore-averaged shoreline position and (2) variability with a wavelength of about 1 km. The observed variability is partitioned into amplitude time series for both scales, as well as a time series of the spatial phase shift of the 1 km scale, which describes alongshore propagation. Finally, we describe the correlation between the shoreline variability and the wave field.

DATA COLLECTION

Video images of the surf zone at Duck, NC have been collected since 1986. Originally, the images were obtained once per day; however, they have been obtained every hour since 1993. The type of images that we will use in this study are time exposures (Lippmann and Holman, 1989, 1990). A time exposure (Figure 1) represents the average image brightness over, in this case, a 10 minute period. In relatively shallow regions where waves tend to break (e.g. over sand bars and at the shoreline), the average brightness is relatively high (white) due to the persistent production of foam, hence, morphologic features are often easily identified. At Duck, time exposures have been used successfully to locate the position of sand bars as well as the shoreline (Lippmann and Holman, 1989, 1990).

Plant and Holman (in press) described the methods that we used to locate and map the shoreline position. To summarize: we assumed that the shore-parallel band of high image intensity at the shoreline, also called the shoreline intensity maximum (SLIM), visually marked the still water level shoreline. The SLIM was identified in each image and its cross-shore position at a series of alongshore sample locations was determined from simple photogrammetric relationships (Lippmann and Holman, 1989). Since the cross-shore position of the SLIM varied with tidal elevation, we selected images corresponding to tidal elevations within 0.25 m of the 0.50 m level. We attempted to locate the shoreline once per day, within a 2 km long region, sampling every 2 m. The shoreline position is overlain on each image in Figure 1, and is plotted in map coordinates on the adjacent panels.

This shoreline estimation technique ought to be most accurate when applied to simple intertidal bathymetry (i.e. slowly varying in both alongshore and cross-shore directions) and when the wave height is low, so that the SLIM is a narrow band located near to the still water shoreline. The beach slope and wave height at the shoreline scale the errors in the estimates of the cross-shore position of the shoreline. For a barred beach, the error is approximately $\frac{1}{2} \frac{H}{\beta}$, where H is the (potentially depth-limited) rms wave height shoreward of the sand bar and β is the beach slope at the shoreline. The intertidal beach slope at Duck is typically about 0.1 and the shoreline wave height is limited by breaking over the bar to 1.0 m, resulting in a maximum error of about 5 m. Finite resolution of the digital images also contributed to measurement errors that

ranged from 0.50 m nearest to the camera to 2.0 m farthest from the camera. The alongshore resolution of the shoreline position estimates varied from 1 m to 50 m .

Figure 1. Examples of time exposure images, from Duck, NC. The location of the shoreline intensity maximum (SLIM) line is identified on each image and the map projection of that line is shown adjacent to each image. On the map projection, the ordinate is the alongshore range; positive is to the north (away from the camera). The cross-shore scale is exaggerated 20x.

RESULTS

Of the 980 days in the study period, 748 images fell within the desired tidal level range ($0.25 \leq \text{tide} \leq 0.75$). Due to problems with image quality (rain on the lens, fog, equipment failure, and very small wave heights that did not produce a SLIM), only 578 images yielded shoreline positions. Of these, some shoreline position estimates did not cover the entire 2 km sample region. Only 336 images yielded data fully spanning a 1 km subset of the sample region ($900 \text{ m} \leq y \leq 1900 \text{ m}$). This subregion was sampled at an average rate of about 1 sample/3 days. We will focus much of the analysis on the 1 km sub region.

Figure 2. Mean and standard deviation of the shoreline position. The time-averaged shoreline position is shown in the upper panel, where error bars are the standard deviation, plotted at 20 m intervals. In the second panel, the standard deviation is plotted again, along with the cross-shore error due to the pixel footprint dimensions (dashed line). The third panel shows monthly-averaged spatial variability. January of each year is marked by a vertical line.

Shoreline Mean and Variance

Over the 3 year study period, the observed shoreline position varied by as much as 45 m. The spatial structures of the shoreline and its variability are summarized by plots of the mean and standard deviation as a function of alongshore location, shown in Figure 2. The mean shoreline position was not straight, but curved smoothly through the entire study area. The bend in the mean shoreline likely stems from geologic constraints. The temporal variability of the shoreline, indicated by its standard deviation, was not uniform either. The minimum variance occurred near the most seaward protrusion of the mean shoreline ($y = 1100$). The observed shoreline variance increased with distance from the camera, which may be due, in part, to the increasing size of the pixel footprint. The expected cross-shore pixel error is plotted for reference. Our choice of coordinate system was not shore-normal everywhere, which also contributed to increased apparent variability.

Figure 3. Gray scale plot of shoreline deviations. The scale bar is in meters. Positive deviations (whiter) correspond to displacement of the shoreline seaward of its mean position. Missing data are filled by hatching, and January 01 of each year is marked by a horizontal line.

Time series of shoreline deviations were obtained by subtracting the mean shoreline position from each observation, at each alongshore location. The final panel in Figure 2 shows the monthly-averaged, spatial variation from the mean shoreline position, as a function of time. In order to visualize the variation of the Duck shoreline, Figure 3 displays low-pass-filtered deviations of the shoreline position at each alongshore location and each time. Positive deviations (light shades) indicate that the shoreline was seaward of its mean position. The low pass filter (Ooyama, 1989) damped variations with time scales less than 1-2 months, and interpolated missing data if the time gaps were shorter than the filter cutoff. The remaining missing data values are filled with hatching.

In Figure 3, the most striking features are lineations that generally trend obliquely from the lower right towards the upper left (traveling toward the south) and have length scales of about 1 km. The behavior of these large scale features was not always characterized by simple southward propagation. For example, their direction reversed at times (e.g. day 200 to day 300). Also, shorter scales contributed to prominent coherent behavior. For example, between days 850 to 900, megacusps with approximately 200 m wavelengths were well developed. The megacusps appeared to propagate at the same speed as the large scale features. An annual cycle is not particularly apparent in Figure 3. We turn now to quantitative descriptions of these shoreline deviations, partitioned into an alongshore-averaged component and a component with an alongshore length scale of 1 km.

Figure 4. Shoreline variance spectra as a function of alongshore wavenumber. The upper panel shows sample spectral estimates averaged over a 34 day period (containing only 8 images) when megacusps were present with 200 m wavelengths. The lower panel is the spectrum averaged over the entire 3 year study period.

Length Scales

The contribution of different length scales to the observed shoreline variability was quantified using wavenumber spectra of the shoreline deviations. A discrete spectrum was estimated on each day, using data within the 1 km subregion, $900 \leq y \leq 1900$ m. Spectral estimates corresponded to the Fourier wavenumbers, $k_y = 0, \pm \frac{1}{1000}, \pm \frac{2}{1000}, \dots$, and $\frac{250}{1000} \text{ m}^{-1}$. The alongshore-averaged shoreline position was removed at each time before estimating the spectra, and was the estimate of the first component, $k_y = 0$. The variance spectrum, $S(k_y)$, on any particular day describes the contribution of each length scale to the spatial variability on that day. As an example, we show several spectra, averaged over time to improve the reliability of the spectral estimates (Figure 4). For instance, megacusps, which were obvious in the space-time map of deviations (days 850 to 900), also appeared as a well defined and significant spectral peak. However, the dominance of large length scales (low wavenumbers) was the most typical characteristic of these spectra. The spectrum averaged over the entire 3 year study period (Figure 4) emphasizes this point. In fact, the first two Fourier components, which are the alongshore-averaged shoreline position ($k_y = 0$) and the 1 km wavelength ($k_y = \frac{1}{1000} \text{ m}^{-1}$), explain nearly 80% of the total shoreline variance. We will focus the remaining analysis on these two components.

Figure 5. Time series of the alongshore-averaged shoreline position over the 1 km subregion ($900 \text{ m} \leq y \leq 1900 \text{ m}$). The dots correspond to the actual samples, while the solid line is the filtered time series. January 01 of each year is marked by a vertical line.

Alongshore-averaged shoreline variability explained 36% of the total, observed shoreline variance. This component represented net onshore or offshore change of the shoreline (Figure 5). Apparent, high frequency fluctuations due to measurement errors associated with rapid variation of the wave height were removed by filtering using a 30-60 day cutoff. The filtered time series of the alongshore-averaged shoreline deviations

shows that dominant variability occurred over time periods greater than one year (inter-annual behavior). More rapid variations likely corresponded to storm/calm cycles. The absence of an annual cycle, as might be predicted with the summer/winter model, is conspicuous.

The second component that we will consider corresponds to the 1 km wave length ($k_y = \frac{1}{1000} \text{ m}^{-1}$), and accounted for 40% of the total shoreline variance. This component may be represented by time series of both amplitude, A , and phase, ϕ .

$$A(k_y, t) = |a(k_y, t) + i b(k_y, t)| \quad (1)$$

and

$$\phi(k_y, t) = \text{Tan}^{-1}[-b(k_y, t)/a(k_y, t)], \quad (2)$$

where $a(k_y, t)$ and $b(k_y, t)$ are the real and imaginary parts of the Fourier amplitudes. The amplitude time series had a strong annual cycle (Figure 6). This is the quantitative representation of typical observations that the shoreline is relatively straight during the winter (largest waves) and develops increased alongshore variation during calmer periods, also evident in Figure 2. The phase time series describes alongshore shifts of a coherent morphological structure. A simple phase ramp (constant slope) is indicative of a progressive wave form, while phase jumps of 180° suggest standing motions. The net phase shift over the study period corresponded to an average southward propagation of about 1 m/day. The estimated celerities are shown in the lower panel of Figure 6. We expect the amplitude and celerity for this component to be correlated to wave height and direction.

Figure 6. Time series of the amplitude (upper panel), phase (middle panel), and celerity (lower panel) of the 1 km wavelength component. The trend in the phase (ramp) corresponds to an average alongshore celerity of -0.95 m/day .

Correlation to Waves

We move now to determining how the two components of variability ($k_y = 0$, $\frac{1}{1000} \text{ m}^{-1}$) were related to variations in the wave field. In particular, we expect that the amplitudes of the two components should be correlated to the wave height, while we expect that the alongshore propagation of morphologic features should be related to the product of the wave height and angle of incidence. The alongshore component of wave energy flux ($Pl \sim H_s^2 \sin[-2\alpha]$) will be used to test this hypothesis. Figure 7 shows a time series of the wave height, wave angle, and wave energy flux over the study period. The wave directions are relative to shore normal and positive wave angles correspond to waves approaching from the north, consequently driving sediment transport to the south. High frequency fluctuations dominate the wave time series, so time series were low-pass filtered with a 30-60 day filter cutoff. The filtered time series contain seasonal cycles in which wave heights tended to be high in the winter months and low in the summer months. Waves tended to approach from the north during winter and south during summer. Comparing the filtered wave time series to the filtered morphologic time series allows us to test for correlation between low-pass variations.

Figure 7. Time series of significant wave height (upper panel), wave direction (middle panel), and alongshore wave energy flux (lower panel). Dashed lines show the monthly wave height range. Wave angles are relative to a shore-normal coordinate system, positive from the north, while a positive alongshore wave energy flux corresponds to expected sediment transport to the north. Dashed lines in the two lower panels correspond to monthly standard deviations.

Figure 8. Cross-correlations between wave parameters and morphologic parameters. The wave parameters (H_s and PI) are labeled at the top of the figure and the morphologic parameters ($k_y=0$, $k_y=1/1000$ amplitude, and celerity) are labeled to the left of each pair of figures. In each plot, dashed lines mark the 95% significance level of the correlation and vertical lines mark lags of ± 1 year. Positive lags correspond to the wave time series leading the morphology.

The time-lagged, cross-correlations between the morphologic time series and both wave height and the alongshore wave energy flux are shown in Figure 8. The lag range is defined such that positive lags correspond to the wave time series leading (forcing) the morphologic response. Time lags between -1 and +2 years are shown in all the correlation plots. The first panel shows the correlations between alongshore-averaged shoreline position and wave height, which were less than the 95% significance level at nearly all lags. In the adjacent panel, the correlation to the wave energy flux was most significant at a lag of about 60 days. The positive correlation suggests that periods of northward sediment transport lead to increased beach width. Both results are surprising, since we expected a correlation to wave height but did not expect the alongshore-averaged response to be a function of wave direction.

The cross-correlations of both the amplitude and celerity of the 1 km wavelength component with the wave parameters contained strong seasonal signatures. The amplitude of the 1 km wavelength component was significantly and negatively correlated to the wave height, at a lag of about 60-90 days. We infer from this that increasing wave heights reduced the amplitude of the 1 km scale features and the response of the morphology lagged behind the change in wave conditions. The amplitude time series was also, surprisingly, correlated to the wave energy flux. This

may stem from the strong correlation between wave height and direction, rather than a direct forcing-response relationship of wave direction on these amplitudes.

The celerity and wave height were correlated significantly at a lag of about 90 days. The negative correlation indicates that when the wave height increased, the celerity increased towards the south. Surprisingly, the correlation between the celerity and wave energy flux was relatively poor, which was not expected. Interpretation of cause and effect relationships between the wave field and morphology is potentially impeded by the possibility that the celerity of the 1 km features was partly a function of their amplitude, which was modulated by the wave height.

DISCUSSION

Source of alongshore propagating waves

Sand waves with various amplitudes and celerities have been observed in several nearshore environments (e.g. Sonu, 1969). Clearly, large scale, progressive, morphologic features exist at Duck. We can suggest a few explanations for the existence of these features. We can also reject some possible explanations, based on characteristic time scales. For example, oblique sand ridges are large scale features, recently discussed by Trowbridge (1995). These features extend to deep water (~10 m), and have characteristic, long-term, alongshore celerities of $O(10^{-2}$ to $10^{-1})$ m/day. The forcing mechanism for them is probably storm driven currents, which, as Trowbridge showed, may cause an initially alongshore uniform coastline and bathymetry to become unstable. Hulscher (1996) presents theoretical descriptions of another type of sand wave, which is an instability driven by tidal currents. However, both oblique sand ridges and tidal sand waves, which are $O(0.1$ to $1)$ km in length, have much slower celerities than those observed at Duck. Since the length scale of these deeper water features matches the scales we have observed, it is possible that there is some interaction between the two.

Another sand wave formation mechanism, treated recently by Thevenot and Kraus (1995), is ejection of sand plugs from tidal inlets. These plugs may weld to the shore and perturb the longshore current field. Then, they are expected to propagate alongshore in the direction of the longshore current. Thevenot and Kraus observed sand waves with wavelengths of about 1 km and celerities of order 1 m/day. The alongshore-progressive behavior was modeled by Thevenot and Kraus. However, the modeled sand waves tended to diffuse more rapidly than those observed in the field. The addition of wave refraction in the model reduced the tendency of the modeled waves to dissipate, and appears to be an important sand wave maintenance mechanism. Although there are no nearby inlets at the Duck field site to allow formation of sand waves as ejected sand plugs, the kinematics of the features we have observed seem consistent with the Thevenot-Kraus model.

Potential Pier Effects

A possibly important physical characteristic of our study site is the presence of a pier, which extends 500 m offshore (6 m depth). Since we observed the shoreline behavior only north of the pier, we have no information about what happens near to and south of the pier. If sand waves propagate past the pier, how are they affected by its presence? Does the pier generate sand waves? We hope to extend analysis to observations from both sides of the pier, as there is an extensive collection of surveyed profiles at Duck, spanning over a decade.

CONCLUSIONS

Observations of the shoreline position at Duck, NC indicated that alongshore progressive features with a length scale of order 1 km were responsible for a large portion (40%) of shoreline variability at this site. The amplitude of these features (~10 m) was modulated by the annual variations in wave height. The amplitude was reduced during periods of increased wave height (winter) and the amplitude increases during calm conditions (summer). Although these features propagated to the south, variations in celerities were not well correlated to the direction of expected wave-driven sediment transport, and were more correlated to changes in the wave height. Surprisingly, the alongshore-averaged shoreline behavior was not well correlated to wave height. Although the wave field varied on an annual cycle, the alongshore-averaged shoreline position did not, in contrast to expectations from a simple conceptual model of summer-winter behavior. Instead, this component varied most dominantly over an interannual period, in which one cycle was completed in about two years.

The observations and analysis presented here describe the contribution of various alongshore length scales to beach variability at Duck, NC. The results of this analysis indicated the importance of large length and time scales to observed nearshore variability. Extending analysis to observations that cover larger lengths and longer time periods will improve our resolution of the phenomena presented here.

ACKNOWLEDGMENTS

The data used here comes from a large image database collected as part of an ever expanding research program called ARGUS. If John Stanley had not organized all the data so well, the pilot study for this project would not have been completed in the two days available to do so and the first author's scientific career would have been ruined. The research staff at the Army corps of Engineers Field Research Facility are similarly appreciated for their maintenance of the wave data. Thanks, also, to those people who discussed this work with us at the ICCE '96 meeting. This work was funded by the Office of Naval Research, Coastal Dynamics Program (grant # N00014-960237).

CHAPTER 273

LONG TERM BEHAVIOUR OF THE SEDIMENT VOLUME INSIDE A TIDAL BASIN AFTER POLDERING

Ernst Schroeder¹, Roland Goldenbogen², Hans Kunz³

ABSTRACT

The development of morphological reactions over time as a result of polderings has been investigated for the Dithmarscher Bucht (Bay of Dithmarsch), a tidal basin which is located in the North Sea/Germany. Two methods of parametrization have been used: the first method is based on volume-differences and the second one refers to the vertical differences of the topography. The results have been used for an estimation of the stability of the tidal basin with respect to an accelerated rise of the relative sea level.

INTRODUCTION

Tidal basins are transition areas between the mainland and the sea. They exist under special hydrological and sedimentological boundary conditions. On account of these special conditions, tidal basins have been formed along the Southern North Sea coast during the last 10,000 years (Bantelmann 1966 and Streif 1990). In most of the areas, the actual situation has been substantially influenced by human interferences, especially by land reclamation.

Besides coastal engineering aspects the Wadden Sea areas are an unique ecological system, which is essential as breeding and feeding ground for migratory birds on their East Atlantic Flyway (Lozán et al. 1994).

³ Director Dr., Coastal Research Station

An accelerated rise of the relative sea level is a realistic prospective; therefore the question about its effects on the long term behaviour of the Wadden Sea-tidal basins along the North Sea coast is important. Only if the morphology of the tidal basin is able to adapt to the changing hydrological conditions, is it ensured, that the whole system keeps its stability.

A tidal basin is a feed-back system which tends towards an equilibrium stage, determined by the hydrological and morphological boundary conditions. Changes in the relation between these boundary conditions lead to reactions of the morphology. The morphology compensates the non-equilibrium stage by more or less intensive accumulation or erosion processes. These adjustments proceed with a phase lag, depending on the quantity of the disturbance in relation to the system itself.

Comparable processes occur after cutting off (poldering) parts of a tidal basin. The daming reduces the catchment area of the tidal basin and alters the relationships between the hydrological and the morphological boundary conditions. Investigations of the morphological development after cutting off parts from a tidal basin led to calculations over time of the adjustment-ability.

The morphological reaction of a tidal basin, forced into a non-equilibrium stage by cutting off parts, can be compared with the effects of the changing hydrological boundary conditions as a result of sea level rise. Thus, the adaptability can be estimated qualitatively for different values of sea level rise.

PARAMETRIZATION

The description of the morphological development has been based on two different methods for the parametrization. The parameters for the first method has been determined by calculating the difference between volumes. The second method is based on the averaged heights difference between bathymetric surveys of the morphology for successive stages. The introduced parameters are named "transpose-rates", for the first method as h_t and for the second one as h_A or h_E , with the dimension m/a . The transpose-rates which are presented and discussed in the paper represent mean yearly values.

Method N^o. 1

The sediment volume V_1 has been calculated above a fixed datum as horizontal reference level (Fig. 1). The reference level has been set below the deepest point of the topography for which morphological changes are recorded. For the total tidal basin

Dithmarscher Bucht, the reference level has been fixed at -22.0 m NN⁴ and for the defined subareas at -12.0 m NN. The upper limit is 2.0 m NN⁵. The volume difference ΔV_I (Fig. 2) of two successive surveys are divided by the time period between the surveys Δt and by the area of the cross section A_I (Schroeder et al.1995b). This parameter is named "transpose rate h_t " (m/a):

$$h_t = \Delta V_I / (\Delta t_i \cdot A_{I,i+1}) = (V_{I,i+1} - V_{I,i}) / ((t_{i+1} - t_i) \cdot A_{I,i+1}). \quad (1)$$

The division by the cross section A_I provides a standardization of the parameter, which allows the comparison of catchment areas A_c with different sizes.

Figure 1. Idealized graphs of the geodetic level h over the cross section A_I

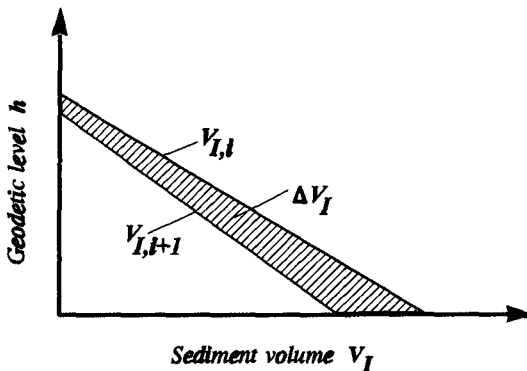

Figure 2. Idealized graphs of the geodetic level h over the sediment volume V_I

⁴ NN = Normal Null = German ordnance-datum (app. MSL)

⁵ MHW app. 1.55 m NN (min. HW/max. HW = 1.46/1.63 m NN; 1942 - 1990) at the tide-gauge Büsum (Fig. 6)

Method N°. 2

The second method leads to "transpose-rates" which have been determined separately for accumulation as " h_A " and for erosion " h_E ". The calculation of these parameters is based on the heights of a standardized area-element (vertical difference). Therefore, the topography has been transformed into square grids (Fig. 3). The resolution of the grid has been fixed as 25 m in x- and y-direction, hence, one grid-element covers an area of 625 m².

The horizontal reference level of one grid yields as mean value of the "average node" H_i (mNN) of the heights of each grid node (see A, B, C and D in Fig. 4):

$$H_i = (A+B+C+D)/4. \quad (2)$$

The difference of the parameter H of two successive surveys (H_i, H_{i+1}) is the accumulation or erosion-rate ΔH_i in m for each grid element:

$$\Delta H_i = H_{i+1} - H_i. \quad (3)$$

This rate, divided by the time interval between the successive surveys, leads to the yearly transpose-rate of each grid element, either as accumulation ($\Delta H_{A,i}$) or as erosion ($\Delta H_{E,i}$). The sum of all elements with accumulation or erosion inside the defined investigation areas (total basin or subarea) yields to the "transpose-rate", which is indicated as h_A (accumulation) and h_E (erosion) with the dimension m/a:

$$\sum \Delta H_{A,i} / \Delta t = h_A \quad (4)$$

$$\sum \Delta H_{E,i} / \Delta t = h_E. \quad (5)$$

Figure 3. Idealized investigation area with grid

Figure 4. Idealized grid element with the grid nodes A, B, C and D and the average node H_i

INVESTIGATION AREA

The investigation area is called the *Dithmarscher Bucht* (Bay of Dithmarsch). It is located on the German North Sea coast on the West side of the German federal state of *Schleswig-Holstein* (Fig. 5).

Figure 5. Location of the investigation area

The shape represents a single bay which opens towards the main wind- and wave direction. Inside the bay, the mean tidal range (semidiurnal tides) is 3.25 m (1942-1990); the dominate wind direction scatters around West. The mean offshore waveheight is about 1.00 m. The geological structure of the bay, developed during the Holozän-time-period, consists mainly of marine sediments (Fischer 1955).

The tidal basin had been reclaimed two times by poldering. The bay covered an area of approximately 157 km² before the polderings had been carried out. The first poldering (1972) reduced the bay-area (A_b) by about 16 km² and the second one (1978) by 26 km² (see dotted lines in Fig. 6).

Figure 6. Investigation area *Dithmarscher Bucht* with poldered areas and the investigated subareas

With regard to the reaction of the bay as result of the polderings, the tidal basin has been split up into subareas according to the application of an applied empirical model (Goldenbogen 1994, Niemeyer et al. 1995 and Schroeder et al. 1995a). The subareas which include the poldered parts are shown on fig. 6: *Speicherkoog*, *Kronenloch* and *Währdener Loch*. The total bay-area is represented by *The Piep*. During the investigation period from 1942 up to 1990 the *Dithmarscher Bucht* had been surveyed 9 times (1942, 1956, 1969, 1973, 1976, 1979, 1982, 1985 and 1990). The bathymetric surveys of 1942, 1956 and 1969 describe an undisturbed topography. The surveys after the year 1973 are influenced by the poldering-means.

The morphological data for the *Dithmarscher Bucht* and parametrizations for "equilibrium stages" have been described by Schroeder 1994.

RESULTS

The following diagrams show the calculated transpose-rates h_i . The data (ordinate) has been plotted over the half period of an investigation intervall Δt_i (abscissa, Fig. 7).

Figure 7. Definition of the investigation intervall Δt_i

Figure 8 shows data which are based on the the total difference of the sediment volume in accordance with the first method. During the period from 1942 up to 1969 the anthropogenic influences are negligible. The scattering of the results can be explained by natural effects and, additionally, in the case of the year 1956, by the quality of the bathymetric survey.

Figure 8. Transpose-rate h_i versus investigation intervall Δt_i

The first poldering was carried out inside the subarea *Speicherkoog* in 1972 (Fig. 6). The value of the subarea *Speicherkoog* shows a distinct tendency of erosion as a result of the first poldering, whereas the other subareas, as well as the total tidal basin, are characterized by accumulation.

The second poldering was carried out in 1978. This poldering extends over the subareas *Kronenloch* and *Wöhrdener Loch* (Fig. 6). After the second poldering, the tendency of erosion continued inside the subarea *Speicherkoog*. The transpose-rate inside the subarea *Wöhrdener Loch* decreased in the range of the average values, as monitored during the undisturbed period before 1969. Only the transpose-rates of the subarea *Kronenloch* increased significantly. However, already during the second investigation interval from 1982 to 1985, the values for this subarea also decreased. All values indicate a low erosion-tendency. The erosion effects continue for the subarea *Kronenloch* during the last interval (1985 to 1990). The results for the last interval scatter within a range which is comparable to the values during the undisturbed investigation period before 1969.

A similar development display the results for the accumulation rate h_E gained by the second method (Fig. 9).

Figure 9. Transpose-rate h_A versus investigation interval Δt .

The value increased after the first poldering. The subarea *Speicherkoog*, where the poldering was carried out, shows the highest value. This value decreased after the second poldering, whereas the transpose-rates of the subarea *Kronenloch* and *Wöhrdener Loch* increase. The next investigation-interval indicates a reduction of the values for all subareas. During the following interval, this tendency continued for the subarea *Speicherkoog* and also for the whole tidal basin, whereas the subareas *Kronenloch* and *Wöhrdener Loch* show more or less constant accumulation-rates.

The data of the erosion rate also indicate clear trends (Fig. 10). The undisturbed period is followed by an increase of the values except for *Kronenloch*. Over the last two investigation intervals the values decrease, including those for the *Kronenloch*. During the last interval (1985-1990), the value scatter already in the range of the undisturbed period before 1969.

Figure 10. Transpose-rate h_E versus investigation interval Δt_i

CONCLUSIONS

The results allow estimations concerning the morphological reactions of a tidal basin on the changes of geographic boundaries by poldering (reduction of the bay-area leading to a disturbance of the equilibrium condition with respect to the tidal volume

as hydrographical boundary condition and the cross-section/area-size as morphological boundary condition). The discussed results show comparable reactions of the described parameters over the whole investigation-period from 1942 to 1990.

The results concerning the development of the *Dithmarscher Bucht* over the last three investigation intervals from 1979 up to 1990 (time period after the polderings) showed, that after approximately 5 years, the parameter-values had decreased, in part, more than 50% of the maximum values after the polderings. The assumption can be drawn that after 5 more years there will be no significant distinction between the anthropogenic and the natural influences of the transpose-rates. With respect to the strongly decreasing tendency of the investigated transpose-rates, the prediction seems to be reliable, that after one to two decades, the influences of the anthropogenic impacts (disturbance of the "equilibrium stage" by poldering) will fade away and the adaptation to the anthropogenically-created new boundary conditions will reach the new equilibrium.

The results indicate the *Dithmarscher Bucht* as an area with strong accumulation. Comparable investigations, described in literature, came up with similar results (Wieland 1984, Siefert 1987, Niedoroda et al. 1994), and Unsöld 1974 with respect to the regeneration after dredging.

With regard to a transfer of the described results to other tidal basin-areas, the available sediment capacity of the area is one of the main restricting factors that has to be taken into account.

The investigation have shown that, for the tidal basin *Dithmarscher Bucht*, there will be no danger concerning the stability of the morphology with respect to changes of the forecasted or feared hydrological boundary conditions, even if the acceleration of the relative mean sea level rise should reach the IPCC-best-estimate-values (IPCC 1990) of about 60 cm in hundred years.

ACKNOWLEDGEMENT

CHAPTER 274

WAVE GROUPS IN A BARRED NEARSHORE

B. Boczar-Karakiewicz¹, W. Romańczyk¹, J.L. Bona² and B. Greenwood³

ABSTRACT

Observations of waves and sediment movement in coastal zones have shown evidence of groupiness in the wave field associated with episodic events of high sediment concentration above the sandy bed. These observations raised the question about the role of wave groups on large-scale coastal sand bars. The present study addresses this question. Analysis is based on data from a lacustrine experimental study site located in Nottawasaga Bay, Lake Huron, Ontario, Canada. The results of field measurements provided initial and boundary conditions for numerical simulations of wave-seabed interactions under waves and wave-groups. Model predictions are compared with observations. The conclusions suggest that nonlinearly modulated wave trains may potentially form and modify sand bars in coastal zones due to large-scale spatial variation in the nonlinear structure of these waves. However, strong irregularities in observed wave groups and related episodic sediment concentration events suggest that these groups do not represent an effective factor in the 'slow' process of sand bar formation.

1. INTRODUCTION

In deep ocean, with limited breaking, wave groups can be described by superposition of linear wave components or by applying nonlinear modulation instabilities. Medina and Hutspeth (1990) have shown that linear algorithms describe observed wave groups in a water depth greater than 10 m with satisfactory agreement. Battjes and Vledder (1984) supported this conclusion for the surf zone.

¹INRS-Océanologie (Université du Québec), Rimouski, Québec, Canada

²University of Texas, Applied Math, Austin, Texas, USA

³Scarborough College Coastal Research Group, University of Toronto, Toronto, Ontario, Canada

However, in the linear approach, waves are assumed to be a Gaussian process, with independent components of the wave field. In earlier studies, it also has been assumed that upon initial breaking, wave groups vanish, except for a small zone surrounding the mean breakpoint.

These assumptions were shown not to be valid in shallow coastal zones. List's quantitative study (1991, 1992), using the concept of wave group envelope, has confirmed that groupiness decreases rapidly through the surf zone, and is sensitive to initial wave breaking. However, he also proved that the degree of groupiness does not become negligible, even in a saturated surf zone. His analysis revealed that groupiness of unbroken waves remains constant over a wide range of incident wave conditions from fairweather swells to storm seas. That observation contradicts the intuitive concept of groupiness resulting from the superposition of sinusoidal waves of similar frequency. According to the linear concept, an increase of spectral bandwidth should result in decreased groupiness.

Laboratory tests and numerical simulations carried out with wave shoaling over a beach of constant slope allowed experimentations with nonlinear wave groups in a simpler environment than a natural coast. A set of such experiments has been conducted in the wave basin of the Hydraulics Laboratory of the National Research Council of Canada (Nwogu 1993). Bichromatic linear waves were generated at the deep-water end of a 1:25 sloping concrete beach. The time series of water surface elevation were measured at two locations: at the toe of the slope and at the initial breaking location. A numerical model based on Boussinesq equations simulated hydrodynamics in the experiment. Comparisons of model results and observations showed good agreement and explained the nature of nonlinear transformations in the initial modulated train composed of sinusoidal waves. When these waves approach shallow water, their shape changes into a complex nonlinear form. The nonlinearity in an individual wave profile increases with decreasing water depth, due to a transfer of energy from the two fundamental frequencies of the incident biharmonic wave train into respective higher harmonic modes. A small amount of energy is also transferred to a low-frequency group-bound wave. That energy increases with decreasing water depth.

The results of a similar numerical study based on a KdV equation with variable coefficients describe the nonlinear evolution of a single group of modulated sinusoidal waves propagating over a gently-sloping beach (Talipova *et al* 1995). Nonlinear and dispersive effects in this group lead to recurrent energy transfer between the fundamental and the higher harmonic components. The initial wave group evolves with increasing distance into a strongly nonlinear wave packet. At a distance of several tens of wavelengths from the deep-water end, the initial modulation changes shape. Higher waves are shifted to the front of the packet due to frequency dispersion. Nonlinearity causes the appearance of secondary crests in the individual waves of the packet. Therefore, it is not

Figure 1: (a) Cross-shore velocity (at 0.10 m above the bed), (b) suspended sediment concentration (at 0.04 m above the bed).

clear how to relate the number and position of waves in the packet with the number of sinusoidal waves in the initial group.

Examples of numerical simulations and laboratory experiments with idealized wave groups show how their properties result from nonlinearity and dispersion of the shallow-water environment. On a natural coast, wave group behaviour is even more complex because of the presence of several flow components.

Observations of waves and sediment movement in coastal sites (Greenwood *et al.* 1992) show evidence of groupiness in the wave field associated with episodic events of high sediment concentration above the sandy bed. A typical record of nearbed velocities and suspended sediment concentration is shown in Figure 1. These observations raised the question about the role of wave groups on large-scale coastal sand bars.

The present study addresses this question and concentrates on the role of wave groups in sand bar formation and dynamics. Our analysis is based on observations from an experimental study site presented in Section 2. Numerical simulations of wave-seabed interactions under waves and wave-groups are presented in Section 3. Model calculations are carried out with initial data from the field experiment. Predictions are compared with observations from the experimental site. The conclusions are formulated in Section. 4.

Figure 2: Field site, Bluewater Beach, Nottawasaga Bay, Ontario, Canada.

2. THE EXPERIMENTAL SITE AND FIELD OBSERVATIONS

The study site (Bluewater Beach, Nottawasaga Bay, Lake Huron, Ontario, Canada) is located in a narrow bay, as shown in Figure 2. Incident wind-generated storm waves arrive to the nearshore zone from a narrow window and impinge on the beach from the shore-normal direction. Under such conditions, we may apply our two-dimensional morphological model in calculations presented in Section 3. In the chosen site, surface hydrodynamics are simpler than on ocean coasts as they are not affected by tidal flows.

The study site has a barred shoreface (see Fig. 3 for the location of sensors used in measurements). The typical multibar shoreface from Figure 3 is not static. In 1987, a beach survey revealed a one-bar profile (Fig. 4a), which transformed into a multi-bar profile in the following year (Fig. 4b).

Field measurements of waves and sediment concentrations at Bluewater Beach analyzed by Osborne and Greenwood (1992) have shown that the lo-

Figure 3: Typical shoreface profile and sensor deployment (pressure sensors, electromagnetic current meters, optical backscatter sensors (OBS)).

cal time-varying suspended sediment flux is a response to high-frequency wind-wave oscillatory currents, low-frequency waves and quasi-steady currents (undertow). The relative importance of these transport components varies spatially and temporally in association with variability in incident wave energy. In contrast to a non barred shoreface, where variations of transport components are strongly controlled by monotonically-decreasing local water depth, across a barred shoreface sediment fluxes are constrained by position with respect to the bars.

Co-spectral analyses of cross-shore velocities and sediment concentrations reveal that grouped, nonlinear shoaling waves induce large onshore sediment transport rates at wind-wave frequencies. However, simultaneously, net offshore-directed transport at low frequencies was also observed. This offshore sediment flux compensates onshore currents induced by grouped waves. During extreme storms, the group-bound long wave could potentially dominate the net oscillatory component of suspended sediment transport and, consequently, displace sediment in the offshore direction.

Additional complexity at a barred foreshore results from waves breaking over a bar crest and waves reforming in the bar trough. Observations show that, typically, outside the surf zone, the re-suspension of sediment under groups of large waves is coherent with the offshore phase of low-frequency modulation of the velocity field due to the presence of wave groups and the group-bound, forced long wave.

However, landward of the zone of wave breaking, on the bar crest and on the upper lakeward slope, the wave-group structure was observed to be diminished.

Figure 4: Shoreface profiles at Bluewater Beach in 1987 and 1988.

Here, low-frequency waves were still evident, which suggests the presence of edge waves or reflected long waves. These waves may contribute to observed high sediment concentrations and to the observed morphodynamic response under highly energetic conditions.

Observations have also shown that bar topography exerts an important constraint on both the magnitude and direction of transport by oscillatory and mean currents. The bar crests experienced the largest oscillatory currents and greatest levels of turbulence induced by wave breaking. Surprisingly, however, the net suspended sediment transport rates were minimal, near balance, between the mean transport rate directed offshore by undertow and the net on-shore oscillatory transport rate controlled by asymmetric waves at or close to breaking. The oscillatory transport rates at wind-wave frequencies decreased with increasing water depth both landward and lakeward of the bar crest.

According to the interpretation of reported spatial changes in suspended transport rates, it has been concluded that spatial variation in sediment transport does concur with bar morphodynamics that resulted from the monitored storm event. After the storm, the inner bar migrated landwards. However,

the lower lakeward slope did not show any erosion despite large and persistent sediment flux gradients and net offshore transport.

The reported results of observations analyzed by Osborne and Greenwood (1992) were concluded by a statement that the net oscillatory sediment transport rate induced by low-frequency waves increases both landward and lakeward of the breaker zone on the bar crest, as does the mean sediment transport rate. Additionally, it was shown that the low-frequency group-bound wave transports sediment offshore. However, it could only be inferred that the secondary low-frequency wave may transport sediment onshore because observations did not provide quantitative data on the structure of the low-frequency wave and about its role in the maintenance of the bar form.

The results of field data analysis presented above show that surface hydrodynamics and related sediment fluxes are extremely complex in a barred foreshore. With available technology and analytical methods applied in the study of Osborne and Greenwood (1992), it is, at present, impossible to discriminate between the contribution of wave groups to sediment transport from the contribution of the remaining transport components active in the nearshore. In their conclusion, Osborne and Greenwood also pointed out that the spatial variation of suspended sediment transport rates correlated only partially with observed changes in bar morphology.

The numerical modeling presented in Section 3 allowed us to investigate the influence of wave groupiness on bar dynamics in idealized, simple conditions. Wave and topography data from field measurements at Bluewater Beach were used in initial and boundary conditions required in the model, and in the experimental verifications of model predictions.

3. METHODOLOGY OF NUMERICAL SIMULATIONS

We present three sets of numerical experiments investigating wave-bed interactions in a coastal environment. In these experiments, surface hydrodynamics are induced by wave trains at wind-wave frequencies characterizing the wave climate at Bluewater Beach. In the first set of calculations, model predictions were carried out with incident nonlinear waves without any group-like modulation. In the remaining calculations (set 2 and set 3), wave-bed interactions were induced by modulated wave trains with some properties of groupiness observed in the coastal wave field.

In the analysis presented, quasi-steady flows (undertow) and low-frequency group-bound waves are not considered. The first simplification is sustained by observations from Bluewater Beach (Osborne and Greenwood 1992). The results of these observations show that despite evidence of steady flow contribution to sediment transport, the changes seen in bar morphology correlated only partially with measured transport rates. The second assumption is based on conclusions from the DUCK'85 field experiment. In this experiment, low-frequency group-bound waves and other secondary, low-frequency flows were

Figure 5: Schematic presentation of modeling non-modulated and modulated wave trains.

shown to contain lower energy levels than oscillations at wind-wave-induced frequencies (List 1991).

To predict the spatial and temporal evolution of the bed morphology under waves, we applied our two-dimensional morphological model (see, e. g., Boczar-Karakiewicz *et al.* 1995). In this modular model, the surface wave induces a nearbed flux of sediment, resulting in a deformation of the underlying seabed. For nonlinear incident, non grouped waves, surface hydrodynamics are described by a simplified Bussinesq equation (Boczar-Karakiewicz *et al.* 1987). To simulate incident trains of wave groups we have modified the original description of the surface wave. In this simulation, group-like modulations in the incident wave train result from superposition of two waves of similar frequency. The original and modified approaches are shown schematically in Figure 5. In all calculations, incident wave conditions are given at the deep-water end of a two-dimensional coastal zone. The initial topography, a uniform featureless slope, corresponds to mean slopes observed at Bluewater Beach (broken line in Fig. 6c).

In the first set of calculations, we analyzed the morphological response to incident nonlinear waves without any group-like modulation (Fig. 6). The spatial evolution of the surface wave (Fig. 6a and 6b) and the temporal change of the underlying bed from the initial featureless slope (broken line in Fig. 6c) to a final multibar profile (heavy line in Fig. 6c) are predicted for an extreme storm event. This event is simulated in the model by a train of regular waves with period T ($T = T_p = 6.9$ s), where T_p denotes the peak period of extreme storms at Bluewater Beach. (In the results presented, the amplitudes of harmonic wave components are non-dimensionalized by the amplitude of the incident wave.)

The temporal evolution of waves and morphology is shown in more detail in Figure 7. The morphological time scale τ (Fig. 7a) characterizing the formation of a multibar morphology from an initially featureless slope is of the order of hundreds of thousands of wave periods. The comparisons presented in Figure 7b show satisfactory agreement between the predicted and observed number of bars and bar-crest locations.

For a sequence of incident waves simulating a typical season (extreme winter

Figure 6: Prediction of wave and morphology evolution under nonlinear waves without group-like modulation (simulation of an extreme storm event with $T_p = 6.9$ s): (a) amplitude of the two first harmonic modes, (b) free-surface elevation, (c) initial and final bed.

storms followed by moderate summer wave conditions, with $T_p = 6.9$ s and $T_p = 3.5$ s, respectively), the model correctly reproduces the observed seasonal variability of the shoreface morphology that transforms from a multiple bar profile into a single bar, as observed at Bluewater Beach (Fig. 3; see also Boczar-Karakiewicz and Jackson 1991, Boczar-Karakiewicz *et al.* 1995).

In the second set of calculations, we simulated the linear effects of groupiness on coastal morphology. In this calculation presented in Figure 8, the group-like modulated wave train (Fig. 8a) propagates over the featureless mean slope of Bluewater Beach (Fig. 8b) without interacting with the underlying bed. A similar result is obtained for an initial multibar bed profile which remains unchanged under a train of linear wave groups (see again Fig. 8b). The amplitude modulation in the train of linear wave groups at $x = 100$ m is shown in Figure 9. Modulation results from a superposition of two waves of similar frequency, derived from the peak period, $T_p = 6.9$ s, of extreme storm events observed at Bluewater Beach.

In the third set of calculations shown in Figure 10, surface hydrodynamics are again induced by a group-like modulation (in the frequency band of extreme storms at Bluewater Beach). In contrast to previous experiments with linear wave groups (set 2), we have imposed spatial, nonlinear energy flow between

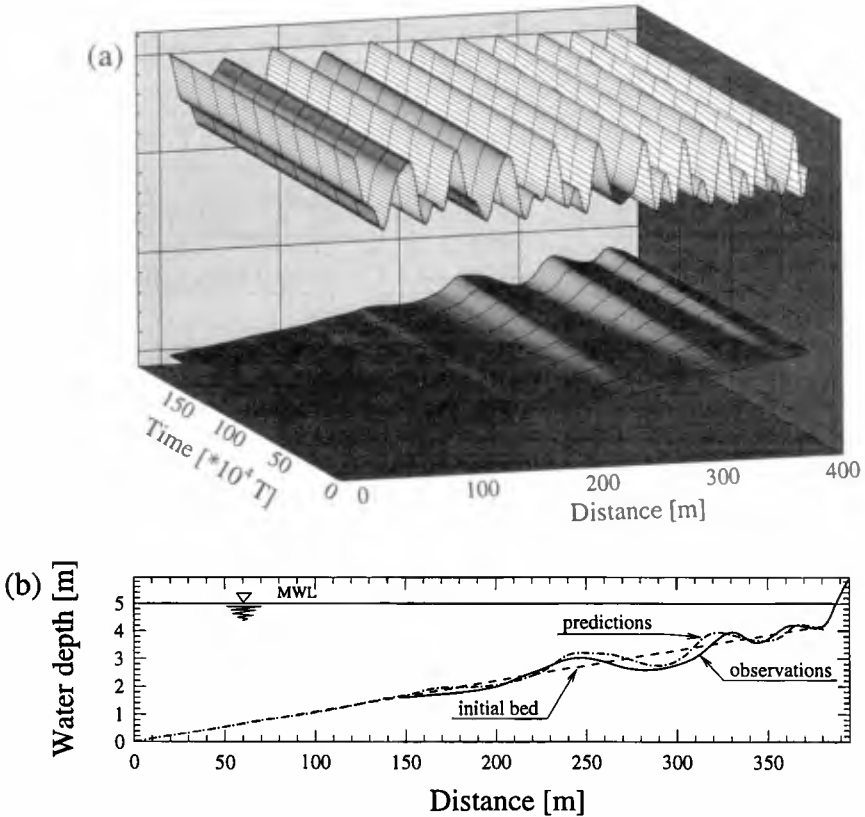

Figure 7: Prediction of morphology evolution under nonlinear waves without group-like modulation (simulation of an extreme storm event with $T_p = 6.9\text{s}$): (a) temporal evolution of waves and morphology, (b) predicted and observed multibar morphology.

fundamental modes of the incident wave train in the present simulation (see Fig. 10a). This pattern results from the solution of approximated Boussinesq equations (Fig. 5; Boczar-Karakiewicz *et al.* 1987). The spatial view of the resulting surface elevation is shown in Figure 10b. The velocity field of simulated wave groups generates nearbed sediment fluxes that gradually deform the underlying bed. Eventually, at time τ ($\tau = 10^4 T_p$), the initially-featureless, uniform slope (broken line in Fig. 10c), evolves into an equilibrium configuration (solid line in Fig. 10c). In the deeper part of the shoreface (at 0-260 m, Fig. 10c), the initial featureless slope remains nearly intact. In the shallower part (at 260-380 m in Fig. 10c), the initial bed deforms into multibar morphology. The spatial distribution of bar crests correlates with the nonlinear pattern of the imposed energy exchange among fundamental modes of the wave group

Figure 8: Evolution of waves and morphology under group-like modulated wave train (linear case): (a) free-surface elevation, and (b) shoreface morphology.

Figure 9: Time history of the incident bimodal wave train (linear case)

(Fig. 10a).

Figure 11 shows, at three chosen locations indicated in Figure 10c, the time history of surface elevation in nonlinear simulation. These records indicate strict periodicity in the time domain, T . In contrast, velocity records from field measurements show evidence of pronounced temporal irregularity in observed wave groups (see again Fig. 1a). The reported results of model calculations suggest that large-scale morphology in coastal zones responds to the passage of nonlinear waves. In both nonlinear cases considered (set 1 and set 3), a rhythmical bed configuration is generated by waves characterized by large-scale nonlinear modulation in their amplitudes. The process of bar formation (Fig. 6 and Fig. 10) and bar transformation (Fig. 4) lasts over time denoted by τ in Figure 6. This morphological time scale τ is several orders of magnitude lower than the hydrodynamical scale T , characterized by the wave period of the incident wind wave.

In contrast, the large-scale coastal morphology (featureless uniform slope and a multibar profile) does not respond to the passage of trains of linear wave groups. This conclusion explains observations reported from the study

Figure 10: Evolution of waves and morphology under a group-like modulated wave train (nonlinear case): (a) initial spatial modulation of wave amplitudes, (b) free-surface elevation, and (c) shoreface morphology.

site according to which the deeper lying outer bar and the lakeward slope of the inner bar were unaltered during the monitored moderate summer storm (with peak period waves $T_p = 3.5$ s). During this storm, part of the unaltered underwater beach was located in a deep-water region for both the incident peak period wave and for observed wave groups related to summer wave conditions (see, e.g., Fig. 8).

4. CONCLUSION

1. Model predictions show that nonlinearly-modulated wave trains may potentially form and modify sand bars in coastal zones. These morphological changes are correlated with large-scale spatial variation in the nonlinear structure of these waves.
2. The predictions presented with strictly periodic nonlinearly-modulated waves suggest that sand bars are formed over time scales in the order of hundreds of thousands of wave periods. Velocity records from Bluewater Beach reveal strong irregularities in observed wave groups and related episodic sediment concentration events. Therefore, on natural coasts, these irregular wave groups do not represent an effective factor in sand bar generation.

Figure 11: Time history of the shoaling group-like modulated wave train (in three chosen cross sections of the shoreface indicated in Fig. 10).

- Predictions and observations show that trains of linear wave groups do not interact with the large-scale nearshore morphology.

CHAPTER 275

COASTAL MORPHODYNAMIC INSTABILITIES

Albert Falqués, Amadeu Montoto and Vicente Iranzo ¹

Abstract

An initially plane beach is considered with waves incoming obliquely. For this basic steady state the Longuet-Higgins solution is used to give set-up and longshore current. The beach is assumed to be erodible. Then, a stability analysis is performed considering infinitesimal disturbances in the current, the free surface and the sea bottom. The basic undisturbed state is found to be unstable giving rise to topographic features similar to oblique or transverse bars and to a meandering in the longshore current. Some comparison with the earlier work by Christensen et al., 1994, is made.

1. Introduction

Beach topography often show tridimensional patterns with some kind of recurrence or rhythmicity in the alongshore direction. Typical examples are oblique/transverse bar systems, crescentic longshore bars, ridge and runnel systems, etc. The explanation for rhythmic topography has followed to main theoretical approaches: i) the infragravity wave influence on sediment transport and distribution (see for instance, Holman and Bowen, 1982) and ii) the morphodynamic instability of the surf-zone under the action of the incoming waves and the longshore current (see Hino, 1974 and Christensen et al., 1994). The basic idea in this latter approach is as follows. Given an initial beach topography, the incoming waves produce some currents. This currents carry sediments and this sediment transport can produce changes in the topography which in turn affects the incoming wave field and the current. In this way there is a feedback and if some perturbation within this loop produces a positive feedback the perturbation will start to grow. Then an instability arises leading to topographic features. In earlier works (Falqués et al., 1996a, Falqués et al., 1996b) the instability of the current-sea bed system

¹ Departament de Física Aplicada, Universitat Politècnica de Catalunya, 08034 Barcelona, Spain

keeping fixed the incoming wave field was analyzed (bed-flow instability). The aim of the present contribution is to include the effect of the perturbations in the incoming wave field. In this way we reproduce and extend the results of Hino, 1974, and Christensen et al., 1994, with a different numerical model. Special attention is paid to the bar shape and orientation, the systematic trends with respect to bottom friction and other parameters and the influence of lateral momentum diffusion.

2. Model equations

Since our aim is to look at large 2D horizontal patterns in the near shore, a 2D shallow water model with time-average over incoming wave period is considered. As governing equations we take the momentum equations:

$$\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \nabla \vec{v} + g \nabla z_s - \frac{\vec{\tau}_b}{\rho \zeta} - \vec{\mathcal{V}} = \frac{1}{\rho \zeta} \nabla \cdot S \quad (1)$$

the mass conservation equation

$$\frac{\partial \zeta}{\partial t} + \nabla \cdot (\zeta \vec{v}) = 0 \quad (2)$$

and the sediment conservation equation

$$\frac{\partial z_b}{\partial t} + \nabla \cdot \vec{q} = 0 \quad (3)$$

A cartesian coordinate system is assumed with x cross-shore, y alongshore and z vertical upwards (see Fig.1). $\zeta = z_s - z_b$ is the total depth, $\vec{\tau}_b$ the bottom friction and S is the radiation stress tensor. The lateral momentum diffusion terms read:

$$v_i = \frac{1}{\zeta} \sum_{j=1}^2 \frac{\partial}{\partial x_j} [\nu_t \zeta (\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i})] \quad i = 1, 2 \quad (4)$$

Here, $x_1 = x$ and $x_2 = y$. The sand transport is parametrized by the formula:

$$\vec{q} = \nu |\vec{v}|^m (\frac{\vec{v}}{|\vec{v}|} - \gamma \nabla h) \quad (5)$$

where h is any bottom perturbation with respect to equilibrium and where the term $\gamma \nabla h$ takes account of the tendency of the sand to move downslope. The exponent m has been set to 3 which is suitable for bed-load transport and $\gamma \sim 1$. Now we are going to perform a linear stability analysis for the system of equations 1, 2, 3. First, let us consider a basic steady equilibrium. In this state we assume waves incoming obliquely on the beach (see Fig. 2). The equilibrium consists of a set-up/down in the mean water level and a longshore current. For simplicity so that to be able to use analytical expressions, we will use the Longuet-Higgins solution (Horikawa, 1988). Thus, we assume a saturated surf zone, $H = \gamma_b \zeta$, $x \leq X_b$. The bottom friction (weak current and small angle) is given by

Figure 1: coordinate system.

Figure 2: basic steady equilibrium.

$$\tau_{bx} = -\frac{4}{\pi} \rho c_f u_0 v_x \quad , \quad \tau_{by} = -\frac{2}{\pi} \rho c_f u_0 v_y \quad (6)$$

and the eddy viscosity reads $\nu_t = Nx\sqrt{g\xi}$.

Consider now a small perturbation on the basic equilibrium of the form:

$$\begin{aligned} \vec{v} &= (0, V(x)) + (\hat{u}(x), \hat{v}(x))e^{\sigma t +iky} \\ z_s &= z_s^0(x) + \hat{\eta}(x)e^{\sigma t +iky} \\ z_b &= z_b^0(x) + \hat{h}(x)e^{\sigma t +iky} \end{aligned}$$

where $\lambda = 2\pi/k$ is the wavelength or the alongshore spacing of the growing bedforms. Then, by linearizing equations 1, 2, 3 we obtain:

$$\frac{\partial u}{\partial t} + V \frac{\partial u}{\partial y} + g \frac{\partial \eta}{\partial x} = \left[\frac{\tau_{bx}}{\rho \zeta} \right]^{\mathcal{L}} + [\mathcal{V}_x]^{\mathcal{L}} + \left[\frac{1}{\rho \zeta} \left(\frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} \right) \right]^{\mathcal{L}} \quad (7)$$

$$\frac{\partial v}{\partial t} + V \frac{\partial v}{\partial y} + \frac{dV}{dx} u + g \frac{\partial \eta}{\partial y} = \left[\frac{\tau_{by}}{\rho \zeta} \right]^{\mathcal{L}} + [\mathcal{V}_y]^{\mathcal{L}} + \left[\frac{1}{\rho \zeta} \left(\frac{\partial S_{yx}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right) \right]^{\mathcal{L}} \quad (8)$$

$$\frac{\partial \eta}{\partial t} - \frac{\partial h}{\partial t} + [\nabla \cdot (\zeta \vec{v})]^{\mathcal{L}} = 0 \quad (9)$$

$$\frac{\partial h}{\partial t} + [\nabla \cdot \vec{q}]^{\mathcal{L}} = 0 \quad (10)$$

These equations are too long to be written here in detail in such a way that we abbreviate 'linear part of' by

$$[\cdot]^{\mathcal{L}}$$

The perturbation in the radiation stress terms will be called bed-surf terms since they describe the perturbation in the incoming wave field due to growing bedforms. The perturbation in the wave refraction should be also included in the bed-surf terms but this has not been done in the present work. The remaining terms in the linearized equations if bed-surf effect is neglected will be called bed-flow terms since they describe the perturbation in the current due to the growing bedforms if the forcing by the waves is kept fixed.

Before solving the linear problem, a scaling and some non-dimensional parameters will be introduced. As horizontal lengthscale, the width of the surf zone, $L_H = X_b$, is chosen and $L_V = \beta X_b$ will be the vertical scale where β is the beach slope (see Fig.3). The velocity scale is the scale for the Longuet-Higgins model,

$$U = \frac{5\pi}{16} \frac{\gamma_b}{c_f} \sqrt{g \zeta_b} \beta' \sin \alpha_b$$

where β' is the effective beach slope including set-up and α_b is the wave angle with respect to the cross-shore at breaking. Two time scales appear, $T_h = L_H/U$, $T_m = L_H L_V/Q$, where $Q = \nu U^m$ is the scale for sediment transport. The second one arises in a natural way from the sediment conservation equation (10) and will be called morphological time scale. It is the scale at which bedforms are expected to grow. The first one will be called hydrodynamical time scale and it is much shorter than the other one.

The variables are made nondimensional by means of:

$$(x, y) = L_H(x', y') \quad , \quad z_b = L_V z'_b \quad , \quad z_s = \frac{U^2}{g} z'_s$$

$$(u, v) = U(u', v') \quad , \quad t = T_m t'$$

Then, we deal with non-dimensional linear equations with the following dimensionless parameters. First a nondimensional wavenumber and growth rate, $k' = kL_H, \sigma' = \sigma T_m$. Also, the breaking index, γ_b , the wave angle at breaking, α_b and the viscosity parameter, N , appear. The parameter related to the tendency of the sediment to go downslope now become $\gamma' = \gamma\beta$. An important parameter is the characteristic Froude number of the longshore current, $F = U/\sqrt{gL_V}$ and the frictional parameter, $r = c_f/\beta$. Finally, the ratio between both time scales, $\epsilon = T_h/T_m$, is very small but not set to 0 (which is usually called quasi-steady hypothesis. See 'response time concept' in Christensen et al, 1994). In this way, the model allows for the computation of purely hydrodynamic instabilities like shear waves or even for the possible interaction between both kind of instabilities. However, we have focussed only in morphological instabilities for the present contribution. Hereinafter, nondimensional quantities will be handled dropping accents for simplicity.

Figure 3: scaling.

Finally, equations (7),(8),(9) and (10) result in an eigenproblem where the eigenvalue is the growthrate, σ , and the eigenfunctions the perturbations $(\hat{u}(x), \hat{v}(x), \hat{\eta}(x), \hat{h}(x))$. This problem is discretized by a numerical spectral method. In the next section, an indication is given of the solution procedure.

3. Numerical method

For simplicity, we will illustrate the numerical method by means of a simpler eigenproblem than (7)-(10). Consider the differential equation

$$p(x)u''(x) + q(x)u'(x) + r(x)u(x) = \sigma u(x) \quad 0 < x < \infty \quad (11)$$

with boundary conditions $u(0) = u(\infty) = 0$. Here, σ is the eigenvalue and $u(x)$ the eigenfunction.

The method uses an expansion in Chebyshev polynomials and a

transformation from $[0, \infty)$ to $[-1, 1)$. First, this map is given by

$$x = \phi(z) = l \frac{1 - z}{1 + z} \tag{12}$$

(see Falqués and Iranzo, 1994).

Second, an expansion in Chebyshev polynomials is assumed:

$$u(x) = \sum_{n=0}^N \hat{u}_n T_n(z) = \sum_{n=0}^N \hat{u}_n T_n(\phi^{-1}(x)) \tag{13}$$

The following step is to find a combination of Chebyshev polynomials which verify the boundary conditions. The $N-1$ functions which satisfy this requirement are:

$$g_n(x) = T_n(\phi^{-1}(x)) - \frac{1}{2}(1 + (-1)^n)T_0(\phi^{-1}(x)) - \frac{1}{2}(1 + (-1)^{n+1})T_1(\phi^{-1}(x)) \tag{14}$$

where $n = 2, 3, \dots, N$. Then, expansion (13) is substituted by

$$u(x) = \sum_{n=2}^N \hat{u}_n g_n(x) \tag{14}$$

where the unknowns (eigenvector) are the $N - 1$ coefficients $\hat{u}_2, \dots, \hat{u}_N$.

Now, to discretize equation (11) we will apply collocation at the Gauss-Lobatto nodes $z_i = \cos(\pi i/N)$ transformed by the map (12) (Falqués and Iranzo, 1994). For this purpose, the first step is to know the values of g_n at the nodes. This is given by the matrix $G_{ij} = g_j(x_i)$, so that

$$u(x_i) = \sum_{n=2}^N G_{in} \hat{u}_n$$

In a similar way, the first derivative of u will be given by a matrix G' :

$$u'(x_i) = \sum_{n=2}^N G'_{in} \hat{u}_n$$

where $G'_{in} = g'_n(x_i)$ can be computed by using the derivatives of the Chebyshev polynomials and the map (12). Similarly, the second derivative will be computed by

$$u''(x_i) = \sum_{n=2}^N G''_{in} \hat{u}_n$$

where $G''_{in} = g''_n(x_i)$ can also be computed by means of the derivatives of the Chebyshev polynomials and the map (12). Explicit expressions of the

derivatives of Chebyshev polynomials combined with (12) can be found in Falqués and Iranzo, 1994.

Finally, after performing collocation at x_i , $i = 1 \dots N - 1$ the discretized eigenproblem reads:

$$p(x_i) \sum_{k=2}^N G''_{ik} \hat{u}_k + q(x_i) \sum_{k=2}^N G'_{ik} \hat{u}_k + r(x_i) \sum_{k=2}^N G_{ik} \hat{u}_k = \sigma \sum_{k=2}^N G_{ik} \hat{u}_k$$

where the eigenvector is $(\hat{u}_2 \dots \hat{u}_N)$.

4. Results

One of the drawbacks of Hino model, 1974, without the quasisteady hypothesis, i.e., hydrodynamic instabilities out of control, has been solved. All hydrodynamic instabilities could be identified as shear waves with a clear maximum in the $\sigma - k$ curve. Shear waves have growth rates an order ϵ^{-1} larger than bed wave growth rates. By comparison with other models (Falqués and Iranzo, 1994) they could be recognized. Usually, however, when a realistic friction and viscosity parameters are chosen, no hydrodynamic instabilities appear. Figure 4 shows the nondimensional growth rate $Re(\sigma)$ as a function of the wavenumber k , for three different cases. In one set of curves only bed-flow terms were kept in the equations while in the other set the full equations (bed-flow + bed-surf) were considered. It can be seen that bed-surf, that is, the effect of the wave field perturbation enhances significantly the instability. This was also found by Christensen et al., 1994. Also, bed-surf gives shorter spacing between the bedforms. The imaginary part of σ is not shown here. It is negative and of order one. This means that the topographic waves migrate downcurrent with a speed of the order L_H/T_m .

Regarding the shape of the topographic features, two kind of bedforms were found. First what we call current dominated bedforms. In this case, the shape of the bars looks very similar when only bed-flow terms were taken or when bed-flow and bed-surf were considered. The bars are upcurrent rotated, very oblique (a small angle with the shoreline of the order of 10°). These topographic waves come out in the case of a relatively high characteristic Froude number, say $F > 0.6$ (note that this is not the maximum local Froude number which can be smaller). According to

$$F = \frac{U}{\sqrt{g\zeta_b}} = \frac{5\pi}{16} \frac{\gamma_b}{\sqrt{1 + 0.375\gamma_b^2}} \frac{\sin \alpha_b}{r} \quad (15)$$

this corresponds to small frictional parameter, r , and large angle, α_b . Figure 5 shows how the bottom perturbations with only bed-flow and with bed-flow and bed-surf look quite similar. Figure 7 shows the full equation bedform when the basic slope is added to the perturbation.

Second, we found what we call wave-dominated bedforms. In this case the shape of the bars with only bed-flow or with bed-flow and bed-surf looks

quite different. With only bed-flow they are similar to alternate bars in a river and in the other case they are similar to transverse bars slightly upcurrent rotated (see Fig.6). Figure 8 shows, in this case, the total topography with bed-flow and bed-surf. Wave-dominated bedforms appear for small Froude number, say $F < 0.6$, that is, for large frictional parameter and small angle.

An important issue of morphological models for rhythmic features is the alongshore spacing or wavelength. This is found by looking at the fastest growing wavenumber, i.e., the maxima in the σ_r, k curves for different values of the parameters. From experimental data (usually from the spacing between rip currents assumed to be related to rhythmic topography) the wavelength to surf zone width ratio is in the order $\lambda/X_b \sim 1.5 - 8$. The mean value is between 3 and 4 (Sasaki and Horikawa, 1975). Christensen et al., 1994 found a ratio about 6. In our modelling this ratio ranges between 1 and 7, depending on the frictional parameter, r , and on the wave angle, α_b . It decreases with increasing r and with decreasing α_b (see Fig. 9).

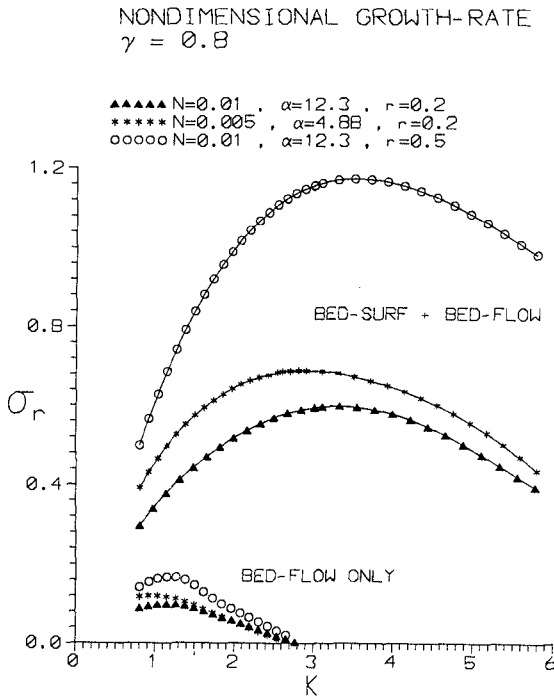

Figure 4: growthrate as a function of wavenumber for three sets of parameters. $F = 0.3, \epsilon = 0.001, \gamma = 0.01$.

The growing bedforms produce a meandering in the longshore current. According to our simulation, the current is deflected offshore over the shoals

Figure 5: perturbation in the bottom for $r = 0.1$, $\alpha_b = 12.3^\circ$, $F = 0.8$, $N = 0.005$, $\gamma_b = 0.4$, $k = 1.14$. Right: only bed-flow, left= bed-flow and bed-surf. In this plot the current runs from the bottom to the top.

and inshore over the pools (see Fig.10). Thinking of rip currents, this is in contrast with many observed rip currents. But two things have to be taken into account. First this is the initial growth. It could be that for finite amplitude features this behaviour would be reversed leading to a non-linear saturation of the growth. Second, these are not exactly rip currents but just the

Figure 6: perturbation in the bottom for $r = 0.5$, $\alpha_b = 12.3^\circ$, $F = 0.16$, $N = 0.005$, $\gamma_b = 0.4$, $k = 3.5$. Right: only bed-flow, left= bed-flow and bed-surf. In this plot the current runs from the bottom to the top.

deflection of the longshore current. Also Christensen et al., 1994, found the same behaviour.

Figure 7: bottom topography for $r = 0.1$, $\alpha_b = 12.3^\circ$, $F = 0.8$, $N = 0.005$, $\gamma_b = 0.4$, $k = 1.14$. Basic slope plus perturbation (with arbitrary amplitude since we are dealing with a linear problem). Current running from left to right.

Figure 8: bottom topography for $r = 0.5$, $\alpha_b = 12.3^\circ$, $F = 0.16$, $N = 0.005$, $\gamma_b = 0.4$, $k = 3.5$. Basic slope plus perturbation. Current running from left to right.

5. Conclusions

It has been shown that the topography of a plane beach can be unstable due to the interaction with the incoming waves and the longshore current. The effect of the perturbation on the waves (bed-surf) turns out to be the most de-stabilizing. This is in line with Christensen et al., 1994. The instability produces the growth of upcurrent rotated bars which is also in agreement with the earlier work of Christensen et al. However, as these authors pointed out, this is sometimes in agreement with the observed bars in the field and sometimes is in contrast. We found two kind of topographic features: i) 'current dominated' (large angle, small friction) and ii) 'wave dominated' (small angle, large friction). Instead of fixed values of the alongshore spacing

Figure 9: Alongshore spacing of the topographic waves.

λ/X_b (4 in the case of Hino and 6 in the case of Christensen et al.,) our alongshore spacing ratio ranges from 1 to 7, decreasing for increasing r , and depending on α_b and N . Finally, the growing bedforms produce a small meandering of the longshore current with an offshore deflection over the shoals. This can be a little surprising but it is also in line with earlier results of Christensen et al. Clearly, more research is needed to clarify the mechanism which produces this perturbed flow in combination with the perturbation in the set-up.

Figure 10: wave-dominated bedform and the perturbation produced on the current. Note the offshore deflection over the shoals. $r = 0.2$, $\alpha_b = 4.88^\circ$, $F^2 = 0.3$, $N = 0.005$, $\gamma_b = 0.8$. Basic current running from bottom to top.

CHAPTER 276

On validation of a sand waves and sand banks model

S. J. M. H. Hulscher *

Abstract

A morphological model is described for the interaction between tidal motion and an erodible bed. This model is able to distinguish between a flat bed, and the generation of tidal sand banks and/or sand waves, based on physical parameters. The physical meaning of the turbulence parameters A_v and S , as used in this model is subject of discussion in the present paper, therefore a simpler system is investigated. A simple flow is described by a logarithmic profile model (a generally accepted turbulence model), as well as by a partial slip model, using A_v and S . It is shown that the two models can be calibrated such that they produce the same bed shear stress, depth-averaged velocity and depth-averaged eddy viscosity. This leads to expressions for A_v and S as function of the roughness height and a shape parameter in the logarithmic profile model. Application of this information to two locations shows that the bed form prediction model gives encouraging results.

1 Introduction

The offshore seabed of shallow seas is covered with rhythmic patterns on a large scale, see e.g. *Off* [1963]. Tidal sand banks have wavelengths of about five kilometers and reach heights up to 40 meters. Sand waves, see figure 1 are smaller, wavelengths of 500 meters, heights up to 10 meters. Both patterns are shown in a schematic way in figure 2. When these two patterns overlap, the crests are oriented differently (angle between 60° - 90°), which suggests that these two patterns

*Civil Engineering & Management, University of Twente, P.O. box 217, 7500 AE, Enschede, The Netherlands.

Figure 1: *Visualization of the North Sea bed near the Eurogeul, from Van Goor & Andorka Gal, 1996.*

Figure 2: Sketch of tidal sand banks and sand waves, the relation to the main tidal current axis is indicated.

are different. Therefore different mechanisms are responsible for their formation and behavior.

A model to describe formation of these large-scale sea-bed patterns due to tide-topography interactions is given in *Hulscher* [1996]. In this model the tide is described by a three-dimensional shallow water model. This model uses a very simple turbulence closure scheme, see also *Engelund* [1970]: constant eddy viscosity A_v in combination with a partial slip parameter at the bottom. The latter introduces a so-called resistance parameter S .

Application of this turbulence model often raises questions how these results compare with more realistic turbulence-closure schemes. Unfortunately it is not completely known how turbulence should be modeled, therefore the answer to this question can never be definite. A further, even more important question is how these, rather abstract, parameters can be determined from observations. Illustrative issue is whether observations are to be collected either on the top and in the trough of the bank or at the adjacent sides.

A start to answer the first question is made studying a simplified system: a two-dimensional horizontal model without Coriolis force and neglecting inertia effects. This system is analyzed in two ways: using a realistic turbulence closure scheme and the simple scheme based on eddy viscosity and the resistance parameter. By comparing the results of these two methods one finds explicit relations between at one hand more accepted model parameters and at the other hand, the eddy viscosity A_v and the resistance parameter S . Furthermore this enables to investigate how the latter two variables are connected, and if they represent two degrees of freedom.

These results can be used to make estimates for the three dimensional model in which Coriolis effects and inertia effects are included. These lead to choices for the parameters which are following *Hulscher* [1996] crucial to determine the

bed structure: a flat bed or sand waves or tidal sand banks or a combination of the latter two patterns. This procedure enables the estimate of these parameters without analyzing an network of current meter recordings. For two cases explicit estimates are given: an average North Sea location and the Middelkerke bank.

The outline of this note is as follows. A short description of the three-dimensional bed form model is given in section 2. Next, the simplified system and subsequent modeling is given in section 3. The analyses in particular for the logarithmic profile and the $A_v - \hat{S}$ model are given in sections 3.3 and 3.4, respectively. Matching of these two models is discussed in section 3.5. These results are transferred to the three dimensional model, which is shown and discussed in section 4. In this section two physical locations are treated as examples. Lastly, conclusions are presented in section 5.

2 Model for sand waves and tidal sand banks

The generation of large-scale bed form patterns is studied based on the idea that these structures might be free instabilities of the coupled morphological system: sea water and sea bed. Therefore a suitable model of this system is formulated and use for analysis.

The morphological shallow water is based on tidal flow described by three-dimensional shallow water equations, bed load transport and conservation of sediment. Tidal averaging and application of a linear stability analysis lead to prediction of the dominant bottom mode starting from a flat bottom. Translating the measures of these fastest growing sinusoidal sea bed waves into physical quantities shows that the pattern is similar to either similar to sand waves or to tidal sand banks; patterns which are significantly different, see figure 2. This leads to the qualitative result in figure 3; the derivation of this figure is described in detail in *Hulscher* [1996].

Figure 3 shows that the bed structure prediction depends strongly on the Stokes number E_v of the tidal flow and the bed resistance parameter \hat{S} . These are defined as

$$E_v = \frac{2A_v}{H^2\sigma} \quad \text{and} \quad \hat{S} = \frac{2S}{H\sigma}, \quad (1)$$

in which H is the local mean depth and σ the frequency of the tidal motion. The constant turbulent eddy-viscosity, A_v (m^2s^{-1}), quantifies the way in which horizontal momentum is transferred in vertical direction. The quantity S (ms^{-1}) is used to model the partial slip near the bed boundary. This overcomes the problem that the constant eddy viscosity is near the bottom too simple to model both velocity and shear stress in a realistic way. After *Engelund* [1970] here A_v and S are considered as two constants which describe together the vertical profile of the vertical flow profile.

Figure 3: *Characteristic bed forms predicted by the three-dimensional shallow water model as a function of the bottom slip parameter \hat{S} and the Stokes number E_v . Quantification depends on values of the Coriolis parameter, local depth, bed-slope effects on sediment transport and the nonlinearity in the bedload transport formula.*

3 Modelparameter derivation

3.1 Simplified situation model

To illustrate the procedure a very simplified model and model-situation is sufficient. Starting from the three-dimensional shallow water model as in *Hulscher* [1996] the simplifications are as follows:

- Coriolis effects are neglected
- tidal flow, $\tilde{u}(z, t)$, is horizontally uniform
- friction dominates inertia effects: the eddy turn-over scale is much smaller than the scale on which the flow varies, such that eddies can reach a statistical equilibrium

Here the tidal flow is driven by pressure gradient, oscillating at the tidal frequency σ and having amplitude P_x . The flow is opposite the pressure gradient; the equation of motion becomes

$$0 = -\frac{P_x}{\rho} \sin \sigma t + \frac{\partial}{\partial z} \left[\nu_t(z, t) \frac{\partial \tilde{u}}{\partial z} \right], \quad (2)$$

in which ν_t is the turbulent eddy viscosity coefficient. The boundary conditions near the sea bed and surface are as follows

$$\begin{aligned} \tilde{u} &= 0 & \text{at } z &= z_0, & (3) \\ \nu_t(z, t) \frac{\partial \tilde{u}}{\partial z} &= 0 & \text{at } z &= H, & (4) \end{aligned}$$

in which z_0 is the roughness height. The z -axis is here directed upwards, from the sea bottom $z = 0$ till the sea surface $z = H$. Here the surface stress component is chosen zero. The bottom shear stress is denoted by $\tilde{\tau}_b(t)$ and is time-dependent:

$$\tilde{\tau}_b = \rho \nu_t(z) \frac{\partial \tilde{u}}{\partial z} \equiv \rho |\tilde{u}_*| \tilde{u}_* \quad \text{at } z = 0, \quad (5)$$

where \tilde{u}_* is the time-dependent friction velocity.

3.1.1 Linearization of the shear stresses

Definition (5) shows that, in general, the friction velocity \tilde{u}_* depends on time, so that the momentum equation is difficult to solve. To deal with this one usually replaces one friction velocity factor \tilde{u}_* by a representative constant \bar{u}_* . Now the bed shear stress condition becomes

$$\tilde{\tau}_b = \rho \nu_t(z) \frac{\partial \tilde{u}}{\partial z} \equiv \rho \bar{u}_* \tilde{u}_* \quad \text{at } z = 0, \quad (6)$$

A possible way to derive such a representative value for \bar{u}_* is requiring that the tidal-averaged shear stresses of both formulations are equal:

$$\rho \langle \tilde{u}_* \tilde{u}_*^2 \rangle = \rho \langle \bar{u}_* \bar{u}_*^2 \rangle, \quad (7)$$

in which $\langle \rangle$ denotes the tidal averaging. Further assuming that the friction velocity oscillates with the tidal frequency σ (like the forcing pressure gradient) and that it has an amplitude \hat{u}_* , the searched constant becomes [Zimmerman, 1981, and Mei, 1989]

$$\bar{u}_* = \frac{8}{3\pi} \hat{u}_*. \quad (8)$$

3.2 Model analysis: general part

In this model the tidal flow is forced by the pressure gradient and as the latter oscillates at frequency σ , so in absence of inertia effects the tidal flow can simply be decomposed as follows

$$\tilde{u}(z, t) = u(z) \sin(\sigma t). \quad (9)$$

Substitution of (9) into the equation (2) leads to the following equation of motion for $u(z)$:

$$0 = -\frac{P_x}{\rho} + \frac{\partial}{\partial z} \left[\nu_t(z) \frac{\partial u}{\partial z} \right]. \quad (10)$$

By integration of (10) using the upper boundary condition (4) and the lower as given in (6), the following equality is obtained

$$\frac{P_x}{\rho} H = \bar{u}_* \hat{u}_* = \frac{8}{3\pi} \hat{u}_*^2. \quad (11)$$

Up till this point no simplifications are made regarding the choice of a specific turbulence closure scheme. In the next two sections equation (10) will be solved using two different turbulence closure schemes.

3.3 Logarithmic profile model and analysis

Viscosity parametrization From turbulence modelling is known that the turbulent eddy viscosity increases from the boundaries in which the distance to the boundary is a measure for the length scale of the turbulent eddies. So at the fixed sea bottom the eddy viscosity equals zero and it increases with the distance from the bottom z :

$$\nu_t(z) \sim z. \quad (12)$$

The sea surface can act as a less stringent boundary. Many physical processes lead to a more effective mixing in the upper part of the water column, e.g. action

of wind waves, swell, stratification. Here this fact is parametrized by a parameter ϵ , which value is here between the limits 1/2 (little influence of surface on turbulence) and 1 (rigid surface). This is chosen such that the viscosity at the sea surface is:

$$\nu_t(H) \sim H(1 - \epsilon). \quad (13)$$

And near the surface $H - \zeta$ (in which ζ positive) the length scale of the turbulent eddies increases following

$$\nu_t(H - \zeta) \sim \nu_t(H) + \zeta(2\epsilon - 1). \quad (14)$$

The previous considerations motivate a parabolic function as parametrization for the dimensional turbulent eddy viscosity ν_t

$$\nu_t(z) = k\hat{u}_*z \left(1 - \epsilon \frac{z}{H}\right), \quad (15)$$

in which κ is the Von Karman constant $\kappa \simeq 0.41$.

Velocity profile Solving equation (10), using boundary conditions (3), (4) and expressing it in terms of \bar{u}_* using (6) yields

$$u(z) = \frac{\bar{u}_*}{\kappa} \left[\ln\left(\frac{z}{z_0}\right) + \frac{(1 - \epsilon)}{\epsilon} \ln\left(\frac{1 - \epsilon \frac{z}{H}}{1 - \epsilon \frac{z_0}{H}}\right) \right]. \quad (16)$$

Depth-averaged quantities The depth-average value of the turbulent eddy viscosity can easily be computed from equation (15) and yields

$$\bar{\nu}_t = k\hat{u}_*H \frac{(3 - 2\epsilon)}{6}. \quad (17)$$

In figure 4 the normalized viscosity profile is shown. The depth-averaged velocity follows from equation (16) and is given by

$$\bar{u} = \frac{\bar{u}_*}{\kappa} \left[\ln\left(\frac{H}{z_0}\right) - \frac{1}{\epsilon} + \frac{1 - \epsilon}{\epsilon} \ln\left(\frac{1 - \epsilon}{1 - \epsilon \frac{z_0}{H}}\right) + \frac{\epsilon - 1}{\epsilon^2} \ln(1 - \epsilon) \right]. \quad (18)$$

3.4 $A_v - S$ model

In this section the highly simplified turbulence model is chosen, here called S and A_v model, which is applied in *Hulscher* [1996]). The model has a vertically constant eddy viscosity, here denoted by A_v . This constant eddy viscosity model lacks variations which lead to describe the correct velocity and shear stress both in the interior as well as at the bottom. However, the aim here is to use this model for studying sediment transport, therefore it has to produce the correct bed shear stress, rather than the exact horizontal velocity near the sea bed. This can be achieved by choosing a partial slip condition, instead of condition (3), at the sea bed. In this context the partial slip condition is formulated as follows

$$\bar{u}_* \hat{u}_* = Su \quad \text{at} \quad z = 0, \quad (19)$$

in which S is the so-called resistance parameter.

Figure 4: The dimensionless viscosity profile $\nu_t(z)/\bar{\nu}_t$ for three values of ϵ (straight $\epsilon = 0.5$, dashed/dotted $\epsilon = 0.75$, dashed $\epsilon = 1.0$).

Velocity profile The solution of equation (2), using (4) and (19) becomes

$$u(z) = \bar{u}_* \hat{u}_* \left[\frac{z}{A_v} \left(1 - \frac{z}{2H} \right) + \frac{1}{S} \right]. \quad (20)$$

Depth-averaged quantities The depth-averaged viscosity in this model is simply the constant

$$\bar{\nu}_t = A_v. \quad (21)$$

The depth-averaged velocity \bar{u} in this model yields

$$\bar{u} = \bar{u}_* \hat{u}_* \left(\frac{H}{3A_v} + \frac{1}{S} \right). \quad (22)$$

3.5 Matching

Now the models, discussed in the previous two sections, section 3.3 and section 3.4, will be matched by appropriate requirements. First remark is that sediment transport is a function of the bed shear stress. This motivates the first requirement: the $A_v - S$ model has to produce the same bottom shear stress as in the logarithmic model. Based on this, the bottom boundary condition in the $A_v - S$ model has already been adapted such that expression (6) is valid in both models.

The second condition is that the water discharge is equal in both models. This condition is here transferred into the requirement of equal depth-averaged velocities resulting from both turbulence formulations. Using equations (18) and (22) this means

$$\ln \left(\frac{H}{z_0} \right) - \frac{1}{\epsilon} + \frac{1-\epsilon}{\epsilon} \ln \left(\frac{1-\epsilon}{1-\epsilon \frac{z_0}{H}} \right) + \frac{\epsilon-1}{\epsilon^2} \ln(1-\epsilon) = \kappa \hat{u}_* \left(\frac{H}{3A_v} + \frac{1}{S} \right). \quad (23)$$

The third condition is that the depth-averaged value of the eddy viscosity $\bar{\nu}_t$ equals the constant eddy viscosity A_v . Using equation (17) this leads to

$$A_v = k\hat{u}_*H\frac{(3-2\epsilon)}{6}. \quad (24)$$

4 Discussion

Before the discussion here starts, it is worthwhile to remark that all values for turbulent eddy viscosity coefficients and bottom shear stress are results of the application of a turbulence closure scheme. The logarithmic model, used as a reference here, is often applied and produces satisfactory results. Therefore this model is generally accepted.

In the present model this leads to the following Stokes number E_v by using equations (11) and (24)

$$E_v = \frac{\kappa\sqrt{\frac{3\pi P_x H}{8\rho}}}{H\sigma} \left(1 - \frac{2}{3}\epsilon\right). \quad (25)$$

So if P_x, H, σ are already determined, the value of E_v is still a function of ϵ .

Using equations (11), (24) and the matching condition (23) the following relation for \hat{S} and E_v is obtained

$$\frac{E_v}{\hat{S}} = \frac{3-2\epsilon}{6} \left[\ln\left(\frac{H}{z_0}\right) - \frac{1}{\epsilon} + \frac{1-\epsilon}{\epsilon} \ln\left(\frac{1-\epsilon}{1-\epsilon\frac{z_0}{H}}\right) + \frac{\epsilon-1}{\epsilon^2} \ln(1-\epsilon) \right] - \frac{1}{3} \quad (26)$$

This relation shows that \hat{S} is a function of the roughness height z_0 , if the other parameters are specified. As z_0 usually is between $5 \cdot 10^{-5}$ m and $2 \cdot 10^{-1}$ m and $\frac{1}{2} \leq \epsilon \leq 1$, this will restrict the values of E_v, \hat{S} which are physically relevant.

4.1 Physical discussion

In general, the pressure gradient P_x can be determined from observations. Here the pressure gradient P_x is roughly estimated from the M_2 tidal (spring) range Δ , following

$$P_x = \rho * g * \frac{2\Delta}{L}, \quad (27)$$

in which L is the tidal wavelength and g the gravity acceleration. Assuming that Δ is 2 meters and the tidal wave follows from shallow water theory (so $L=770$ kilometers on a depth of 30 meters) one derives $P_x = \rho * 5.1 \cdot 10^{-5} \text{ms}^{-2}$; the tidal frequency is $\sigma = 1.4 \cdot 10^{-4} \text{s}^{-1}$.

Figure 5: (a) The ratio E_v/\hat{S} and (b) \hat{S} for three values of ϵ (straight $\epsilon = 0.5$, dashed/dotted $\epsilon = 0.75$, dashed $\epsilon = 1.0$). Here average North Sea conditions are chosen, the depth $H = 30$ meters.

Offshore North Sea A suitable North Sea average depth is 30 m. Using equation (25) gives that $1.4 \leq E_v \leq 2.8$ due to the range of $0.5 \leq \epsilon \leq 1$. The correct value of ϵ has to be estimated based on current profiles. Using many field measurements *Sousby* [1990] has found that the roughness height z_0 in the North sea usually is between $5 \cdot 10^{-5}$ m and $6 \cdot 10^{-3}$ m, in which the larger values are found for rippled sand. Using (26) the ratio E_v/\hat{S} and subsequently the resistance parameter itself can be evaluated. Figure 5(a) shows the ratio E_v/\hat{S} and in figure 5(b) the resistance parameter \hat{S} is shown.

Middelkerke Bank The Middelkerke Bank is part of the Flemish Banks system; these large tidal sand banks are partly covered with sand waves. At the Middelkerke Bank the mean depth is significantly smaller, being about 15 meters. So here the expected range for the Stokes number becomes $2.0 \leq E_v \leq 3.9$. *Vincent & Stolk* [1993], p 217, reported that the roughness height z_0 at two stations around the Middelkerke Bank is between $9 \cdot 10^{-4}$ m and $3.3 \cdot 10^{-2}$ m. For these values the ratio E_v/\hat{S} and the resistance parameter \hat{S} are shown in figure 6.

General The areas in parameter space of both discussed locations are shown in figure 7. In this figure also the expected bed structure based on the bed form prediction model *Hulscher* [1996] is also indicated. For the offshore North Sea bed a part of the possible parameter combinations predict a flat sea bed, also a part of these combinations predicts tidal sand banks. Around the Middelkerke bank a part of the parameter combinations predicts tidal sand banks, for a different part the slowly growing tidal sand banks are dominated by sand waves, which grow faster. Comparison between prediction and the actual bed structure show that these results are not unrealistic. So the ranges in the parameters E_v and \hat{S}

Figure 6: (a) The ratio E_v/\hat{S} and (b) \hat{S} for three values of ϵ (straight $\epsilon = 0.5$, dashed/dotted $\epsilon = 0.75$, dashed $\epsilon = 1.0$). Here Middelkerke Bank conditions are chosen, the depth $H = 15$ meters.

Figure 7: Parts of the parameter space E_v and \hat{S} possible in the offshore North Sea bed and around the Middelkerke bank. Also the expected bed behavior as found by Hulscher [1996] is indicated.

based on natural variations in the quantities roughness height z_0 and turbulence characteristics ϵ cover different bed structures. These results show that it will be worthwhile to determine the value of z_0 and ϵ more precise and subsequently compare the model prediction with the observed local bed structure, for several locations in the North Sea.

5 Conclusions

A way to investigate the implication of a potential sea-bed prediction model is presented. To quantify the parameters which describe the turbulence processes, first a simpler system, based on steady flow, is analyzed.

In the simpler system is shown that the S, A_v -turbulence model is able to produce the same bed shear stress as the accepted logarithmic model. The comparison between these models gives expressions for S and A_v in terms of the model parameters in the logarithmic model: ϵ and z_0 . So based on this comparison between the logarithmic model and the S, A_v model can furthermore be concluded that there are two basic degrees of freedom to choose S and A_v left, here expressed as ϵ and z_0 . One might argue that these two degrees of freedom are restricted, however these restrictions are the result of a calibration of the S, A_v -model with a logarithmic model. Boundaries limiting the physical realistic values of \hat{S}, E_v will certainly be different if the S, A_v -model is calibrated using another turbulence closure scheme than the one used in this note.

The results of the steady flow case are used to estimate the model parameters in the tidal morphological model. For two cases the prediction of the model and the local bed structure are compared and show good agreement. This indicates that it is worthwhile to continue this line of validation.

CHAPTER 277

Transverse Bars in Duck, North Carolina

Kathryn M. Konicki¹ and Rob A. Holman¹

Abstract

In 1985, unusual streaks were first seen in time exposure images of nearshore wave breaking. These features were persistent from image to image and ran perpendicular or oblique to the shoreline. They have been observed both between the shoreline and inner bar and offshore of the inner bar, and have a typical longshore wavelength of ~40-130 m, substantially shorter than normal sand bar length scales. Comparison with bathymetric data collected by the CRAB showed the bands to be bathymetric ridges with a relief of 0.3-0.5 m.

Both intensity transects as well as geometrically rectified images were used to determine the length scales of the bars. Longshore length scales of offshore bars (mean spacing of 131 m) were typically three times the spacing of trough bars (mean spacing of 41 m). The offshore limit of the visible features in the trough varied from as short as 5 m to a maximum of 35 m.

Frequency of occurrence statistics for the bars were determined by viewing Argus data from 1987-1995. Trough bars appeared in the images an average of 62 days/year while offshore bars appeared 41 days/year although there was substantial interannual variability. Offshore bar occurrence is more frequent in the winter, and trough bar occurrence is more frequent in the summer.

Introduction

The classic model of a sandbar is a large-scale feature aligned parallel to the shoreline. Sandbars that are oriented slightly oblique to the shoreline have also been observed and are called welded bars. In 1952, Shephard described a feature oriented perpendicular or at a high angle to the shoreline with a relatively short length scale that he called a transverse bar. Only a few studies have been done on these transverse bars, including Barcilon and Lau's (1973) and Niedoroda and Tanner's (1970) work on transverse bars off the coast of Florida.

In 1985, similar features were first observed in time exposure images off the coast of Duck, North Carolina. Figure 1a shows an oblique snapshot from January 10, 1994. The vegetated dunes, dry beach, and shoreline are evident, as is the pattern of breaking waves in the nearshore. By contrast, Figure 1b shows an oblique ten-minute time exposure. The time-averaged breaking waves now show up as smooth bands, clearly delineating the shoreline (from the shorebreak) and the

Figure 1. Images from Duck, NC. a). Snapshot from January 10, 1994. b). 10-minute time exposure from January 10, 1994. Transverse features are evident in the trough as well as offshore of the shore-parallel bar. Box shows area rectified in Figure 2.

offshore bar (Lippmann and Holman 1989). Intermediate-scale white bands, oblique to the shoreline, are also obvious in the trough, as well as offshore of the shore-parallel bar. Research has been carried out on these features to first determine whether or not the oblique bands in the video images are real bathymetric features or simply an artifact of the imaging technique. Statistics of the features, such as their frequency of occurrence and longshore and cross-shore lengths were then calculated.

Methodology

The data were taken at the Field Research Facility (FRF) at Duck. Duck is a dune-backed beach located on one of the barrier islands of the Outer Banks. It is a low-energy, intermediate to reflective beach that is barred. An inner bar is located at ~125 m offshore and an outer bar is also present at times. The spring tide range is 1.6 meters and the mean water level is 0.35 m above NGVD. The average annual breaker height is 88 cm (Birkemeier 1981). The study area for our research was a 1700 meter stretch along the beach.

The data were collected automatically as part of the Argus program. An Argus station is a video camera operated by a personal computer. Every hour, both a snapshot and a ten-minute time expose are taken of the nearshore region. These images are sent back to the Coastal Imaging Lab at Oregon State University every night. A data set of images sampled with Argus is available for Duck spanning 10 years (1986-1996).

A great deal of information can be extracted from time exposures such as the one shown in Figure 1b. Since the geometries of the video camera are known, the exact location on the ground for each pixel in the image is also known. The coordinate system that is used for the images is the FRF coordinate system. The video camera is located at $x=32.54$, $y=585.78$, with x and y increasing positively offshore and away from the camera, respectively.

One method of determining length scales and positions of the features is to use geometrically rectified images (plan views) of the study area. Knowledge of the camera geometries allows a rectification of a region on an oblique image to be made. (Figure 2). Measurements such as longshore length spacing, cross-shore position and cross-shore length can be manually made from such rectifications. Transects can also be taken along the rectification, or along the oblique images, to measure intensity. Intensity data were compared with bathymetric data that were collected using the FRF's Coastal Research Amphibious Buggy (CRAB) to determine if the features have a bathymetric nature.

Figure 2. Rectification of boxed area in Figure 1b. Measurements can be made manually from the rectification.

In order to determine the frequency of occurrence of the bars, 8 years of Argus images (1987-1994) were viewed. One image from each day was studied for a total of 2600 images. There were some days when no data was available due to equipment failure, bad weather, or other reasons that an image could not be obtained. In order to quantify the presence/absence of transverse bars, each image was given a rating on a scale of 0-5, with 0 being no evidence of transverse bars and 5 being a clear indication of multiple transverse bars. A rating was given both for the *trough bars* (transverse bars found in the trough) as well as *offshore bars* (transverse bars found offshore of the shore-parallel bar). Figure 3 shows examples of images that were given ratings of 1, 3, and 5.

All the images were separated into two categories. An image that was given a rating of 3, 4, or 5 was considered a day in which bars were present. Images that received a rating of 0, 1, or 2 were considered as days in which bars were not present.

Results

The first objective of this study was to determine the persistence of the intensity streak features to insure that they are not random processing features. Longshore intensity transects were taken along a line at $x=145$ m, from $y=790$ to 1060 m, for a series of 4 hours (5 images) for January 10, 1994 (Figure 4a). From Figure 4b, it is evident that there was a peak in intensity where there was a white band in the time exposure. This figure also shows that intensity peaks were persistent over substantial periods, including tidal variations, suggesting that these features are not a random artifact of the image processing. Figure 5 shows intensity transects that were taken across a set of offshore transverse bands for 3 consecutive days in November of 1993. Transects were taken at $x=300$ m, from $y=1200$ m to 1700 m. The intensity maxima and corresponding white bands in the video images persisted for a period of days, supporting the fact that these features are real, not artifacts.

On July 18, 1995, a detailed CRAB survey was carried out to determine if the white bands in the images are real bathymetric features. Figure 6a shows a transect along which intensity data were taken and also shows the transect along which bathymetric data were collected. Intensity and depth along the transects in Figure 6a are shown in Figure 6b. It is evident that intensity maxima correspond to bathymetric highs and intensity minima correspond to bathymetric lows, proving that the oblique bands in the video images are ridges. The bathymetric data showed the relief of these bars to range from 0.3-0.5 m.

Length scales and positions for both the trough and offshore bars were calculated from intensity plots and rectified images. The mean longshore length spacing (distance between two consecutive bars), distance offshore (offshore extent of bars as measured from the shoreline), and cross-shore length of the bars, were determined. Longshore length spacing was determined using 18 images for trough transverse bars and 33 images for offshore transverse bars. Five images (up to 3 bars per image) were used to determine the distance offshore and cross-shore length for trough bars, and 7 images (up to 3 bars per image) were used to calculate those statistics for the offshore bars. These data are summarized in Tables 1 and 2 for trough and offshore bars, respectively.

Figure 3. Examples of ratings on a scale of 0-5 that were given to images. a). Time exposure from November 13, 1993. Trough bars were given a rating of 1. b). Time exposure from November 11, 1994. Trough bars were given a rating of 3. c). Time exposure from February 9, 1993. Both trough and offshore bars were given a rating of 5.

Figure 4. a). Time exposure from January 10, 1994 showing transverse bars in the trough. Transects along which intensity data were collected for 5 consecutive images are also shown. b). Intensity vs. longshore length from 1600-2000 hours along transect shown in a). This graph shows that the bars remain fixed over a period of 4 hours.

Figure 5. a). Time exposure from November 27, 1993 showing transverse bars offshore of the inner bar. Transects along which intensity data were collected are also shown. b). Intensity vs. longshore position for November 25, 26, and 27, 1993 along transects shown in a). This graph shows that most of the bars remain fixed over a period of days.

Figure 6. a). Time exposure from July 18, 1995 showing transverse bars in the trough. Transects along which intensity and bathymetric data were collected are shown. b). Comparison between intensity vs. longshore position and depth vs. longshore position for transects in a). This figure clearly shows that there is a correlation between the high pixel intensity in the video images and topographic highs.

	<i>longshore length spacing (m)</i>	<i>distance offshore (m)</i>	<i>cross-shore length (m)</i>
mean	45.0	20.0	23.8
std dev.	21.4	9.2	15.5
range	12-87	5-35	5-50

Table 1. Length scales and locations for **offshore bars**.

	<i>longshore length spacing (m)</i>	<i>distance offshore (m)</i>	<i>cross-shore length (m)</i>
mean	130.7	249.1	180.0
std dev.	62.9	37.4	117.9
range	45-325	175-300	75-400

Offshore transverse bars are larger scale features than trough transverse bars. Their longshore length spacing is almost 3 times as large and their cross-shore length is up to an order of magnitude longer than the trough bars.

From the extensive Argus database, presence/absence data for the transverse bars were determined. We calculated the number of days transverse bars were observed annually and the average number of days transverse bars were observed per month. One problem that was encountered when calculating the statistics was the fact that there were many days for which no image was available. Taking this into consideration, the frequency of occurrence of transverse bars was determined as follows:

$$\text{For annual statistics: } N_{\text{annual}} = \frac{N_{\text{obs}}(\text{yr})}{N_{\text{images}}(\text{yr})} * 365$$

$$\text{For monthly statistics: } \bar{N}_{\text{month}} = \frac{N_{\text{obs}}(\text{month})}{N_{\text{images}}(\text{month})} * N_{\text{days}}(\text{month})$$

where N_{obs} is the number of images in a year or month in which transverse bars were present, N_{images} is the number of images available for that month or year, N_{annual} is the number of days transverse bars were observed annually, and \bar{N}_{month}

is the average number of days transverse bars were observed per month. If less than 20 images were available for a given month, that month was excluded from the monthly statistics because a representative average could not be determined.

The average number of days trough and offshore transverse bars appeared in the video images each month for the 8 years varies greatly (Figure 7). Trough bars were observed from 3 to 7 days/month and offshore bars were observed less frequently (~1 to 5 days/month). Trough bars were most frequently observed in the summer while offshore bars seem to follow a seasonal cycle, appearing in the video images more frequently in the winter than in the summer.

Each year, trough bars were observed more frequently than offshore bars (an average of 62 and 41 days/year, respectively), and there was an interannual variability in the statistics as well (Figure 8). There is a positive correlation between trough and offshore bars for most years and there seems to be an increasing trend for both sets of bars.

Figure 7. Average number of days transverse bars are observed per month.

Discussion

Transverse bars seem to be a common feature in the nearshore at Duck. They persist in the video images for periods up to days. There were, however, many instances when they were seen for consecutive days, "disappeared" from the images for a few days and then returned to what seems to be the exact location in which they

Figure 8. Number of days transverse bars are observed annually. Trough bars are observed more frequently than offshore bars.

were previously seen. This appearance/disappearance may be due to fluctuations in wave height. The bars are only seen in the images on days in which the waves are high enough to be breaking. Although they may “disappear” from the images when the wave height is lower and no breaking is taking place, they may still be present, but not observable. Wave height has not yet been taken into consideration in the calculation of bar statistics. Images in which no bars were seen were given a rating of 0 even when wave height was low. Wave height data from 1987-1995 will be studied to determine whether or not bars were always present during conditions of high wave height. This information will be used to better determine the statistics of the bars, as only days in which waves are breaking will be included in the statistics.

The mechanism for transverse bar formation is unclear. Their presence may be attributed to strong longshore currents and they may be formed in the same way that bedforms in a river are created. While longshore currents could perhaps be the mechanism for trough bar formation, it is not clear that they will be strong enough to locally form offshore bars.

Research will continue on the transverse bars at Duck. More complete statistics will be calculated for bar lengths and positions, and images from 1995 and 1996 will be viewed to augment the existing database. The movement, if any, of the bars will be determined, and an attempt will be made to understand the environmental conditions that are conducive to transverse bar formation. Finally, the Argus database for other beaches will be searched to determine if this process is unique to Duck.

Conclusions

Time exposures from Duck frequently show white bands perpendicular or oblique to the shoreline. These bands, which have been observed both in the trough and offshore of the shore parallel bar, persist for periods of hours up to days. Ground truthing has shown that they are transverse ridges with a relief of 0.3-0.5 m. Trough transverse bars (ridges in the trough) are a smaller scale feature than offshore transverse bars (ridges offshore of the shore-parallel bar). Their mean longshore length spacing is 3 times smaller than that of the offshore bars (44 m and 131 m, respectively). Trough bars obliquely extend up to 35 m from the shoreline while their actual cross-shore lengths may be up to 50 m. Offshore bars obliquely extend up to 300 meters from the shoreline with actual lengths up to 400 m. It appears that the cross-shore length of trough bars is constrained by the shore-parallel bar.

Trough transverse bars appear in the video images an average of 62 days/year and offshore transverse bars appear in the images an average of 41 days/year. There is an interannual variability in the statistics and a seasonal cycle. Offshore bars appear more frequently in the winter and trough bars appear most often from June-August and in December and January.

ACKNOWLEDGMENTS

We would like to thank Mike Leffler and Bill Birkemeir of the FRF for carrying out the CRAB survey. Thanks also to John Stanley for help with the wave data, and Eric Gilbert, Hilary Stockdon, Nathaniel Plant, and Peter Ruggiero for their continual help. Funding for this research is made available from The Office of Naval Research, Coastal Dynamics Program (grant number N00014-95-10753).

CHAPTER 278

On the systematic offshore decay of breaker bars

Kathelijne M. Wijnberg ^{1,2}

ABSTRACT

Multiple breaker bar systems along the Holland coast exhibit long term cyclic behaviour. Over periods of many years, all bars migrate in a net seaward direction; the outer bar decays offshore, and a new bar is generated near the shoreline. This behaviour is essentially a cross-shore redistribution of sediment; the sediment of the offshore decaying outer bar is transported back onshore.

This paper presents a tentative evaluation of a part of the hypothesis formulated by Wijnberg (1995) to explain the cyclic bar system behaviour. The systematic offshore decay of the outer bar is considered to be the key to explaining the cyclicity in this behaviour. The offshore decay is assumed to occur due to a change in the long term balance of bar maintaining conditions (breaking waves) and bar diminishing conditions (very asymmetric waves). This balance will change as a result of offshore migration of the outer bar to deeper water during single storm events.

The calculations presented in this paper support the hypothesis, but field observations of the hydrodynamic conditions during the process of bar decay are required for a more rigorous verification.

1. INTRODUCTION

Along the Dutch coast, multiple bar systems of nearshore breaker bars exist that exhibit systematic, cyclic behaviour on a time scale of many years (Edelman, 1974; Bakker and De Vroeg, 1988; Ruessink and Kroon, 1994; Wijnberg and Terwindt, 1995). This behaviour consists of a net seaward migration of all bars, with the outer bar decaying offshore and a new bar being generated near the shoreline (Fig. 1). This

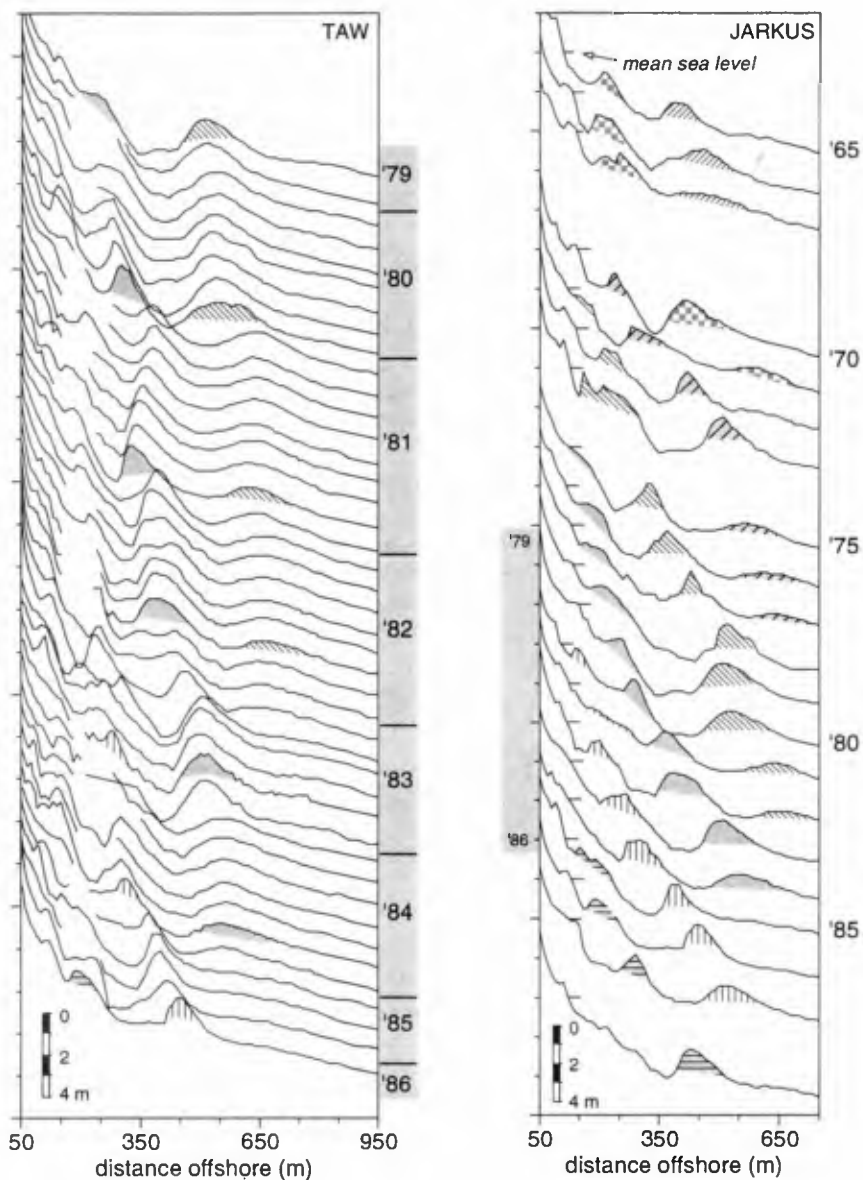

Fig. 1: Illustration of the offshore progression cycle for one profile line (line 8425). Left-hand figure based on TAW data base (several surveys per year, 1979-1986); right-hand figure based on JARKUS data base (one survey per year, 1965-1989). Bars are shaded to emphasise the offshore progression cycle; each bar has its own shading pattern through time.

behaviour implies that every so many years the same general cross-shore bar system configuration re-appears (i.e. when one offshore progression cycle has been completed). The time scale for the offshore progression cycle varies between bar systems, but seems to be quite constant for a given bar system (Wijnberg and Terwindt, 1995; Ruessink and Kroon, 1994).

Sediment budget considerations (Wijnberg, 1995; Wijnberg, in prep.) revealed that this cyclic morphologic behaviour is essentially a redistribution of sediment within the nearshore zone. So, although bar shapes are progressing in a net offshore direction, they are not representing a net offshore directed sediment transport. This implies that the sediment of the offshore decaying bar is transported back onshore.

The observed long term cyclic behaviour of multiple breaker bar systems is very intriguing in its own right, but may also have implications for the application and design of shoreface nourishments. For example, what is the best location and timing of a shoreface nourishment on a barred coastal profile? (eg. Hoekstra et al., 1994). Therefore, the identification of the mechanism that drives this systematic behaviour deserves further attention.

Wijnberg (1995) formulated a hypothesis to explain the cyclic bar system behaviour. In this hypothesis, which is briefly summarized in section 3, morphologic feedback in the coastal system is identified as the cause for the cyclicity in the bar behaviour rather than a cyclicity in the external forcing. The key to explaining the cyclic nature of the bar system behaviour is sought in the systematic offshore decay of the outer bar. In this paper, the part of the hypothesis dealing with the systematic offshore decay of the outer bar will be tentatively evaluated by studying the relation between the development stage of the outer bar and a wave climate integrated 'decay parameter'.

2. THE STUDY AREA

The hypothesis on the systematic decay of the outer bar will be evaluated for two multiple bar systems that exhibit similar cyclic behaviour but on a different time scale. The two multiple bar systems are located along the Holland coast (Fig. 2). These two bar systems have very different cycle times, viz. the bar system north of the IJmuiden breakwaters exhibits an approximately 15 year cycle, whereas the bar system south of the breakwaters has a typical cycle time of about 4 years. The alongshore change in the cycle times is rather abrupt, and coincides with the breakwaters (Wijnberg and Terwindt, 1995).

The northern bar system consist of 2 to 3 bars, depending on the phase in the offshore progression cycle (i.e. either 2 well developed bars or, in the case of 3 bars, a gentle outer bar and a small new inner bar, with a well developed middle bar in between). The whole bar system extents about 30 km alongshore.

In the southern bar system the number of bars changes alongshore: in the very south the number varies between 1 and 2, going north this changes into 2 to 3 bars, then 3 to 4 bars, and finally in the very north back to 2 to 3 bars. This bar system has a total length of about 40 km. The alongshore change in the number of bars has no obvious effect on the time span of the offshore progression cycle (Wijnberg and Terwindt, 1995).

Along the Holland coast, the mean wave height (H_{m0}) is about 1.2 m and the mean wave period (T_{m01}) is about 5 s; the mean tidal range is about 1.6 m. The grain size of the sediment in the breaker bar zone is generally in the fine sand range. There seems to be no significant difference in grain size between the two bar systems (Wijnberg, 1995)

Except for the large breakwaters that separate the two studied bar systems, the considered coastal stretch is almost free from engineering structures. In the northern bar system groins are present along about 5 km of beach at the northern end of the region (so still 25 km of beach has no groins). In the southern bar system a small discharging sluice is present (Fig. 2) which discharges some fresh water into the North Sea.

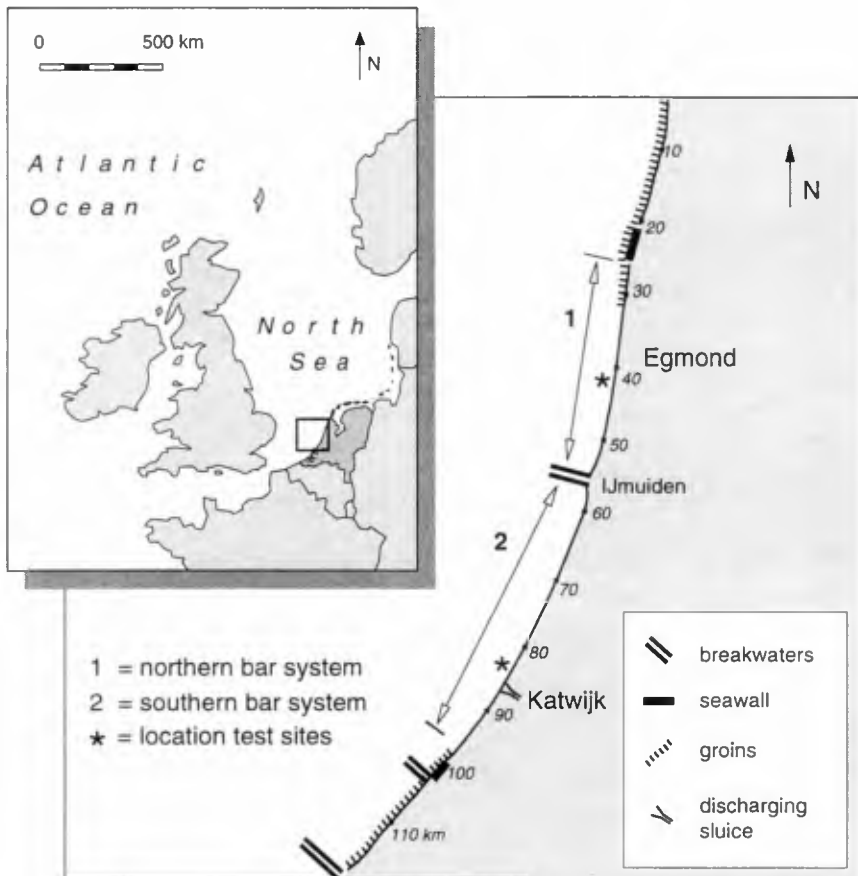

Fig. 2: Location of the study area

3. A CONCEPTUAL MORPHODYNAMIC MODEL

The multi-year cyclic behaviour of breaker bar systems can not readily be explained by existing theories on bar behaviour. These theories focus on the formation and maintenance of bar topography and pay little attention to the degeneration of bars. Our lack of understanding of the decay of bar features is illustrated by one of the findings of Roelvink et al. (1995) who mimicked long term cyclic bar behaviour with a cross-shore profile model. Roelvink et al. had to prescribe a reduced angle of repose for the sediment in the outer nearshore zone to force the outer bar to decay offshore.

According to Wijnberg (1995; in prep.), the cyclicality in the long term bar behaviour is most likely explained by morphologic feedback in the breaker bar system rather than by cyclicality in the external forcing. To explain the observed cyclic bar system behaviour, a central role was attributed to the behaviour of the outer bar. As long as the outer bar remains well developed at a certain position, the inner bar(s) do not move net offshore and will only move to and fro within a limited cross-shore range. Only as the outer bar disappears can the inner bar migrate net offshore (cf. Lippmann et al., 1993). This key role of the outer bar is plausible because the outer bar will obviously affect the hydrodynamic conditions in a down-wave direction, and therefore systematically affects the wave and current climate in the inner nearshore zone. Therefore, attention is further focused on mechanisms that may explain the systematic decay of the outer bar.

It was hypothesized by Wijnberg (1995; in prep.) that the systematic decay of the outer bar occurs due to a changing balance in the occurrence of conditions that favour decay of the outer bar topography (%DCA) and the occurrence of conditions that favour maintenance of the bar topography (%MAIN). The bar-maintaining conditions were identified as those with breaking waves across the bar, favouring the occurrence of break-point or long-wave mechanisms for the formation and maintenance of bar features. The bar-diminishing conditions were identified as those with very asymmetric waves across the bar (so the highest waves in the wave field will just start to break), allowing for an onshore directed sediment transport. A more complete justification for the choice of these two process 'regimes' can be found in Wijnberg (1995) or Wijnberg (in prep.)

The change in balance between the two types of conditions is induced by the offshore migration of the outer bar on a seaward sloping bed. The latter happens when the bar is migrating into deeper water during individual storm events, i.e. when waves are breaking on the outer bar. The deeper the bar gets, the less likely that bar-maintaining conditions occur. Consequently, the relative dominance of bar-diminishing conditions will increase. The rate of increase will depend on the characteristics of the wave climate.

4. METHODS

To evaluate the proposed mechanism for the systematic offshore decay of the nearshore bars, the balance of %DCAY and %MAIN will be calculated for various development stages of the outer bar (Fig. 3). The balance is expressed in terms of the decay parameter I_{decay} :

$$I_{\text{decay}} = \frac{\%DCAY}{\%DCAY + \%MAIN} = \frac{\%DCAY}{\%ACT} \quad (1)$$

%DCAY = mean annual percentage of occurrence of bar-diminishing conditions on the outer bar

%MAIN = mean annual percentage of occurrence of bar-maintaining conditions on the outer bar.

%ACT = mean annual percentage of occurrence of morphologically active conditions on the outer bar.

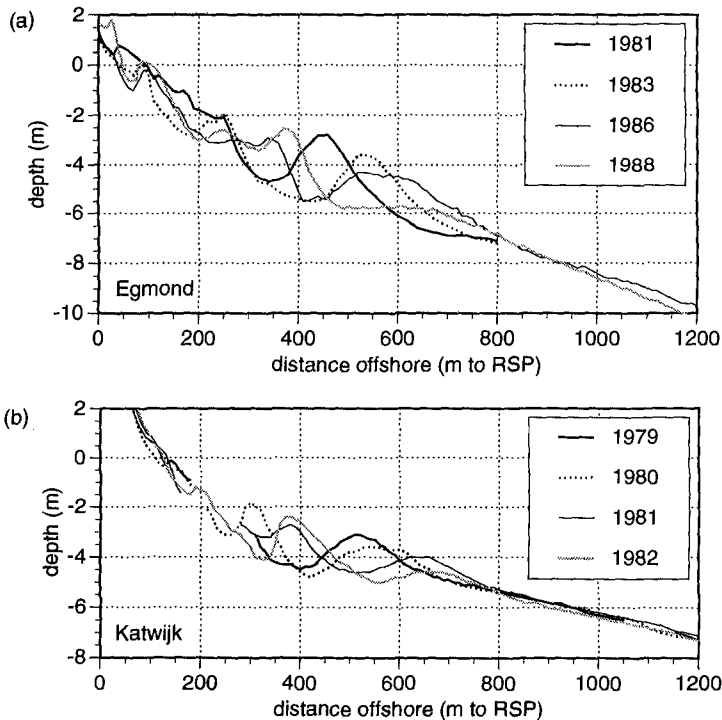

Fig. 3: Nearshore profiles used in the model computations at (a) the Egmond site, and (b) the Katwijk site. (All profiles extend down to about 20 m water depth.)

'Morphologically active conditions' (%ACT) are those conditions during which the outer bar is changing its morphology. This does not necessarily imply that during morphologically *inactive* conditions the sediment is completely immobile; it is just so that any sediment transport under those conditions does not result in noticeable morphological change. The outer bar has been observed to be morphologically inactive during the calm summer months (Wijnberg, 1995).

Bar-maintaining conditions are defined (Wijnberg, 1995; Wijnberg, in prep.a) as those conditions that produce more than 5% of breaking waves on the bar. Bar-diminishing conditions are defined as those which produce only 0.1% to 5% of breaking waves on the bar. %DCAY and %MAIN are estimated from the mean annual offshore wave climate.

The data on the offshore hydrodynamic climate along the Holland coast are of the following type: a mean annual percentage of occurrence, $P(H_{m0}, \alpha)$, and a mean water level elevation, $h(H_{m0}, \alpha)$, are available, with wave height bands of 0.5 m and wave direction bands of 15 degrees. The mean water level represents the average set-up or set-down that occurs during given wave conditions. H_{m0} and α are the central values of the wave height class respectively wave directional class that they represent.

To estimate %DCAY and %MAIN one needs to know the percentage of breaking waves occurring on the outer bar for each of the wave climate 'cells' (H_{m0}, α). Adding all $P(H_{m0}, \alpha)$ for all (H_{m0}, α) cells that produce more than 5% of breaking waves gives %MAIN; adding all $P(H_{m0}, \alpha)$ for all (H_{m0}, α) cells that produce between 0.1% and 5% of breaking waves gives %DCAY. The WAVIS model (Van Rijn and Wijnberg, 1996) was used to calculate the percentages of breaking waves for each (H_{m0}, α) cell.

Since WAVIS is a probabilistic type of wave model, a representative wave field (H_i, T_i, p_i, α_i) was generated for each (H_{m0}, α)-cell, where: H_i is the central value of the i^{th} (0.25 m wide) wave height class; T_i is an empirically determined wave period that goes on average with H_i ($T_i = 6 * H_i^{0.333}$ (Wijnberg, 1995)); p_i is the probability of occurrence of the i^{th} wave height class assuming the wave heights are Rayleigh distributed; α_i was chosen constant for all wave height classes, viz. equalling α .

The values of %DCAY and %MAIN are calculated for the outer bars at two locations, viz. near Katwijk and near Egmond. The Katwijk site is located in the southern bar system, and the Egmond site in the northern bar system (Fig. 2).

5. RESULTS

5.1 The decay parameter and the development stage of the outer bar

The values of %ACT, %DCAY, %MAIN, and I_{decay} in relation to the depth of the outer bar crest are shown in Fig. 4, for both the Katwijk site and the Egmond site. The depth of the outer bar crest represents the development stage of the outer bar (Fig. 3). The depth of the bar crest is given relative to the Dutch ordnance datum NAP which approximates mean sea level.

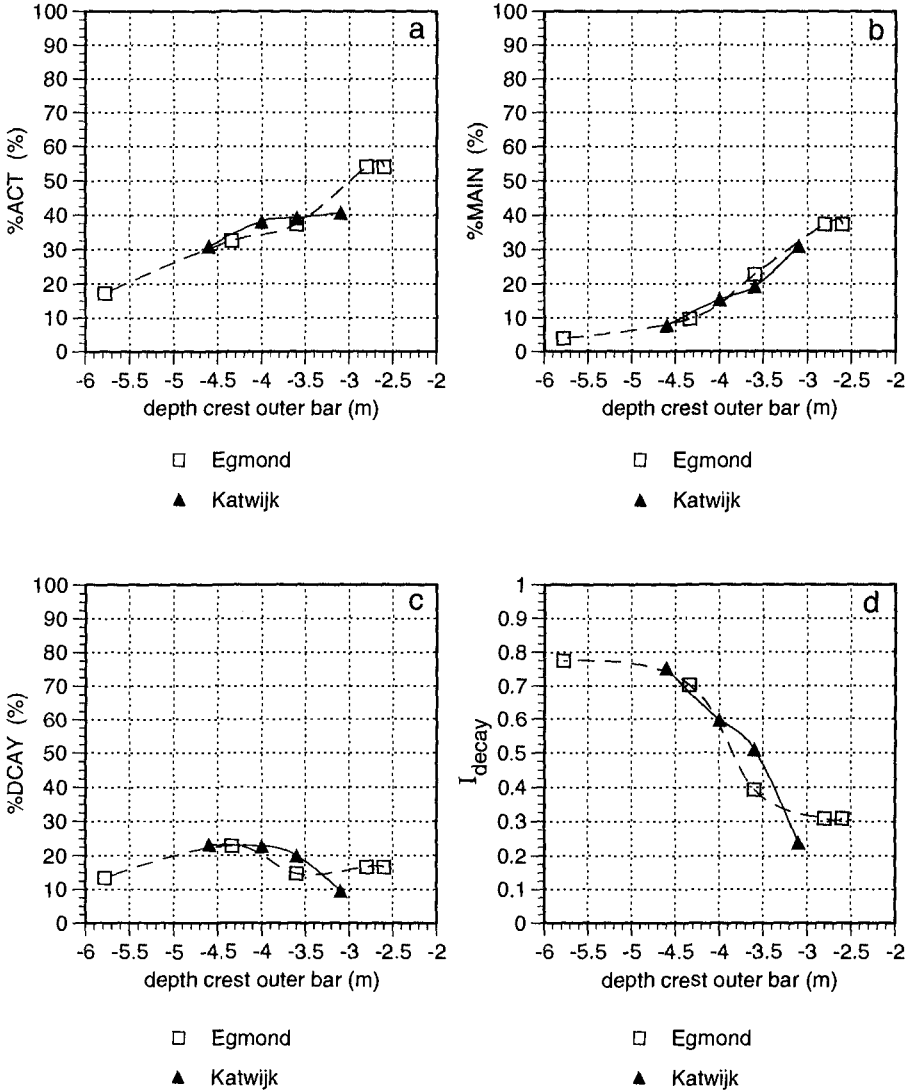

Fig. 4: Nearshore wave climate parameters as a function of the development stage of the outer bar. (a) %ACT, (b) %MAIN, (c) %DCAY, and (d) I_{decay} .

As expected, the percentage of time that morphologically active conditions occur on the outer bar decreases with the increase of depth of the bar crest (Fig. 4a). The percentage of time that bar-maintaining conditions occur on the outer bar decreases steadily with the increase of depth of the bar crest as well (Fig. 4b). The percentage of time that conditions occur that favour decay of the outer bar appears to vary between about 15% and 25% (Fig. 4c). %DCAY seems to reach a maximum around 4 to 4.5 m water depth. The balance between bar-diminishing conditions and bar-maintaining conditions, expressed by I_{decay} , changes with the depth of the crest of the outer bar. The deeper the bar crest, the larger the relative importance of conditions that favour bar decay (Fig. 4d).

The explanation for the fact that %DCAY does not steadily decrease with depth like %ACT and %MAIN, is the following. As the outer bar gets to deeper water, wave conditions that previously (i.e. when the bar was located shallower) produced just over 0.1% of breaking waves, will now produce less than 0.1% of breaking waves. Those wave climate classes will no longer add to the value of %DCAY. However, some of the wave climate classes that previously produced more than 5% of breaking waves on the outer bar will now produce between 0.1% and 5% of breaking waves, and consequently will add to the value of %DCAY.

5.2 Sensitivity of the decay parameter to the definition of %DCAY and %MAIN

The decay parameter I_{decay} reflects the relative importance of %DCAY vs. %MAIN and therefore depends on the definition of the two process regimes in terms of the fraction of breaking waves on the outer bar (Q_b). In this section, the extent to which the results shown in Fig. 4 are sensitive to the choice of the boundaries will be evaluated.

The sensitivity of the values of %DCAY and %MAIN, and consequently %ACT and I_{decay} , to the definition of the process regimes is analysed by plotting the cumulative percentage of occurrence of wave conditions with increasingly higher fractions of breaking (Q_b) waves on the outer bar (Fig. 5). These plots will reveal whether the values of %DCAY and %MAIN are sensitive to the choice of the boundaries between the process regimes in a reasonably close range around the previously defined values of $Q_b=0.001$ and $Q_b=0.05$. For the boundary between %DCAY and %MAIN a value of Q_b between 0.04 and 0.06 is considered, and for the lower boundary of %DCAY a value of Q_b between 0.001 and 0.01

The cumulation in the plots in Fig. 5 starts at a fraction of breaking waves of 0.001. Therefore, the cumulative percentage in Fig. 4 only refers to wave conditions that produce at least 0.1% of breaking waves on the outer bar. For example, on the bar crest at 3.1 m -NAP (Fig. 5a) about 22.5% of the mean annual wave conditions will produce between 0.1% and 8.3% of breaking waves on the outer bar (near Katwijk).

It appears that for the bar crest at 3.1 m -NAP, the variables %DCAY and %MAIN will be quite sensitive to the location of the boundary at $Q_b=0.05$. For the bar crest at 3.1 m -NAP about 11 % of the wave climate is enclosed in the discretely defined wave climate cells that produce a fraction of breaking waves of 0.055 on the outer bar (Fig. 5a). The value of %ACT will be hardly affected at this position of the bar crest.

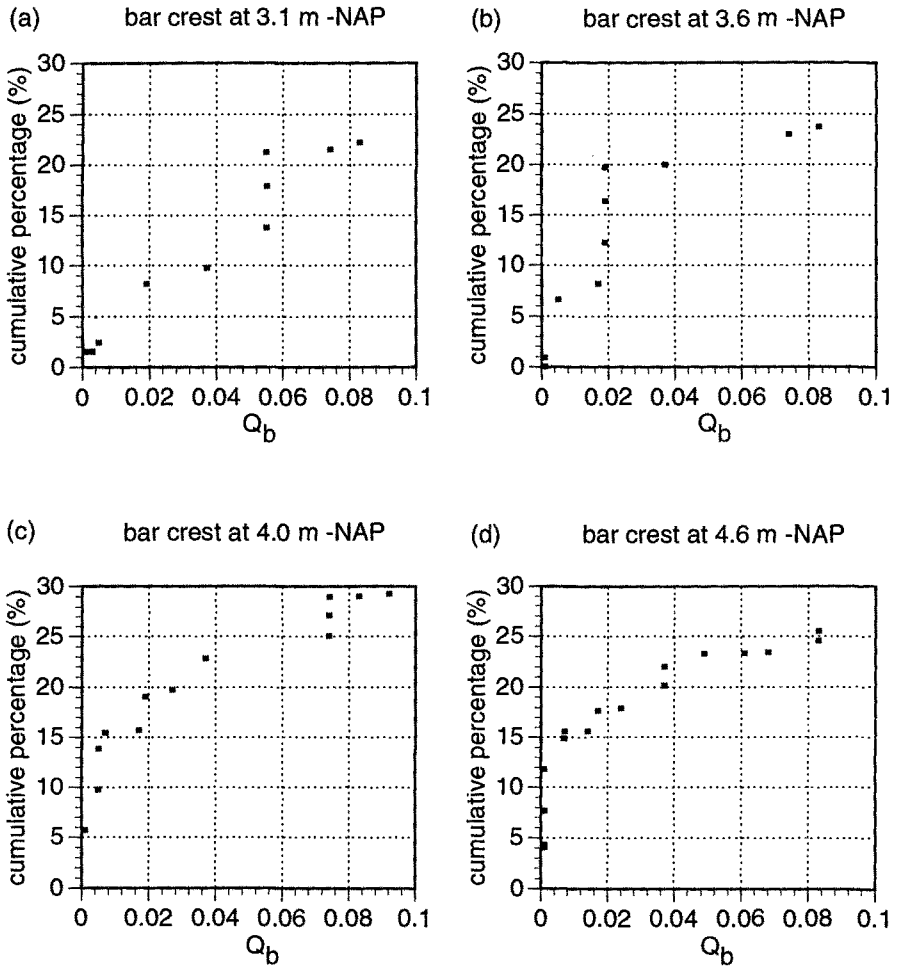

Fig. 5: Cumulative percentage of occurrence of wave conditions with increasingly higher fraction of breaking waves on the outer bar, for $Q_b \geq 0.001$ (Katwijk site). (a) Bar crest at 3.1 m -NAP, (b) bar crest at 3.6 m -NAP, (c) bar crest at 4.0 m -NAP, (d) bar crest at 4.6 m -NAP

A comparable sensitivity to the $Q_b=0.05$ boundary exists at the Egmond site for the bar crests at 2.6 m depth and 2.8 m depth (not shown).

The values of %DCAY and %MAIN on the bar crest located at 3.6 m -NAP will be insensitive to a shift between $Q_b=0.04$ and $Q_b=0.06$ (Fig. 5b). However, %DCAY will be somewhat affected by a raise of the lower boundary to $Q_b=0.01$.

For the positions of the bar crest at 4 m -NAP and 4.6 m -NAP, about 15% of the wave climate appears to be enclosed in wave climate cells that produce a fraction of breaking waves between 0.001 and 0.01 (Fig. 5c,d). Consequently, for these deeper bars the choice of the boundary between morphologically inactive conditions and morphologically active conditions is quite important for the values of %ACT and %DCAY.

The sensitivity of %DCAY and %MAIN - and consequently of %ACT and I_{decay} - to the choice of the boundaries is related to the stepwise increase of cumulative "curves" shown in Fig. 4. This shape is probably related to the discrete description of the wave climate and the discrete description of the input wave fields in the WAVIS model. Only a limited set of combinations of wave heights and wave directions is used for the wave climate description. Each single wave height represents an interval of wave heights and each single wave direction represents a sector of wave directions. In addition, the discrete description of the wave field input in the WAVIS model allows the value of Q_b to change in discrete steps only.

The effect of the discrete description of the wave climate and wave field on Fig.4 can be smoothed by averaging over a set of calculations where the lower boundary of %DCAY was varied between $Q_b=0.01$ and $Q_b=0.001$, and the boundary between %DCAY and %MAIN was varied between $Q_b=0.04$ and $Q_b=0.06$. The result of the averaging is shown in Fig. 6. This figure appears to be very similar to Fig. 4. The smoothed figures, however, reveal more clearly the similarities and differences between the Egmond site and the Katwijk site.

5.3 Differences between the Katwijk and Egmond site

To discuss differences between the Katwijk and Egmond site the smoothed results are analysed (Fig. 6), because these are less affected by the discrete representation of the wave information (see section 5.2).

A difference between the Egmond site and the Katwijk site in the occurrence of morphologically active conditions (Fig. 6a) only occurs for the shallower positions of the outer bar (bar crests shallower than 3.5 m -NAP). At both sites, those shallower outer bars are still in the non-decaying stage of their development. In that non-decaying stage, the percentage of time that morphologically active conditions occur on the outer bar seems to be slightly larger at the Egmond site than at the Katwijk site.

The bar-maintaining conditions occur about equally often at both sites for the deeper positions of the outer bar (Fig. 6b). However, for bar crest positions shallower than 4 m -NAP the bar-maintaining conditions occur somewhat more often near Egmond than near Katwijk.

Regarding the bar-diminishing conditions (Fig. 6c), an obvious difference only occurs for the bar crest position at 3.6 m -NAP, where the bar-diminishing conditions occur more frequently near Katwijk than near Egmond.

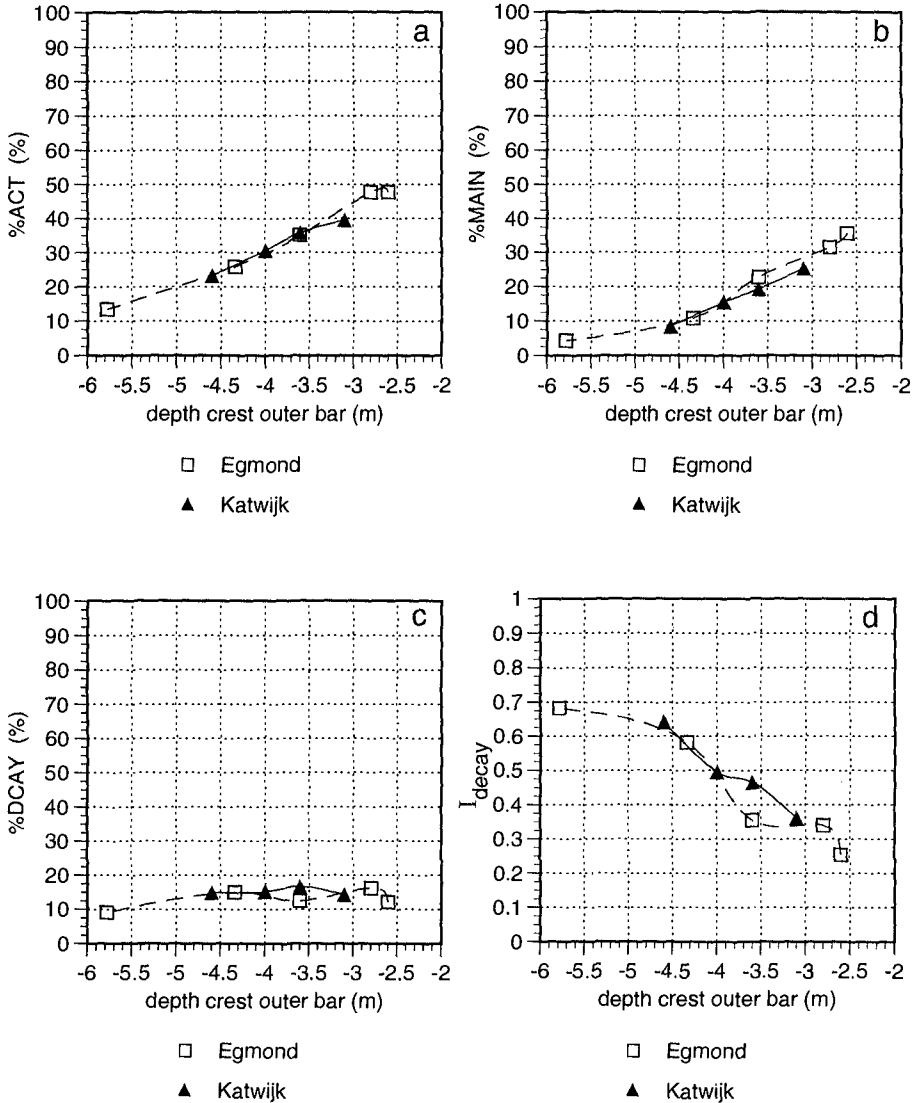

Fig. 6: Smoothed values of the nearshore wave climate parameters as a function of the development stage of the outer bar.
 (a) %ACT, (b) %MAIN, (c) %DCAY, and (d) I_{decay}

The slight differences between the %MAIN and %DCAY 'curves' for Egmond and Katwijk result in I_{decay} 'curves' for Egmond and Katwijk that clearly deviate for the bar crest position at 3.6 m -NAP. This discrepancy was consistently present irrespective of the exact definitions of the boundaries between the process regimes in terms of Q_b (Wijnberg, 1995). The relatively frequent occurrence of bar-diminishing conditions near Katwijk around 3.6 m -NAP coincides with the onset of bar decay at this location. Near Egmond, an outer bar with its crest at 3.6 m -NAP is still in a non-decaying stage.

6. DISCUSSION AND CONCLUSIONS

The relationship found between the decay parameter and the development stage of the outer bar, as shown in Fig. 4d and 6d, supports the concept that the balance between bar-diminishing conditions (very asymmetric waves) and bar-maintaining conditions (breaking waves) is important for the fate of the outer bar. These results support the bar-decay hypothesis for two reasons. Firstly, the value of the decay parameter increases with the depth of the outer bar crest. This indicates an increase in the relative importance of the bar-diminishing conditions with depth, as was expected from the formulated hypothesis. Secondly, the difference between the Egmond and Katwijk site in the depth of onset of bar decay is well indicated by the decay parameter.

The results presented in Section 5 further indicate that the chosen definitions of the two process regimes in terms of the fraction of breaking waves (Q_b) enclose the relevant processes for respectively maintaining bar topography and diminishing bar topography. It is emphasized that no choice is made here for a particular mechanism that maintains the bar topography other than that this mechanism is directly or indirectly related to the occurrence of wave breaking. Long-wave mechanisms are therefore not excluded here (eg. bound long waves can be released in the surfzone by the breaking of the short waves).

The suggested mechanism for the systematic decay of the outer bar could not directly be verified with field observations. The currently existing bathymetric surveys in the studied area are too widely spaced in time to pinpoint the hydrodynamic conditions responsible for the observed (net) changes in the outer bar topography. The relatively wide spacing of the surveys is due to the fact that ships can only survey the nearshore bathymetry during relatively calm conditions, and consequently cannot survey during the conditions that are hypothesized to be important for the behaviour of the outer bar. Remote-sensing systems like the video-monitoring system introduced by Lippmann and Holman (1989) might be a valuable tool for obtaining the required high resolution morphologic information during the more severe wave conditions.

To conclude, the presented conceptual model for the systematic offshore decay of breaker bars seems viable. However, the results presented in this paper are considered to be supporting evidence for the hypothesis rather than a real proof of it. For a more rigorous verification of the conceptual model field observations are needed of the process of bar decay itself.

ACKNOWLEDGEMENTS

This paper is based on work in the PACE-project, in the framework of the EU-sponsored Marine Science and Technology Programme (MAST-III), under contract number MAS3-CT95-0002. The work was co-sponsored by the Andrew Mellon Foundation.

The *Rijkswaterstaat* (Dutch Ministry of Transport, Public Works and Water Management) is thanked for providing the wave climate data and the bathymetry data.

CHAPTER 279

LONGSHORE BED-LOAD TRANSPORT

Jesper S. Damgaard ¹ and Richard L. Soulsby ¹

Abstract.

An analytical formula for longshore bed-load sediment transport is derived. The derivation is based on sediment physics and the formula is therefore less dependent on calibration. The formula is compared to the CERC formula, a numerical model and field data.

1 Introduction.

Around the UK coastline shingle and gravel beaches are common and considerable resources are spent on preserving and/or predicting the behavior of these beaches. Therefore, it is important for coastal engineers to have an easily applicable tool with which to predict the littoral drift of sediments consisting of larger grain sizes.

The most widely used longshore sediment transport formula is probably the CERC -formula (Coastal Engineering Research Center, 1977) which is based on the concept that the longshore sediment transport rate is dependent on the longshore component of wave energy flux $E_b(C_g)_b \cos(\alpha_b) \sin(\alpha_b)$, where subscript 'b' denotes values at the breaking point, E is the wave energy, C_g is the group velocity and α is the angle of wave incidence. There exist numerous extensions and variations of the CERC formula. Despite its popularity there are three major shortcomings of this type of formulae: i) it relies heavily on calibration, ii) it does not contain a threshold term, iii) it contains no dependence on grain or beach properties. The necessity of a calibration limits the predictive quality of the formula. Furthermore the calibrations of CERC type formulae are often performed using field data sets with different levels of variance within those data sets and with considerable systematic errors (Greer and Madsen, 1978). The inclusion of a threshold term is especially important for the determination of transport rates for large grain size sediments, as will be shown in the present paper.

¹Marine Sediments Group, HR Wallingford Ltd., Wallingford, Oxon OX10 8BA, UK.

2 The present study

It is the purpose of the present study to derive an analytical cross-shore integrated bed-load transport formula. The derivation is based on a bed-load transport formula for combined waves and currents developed by Soulsby (1996), which relates the wave-averaged value $\langle \dots \rangle$ of the non-dimensional bed-load transport rate vector $\vec{\Phi}$

$$\vec{\Phi} = \frac{\vec{q}_b}{\sqrt{(s-1)gd^3}} \tag{1}$$

to the non-dimensional bottom shear-stress vector due to skin friction induced by waves plus currents (Shields parameter) $\vec{\theta}$

$$\vec{\theta} = \frac{\vec{\tau}'_b}{\rho g(s-1)d} \tag{2}$$

where q_b is the volumetric bed-load transport rate per unit width and time, s is the relative density of the sediment, g is the acceleration of gravity, d is the grain size and τ'_b is the skin friction at the bed. The bed-load transport formula is based on a separation of the shear stress vector into a mean and an oscillatory part:

$$\vec{\theta}(\omega t) = \vec{\theta}_m + \vec{\theta}_w \cos(\omega t) \tag{3}$$

where ω is the frequency of the incoming waves. The coordinate system (x, y) is chosen such that $\vec{\theta}_m$ is parallel to the x -axis (see figure 1).

The formula has been extended to cover asymmetric waves (Damgaard *et al*, 1996) but since the asymmetry will have no significant impact on long-shore sediment transport calculations all higher order harmonics are set to zero for the present application. The bed-load transport formula of Soulsby (1996) reads:

$$\langle \vec{\Phi} \rangle = \begin{pmatrix} \Phi_x \\ \Phi_y \end{pmatrix} \tag{4}$$

with the components given as

$$\Phi_x = \text{sign}\{\Phi_{x1}, \Phi_{x2}\} \max\{\Phi_{x1}, |\Phi_{x2}|, |\}\tag{5}$$

$$\Phi_{x1} = \begin{cases} 12\sqrt{\theta_m}(\theta_m - \theta_{cr}) & \text{for } \theta_m > \theta_{cr} \\ 0 & \text{for } \theta_m \leq \theta_{cr} \end{cases} \tag{6}$$

$$\Phi_{x2} = 12(0.95 + 0.19 \cos 2\varphi)\theta_m\sqrt{\theta_w} \tag{7}$$

$$\Phi_y = \frac{12(0.19\theta_m\theta_w^2 \sin 2\varphi)}{\theta_w^{3/2} + 1.5\theta_m^{3/2}} \tag{8}$$

Figure 1: Definitions.

subject to the threshold condition

$$\Phi_x = \Phi_y = 0 \text{ for } \theta_{max} \leq \theta_{cr} \quad (9)$$

where φ is the angle between $\vec{\theta}_m$ and $\vec{\theta}_w$ and θ_{max} is the maximum Shields parameter for waves + currents within a wave cycle. Current dominated conditions correspond to Φ_{x1} and wave-dominated conditions to Φ_{x2} . The threshold condition is necessary as no threshold term appears explicitly in the formula for Φ_{x2} . It is important to note the fact that the formula is based on dimensionless parameters which makes it applicable to model as well as prototype scale.

The procedure of derivation for the analytical formula is as follows: Approximate expressions for the mean bottom shear-stresses, required as input to the bed-load transport formula are derived directly from the depth-integrated momentum equation. This avoids the need to calculate the speed of the longshore current. In order to solve the momentum equation analytically a number of assumptions have been made.

- (i) The ratio of wave-height, H_b , and water depth, h_b , at the breaker point is constant, $H_b/h_b = \gamma_b = 0.8$.
- (ii) After breaking the 1 decays linearly, so that $H = \gamma_b h$.
- (iii) No further refraction takes place beyond the breaking point, i.e. the angle of wave incidence, α , is constant in the surf zone, $\alpha(y) = \alpha_b$.
- (iv) All waves break at the same location.

- (v) Shallow-water linear wave theory is used in the surf zone.
 (vi) The effect of a lateral bed slope on the sediment transport is neglected.
 (vii) The effect of cross-shore currents (e.g. undertow) on the longshore transport is neglected.

Furthermore the variation in mean water level (set-down and set-up) is ignored and the beach is assumed to be plane with a constant slope, $\tan\beta$. Ignoring the lateral transfer of turbulent momentum the depth-integrated momentum equation for a longshore uniform beach reduces to a balance between the cross-shore gradient of the shear component of the radiation stress and the bottom friction:

$$\frac{\partial S_{xy}}{\partial y} = -\tau_{b,x} \quad (10)$$

where S_{xy} is the shear component of the radiation stress and $\tau_{b,x}$ is the x -component of the bed shear stress. The (x, y) -coordinate system used here is chosen such that the x -axis is parallel to the coast, and y is directed on-shore with origin shoreward of the breaker line. The relation between φ and α_b is $\varphi = \frac{\pi}{2} - \alpha_b$. The radiation stress can be expressed in terms of the momentum flux, F_m , in the direction of wave propagation:

$$S_{xy} = F_m \cos(\alpha) \sin(\alpha) \quad (11)$$

in which α is the angle of wave incidence and F_m is determined according to linear wave theory as:

$$F_m = \frac{1}{8} \rho g H^2 \quad (12)$$

Combining equations (10), (11) and (12) yields an expression for τ_b

$$\tau_b = -\frac{1}{16} \rho g \frac{\partial}{\partial y} (\sin(2\alpha) H^2) \quad (13)$$

According to the assumptions employed regarding refraction and wave height decay, (13) reduces to:

$$\begin{aligned} \tau_b &= -\frac{1}{16} \rho g \sin(2\alpha_b) 2H \frac{\partial H}{\partial y} \\ &= \frac{\gamma_b}{8} \rho g H \sin(2\alpha_b) \tan\beta \end{aligned} \quad (14)$$

in which h is the depth and γ_b is the constant ratio between wave height and depth in the surf zone. Thus the shore parallel component of the mean Shields parameter can be expressed as:

$$\theta_{m,x} = \frac{\gamma_b H \sin(2\alpha_b) \tan\beta}{8(s-1)d} \quad (15)$$

The amplitude of the oscillatory component of the bottom friction is calculated using a quadratic friction law

$$\tau_w = \frac{1}{2} \rho f_w U_w^2 \quad (16)$$

where f_w is the wave friction coefficient. The wave orbital velocity is estimated using shallow water linear wave theory i.e. $kh \ll 1$, $c = \sqrt{gh}$:

$$\begin{aligned} U_w &= \frac{\pi H}{T} \frac{1}{\sinh(kh)} \\ &\simeq \frac{1}{2} \sqrt{\frac{g}{h}} H = \frac{1}{2} \sqrt{g\gamma_b H} \end{aligned} \quad (17)$$

where T is wave period and k is the wavenumber. Two different friction factors were used. For rough turbulent flows Soulsby (1994) obtained an expression for the wave friction factor $f_{w,r}$ based on the analysis of a large data set:

$$\begin{aligned} f_{w,r} &= 1.39 \left(\frac{A}{z_0} \right)^{-0.52} \\ &\simeq \sqrt{\frac{d}{U_w T}} \\ &\simeq (g\gamma_b H)^{-1/4} \sqrt{\frac{2d}{T}} \end{aligned} \quad (18)$$

in which A is the amplitude of the near bed orbital motion, and the roughness length $z_0 = d/12$. The above equation is valid for weak sediment motion or immobile beds. For sheet flow conditions ($\theta > \text{say } 1$) Wilson (1989) derived a friction coefficient, $f_{w,sf}$:

$$\begin{aligned} f_{w,sf} &= 0.114 \left(\frac{A}{g(s-1)T^2} \right)^{2/5} \\ &\simeq 0.0655 \left(\frac{\gamma_b H}{g} \right)^{1/5} (\pi(s-1)T)^{-2/5} \end{aligned} \quad (19)$$

The actual friction coefficient for a particular wave condition was taken as the maximum of $f_{w,r}$ or $f_{w,sf}$. In accord with experimental observations (Simons *et al.*, 1994), the friction factor for the waves is not enhanced by the presence of a near-normal incidence current.

The oscillatory component of the Shields parameter can be expressed using equations (2), (16), (17) and (18) and (19) respectively

$$\theta_{w,r} = \frac{\sqrt{2}}{8} g^{-1/4} \frac{(\gamma_b H)^{3/4}}{(s-1)\sqrt{dT}} \quad (20)$$

and

$$\theta_{w,sf} = 8.187 \cdot 10^{-3} g^{-1/5} (\pi(s-1)T)^{-2/5} \frac{(\gamma_b H)^{6/5}}{(s-1)d} \quad (21)$$

Now the current-dominated case of the dimensionless bed-load transport rate is calculated by inserting equation (15) into equation (6)

$$\Phi_{x1} = 0.530 \left(\frac{\gamma_b H \tan \beta}{(s-1)d} \right)^{3/2} (\sin(2\alpha_b) - \theta_{cr}^*) \sqrt{|\sin(2\alpha_b)|} \quad (22)$$

where

$$\theta_{cr}^* = \theta_{cr} \frac{8(s-1)d}{\gamma_b H \tan \beta} \tag{23}$$

and the wave-dominated case (subject to flow regime) is determined by inserting equation (15) and (20) or (21) into equation (7)

$$\Phi_{x2,r} = (0.602 + 0.120 \cos(2\varphi)) \frac{(\gamma_b H)^{11/8} \tan \beta \sin(2\alpha_b)}{g^{1/8} d^{5/4} T^{1/4} (s-1)^{3/2}} \tag{24}$$

or

$$\Phi_{x2,sf} = (0.129 + 0.0259 \cos(2\varphi)) \frac{(\gamma_b H)^{8/5} \tan \beta \sin(2\alpha_b)}{g^{1/10} d^{3/2} (\pi T)^{1/5} (s-1)^{17/10}} \tag{25}$$

In order to transform to a bulk transport formula, equations (22), (24) and (25) are integrated across the surf zone, using assumptions (i) and (ii) above:

$$\int_{\text{surf zone}} \Phi_x dy = \int_{H_b}^0 \Phi_x \frac{1}{dH/dy} dH = \frac{-1}{\gamma_b \tan \beta} \int_{H_b}^0 \Phi_x dH \tag{26}$$

The cross-shore integrated volumetric sediment transport rate $Q'_{b,l}$ [m^3/s] is given as

$$Q'_{b,l} = \sqrt{g(s-1)d^3} \int_{\text{surf zone}} \Phi dy \tag{27}$$

and the resulting analytical formula for $Q_{b,l}$ is expressed as a combination of a current dominated transport (Q_{x1}) and a wave dominated transport (Q_{x2}):

$$Q'_{b,l} = \text{sign}\{\alpha_b\} \max\{|Q_{x1}|, |Q_{x2}|\} \tag{28}$$

$$Q_{x1} = \begin{cases} 0.21 \frac{\sqrt{g\gamma_b \tan \beta} H_b^{5/2}}{(s-1)} \left(\sin(2\alpha_b) - \frac{5}{3} \theta_{cr}^* \right) \sqrt{|\sin(2\alpha_b)|} & \text{for } \sin(2\alpha_b) > \frac{5}{3} \theta_{cr}^* \\ 0 & \text{for } \sin(2\alpha_b) \leq \frac{5}{3} \theta_{cr}^* \end{cases} \tag{29}$$

$$Q_{x2} = \begin{cases} (0.25 + 0.051 \cos(2\varphi)) \frac{g^{3/8} d^{1/4} \gamma_b^{3/8} H_b^{19/8}}{T^{1/4} (s-1)} \sin(2\alpha_b) & \text{for } f_{w,r}/f_{w,sf} > 1 \\ (0.050 + 0.010 \cos(2\varphi)) \frac{g^{2/5} \gamma_b^{3/5} H_b^{13/5}}{(\pi T)^{1/5} (s-1)^{6/5}} \sin(2\alpha_b) & \text{for } f_{w,r}/f_{w,sf} \leq 1 \end{cases} \tag{30}$$

subject to the threshold condition

$$Q'_{b,l} = 0 \text{ for } \theta_{max} \leq \theta_{cr} \quad (31)$$

where

$$\theta_{max} = \sqrt{(\theta_m + \theta_w \cos \varphi)^2 + (\theta_w \sin \varphi)^2} \quad (32)$$

In general the current dominated term, Q_{x1} , is used for large wave heights, small grain sizes and large beach slopes. In most cases $f_{w,r} > f_{w,sf}$. This is especially true for larger grain sizes which are rarely transported as sheet flow. A study of a field data set with approximately 25000 wave conditions sampled throughout a 4 year period (see section 4) showed that Q_{x1} was applied for approximately 60 % of the wave conditions, Q_{x2} with $f_{w,r}$ for the remaining 40 % of the conditions and Q_{x2} with $f_{w,sf}$ was not applied at all for that particular data set.

3 Comparison with the CERC formula.

The CERC-formula is probably the most widely used longshore sediment transport formula. In the course of the time since the CERC-formula was derived, several 'mutations' have emerged; only some of them will be mentioned here. Van Hijum and Pilarczyk (1982) analysed laboratory experiments on shingle transport and, using dimensional analysis, came up with an expression for littoral shingle drift. Their expression did contain a threshold term. Bailard (1987) derived an energetics based sediment transport formula which had the ratio of amplitude of orbital velocity to fall velocity of the sediment as an additional parameter. Kamphuis (1991) derived a longshore sediment transport formula based on dimensional analysis. The formula was calibrated using laboratory results obtained by Kamphuis and co-workers at Queens University. The drawback of these formulations is that they are not founded on sediment transport physics but on a relation between overall dissipation of wave energy and transport of sediments in a heuristic way.

Since the present formula (equations (28) to (32)) claims to be an improvement compared to the CERC- formula it is relevant to compare them. Using linear shallow-water wave theory and a constant breaking criterion the CERC-formula can be written as

$$Q_{CERC} = \frac{K_{CERC}}{16} \sqrt{\frac{g}{\gamma_b}} \frac{H_b^{\frac{5}{2}} \sin(2\alpha_b)}{(s-1)} \quad (33)$$

in which Q_{CERC} is the longshore sediment transport rate in solid volume per second. The constant K_{CERC} is equal to 0.77 for regular waves and for irregular waves with $H = H_{rms}$. Figure 2 shows a comparison between the analytical model (equations (28) to (32)) and the CERC formula (equation (33)). Figures 2(a) to

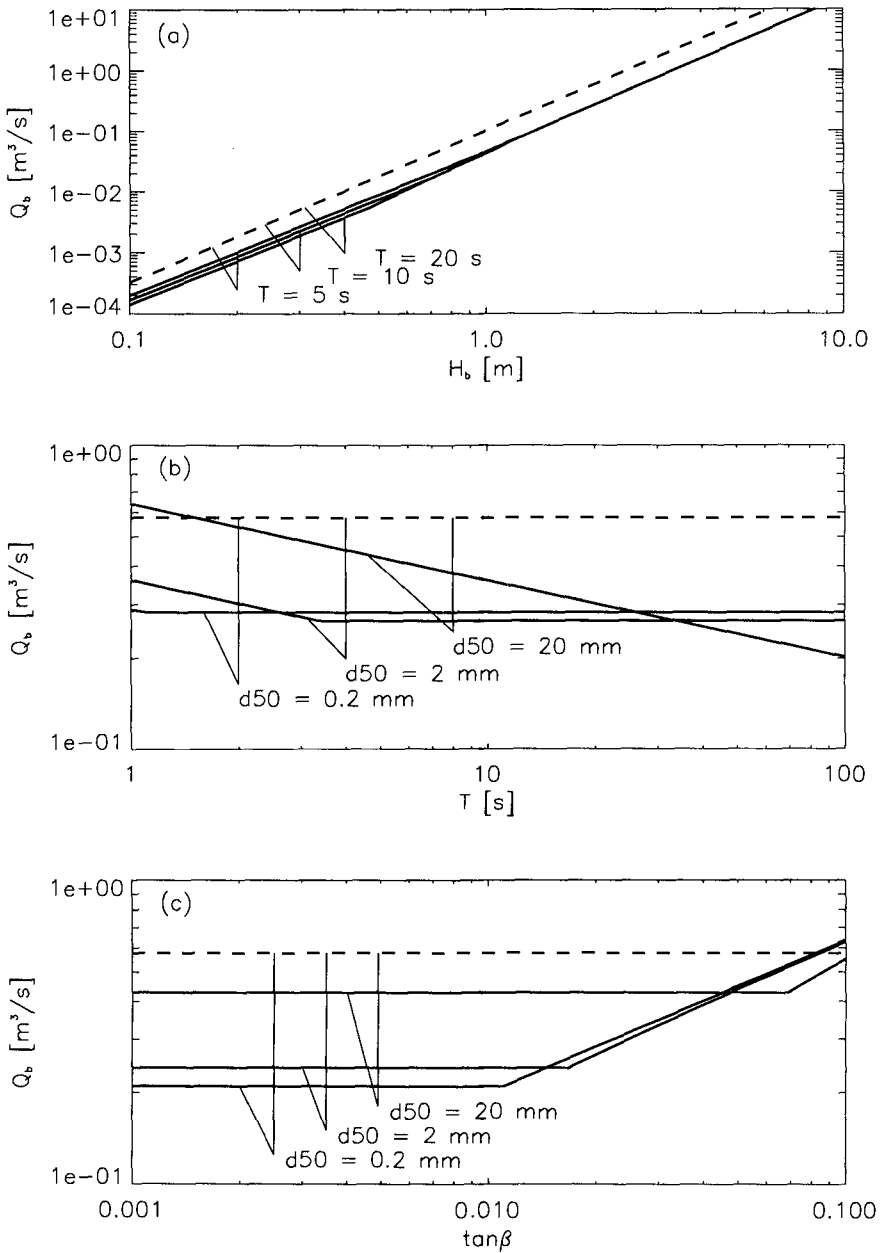

Figure 2: Comparison between the CERC formula (dashed line) and the analytical model (solid lines).

2(e) depicts the respective values of the littoral drift for the parameter range of the governing variables. The basic values of the parameters are: $H_b = 2.0m$, $T = 5s$, $d_{50} = 2.0mm$, $\tan\beta = 1/50$, $\alpha_b = 45$ and $\theta_{cr} = 0.05$. Each plot uses mainly the basic values, and varies the values of two parameters over a range. The parameter ranges are supposed to represent realistic values plus a bit more at each end of the range. Figure 2(f) shows a direct comparison between the analytical model and the CERC formula. The new method follows a broadly similar pattern to the CERC formula, but differs by up to a factor of 3 (generally smaller), depending on the value of T , d_{50} , $\tan\beta$, and α .

One of the shortcomings of the CERC formula is its lack of a grain size dependency. The sediment transport rate might actually not be so sensitive to modest changes in grain size but since the grain size on natural beaches can easily vary by two orders of magnitude (from fine sand $\simeq 100\mu m$ to gravel $\simeq 10mm$) the grain size dependency can be important. Thus, when it is taken into account that the CERC formula was calibrated using data from sandy beaches with values of d_{50} less than $500\mu m$, it is not surprising that it does not perform well for large grain sizes. For use on shingle or gravel beaches it is customary to multiply the CERC formula with a factor $\simeq \frac{1}{18}$ (see Brampton and Motyka, 1984) however, it is not clear what the procedure is for grain sizes in the intermediate range and this highlights one of the shortcomings of the CERC formula *viz.* the CERC-constant is not constant throughout the range of naturally existent grain sizes.

4 Comparison with data.

In order to quantify the deviation caused by the hydrodynamic assumptions employed, the results of the analytical formula were compared to the results of a numerical profile model using a state-of-the-art hydrodynamic module to propagate the waves inshore and calculate the bed shear-stress distribution (Southgate and Nairn, 1993). Bed-load transport was predicted by the formula of Soulsby (1996) given by equations (4) to (9) at a number of grid points across the profile and then cross-shore integrated numerically. The field data were provided by an extensive field observation programme of shingle beach re-nourishment at Seaford Beach on the south coast of England including more than three years of wave and sediment data. The wave data were obtained by a buoy located offshore at 10 m depth. Data were sampled every third hour and from the spectra the significant wave height, $H_s = \sqrt{2}H_{rms}$, the peak period, T_p , and the direction, α , were derived. For the analytical model and the CERC formula, the waves were propagated to the breaking point using Snel's law. Shingle transport volumes were determined through analysis of the beach profile surveys taken every 2-3 months during the period in question, at transects positioned along the beach at approximately 100m intervals. The results of the comparison are shown in figure 3, for the analytical model (equations (28) to (32)), the numerical model and the CERC formula. The full numerical model in conjunction with the bed-load trans-

Figure 3: Comparison between the CERC formula, the numerical model, and the analytical model (equations (28) to (32)) for the Seaford data.

port formula gave relatively good results: it predicted the littoral drift within a factor 3, whereas the analytical model consistently over predicted by a factor 12, and the CERC formula over predicted by a factor 20. The fact that the hydrodynamically more advanced numerical model performed better was taken as an expression of the relevance of the sediment transport formulation and the factor 12 was interpreted as a quantitative representation of the errors made in applying the before mentioned hydrodynamic assumptions to the analytical model. The formula has therefore been corrected through dividing by this constant factor. Thus the corrected analytical formula gives the longshore transport rate, $Q_{b,l}$, as $Q_{b,l} = \frac{1}{12} Q'_{b,l}$ with $Q'_{b,l}$ given by equations (28) to (32).

The existence of a threshold term is very important particularly for larger grain sizes. The study of the Seaford data showed that a decrease in θ_{cr} from 0.05 to zero, increased the shingle transport by a factor 3.

The corrected analytical formula has been applied to a number of shingle field and laboratory data sets: Van Hijum and Pilarczyk (1982) did laboratory experiments at Delft Hydraulics (DH) with shingle transport under the action

Figure 4: Comparison of the corrected analytical formula with existing field and laboratory data.

of regular and irregular waves, Chadwick (1989) collected field data of longshore shingle transport near Brighton, UK, and Coates (1994) did physical model studies of shingle transport at HR Wallingford. The results are shown in figure 4: Most transport rates are predicted within a factor 2 and all data sets are predicted within a factor 10.

5 Conclusions.

An analytical longshore bed-load transport formula has been developed from a bed-load transport formula developed at HR. Thus, the analytical formula is based on sediment transport physics and has been verified against a state-of-the-art numerical model and field data. This indicated the need to introduce a correction factor arising from grossly simplified assumptions about the hydrodynamics in the analytical model.

A major improvement on the CERC formula is dependencies on the grain size, beach slope and wave period, and the inclusion of a threshold term, which

has proven to be very important for the quantitative prediction of littoral shingle drift.

CHAPTER 280

Design Capacity of a Longshore Current Recirculation System for a Longshore Sediment Transport Laboratory Facility

David G. Hamilton¹, Julie D. Rosati², Jimmy E. Fowler², and Jane M. Smith²

ABSTRACT

A new longshore sediment transport laboratory facility for conducting three-dimensional moveable-bed experiments is being developed by the U.S. Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory. This paper focuses on the problem of designing the pumping capacity for an external longshore current recirculation system, designed to minimize adverse laboratory effects created by the updrift and downdrift lateral boundaries of the new facility. A review of longshore current recirculation systems used in other laboratory facilities is presented. The numerical model NMLONG is used to predict the magnitude and cross-shore distribution of the wave-driven longshore current that will be generated during experiments in the new facility. This paper concludes with a performance curve that defines the required pumping capacity of each of the individual pumps in the longshore current recirculation system.

1. INTRODUCTION

In performing its mission to maintain navigable waterways along U.S. coasts, the U.S. Army Corps of Engineers (USACE) regularly applies analytical and numerical models to estimate the total longshore sediment transport (LST) rate. Accurate prediction of LST rate is essential when predicting beach response in the vicinity of coastal structures, designing artificial beach nourishment projects, and approximating sedimentation rates in navigation channels. For design applications with adequate field measurements, the commonly used CERC formula (Shore Protection Manual, 1984) can be calibrated and applied to estimate total LST rates with reasonable confidence. However, for design applications without calibration data, the CERC formula provides only order-of-magnitude accuracy.

The present work is part of a research program intended to improve the USACE's capabilities to predict local and total LST rates and to evaluate errors associated with these predictions. The first goal of this research is to develop a world-class Longshore Sediment Transport Facility (LSTF) for conducting three-dimensional moveable-bed experiments. The LSTF will simulate nearshore hydrodynamic and sediment transport processes at a relatively large geometric scale. Further information on the objectives of this research program and general planning and design considerations for this new laboratory facility can be found in Rosati et al. (1995).

² Research Hydraulic Engineer, USAE Waterways Experiment Station, Coastal and Hydraulic Laboratory, 3909 Halls Ferry Road, Vicksburg, Mississippi, USA, 39180-6199

This paper focuses on the problem of calculating the required pumping capacity of a longshore current (LSC) recirculation system being designed to minimize the adverse laboratory effects created by the updrift and downdrift lateral boundaries of the LSTF.

The following sections review other LSC recirculation systems, provide a brief description of the LSTF, and discuss results obtained using the numerical model NMLONG to estimate the magnitude and cross-shore distribution of LSC that will be generated in the LSTF. Subsequent sections discuss limitations of the numerical analysis and other design parameters required to determine the design capacity of the LSC recirculation system. The final section provides a performance curve that defines the required pumping capacity for each of the individual pumps in the LSC recirculation system.

2. REVIEW OF OTHER LSC RECIRCULATION SYSTEMS

Early longshore current laboratory experiments were conducted without a LSC recirculation system that would have minimized the adverse laboratory effects created by the updrift and downdrift boundaries of each facility. Putman, Munk and Taylor (1949) used the sidewalls of the tank as wave guides to train the waves onto the beach. The LSC generated on the beach became part of the internal circulation pattern in the wave basin, which is considerably different than the situation on a long straight coast. Brebner and Kamphuis (1963) terminated the wave guides near the break point allowing the LSC to passively enter and exit the beach. Galvin and Eagleson (1965) and Mizuguchi and Horikawa (1978) terminated the downdrift wave guide at the break point, and completely closed the updrift wave guide. Apparently the longshore flux, in both of these experiments, was entering the test area underneath the wave generator, which would cause a non-uniform LSC distribution along the beach. Galvin and Eagleson (1965) were the first to measure the cross-shore distribution of LSC at several transects along the beach. Their data revealed the adverse effects created by the updrift and downdrift boundaries of the facility, in that the LSC was not able to reach its equilibrium magnitude and cross-shore distribution.

Visser (1982) conducted what appears to be the most detailed LSC experiments conducted to date. The wave basin was relatively large with a beach length between the wave guides of approximately 20 m. Visser's experiments were the first to use a LSC recirculation system to recirculate water from the downdrift to the updrift end of the beach. For most of Visser's experiments, the cross-shore distribution at the updrift boundary was controlled using 12 flow channels and control gates. Each flow channel was 0.2 and 0.4 m wide for tests with beach slopes of 1:10 and 1:20, respectively. Visser found it impossible to optimize the recirculation procedure from measurements of the mean water level in the longshore direction. He developed an alternative method where the optimum rate of external recirculation was determined by minimizing the internal circulation between the wave guides.

Simons et al. (1995) described some of the evaluation tests conducted in the recently developed Coastal Research Facility at HR Wallingford, in the United Kingdom. This facility was constructed in a large wave basin (27 x 54 m) and has a 36-m long directional wave generator. The most impressive component of the facility is the LSC recirculation system that has 4 independent reversible axial flow pumps with a total pumping capacity of

1.2 m³/s. Currents are introduced into the basin at the updrift boundary through 40 flow channels, each controlled by its own undershoot weir, with a matching set of flow channels at the downdrift end of the facility. All of the flow channels are 0.5 m in width and the fixed-bed beach has a slope of 1:20. This system allows the wave-driven LSC to be externally recirculated to establish longshore uniformity of waves and wave-driven currents. Some technical specifications on the facility were found in HR Wallingford (1994).

3. PHYSICAL DESCRIPTION OF THE NEW LABORATORY FACILITY

The LSTF occupies a 30-m cross-shore by 50-m longshore by 1.4 m deep wave basin (Figure 1). Monochromatic and random waves can be generated with four digitally controlled, piston-type, servo-electric wave generators. The wave generators are synchronized to create unidirectional long-crested waves up to 0.5 m in height for wave periods up to 3.0 s, and can be oriented at various angles ranging from 0 to 20 deg with respect to shore normal. For oblique angles of wave attack, the wave generators are phase-shifted to maximize the cross-shore dimension of the testing area. End-baffles, located between two adjacent wave boards, are used to guide the waves and prevent the formation of spurious waves caused from wave diffraction from the ends of each wave board and from wave energy reflected from the wave absorber located behind the wave generators. Wave guides that follow the refracted wave ray will be designed to facilitate current and sediment input and output at the lateral boundaries of the beach. Wave, current, and bathymetric data will be collected using a suite of sensors located on a custom-designed instrumentation bridge, as described by Rosati et al. (1995).

Figure 1: Plan View of the Longshore Sediment Transport Facility

The fixed-bed (concrete) beach has a longshore dimension of 30 m and a cross-shore dimension of 21 m, and was accurately constructed (tolerance of ± 2.0 mm) with parallel contours. The main section of the concrete beach has a constant slope of 1:30, and the toe

of the beach slopes down to the basin floor at a slope of 1:18. During future LST experiments, a 0.3 m thick moveable-bed of quartz sand will be placed on top of the fixed-bed beach and will extend 18.0 m offshore (see toe of moveable-bed beach in Figure 1). The toe of the beach will taper down to the basin floor at a slope of 1:6.5.

A LSC recirculation system is being designed to minimize the adverse laboratory effects resulting from the updrift and downdrift boundaries, and to maximize the length of beach over which longshore uniformity of waves and wave-driven currents exist in the facility. A LSC recirculation system creates a closed-loop system that continuously recirculates LSC from the downdrift to the updrift lateral boundary of the beach, while waves are being generated. As shown in Figure 1, the LSC recirculation system will extend 18.0 m offshore corresponding to the offshore limit of the moveable-bed beach which will be constructed for future LST experiments. A series of pumps will be located at the downdrift end of the facility and will recirculate the wave-driven LSC back to the updrift end of the facility through a series of pipes.

4. NUMERICAL SIMULATIONS OF LSC

The first part of this section provides a description of the numerical model used to estimate the magnitude and cross-shore distribution of the longshore current that will be generated in the LSTF. Subsequent sections describe the setup of the numerical model, validate the results obtained from the numerical model with dye measurements in the LSTF, and show the influence of wave height, period and direction on the estimated magnitude and cross-shore distribution of the longshore current.

4.1 Description of the Numerical Model

Kraus and Larson's (1991) numerical model NMLONG (Numerical Model of the LONGshore current) was used to estimate the wave-driven longshore current in the LSTF. NMLONG is a PC-based model that calculates wave transformation, mean water surface elevation, and longshore current for a 1-D cross-section of beach. The major assumptions in NMLONG are longshore homogeneity and linear wave theory.

Wave transformation in NMLONG includes shoaling, refraction, breaking with energy dissipation, and wave reformation. Random wave transformation is simulated by assuming a Rayleigh distribution of wave heights offshore (waves are assumed to be narrow banded in frequency and direction, so randomness enters only in variability in wave height). NMLONG randomly selects wave heights from the Rayleigh distribution and transforms them as individual waves. The individual wave heights are used to calculate root-mean-square wave height at each point across the profile. This approach neglects wave-wave interactions. The mean water surface elevation (setup and setdown) produced by waves is calculated from the cross-shore momentum balance. The wave forcing (radiation stress) is calculated from linear wave theory.

Wave-driven longshore current is calculated from the longshore momentum balance. The model includes wave forcing (gradients in radiation stress), lateral mixing, and bottom friction. Lateral mixing is modeled with an eddy viscosity approach. Bottom friction is

nonlinear (in the unknown current velocity) and requires time-averaging of nonlinear terms over the wave period. The offshore boundary condition for the current is zero wave-driven velocity. For random wave simulation, longshore currents from individual waves are averaged at each profile point.

Using the data from Visser (1982), Kraus and Larson (1991) illustrated that NMLONG can be calibrated to reproduce the LSC measured in the laboratory with reasonable success. In particular, the magnitude and cross-shore location of the peak of the LSC distribution was reproduced with reasonable accuracy. This suggests that NMLONG can be used to provide a reasonable estimate of the magnitude and cross-shore distribution of LSC that can be generated in the LSTF. However, in the Visser cases, NMLONG predicted that the magnitude of the offshore tail of the LSC distribution was higher than measured by Visser, even after the numerical model had been calibrated.

4.2 Numerical Model Setup

NMLONG requires the following input parameters: offshore wave height, period, and direction, specification of regular or random waves, offshore water depth, and beach profile elevation relative to mean water level. Random waves are characterized in NMLONG using the root-mean-square wave height, H_{rms} . Values of H_{rms} were converted to significant wave height, H_s assuming $H_s = 1.414 \times H_{rms}$. Nonlinear bottom friction with a friction coefficient equal to 0.01 was used in the LSTF simulations. For one wave condition, the sensitivity of results to this value was evaluated by reducing and increasing the coefficient to 0.005 and 0.02, respectively. All other empirical parameters were set to the default values: incipient breaking-wave-height-to-water-depth-ratio equal to 0.8, stable wave-height-to-water-depth-ratio equal to 0.4, energy flux dissipation rate equal to 0.15, and lateral mixing coefficient equal to 0.3.

NMLONG was set up to calculate the depth-averaged LSC velocities at each cell spaced 1 m across the beach profile. These depth-averaged velocities were multiplied by the corresponding mean water depth and integrated across the entire profile to estimate the total longshore volume flux for each wave condition.

Two series of numerical simulations were conducted to represent two different experimental configurations planned for the LSTF. The first series was conducted with an offshore water depth equal to 0.6 m and represents the configuration that will be used in the LSTF during the hydrodynamic testing phase. The second series was conducted with a water depth equal to 0.9 m and represents the configuration that will be used for the moveable-bed LST experiments. In this configuration a 0.3 m thick uniform layer of sand will be placed on top of the existing concrete beach. Increasing the water level from 0.6 to 0.9 m translates the shoreline directly upwards (i.e., there is no cross-shore translation of the nearshore zone). However, the resulting magnitude and cross-shore distribution of the LSC is slightly different for the two different configurations, due to the slight difference in wave transformation caused by the steeper toe of the beach in the case with the moveable-bed.

Numerical simulations in both test series covered the following range of hydrodynamic conditions: significant wave height, $H_s = 0.1$ to 0.4 m, peak wave period, $T_p = 1.0$ to 2.5 s, and angle of wave incidence, $\theta = 5$ to 20 deg relative to shore normal. For these test conditions total longshore volume flux ranged from 0.04 m³/s for $H_s = 0.1$ m, $T_p = 2.5$ s, and $\theta = 20$ deg to 1.3 m³/s for $H_s = 0.4$ m, $T_p = 2.5$ s, and $\theta = 20$ deg.

The sensitivity of the bottom friction coefficient was evaluated for a relatively energetic wave condition; namely $H_s = 0.3$ m, $T_p = 2.5$ s and $\theta = 20$ deg. The bottom friction coefficient was varied over a range of two times the default value of 0.01 (i.e., from 0.005 to 0.02). Results obtained using the lower friction coefficient (0.005) resulted in a total longshore volume flux of 1.1 and 1.2 m³/s for the 0.6 and 0.9 m water depth cases, respectively. The higher friction coefficient (0.02) reduced the total longshore volume flux to 0.4 m³/s for both water depth cases. Therefore, the results obtained using NMLONG to predict the total longshore volume flux in the LSTF are sensitive to the value of the bottom friction coefficient.

4.3 Validation with Dye Measurements in the LSTF

Preliminary estimates of the magnitude of the LSC were obtained in the LSTF by injecting dye into the surf zone while generating monochromatic waves. These measurements were then used to assess the validity of the numerical simulations. However, the following facility components had not been installed in the LSTF at the time these measurements were required: (1) lateral wave guides were not available to train the incident waves from the wave generators to the surf zone, (2) none of the LSC recirculation system components were available to minimize the laboratory effects caused by the lateral boundaries of the facility (i.e., pumps and flow channels), and (3) only monochromatic waves could be generated with the wave makers. As a result, strong adverse reflection patterns (from the vertical walls at the two ends of the basin) and circulation cells developed throughout the facility as the first 5-10 waves were generated. In addition, no flow velocity measurement sensors were available to accurately measure the wave driven LSC in the surf zone.

Three conclusions were made based on these limited dye measurements. First, NMLONG produced reasonable estimates of the peak LSC magnitude and cross-shore location, using the default bottom friction coefficient of 0.01 . However, insufficient data were collected to calibrate this coefficient. Secondly, we were unable to verify the cross-shore distribution of the LSC predicted using NMLONG due to the physical limitations and resulting adverse laboratory effects discussed above. Therefore, the default lateral mixing coefficient (0.30) was used. Thirdly, observations made while these dye measurements were being carried out strongly reinforced the expectation that a properly designed external LSC recirculation system would be required to maintain longshore uniformity of waves and wave-driven currents in the facility, especially for energetic wave conditions.

4.4 Influence of Hydrodynamic Variables

The influence of wave height, period and direction on the magnitude and cross-shore distribution of the LSC was investigated. All numerical simulations were conducted using

random waves. Figure 2 shows the LSC distribution for $H_s = 0.2, 0.3,$ and 0.4 m, with $T_p = 2.5$ s and $\theta = 20$ deg at the wave generator. Three general trends can be seen in this figure. First, as H_s increases, the magnitude of the LSC at the peak of the distribution significantly increases. The magnitude of the peak LSC equals $0.21, 0.28$ and 0.36 m/s for $H_s = 0.2, 0.3$ and 0.4 m, respectively. This is a relative increase of approximately 30% for each 0.1 m increase in wave height. Secondly, the peak of the LSC distribution moves offshore as H_s increases, because the incident waves begin to break further offshore. Thirdly, the width of the LSC distribution increases as the H_s increases, since the width of the surf zone increases.

Figure 2: Influence of Significant Wave Height

Figure 3 shows the LSC distribution for $T_p = 1.0, 1.5, 2.0$ and 2.5 s with $H_s = 0.3$ m and $\theta = 20$ deg at the wave generator. Three general trends can be seen in this figure. First, as T_p increases, the magnitude of the LSC at the peak of the distribution increases slightly. The magnitude of the peak LSC equals $0.25, 0.26, 0.27$ and 0.28 m/s for $T_p = 1.0, 1.5, 2.0$ and 2.5 s, respectively. This is a relative increase of only 4% for each 0.5 s increase in T_p . Secondly, the peak of the LSC distribution moves slightly further offshore as T_p increases, since the incident waves begin to break slightly further offshore. Thirdly, the width of the LSC distribution increases slightly as T_p increases, since the width of the surf-zone increases slightly.

Figure 3: Influence of Peak Wave Period

Figure 4 shows the LSC distribution for $\theta = 5, 10, 15$ and 20 deg with $H_s = 0.3$ m and $T_p = 2.5$ s. Three general trends can be seen in this figure. First, as θ increases, the magnitude of the LSC at the peak of the distribution significantly increases. The magnitude of the peak LSC equals $0.10, 0.18, 0.23$ and 0.28 m/s for $\theta = 5, 10, 15$ and 20 deg, respectively. This is a relative increase of about $80\%, 28\%$, and 22% , for each consecutive increase in θ . Secondly, the cross-shore location of the peak of the LSC distribution remains constant as θ increases. Thirdly, the width of the LSC distribution remains reasonably constant as θ increases.

Figure 4: Influence of Incident Wave Direction

In summary, increasing H_s has a strong influence on increasing the magnitude and cross-shore location of the peak of the LSC distribution, whereas, increasing T_p has a much milder effect. Increasing θ has a very strong influence on increasing the peak magnitude, but no influence on the cross-shore location of the peak of the LSC distribution.

5. DESIGN PARAMETERS FOR THE LSC RECIRCULATION SYSTEM

The first part of this section describes the design wave condition used to determine the required pumping capacity of the LSC recirculation system. Subsequent sections discuss a factor of safety applied to the numerical modeling results, and incorporate the requirements of a moveable-bed beach and a variable operating water level into the design.

5.1 Design Wave Condition

To determine the design capacity of a LSC recirculation for the LSTF, a maximum design wave condition was selected. After observing the location of the break point for a number of different wave height and period combinations in the LSTF (and comparing these results with the numerical simulations), it was decided that $H_s = 0.3$ m and $T_p = 2.5$ s is probably the most energetic wave condition that will be generated during the moveable-bed LST experiments. As mentioned previously, the maximum angle of wave incidence (measured at the wave generators) to be tested in the LSTF is 20 deg. Therefore, the “design wave condition” used to determine the maximum required pumping capacity of the LSC

recirculation system was characterized by $H_s = 0.30$ m, $T_p = 2.5$ s and $\theta = 20$ deg with an offshore water depth of 0.9 m. This is the LSC distribution shown previously in Figure 2 (middle curve) and Figure 3 and 4 (upper curve). Results obtained using NMLONG to predict the magnitude and cross-shore distribution of LSC for this "design wave condition" indicated a total longshore flux of 0.76 m³/s within the surf zone.

5.2 Determining a Factor of Safety

A factor of safety was incorporated into the design to compensate for inaccuracies in calculating the magnitude and cross-shore distribution of LSC that will be generated in the LSTF. Our concerns included: (1) having inadequate data to calibrate the bottom friction coefficient and the lateral mixing coefficient in the numerical model, and (2) changes in the bottom roughness between the initial hydrodynamic tests on a fixed-bed concrete beach and multiple grain sizes used for the moveable-bed beach for the LST experiments. The surface of the concrete beach was broom-finished to simulate the roughness of a coarse grained sand. However, because bed-forms will develop in the LST experiments it is likely that the moveable-bed beach will have a higher friction coefficient for a given wave condition. Due to these uncertainties, the magnitude of the LSC at each cross-shore location was increased by 10% (i.e., a Factor of Safety = 1.1) for the purpose of determining the required pumping capacity of the LSC recirculation system.

5.3 Allowance for Maximum Depth of Erosion of the Moveable-Bed Beach

At this point in the design process, predictions of the LSC magnitude and cross-shore distribution to be generated in the LSTF are based on a 1:30 plane sloping fixed-bed beach having parallel contours. However, for future moveable-bed experiments in the LSTF, the beach profile will respond to incident wave conditions, creating a shore-parallel bar and trough feature near the location of initial wave breaking. Assuming longshore uniformity in the beach bathymetry, the capacity of the LSC recirculation system must be increased wherever the beach profile erodes, due to the increased longshore flux at the cross-shore location. For example, in the trough located shoreward of the offshore bar.

To investigate this problem, 2-D flume tests were conducted to estimate the maximum depth of erosion during future moveable-bed LST experiments in the LSTF. Each test started with a 1:30 plane sloping sand beach, with $D_{50} = 0.11$ mm. This is the same initial beach slope and sediment size to be used for the fine-grained sediment test series in the LSTF. In each experiment, the maximum depth of erosion was located just offshore of the still-water shoreline. For the design wave condition the maximum depth of erosion did not exceed 0.1 m, however, this conclusion is based on 2-D flume tests, and not 3-D tests in the LSTF.

For design purposes, it was assumed that the entire 18-m width of the moveable-bed beach will erode by 0.1 m. This is a fairly crude assumption, although it is conservative in that it allows for the maximum scour depth to occur at any location across the beach profile. In particular, this is a very conservative assumption near the offshore end of the beach where accretion should occur (as opposed to erosion) as the offshore bar develops. However, future plans for the LSTF include a test with a terminal groyne located at the downdrift end

of the moveable-bed beach. If this physical model behaves as expected, a scour hole will develop at the head of the groyne and the longshore flux (shoreward of the offshore end of the groyne) will be deflected offshore and bypass the end of the groyne. Therefore, over designing the LSC recirculation system near the offshore region of the beach will give the system more flexibility in the future when conducting experiments with coastal structures.

Note that this analysis assumes that the depth-averaged LSC at any cross-shore location does not change substantially (from the case with a plane sloping fixed-bed beach) as the offshore bar and trough feature develop in the moveable-bed experiments. Although this may not be the case, we feel that changes to the depth-averaged LSC (as the beach profile develops) will be relatively small since the initial beach slope is relatively gentle (1:30) and the total profile adjustment should be relatively small. Therefore, this assumption should be adequate for design purposes.

5.4 Allowance for Variable Operating Water Levels in the Facility

The design of the LSC recirculation system also accounted for the requirement to conduct experiments with variable water levels in the facility. As mentioned previously, we plan to conduct the majority of the moveable-bed LST experiments with an offshore water depth of 0.9 m. However, if we decide to increase the water level in the future, the LSC distribution will be translated shoreward on the beach.

A number of physical constraints in the vertical dimension of the facility dictate that the maximum operating water level in the facility will not exceed 1.0 m (at least for energetic wave conditions). Lower water levels can be used, however, the wave generation capability of the wave makers will decrease with decreasing water level. Therefore, the critical design parameter is the maximum operating water level in the facility. The first curve in Figure 5 shows the longshore flux distribution for the design wave condition, with an offshore water depth of 0.9 m. This curve includes the increased capacity required by using a factor of safety of 1.1 and assuming the moveable-bed erodes 0.1 m across the entire width of the beach. The abrupt change in cross-shore gradient at $X = 18$ and 21 m is caused by the sudden change in beach slope at these locations. The second curve was obtained by increasing the offshore water depth to 1.0 m, for the same design wave condition. Essentially, this 0.1 m increase in operating water level translates the LSC distribution 3.0 m shoreward, because the slope of the concrete beach is 1:30. The third curve in the figure encompasses both the first and second curve, and represents the required pumping capacity of the LSC recirculation system for water levels ranging from 0.9 to 1.0 m. As shown in the figure, incorporating a variable water level into the design essentially broadens the width of the LSC distribution that needs to be recirculated within the facility.

6. OTHER DESIGN CONSIDERATIONS

The following sections describe uncertainties related to how far the LSC distribution extends offshore, the magnitude of the longshore flux of water flowing in the swash zone, and the issue of what percentage of the wave-driven LSC needs to be recirculated.

Figure 5: Influence of Offshore Water Depth

6.1 Offshore Tail of the LSC Distribution

Another design consideration is the possibility that a small longshore flux may exist offshore of the toe of the moveable-bed beach ($X > 18.0$ m), for very energetic wave conditions. Approximately 17% of the area under the curve in Figure 5 is offshore of $X = 18$ m, which is the location of the offshore end of the recirculation system, as shown in Figure 1. In Section 4.1, it was discussed that NMLONG may over predict how far the LSC distribution extends offshore. Unfortunately, this was impossible to verify due to problems encountered making dye measurements in the partially constructed LSTF, as discussed in Section 4.3. If the numerical simulations are correct, this offshore tail of the LSC distribution may cause adverse internal circulation patterns within the facility.

If this problem exists in the future, there are a number of possible solutions. First, we could decrease the magnitude of the maximum wave condition that is generated in the facility. Second, we could increase the offshore water depth to 1.0 m for very energetic wave conditions, which would shift the LSC distribution 3.0 m shoreward. The area under the curve (offshore of $X = 18$ m) associated with an offshore water depth of 1.0 m, is only 9% of the total area. Third, it may be possible to oversize the furthest offshore pump, and use the additional capacity to recirculate some of the LSC which exists offshore of $X = 18$ m. Based on these considerations, it was decided that the LSC recirculation system would initially be constructed to extend offshore to $X = 18.0$ m. If the numerical predictions turn out to be correct, one or more of the options discussed above will be employed.

6.2 Longshore Flux of Water in the Swash Zone

Another design feature to be considered is the longshore flux of water flowing downdrift within the swash zone. The swash zone was defined as the area between the still-water shoreline and the maximum point of wave uprush, including any setup in the mean water level. Unfortunately, it is impossible to accurately calculate the longshore flux in the swash zone due to our limited understanding of swash zone processes. One of the interesting

results obtained from the 2-D moveable-bed tests, discussed previously in Section 5.3, is that the swash zone was approximately 4 m in width for the design wave condition. Therefore, it is believed that it will be necessary to recirculate the longshore flux in the swash zone, due to the physical size of the swash zone that develops at this relatively large geometric scale.

Figure 5 indicates that at $X = 5.0$ m, the longshore flux of water will be approximately $0.045 \text{ m}^3/\text{s}$ per meter width of beach. In addition, we know that the longshore flux of water at the landward boundary of the swash zone will be zero. Therefore, we can make a somewhat crude assumption and draw a straight line between these two points to represent the time-averaged longshore flux of water flowing downdrift in the swash zone. Although we expect the longshore flux of water to have a nonlinear distribution across the swash zone, this assumption provides a first-order estimate for design purposes.

6.3 Percentage of Longshore Flux to be Externally Recirculated

Intuitively one would expect that 100% of the longshore flux within the surf zone should be externally recirculated back to the updrift end of the facility with a LSC recirculation system. However, laboratory facilities are not ideal systems and in many cases an internal circulation pattern may exist, in which case it may not be necessary (or possible) to externally recirculate 100% of the wave-driven longshore flux without adding too much momentum into the system. Visser (1982) developed a method to obtain a uniform LSC distribution along the finite length of a straight beach in a 3-D wave basin. Visser determined the “proper” rate of external recirculation by adjusting the pumping rate and inflow distribution until the internal circulation between the wave guides was minimized. However, after reviewing Visser’s work, Svendsen (1991) concluded that in some of Visser’s experiments the internal circulation was still disturbingly large (as much as 40-50% of the wave-driven longshore flux within the surf zone), even though Visser’s data indicate that he was able to establish a LSC distribution that was relatively uniform alongshore.

Based on Svendsen’s conclusion and the principle of continuity, Visser’s external recirculation flow rate must have been substantially less than the total longshore flux in the surf zone. This indicates that it may not be necessary to recirculate 100% of the longshore flux in the LSTF, to obtain longshore uniformity. This problem will be investigated in the LSTF during the initial hydrodynamic experiments on a fixed-bed beach. However, for the purpose of estimating the required pumping capacity of the LSC recirculation system, it was prudent to assume that 100% of the longshore flux will need to be externally recirculated.

7. DESIGN CAPACITY FOR EACH INDIVIDUAL PUMP

The last step in this phase of the design process was to determine the design capacity of each of the individual pumps that make up the LSC recirculation system. Required pump capacity is a function of the width of the flow channels at the downdrift end of the facility, which is directly related to the cross-shore resolution of the LSC recirculation system. Intuitively, one would expect that the higher the cross-shore resolution, the longer the “working beach region” where longshore uniformity of waves and wave-driven LSC’s exist. After reviewing the design of LSC recirculation systems used in other laboratory facilities

(see Section 2) it was decided that the flow channels at the downdrift and updrift end of the LSTF should be 0.75 m in width. This was a compromise between cross-shore resolution and the estimated cost of construction of the entire LSC recirculation system.

Knowing the required pumping capacity of the LSC recirculation system, shown in Figure 5 (third curve), and given a flow channel width of 0.75 m, the capacity of each individual pump could be readily calculated. Figure 6 shows a bar graph expressed in m^3/s for every 0.75 m of beach width, and the magnitude of each bar represents the required pumping capacity of each individual pump. This figure also includes the required pumping capacity to recirculate the longshore flux in the swash zone (see Section 6.2). Figure 6 shows 23 pump capacities. However, to reduce the number of pumps near the shoreline, where the longshore flux is relatively small, one large pump will be used as opposed to four smaller pumps, as illustrate in Figure 1. Therefore, there will be a total of 20 pumps in the system.

Figure 6: Design Capacity of the LSC Recirculation System

The total design capacity of the LSC recirculation system was calculated to be approximately $1.25 \text{ m}^3/\text{s}$. To put this pumping capacity into perspective, HR Wallingford (1994) states that the LSC recirculation system in the Coastal Research Facility has a design capacity of $1.2 \text{ m}^3/\text{s}$ (i.e., four axial flow pumps each with a capacity of $0.3 \text{ m}^3/\text{s}$). The LSC recirculation system in the Coastal Research Facility is used to generate not only wave-driven LSC within the surf zone, but also tidal currents offshore of the toe of the concrete beach. Therefore, although the purpose of the two systems is not exactly the same, the total design pumping capacities are very similar.

8. SUMMARY

This paper documents the design process used to determine the required pumping capacity of an external longshore current recirculation system for the development of a longshore sediment transport laboratory facility. A design wave condition of $H_s = 0.3 \text{ m}$, $T_p = 2.5 \text{ s}$, and $\theta = 20 \text{ deg}$, with an offshore water depth of 0.9 m was used to estimate the magnitude and cross-shore distribution of the longshore current that will be generated in the new

facility. By including a factor of safety and considering a number of functional design requirements, the total required design pumping capacity was determined to be 1.25 m³/s. It was estimated that twenty independent pumps and flow channels would be required to provide adequate cross-shore resolution for the system and to provide the required capability to recirculate a broad range of LSC distributions for a wide range of incident wave conditions, water levels and moveable-bed beach profiles.

9. ACKNOWLEDGEMENTS

The authors would like to thank the staff at HR Wallingford, in the United Kingdom for generously providing technical information about the Coastal Research Facility. This paper benefited from the review comments of Bruce A. Ebersole. This research is funded by the "Large-Scale Laboratory Investigation of Longshore Sediment Transport" work unit of the Coastal Sediment and Dredging Program, under the Coastal Navigation and Flood Damage Reduction Research Area. Permission to publish this paper was granted by the Chief of Engineers, U.S. Army Corps of Engineers.

CHAPTER 281

INFLUENCE OF NEARSHORE HARDBOTTOM ON REGIONAL SEDIMENT TRANSPORT

Paul C.-P. Lin, Ph.D., P.E.¹ and R. Harvey Sasso, P.E.²

ABSTRACT

The influence of nearshore hardbottom on longshore and cross-shore sand movement along a 21.2 km long southeast Florida coastline is evaluated. This study correlates a variation of longshore sediment transport rate within the region with the extent of nearshore hardbottom. The nearshore sand movement within this region was determined based on analysis of the hydrographic survey data over a 15-year period. The study area includes three major beach renourishment sites, which were renourished a combined total of seven (7) times with 5.5 million cubic meters of sand. The objectives of this study are to obtain a greater understanding of the causes of severe beach erosion and a more accurate estimate of nearshore sand movement in the region, thus providing a better design tool for future beach nourishment projects and inlet sand bypassing practices.

INTRODUCTION

The area of study extends from Port Everglades Inlet in Broward County to Bakers Haulover Inlet in Dade County. This region of coastline encompasses six (6) municipalities including, from north to south, John U. Lloyd, Dania, Hollywood/Hallandale, Golden Beach, Sunny Isles, and Bakers Haulover Park, with their major beach nourishment projects illustrated in Figure 1.

This study region is bounded by Port Everglades Inlet to the north and Bakers Haulover Inlet to the south. Port Everglades Inlet was opened in 1926 and stabilized by north and south jetties in 1931. Its 190-meter wide and 15 m deep inlet channel acted as a complete sand barrier and allowed no sediment bypassing

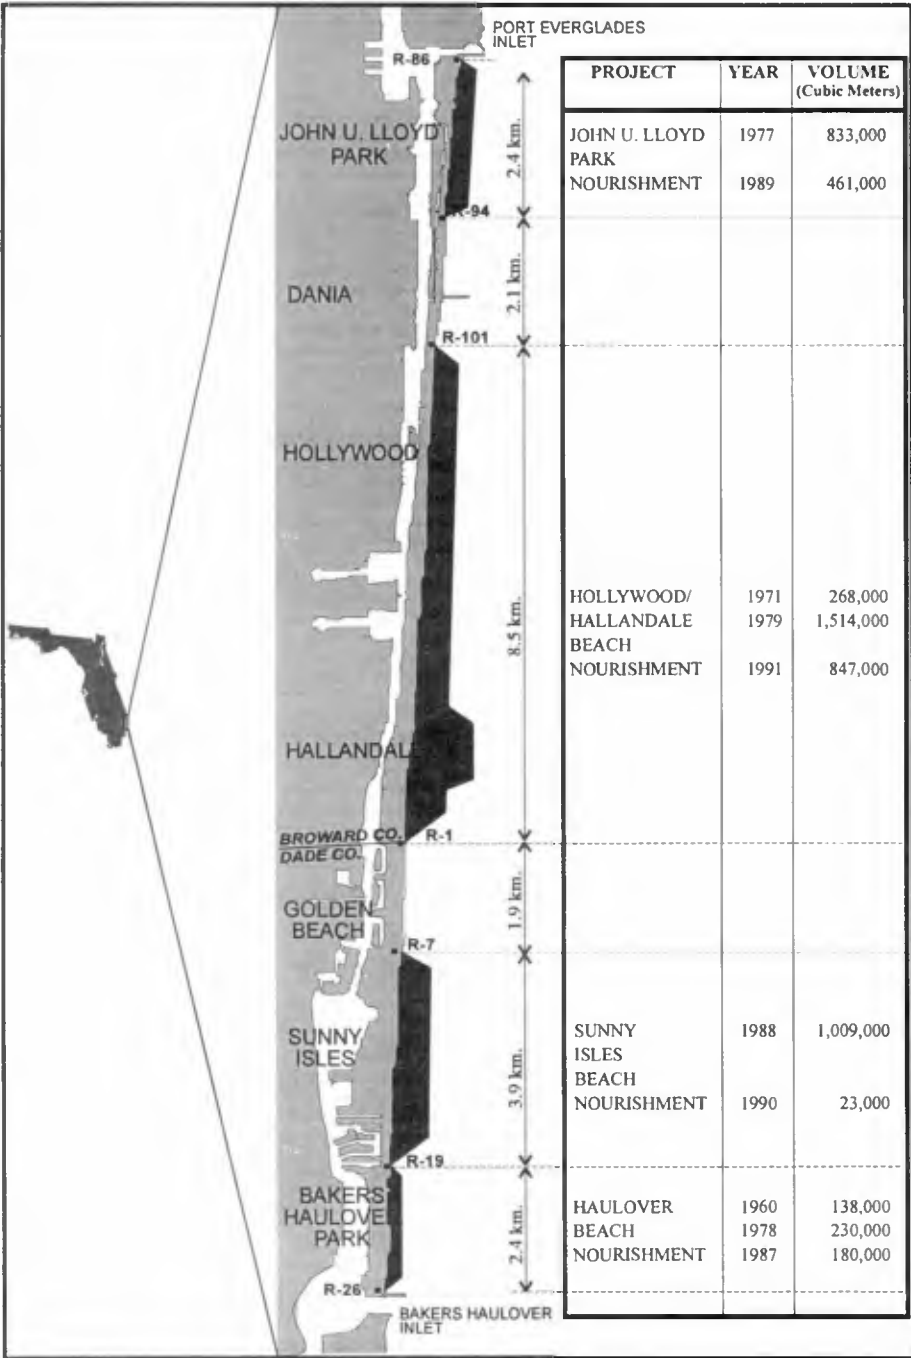

Figure 1. Study Area and Historic Beach Nourishment Projects

across the inlet (Coastal Tech, 1994). The Bakers Haulover Inlet is a man-made improved inlet measuring approximately 90 m wide and 5 m deep. This Inlet was opened in 1925 (CP&E, 1992a).

In the region, John U. Lloyd, Hollywood/Hallandale, and Sunny Isles have been periodically renourished. Some small-scale beach fill activities were also conducted in the Bakers Haulover Park. Meanwhile, Dania and Golden Beach have been accreting as a result of adjacent beach renourishment projects. The 2.4 km beach of John U. Lloyd Park was nourished in 1977 and 1989 with placement of approximately 0.83 million and 0.46 million cubic meters of sand, respectively. An estimated 0.27, 1.5, and 0.85 million cubic meters of sand were placed along the 8.5 km of Hollywood/Hallandale beach in 1971, 1979 and 1991, respectively. A major beach nourishment project took place along the 3.9 km of Sunny Isles beach in 1988 with placement of 1.0 million cubic meters of sand. Other small-scale beach fill projects within this region were detailed in the Sunny Isles report (Coastal Tech, 1993).

Extensive nearshore hardbottom was found within this study area, which aligned in a shore-parallel direction with an offshore distance between the hardbottom and shoreline increasing from north to south. Specifically, the nearshore hardbottom is located approximately 200 m offshore at the north end of the region and increases to 900 m offshore at the south end. The average width of the nearshore hardbottom area is 2,400 m.

REGIONAL SEDIMENT TRANSPORT

The overall sand movement within the study region is evaluated by examining volumetric changes at each DEP (formerly DNR) monument. The volumetric changes occurring above and below the -2 m National Geodetic Vertical Datum (NGVD) elevation are calculated. The depth of closure for sand movement in this region varies from approximately -4 m NGVD to -6 m NGVD, depending on the location of nearshore hardbottom. A detailed variation of volumetric changes along the region is illustrated in Figure 2.

Table 1 summarizes the average and total volumetric changes within each coastal municipality. In general, long-term hydrographic data for two consecutive beach nourishment projects were used to obtain an average volumetric change rate after a beach renourishment project. In the area of Sunny Isles and Bakers Haulover Park, relatively short-term data (approximately a three-year time period) was used due to the lack of accurate and extensive hydrographic survey data.

Figure 2. Net Volumetric Changes and Cross Shore Sand Movement

TABLE 1

VOLUMETRIC CHANGES WITHIN EACH COASTAL MUNICIPALITY

Coastal Municipality	Distance (km)	Survey Period	Volumetric Changes (c.m./m/yr)			Total Volumetric Changes (c.m./yr)
			Above -2 m NGVD	Below -2 m NGVD	Total	
John U. Lloyd State Park	2.4	1978-1989	-14.5	1.0	-13.5	-33,000
Dania	2.1	1978-1993	0.8	4.3	5.1	11,000
Hollywood/Hallandale	8.5	1979-1991	-8.0	4.0	-4.0	-34,000
Golden Beach	1.9	1980-1991	-2.3	9.5	7.2	14,000
Sunny Isles	3.9	1989-1991	-30.6	22.1	-8.5	-34,000
Bakers Haulover Park	2.4	1989-1991	-8.8	14.0	5.2	13,000
Total	21.2	—	—	—	—	-63,000

The nourished beach at John U. Lloyd, Hollywood/Hallandale (CP&E, 1992b) and Sunny Isles was found to be eroding at similar rates of 33,000, 34,000 and 34,000 cubic meters per year, respectively. The erosion rate per meter of shoreline decreased with increasing length of the renourishment project. For instance, Hollywood/Hallandale, having the greatest project length of 8.5 km, was found to have the least erosion rate per linear meter of shoreline at 4.0 cubic meters per meter per year. The greatest erosion of 13.5 cubic meters per meter per year occurred at John U. Lloyd Park. This high erosion rate is mainly due to the downdrift impacts associated with Port Everglades Inlet.

Non-nourished areas adjacent to the renourished beaches were accreting, as illustrated in Table 1. Dania, Golden Beach and Bakers Haulover Park were accreting at a rate of 11,000, 14,000 and 13,000 cubic meters per year, respectively. The accretion rates in these areas were relatively uniform, ranging from 5.1 to 7.2 cubic meters per meter per year.

A sediment budget, as illustrated in Figure 3, is developed for the region based on a known boundary condition and the results of the above volumetric changes. This sediment budget encompasses a region that extends beyond the area that is conventionally studied under inlet management plans and beach renourishment projects. The well-defined northern boundary condition of Port Everglades Inlet has improved the accuracy in the derivation of this regional sediment budget. A number of studies have reported that Port Everglades Inlet has interrupted 100 percent of longshore sediment transport and resulted in no sediment being naturally bypassed from north of the inlet to John U. Lloyd Park (COE, 1990; Coastal Tech, 1988 and 1994).

The regional sediment budget indicates that the longshore sediment transport rate at the north end of the region is less than the rate at the south end. This is contradictory to the trend experienced along the east coast of Florida, where longshore sediment transport rates usually decrease toward the south. The wave-induced longshore transport rate is found to be 33,000 cubic meters per year at John U. Lloyd/Dania, as compared to 76,000 cubic meters per year at Sunny Isles/Bakers Haulover Park. A net southern longshore transport rate of 77,000 cubic meters per year at Bakers Haulover Park was predicted by COE (1995) using the GENESIS numerical model.

The results of volumetric changes show that beach erosion generally occurred above the -2 m NGVD elevation and accretion occurred below the -2 m NGVD. Among all the beach renourishment projects, the amount of erosion that occurred above -2 m NGVD elevation was greater than the accretion in the area below -2 m NGVD.

Substantial beach erosion occurred above -2 m NGVD elevation in Sunny Isles, where a great amount of sand that was placed on the beach moved offshore. More substantial cross-shore sand movement occurred in Sunny Isles than that in other areas, as illustrated in Figure 2. This is due to the nearshore hardbottom in these other areas that have restricted sand movement in a cross-shore direction.

IMPACTS OF HARDBOTTOM ON SAND MOVEMENT

The relationship between the net longshore sediment transport rate and offshore location of hardbottom is presented in Figure 4. In general, the longshore sediment transport rate increases from north to south, as does the offshore

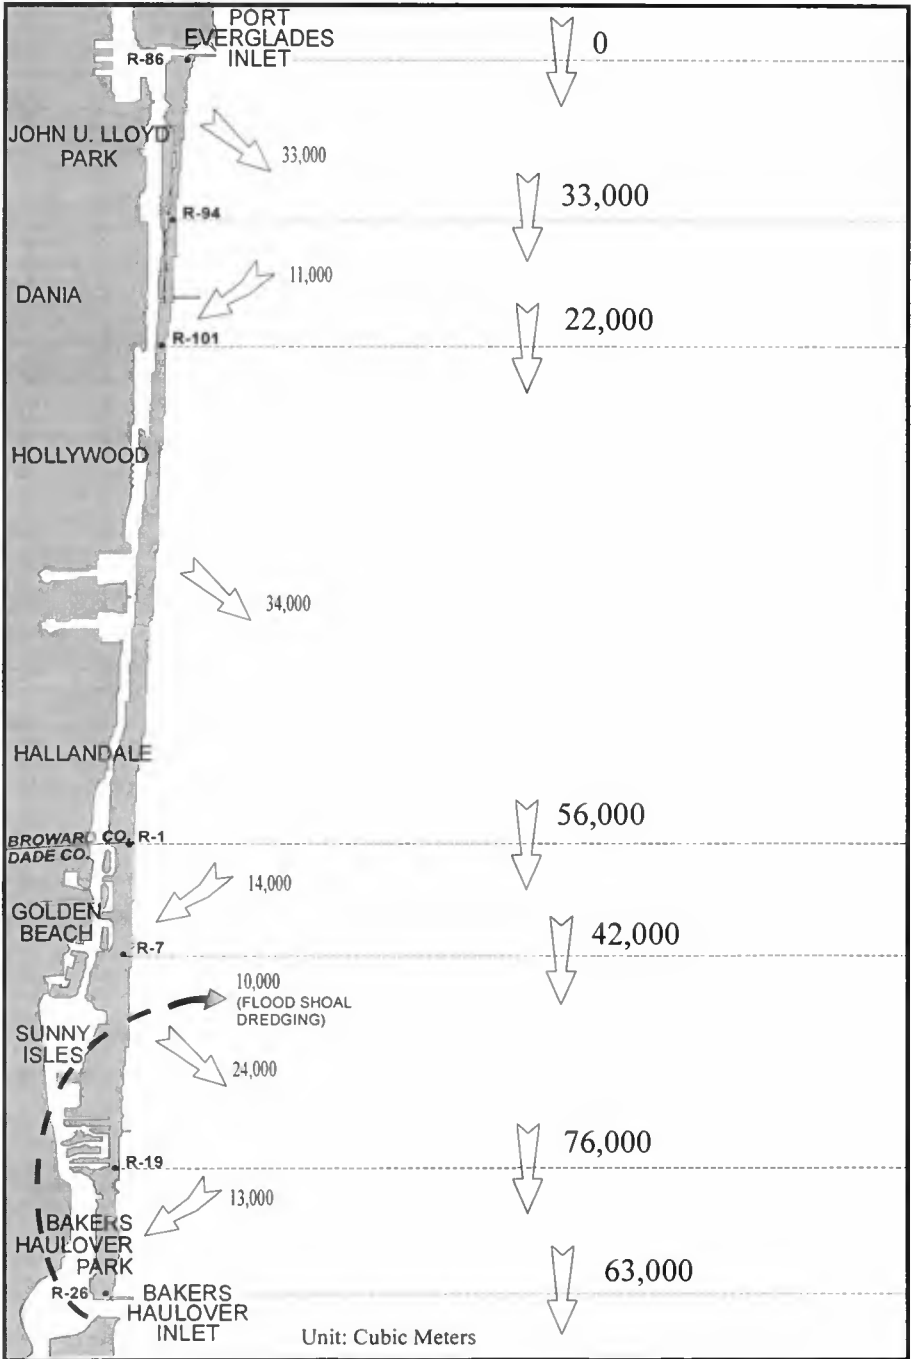

Figure 3. Regional Sediment Budget

Figure 4. Longshore Sediment Transport Rate vs. Offshore distance of Hardbottom

distance of hardbottom.

Offshore wave climates along this study area are generally similar (Stauble, 1993). Along the north end, nearshore hardbottom has reduced wave energy and resulted in less longshore sand movement. In the northern half of the region, the hardbottom is located between 120 m and 300 m offshore, while the net longshore sediment transport rate ranged from 22,000 to 33,000 cubic meters per year. However, the hardbottom was located further offshore along the southern half of the area with the offshore distance between 300 m to 1,000 m, while the annual net longshore sediment transport rate ranged from 42,000 to 76,000 cubic meters.

Due to the differential sediment transport rate, there is an inherent sediment supply deficit within the region that would result in beach erosion. This may explain historically the need for beach renourishment projects for a combined total of 14.8 km of shoreline within the region.

CONCLUSIONS

The results of this study indicate that the existence of nearshore hardbottom has a significant impact on longshore and cross-shore sand movement within the region between Port Everglades and Bakers Haulover Inlet. Specifically, the net longshore sediment transport rate within the study area increased from north to south as the nearshore hardbottom aligned further offshore at the southern part of the area. The annual net longshore sediment transport rate increased from 33,000 cubic meters at John U. Lloyd State Park to 63,000 cubic meters at Bakers Haulover Inlet with a maximum of 76,000 cubic meters at the area between Sunny Isles and Bakers Haulover Park.

The hardbottom remains relatively close to the shore at approximately 120 m offshore at John U. Lloyd, then increases to 300 m offshore at Dania, Hollywood, Hallandale and Golden Beach, 600 m offshore at Sunny Isles, and 1,000 m offshore at Bakers Haulover Park. It is evident that the longshore sediment transport rate increases as the protection of nearshore hardbottom is diminished. At the southern end of the region, the net longshore sediment rate is consistent with that predicted by the COE using the GENESIS numerical model without consideration of hardbottom effect. Hence, the offshore hardbottom at Sunny Isles and Bakers Haulover Park has little or no effect on reducing wave energy and subsequently on the sand movement.

The effect of nearshore hardbottom on cross-shore sand movement is also evident. By examining the volumetric changes above and below -2.0 m NGVD as illustrated in Figure 2, less active offshore sand movement was observed in the area from John U. Lloyd to Hallandale. It suggests that the nearshore hardbottom may act as a perch structure preventing sand from moving offshore.

The use of the GENESIS numerical model to predict shoreline changes and sediment transport, may not provide reasonable results in regions with extensive nearshore hardbottom, such as occurs in southeast Florida. The effects of these nearshore hardbottom areas on longshore and cross-shore sand movement should be considered in developing a sediment budget for inlet or beach management plans.

ACKNOWLEDGEMENT

Assistance from the Department of Natural Resources Protection (DNRP) in Broward County, Florida, in providing valuable data is greatly appreciated.

CHAPTER 282

IMPROVEMENT OF THE MOST ACCURATE LONGSHORE TRANSPORT FORMULA

by
J S Schoonees¹ and A K Theron¹

ABSTRACT

The ability to predict the longshore sediment transport rate accurately is essential for many coastal engineering applications. Because of the existence of a large number of existing longshore transport formulae, it is important to know which formula to use/apply. Thus, the most universally applicable formula was identified and tested against a comprehensive data set. This formula (Kamphuis formula) was also re-calibrated and guidance is given regarding its use.

INTRODUCTION

The ability to predict the time-averaged longshore sediment transport rate accurately is essential for the design of breakwaters at harbour entrances, navigation channels and their dredging requirements, beach improvement schemes incorporating groynes, detached breakwaters and beach fill as well as for the determination of the stability of inlets and estuary mouths.

Because of the large number of existing longshore transport formula it is important to know which formula to apply in practice. The aim of this paper is therefore to identify the most universally applicable formula and to test this formula against a comprehensive field data database. Finally, this formula is re-calibrated and guidance is given regarding its use.

The data considered in this paper are only for particulate (non-cohesive) sediment (including sand, gravel and shingle) being transported alongshore from the swash zone across the surf zone to deep water. Bulk (total rate calculated perpendicular to the shoreline) as well as local (at a specific point)

¹Research Engineers, CSIR, P O Box 320, Stellenbosch, 7599, South Africa

point) transport rates are considered. These bulk rates include both the bedload and the suspended load. Only field data are used because laboratory investigations often contain possible scale effects and/or use regular waves. Furthermore, the ultimate aim is to be able to predict longshore transport accurately in the *field* (Komar, 1988).

It is assumed that if a longshore transport formula is capable of predicting transport rates accurately for the wide ranging data sets described herein, it can be used with reasonable confidence at similar sites to determine the long-term longshore sediment transport budget if representative wave and other input parameter data are available. It would of course be preferable to have site-specific calibration data before calculating average long-term transport rates at a specific site.

Previous studies where longshore transport formulae have been tested against data include Swart (1976), Fleming *et al.* (1986) and Kamphuis *et al.* (1986). These studies entailed a relatively small number of formulae and limited data. Schoonees (1996) evaluated 52 formulae against an extensive data base. This paper reports some of the findings of the above-mentioned study, with specific regard to the Kamphuis formula (Kamphuis, 1991).

FIELD DATA ANALYSIS

Schoonees and Theron (1993) compiled and reviewed almost all the available field data on longshore transport (as recorded up to 1993).

The data were collected at a wide variety of sites around the world, yielding a large number of data-points, of which 273 points give bulk transport rates. (This is considerably more than the 41 data points used in the Shore Protection Manual by US Army, Corps of Engineers, 1984). Included in the database are also 184 points which give local transport rates.

A point rating system was devised whereby the quality of the data could be assessed. The recording method and the accuracy thereof as well as the representativeness of the data were taken into account. It was found that this evaluation was done reasonably objectively and consistently (Schoonees and Theron, 1993).

According to this evaluation, the data sets were assigned to three categories, namely, the lower, middle and higher quality categories. Most of the data sets fell in the middle category which exhibited a very gradual increase in the overall accuracy of the data within this category. Distinguishing between short- and long-term bulk transport data yielded similar trends in the accuracy of the data. The highest score achieved in the data evaluation was only 71%, thus reflecting the difficulty of measuring longshore transport accurately.

EVALUATION OF LONGSHORE TRANSPORT FORMULAE

The method used in this study to evaluate the longshore transport formulae, was to compare the predicted longshore transport rates to the measured rates and to calculate the relative standard error of estimate (σ). (For a definition of σ , see Schoonees and Theron (1994)). The lower σ is, the better the predictions by the particular formula. In addition the residuals (e_i = measured transport rate - predicted rate) and the distribution of the discrepancy ratio (r_d = predicted/measured rate) were also determined. (The residuals were plotted against the predicted rates to check whether there are systematic trends in the residuals - these are not shown here (Schoonees, 1996)). The longshore transport formulae were also tested under as many different conditions and at as many sites as possible.

From the above-mentioned field data database, Data Set 1 containing 123 points was extracted (see Schoonees and Theron, 1994 for a full description of Data Set 1). In Data Set 1 all the parameters required for testing the transport formulae are available. This same data set was used to evaluate existing longshore transport formulae as well as a newly derived formula (Schoonees, 1996) based on the applied wave power concept.

It is important to note that the data ranges of Data Set 1 are:

0,058	< H_{bs} (significant breaker height, m)	< 3,400
2,32	< T_p (peak wave period, s)	< 16,60
0,30	< θ_b (breaking wave angle, °)	< 35,00
0,007 (=1/143)	< beach slope	< 0,138 (=1/7,2)
0,154	< D_{50} (median grain size, mm)	< 15,000
600	< S (longshore transport rate, m ³ /year)	< 14 793 000

From the above values it is clear that the data ranges of this data set are quite wide. Most conditions encountered on natural beaches are covered and the data were collected on beaches from a variety of sites from around the world. These factors give credibility to the conclusions drawn in this comparison of predicted versus measured transport rates.

In total, 52 different longshore transport formulae were evaluated (Schoonees, 1996). These formulae were classified into different categories with regard to the theories on which they are based. The following three formulae were found to be the most accurate as tested against Data Set 1:

Order of accuracy	Name of the formula	Relative standard error of estimate (σ)	Category
1	Kamphuis (1991)	0,393	Dimensional analysis
2	Van Hijum, Pilarczyk and Chadwick (1989)	0,417	Energetics (energy flux)
3	Van der Meer (1990)	0,447	Empirical

These formulae are all bulk (total rate) as opposed to detailed predictors. Figures 1, 2 and 3 illustrate the fit of the predicted transport rates against the measured rates (log-log scales).

The formulae were also ranked according to the highest percentage of discrepancy ratios (r_d) between 0,5 and 2 (i.e. under or over prediction by a factor of 2; $r_d = 1$ indicates perfect agreement). A similar ranking of the "best" five formulae was found. However, it was found that σ provides a better way to judge the accuracy of a formula than using the percentage of r_d between 0,5 and 2. This is because, when applying a transport formula to determine a longshore transport budget at a site, a single badly predicted transport rate can distort the calculated budget greatly. At the same time, however, the above-mentioned percentage of r_d can still be very high compared to σ which would be affected greatly by a single badly predicted rate. Therefore σ is a better yardstick.

Dimensional analysis incorporating all relevant variables ensured that the Kamphuis formula contains the most important parameters. The three top formulae (Kamphuis; Van Hijum, Pilarczyk and Chadwick and Van der Meer) are relatively simple. These "simpler" methods performed well probably because a lower degree of inaccuracy is or can be introduced by having fewer (but all the most important) parameters. It is very difficult to acquire accurate input data; and the more parameters incorporated in a formula, the more input data is required (thereby potentially increasing the noise).

It is common practice to compare the predictions from different longshore transport formulae when computing the annual longshore transport regime at a site. Swart and Fleming (1980) advocated the use of a so-called package deal approach. In this approach, the highest and lowest transport rates predicted by six formulae were ignored and the median of the remaining values was determined. The question then remains whether better results can be achieved by means of this or a related method. Three approaches were tried

(Schoonees, 1996). Firstly, by considering the median of the predictions by the five best formulae; secondly, by determining the mean of the three middle values after discarding the highest and lowest predictions; and thirdly, by computing a weighted mean transport of the five predictions. The variation in the transport rates predicted by the five best formulae was investigated. It was found (Schoonees, 1996) that these predictions are reasonably consistent; that is, the individual formulae do not yield excessive outliers. It can therefore be concluded that none of the package deal approaches yield better answers than the best formula (the Kamphuis method) and as such, are not worth pursuing if the above-mentioned five best formulae are used. The reason for this probably lies in the consistency (reliability) of the five best formulae.

RECALIBRATION OF THE KAMPHUIS FORMULA

The Kamphuis formula can be written as follows:

$$\begin{aligned} S &= (31\ 557\ 600.1.3.10^{-3}) x_{Kamphuis} \\ &= 41\ 024,88 x_{Kamphuis} \text{ (m}^3/\text{yr)} \end{aligned} \quad (1)$$

$$\begin{aligned} x_{Kamphuis} = & \frac{1}{(1 - \rho) \rho_s} \cdot (\rho / T_p) L_o^{1,25} H_{bs}^2 (\tan \alpha_k)^{0,75} \\ & \cdot (1/D_{50})^{0,25} (\sin 2\theta_b)^{0,6} \end{aligned} \quad (2)$$

where ρ = porosity
 ρ_s = density of the sediment grains
 ρ = density of sea water
 L_o = deep-water wavelength
 $\tan \alpha_k$ = beach slope to the breaker line

See Kamphuis (1991) for a more comprehensive definition of all the parameters.

Equation (1), the original Kamphuis formula, is plotted *on linear scales* in Figure 4a and b. Note that Figure 4b shows the detail of Figure 4a for $x_{Kamphuis}$ values up to 80 (instead of 200). The 80%, 90% and 95% confidence intervals for the predicted responses of the original Kamphuis formula are also shown in Figures 4a and b. Despite the fact that the Kamphuis formula fares the best of the 52 formulae tested, it is immediately apparent that the confidence intervals are very wide. For example, at the 80% confidence level, the predicted transport rate for $x_{Kamphuis} = 8,7$ varies between -1 290 000 m³/year and + 2 004 000 m³/year (predicted rate = +357 000 m³/year) - Figure 4b. The coefficient of determination (R^2) is 0,284.

Illustrated in Figure 5 is the best-fit straight line through all the data (called S_{Kamphuis} recalibrated, 1):

$$S = 88\,248 + 61\,892 x_{\text{Kamphuis}} \text{ (m}^3\text{/year)} \quad (3)$$

If Equation (3) is used, it is evident that the lowest transport rate that can be predicted, is 88 248 m³/year, which is when $x_{\text{Kamphuis}} = 0$. This is clearly unacceptable, because the transport rate must be zero if $x_{\text{Kamphuis}} = 0$. Furthermore, it can be seen from Figure 4a that there are three main outliers (which fall beyond the 95% confidence limit) and that Equation (3) fits the higher transport rates better than the original Kamphuis formula. Therefore, disregarding the three main outliers and fitting the line through the origin, the following equation is found:

$$S = 75\,549 x_{\text{Kamphuis}} \text{ (m}^3\text{/year)} \quad (4)$$

This relationship, S_{Kamphuis} recalibrated 2, is shown in Figure 5a and b (the latter Figure 5b again presents the detail of Figure 5a). Although this formula fits the high transport rates well, it over predicts significantly for x_{Kamphuis} values below 10 (Figure 5b). This is caused by two influential points where transport rates higher than 3×10^6 m³/year were measured (Figures 5a and b). (Remember that the three main outliers, although shown, have not been used in this regression).

To eliminate this problem all the data points (123) were again considered to yield the third regression line, the S_{Kamphuis} recalibrated, 3:

$$S = 63\,433 x_{\text{Kamphuis}} \text{ (m}^3\text{/year)} \quad (5)$$

This formula fits the data reasonably well over the whole range (Figures 5a and b). It gives virtually the same answers at high x_{Kamphuis} values than the first recalibrated formula Equation (3). It also fits the data at lower transport rates quite well. R^2 is 0,620 and thus Equation (5) explains 62% of the variance in the data (which is a 118% improvement compared with Equation (1)). However, the standard error of estimate (σ) for this formulation is 0,405, which is slightly poorer than the 0,393 of the original Kamphuis equation. The reasons for this apparent contradiction are:

- The least squares approach (Equations (3), (4) and (5)) minimizes $\sum (S_{m,i} - S_{p,i})^2$ while the standard error of estimate (σ) uses $(\log S_{p,i} - \log S_{m,i})^2$. (Subscripts m and p denote "measured" and "predicted" respectively while i is the number of the data point).
- The effect of a few data points with high transport rates act as influential points in the least squares approach. On the other hand, the number of data points at low transport rates play an important role in the value of the standard error of estimate (σ).

To investigate the effect of such low rates on the standard error of estimate, certain data points below a cut-off transport rate were temporarily disregarded and σ re-calculated. The result was the following:

Cut-off measured transport rate (m ³ /year)	Number of data points	σ for $S = 63433 x_{\text{Kamphuis}}$ (Equation 5)	σ for the original Kamphuis formula (Equation 1)
0	123	0,405	0,393
5 000	115	0,392	0,393
10 000	106	0,368	0,380
25 000	103	0,365	0,383
50 000	87	0,324	0,377
100 000	68	0,299	0,374

These values have been plotted in Figure 6. It is clear from the above table that except when very low transport rates of less than 5 000 m³/year are included, Equation (5) is superior to the original Kamphuis formulation. Figure 6 shows that the original Kamphuis formula is relatively insensitive to the cut-off transport rate. On the other hand, the standard error of estimate decreases significantly (to only 0,299 compared to 0,374 of the original formula, which is a 20% improvement) for Equation (5), if the cut-off transport rate increases. If a cut-off rate of 50 000 m³/year is applied, σ reduces from 0,377 to 0,324, a 14% improvement. This finding is important because relatively few storm conditions at any site usually contribute the major part of the longshore sediment transport budget. It is therefore important that the higher transport rates are predicted accurately.

In order to obtain an indication of which wave conditions would cause such cut-off transport rates, the following typical values were chosen:

$T_p = 10s$, $\theta_b = 2^\circ$, $D_{50} = 0,3 \text{ mm}$ and $\tan \alpha = 1/25 (= 0,04)$. It was also assumed that these wave conditions will occur throughout the year.

Using the *original* Kamphuis formula, the longshore transport was then computed for a range of wave heights:

H_{bs} (m)	Longshore transport rate ($S_{Kamphuis}$) ($m^3/year$)
0,1	2 007
0,3	18 067
0,5	50 187
0,7	98 366

For this particular (typical) case, it is clear that relatively low wave heights of about 0,5 m and 0,7 m will already cause transport rates of about 50 000 $m^3/year$ and 100 000 $m^3/year$ respectively. For these cut-off rates, the standard errors of estimate are 0,299 and 0,324 respectively (Figure 6). Equation (5) is therefore judged to be "good".

Instead of using the least squares approach, the question may also be asked: What value of K will cause the minimum standard error of estimate (σ) when using *all* the data points? That is, K in:

$$S = Kx_{Kamphuis} (m^3/year) \quad (6)$$

Computations with different K values yielded the following:

K	σ
30 000	0,438
41 025 (Equation (1))	0,393
45 000	0,388
48 000	0,387
49 000	0,387
50 000	0,387
55 000	0,391
64 433 (Equation (5))	0,405
70 000	0,420

These data have been plotted in Figure 7. From this figure it is evident that the minimum standard error of estimate(s) is 0,387. It can also be seen that σ is not very sensitive with regard to the value of K near the turning point: $\sigma = 0,387$ even if K varies from 48 000 to 50 000. Taking the accuracy of predicted transport rates during storms into account, the preferred (rounded off) equation is:

$$\begin{aligned} S &= 50\,000 \times x_{\text{Kamphuis}} \text{ (m}^3\text{/year)} & (7) \\ \text{with } R^2 &= 0,397 \end{aligned}$$

FINAL RECOMMENDATIONS

The least squares as well as the minimum standard error of estimate approaches were used to recalibrate the Kamphuis formula, yielding Equations (5) and (7) respectively. Finally the recommended procedure for calculating longshore sediment transport is as follows:

For obtaining bulk longshore transport rates, it is recommended that **Equation (5)** be applied at sites where the significant wave heights normally exceed say, 0,3 m and where the sediment grain size is usually less than 1 mm; that is, at partially protected and exposed sites (i.e. relatively high transport rates). Only at sites where very calm conditions prevail and/or where the sediment is coarse, is **Equation (7)** expected to yield better answers. The considerably higher R^2 for Equation (5) compared with the corresponding value for Equation (7) supports the preference for Equation (5). A significant improvement of 118% according to R^2 and up to 20% in σ in the predicted transport rates was obtained.

CHAPTER 283

Cross-shore Structure of Longshore Currents during Duck94

Falk Feddersen¹, R.T. Guza², Steve Elgar³, and
T.H.C Herbers⁴

Abstract

The cross-shore structure of the mean longshore current on a barred beach is investigated with observations from the Duck94 field experiment. Maxima of the hourly-averaged longshore current are most frequently located either slightly inshore of the bar crest or near the shoreline. At low tide the longshore current maxima are located closer to the bar crest, and the current is stronger and narrower than at high tide. The tidal cross-shore displacement of the longshore current maximum is qualitatively consistent with the observed radiation stress, S_{xy} , although the maximum currents are displaced shoreward of the maximum S_{xy} gradients at both high and low tide. This spatial lag suggests that some mechanism (such as wave rollers) delays the transfer of momentum from waves to the mean flow. Bathymetric longshore inhomogeneities may also affect the cross-shore structure of the longshore current.

Introduction

Selected observations from the DELILAH field experiment at Duck N.C. suggest that the maximum of the mean longshore current, \bar{v} , occurs between the crest of the sand bar and the trough between the bar and the shoreline (Figures 8-11 of *Church and Thornton*, (1993)), and that longshore current variability is coherent with the approximately 1 m semidiurnal tidal fluctuations in water level (*Thornton and Kim*, 1993). However, the generality of these results over the wide range of wave (*Long*, 1996), wind, and bathymetric (e.g. pronounced sandbars and alongshore inhomogeneities (*Lippmann and Holman*, 1990; *Gallagher*, 1996)) conditions observed at Duck is unknown. Here the cross-shore structure of \bar{v} is further explored with observations from the Duck94 field experiment.

Duck94 Observations

The experiment site is located on a long straight barrier island exposed to the Atlantic Ocean. Directional properties of sea and swell (including the wave radiation stresses, S_{xy}) were estimated with data from a 2-dimensional array of 15 bottom-pressure sensors located in 8 m water depth operated by the Field Research Facility (FRF) of the U.S. Army Corps of Engineers (Long, 1996). Longshore currents, wave-induced bottom pressures, and the location of the sea floor were observed with colocated bidirectional electromagnetic current meters, pressure sensors, and sonar altimeters (Gallagher *et al.*, 1996) deployed on a cross-shore transect extending 750 m from the shoreline to 8 m water depth (Figure 1). The sensors were sampled at 2 Hz for approximately two months. At each pressure sensor-current meter pair, hourly values of S_{xy} were crudely estimated using linear theory.

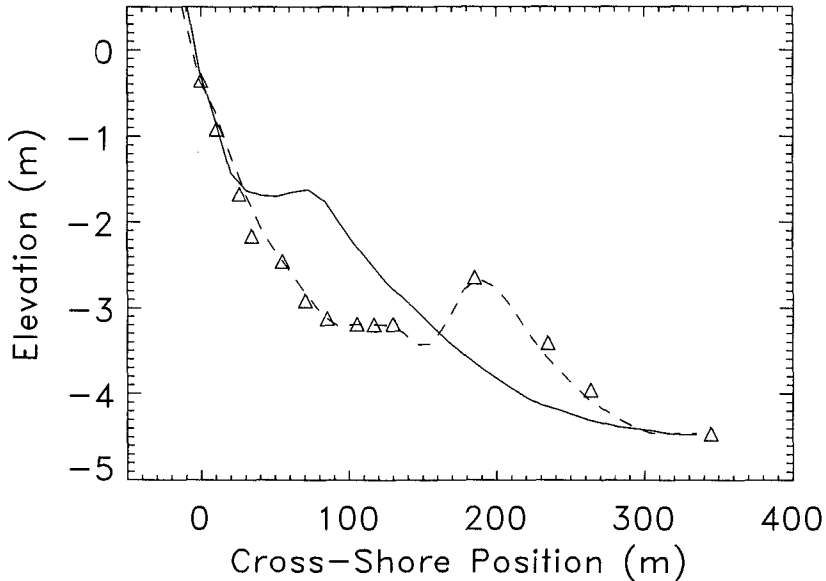

Figure 1. The cross-shore location of current meters (Δ), and measured bathymetry relative to sea level on August 25 (solid line) and October 26 (dashed line). An additional current meter at cross-shore location 749 m in 8 m water depth is not shown.

Conditions during Duck94 are shown in Figure 2. In 8 m water depth, the significant wave height (H_{sig}) ranged between 0.2 m to 4 m and the mean wave angle between $\pm 50^\circ$, so that the total (e.g. frequency-integrated) incident wave radiation stress S_{xy}/ρ (where ρ is the water density) in 8 m depth ranged from -0.7 to 0.5 m^3/s^2 (figures 2a-c). The mean (e.g. centroidal) wave frequency ranged from about 0.08 to 0.2 Hz (not shown). Maximum mean longshore currents (in each hour-long record, \bar{v}_{max}) ranged from 0.1 to 1.4 m/s (Figure 2d). The bar crest, originally located 80 m from the mean shoreline, gradually migrated 120 m offshore (Figure 2e, after *Gallagher*, 1996). Fluctuations in mean water level were about 1 m at spring tide. The slope of the beach foreshore is about 1/10 (Figure 1), so tidal fluctuations in the location of the mean shoreline are about 10 m. Tidal currents in depths less than 8 m are less than 0.03 m/s (S. Lentz, personal communication 1996).

Results

The sand bar is expected to strongly effect the longshore current, so a normalized cross-shore coordinate is defined as,

$$x' = \frac{x - x_{02}}{x_{bar} - x_{02}}$$

where x is the cross-shore coordinate, x_{bar} is the cross-shore location of the bar crest, and x_{02} is the cross-shore location of the most nearshore sensor uv02. The distance from sensor uv02 to the mean shoreline was typically less than 10 m. Depths at uv02 ($x'=0$) ranged from about 0.2 to 1.2 m. In this coordinate system, the bar crest is always located at $x'=1$, but the location of the trough is not constant because of variability in the shape of the cross-shore seafloor profile (e.g. Figure 1).

The location of the longshore current maximum, \bar{v}_{max} , is broadly distributed and roughly bimodal in the normalized coordinate system (1) (Figure 3, after *Gallagher*, 1996). Maxima most often occur either slightly inshore of the bar crest ($0.65 \leq x' \leq 1.2$) or near the shoreline ($x' < 0.3$). Rarely does \bar{v}_{max} occur seaward of the bar crest, even when large waves were breaking well seaward of the bar ($x' > 2$). The few maxima located well seaward of the bar crest typically are weak ($\bar{v}_{max} \sim 0.3 - 0.4$ m/s) and approximately correspond to times of strong buoyancy driven flows (Rennie and Largier, personal communication 1996). The stronger longshore currents ($\bar{v}_{max} > 0.8$ m/s) are associated with large offshore S_{xy} (Figures 2c and 2d) and occur near the bar crest ($0.65 < x' < 1.2$). Weaker maxima (0.25 - 0.7 m/s) occur typically near the shoreline ($0 < x' < 0.3$) or near the bar crest, with few maxima in the region in between. Many of the larger \bar{v}_{max} (0.4 - 0.6 m/s) in the region $0 < x' < 0.3$ occur after the sandbar migrated far offshore in mid-October (Figure 2e).

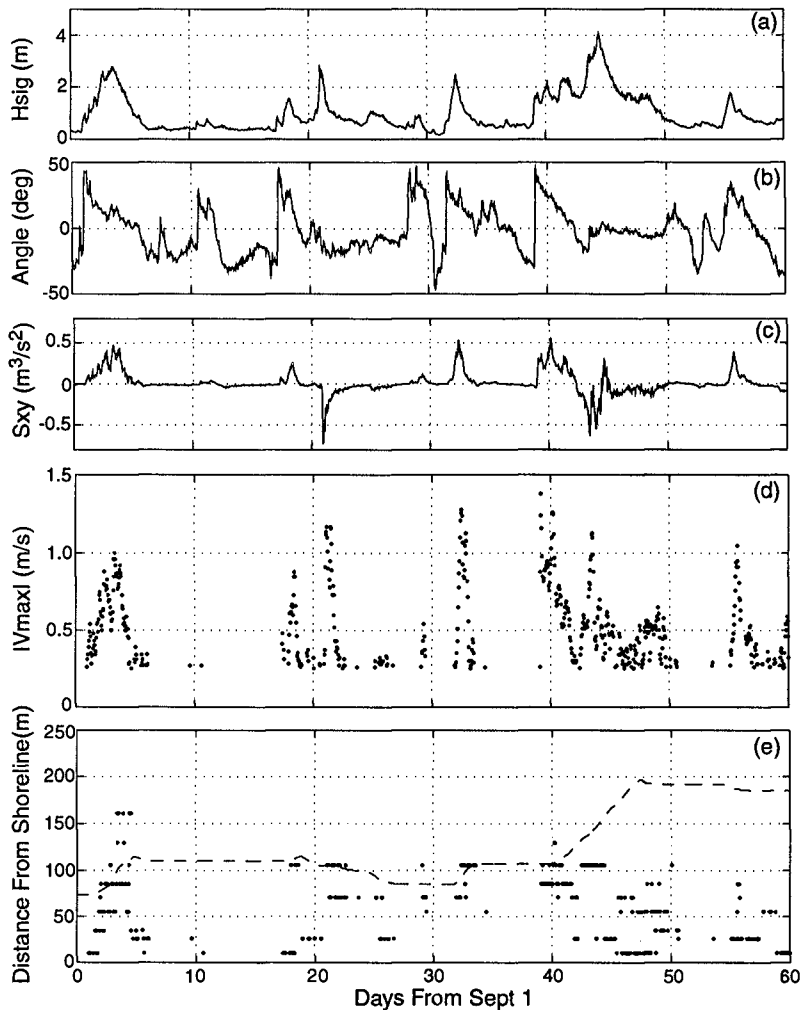

Figure 2. Hourly values of (a) significant wave height H_{sig} in 8 m depth (b) deviation of the mean incident wave angle from shore normal (positive angles correspond to waves from the northern quadrant) (c) S_{xy}/ρ in 8 m depth (d) maximum hour-averaged longshore current \bar{v}_{max} (e) bar crest location (dashed) and the cross-shore location of \bar{v}_{max} . \bar{v}_{max} is plotted only if there were at least five active current meters and $\bar{v}_{max} \geq 0.25$ m/s. Out of 1464 possible values, 572 hourly maxima pass these criteria. The few maxima occurring more than 250 m from shore are not shown in (e).

Figure 3. Magnitude of the maximum of the hourly averaged longshore current in normalized cross-shore coordinate, x' (1). the upper panel shows the entire cross-shore region. The region $0 < x' < 2$ is enlarged in the lower panel.

Tides dominate the variability of the local water depth, and thus affect wave shoaling, breaking, and the longshore current. When \bar{v}_{max} is near the bar crest ($0.65 \leq x' \leq 1.2$), the location of \bar{v}_{max} is tidally modulated (Figure 4). At high tide, \bar{v}_{max} is rarely located seaward of $x' = 0.8$, whereas at low tide \bar{v}_{max} is near $x' = 1$. Tidal effects on the location of \bar{v}_{max} are smaller when \bar{v}_{max} is near the shoreline ($x' < 0.3$). Tidal differences in the cross-shore structure of \bar{v} are further illustrated in Figure 5. The current profiles at low tide exhibit a number of similar features; \bar{v}_{max} is located close to $x' = 1$, and the current falls off rapidly shoreward of the maximum. Close to the beach, \bar{v} is approximately 1/4 of \bar{v}_{max} . In contrast, at high tide \bar{v}_{max} is farther shoreward (around $x' = 0.7$, consistent with Figure 4) and weaker. The current profile is broader, and near the shoreline \bar{v} is about 1/2-2/3 of \bar{v}_{max} . The observed \bar{v} tidal variation is consistent with the phase relationships between \bar{v} and sea-level at tidal frequencies found by *Thornton and Kim* (1993). Wave-breaking induced gradients in significant wave heights are greater during low tide than high tide ($0.8 < x' < 1.5$ in Figure 6), resulting in smaller waves shoreward of the sandbar at low tide ($H_{sig} \sim 0.7$ m) relative to high tide ($H_{sig} \sim 1.0$ m).

The differences within the low (Figure 5a) and high (Figure 5b) tide cross-shore structure of \bar{v} are primarily owing to differences in the conditions over the two days spanned by the observations. The bar was relatively stationary moving 7 m, H_{sig} in 8 m depth ranged from 1 to 2 m (Figure 6), the mean incident wave angle from 15 to 45 degrees, and S_{xy}/ρ from 0.2 to 0.5 m³/s². Similar qualitative features in the tidal variation of \bar{v} were observed at other times when the longshore current was strong for several tidal cycles (e.g. Sept 2-5 and Oct 10-16).

The modeled tidal variation of H_{sig} and \bar{v} , for waves and bathymetry representative of Figures 5 and 6, are shown in Figure 7. The wave heights are modeled using *Church and Thornton* (1993), with free model parameters selected to best fit the observed wave heights. The qualitative features of the observed H_{sig} distributions (Figure 6) are reproduced by the model (Figure 7a), except close to the shoreline. The longshore current predictions are made using the modeled H_{sig} variation and observed (in 8 m depth) directional wave properties in the *Thornton and Guza* (1986) longshore current model. A drag coefficient of 0.015 results in similar magnitudes for the modeled (Figure 7b) and observed (Figure 5) currents. Similar to previous results (e.g. *Church and Thornton*, 1993 and others), the modeled longshore currents have the familiar problem of predicting a flow with two maxima, one seaward of the bar crest and one near the shoreline, with no flow in the bar trough. The modeled low and high tide maxima occur at $x' = 1.25$ and $x' = 1.1$ respectively, farther offshore than observed (Figure 5). In physical units, the displacement of the maximum is about 30 m.

Figure 4. Location and magnitude of \bar{v}_{max} , observed within about 1.5 hours of tidal extrema in normalized cross-shore coordinate. There are 157 low tide (+) and 108 high tide (o) values.

Two commonly given reasons (among many) for the model failure are: (1) There may be a spatial lag in the transfer of momentum from the waves to the mean flow, possibly associated with wave rollers (Svendsen, 1984; Dally and Brown, 1995; and many others). (2) Longshore inhomogeneities in the bathymetry and wave field may result in nonlinear terms or longshore pressure gradient terms in the longshore momentum equation (e.g. Putrevu et al., 1995). Some of the observations are consistent with the lag hypothesis, and there are other examples where alongshore inhomogeneities are likely dominant.

The cross-shore variation of S_{xy} for the successive low and high tide cases (Figure 5 and 6) is shown in Figure 8. At low tide, strong S_{xy} gradients are observed seaward of the bar ($1 \leq x' \leq 1.5$, Figure 8a), whereas shoreward of the bar crest, S_{xy} is relatively constant. The shoreward displacement of the observed longshore current maxima (Figure 5a) relative to strong S_{xy} gradients (Figure 8a) is consistent with a spatial lag in the transfer of momentum to the mean longshore current. At high tide, the region of strong S_{xy} gradients is

slightly seaward of the bar crest ($0.9 \leq x' \leq 1.25$, Figure 8b), and seaward of the location of \bar{v}_{max} ($x' \sim 0.7$) again indicating a spatial lag in the transfer of momentum to the mean flow. The tidal differences in the cross-shore structure of \bar{v} (i.e. the the broadening of \bar{v} at high tide, Figure 5) may be related to tidal variations in the lagging mechanism.

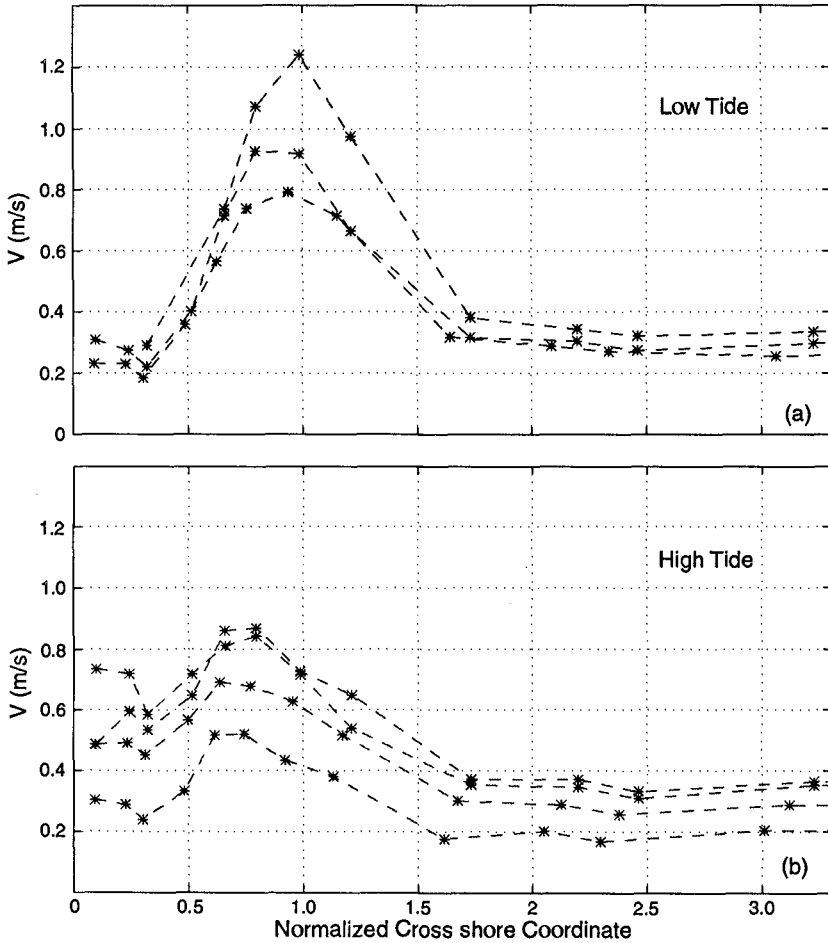

Figure 5. Mean longshore currents in the normalized cross-shore coordinate x' (1) during October 10 and 11. (a) 3 low tides (b) 4 high tides.

Figure 6. Significant wave height in the normalized cross-shore coordinate x' (1) during October 10 and 11. (a) 3 low tides (b) 4 high tides.

Figure 7. Modeled (a) significant wave heights (b) mean longshore currents (c) model bathymetry in normalized cross-shore coordinate (1). Solid curves represent low tide and dashed curves are high tide. The incident wave parameters are representative of conditions in Figure 5 and 6: $H_{sig} = 1.5$ m and $\theta = 25^\circ$.

An example of longshore currents likely affected by longshore bathymetric inhomogeneities is shown in Figure 9. Although the waves were energetic ($H_{sig} = 3$ m in 8 m depth), they were nearly normally incident (the mean incident wave angle in 8 m depth was 2°) and thus S_{xy} in 8 m depth was small (about 0.1 of S_{xy} with less energetic but more obliquely incident waves in Figure 8). The observations suggest that S_{xy} and S_{xy} gradients are small everywhere (Figure 9b), and that wave breaking began ($x > 200$ m, Figure 9a) far

Figure 8. S_{xy}/ρ for the cases (October 10 and 11) shown in Figures 5 and 6 in the normalized cross-shore coordinate $x'(1)$. (a) low tide (b) high tide. The accuracy of S_{xy} estimates is limited because of uncertainties in current meter response and orientation, and because errors in linear theory may be significant in the surfzone. Only two low tide profiles are shown because of unavailable data.

offshore of the location of \bar{v}_{max} ($x \approx 25$ m, Figure 9c). The observed longshore current jet (Figure 9c) near the shoreline is inconsistent with model predictions (based on *Thornton and Guza, 1986*) of negligibly small currents (not shown). Time elapsed video images (R.A. Holman, personal communication, 1996) suggest that the bathymetry was longshore inhomogeneous. Three dimensional bathymetric surveys were not available because of the stormy conditions, however, the first post-storm survey (October 20) did reveal strong longshore inhomogeneity. *Sancho et al. (1996)* demonstrated that this inhomogeneous bathymetry can cause pressure gradients and nonlinear terms to become important in the longshore momentum balance.

Conclusions

Observations spanning a wide range of bathymetric and wave conditions show that the probability distribution of cross-shore location of longshore current maxima is bimodal. Maxima typically occur near the crest of the sand bar or near the shoreline (Figure 3). At both high and low tide, the observed currents (Figure 5) are qualitatively consistent with the observed S_{xy} (Figure 8), although with a spatial lag, perhaps associated with wave rollers. The 1 m tidal fluctuations in sea level affect the cross-shore structure of the longshore current (Figure 4). At low tide, the current jet is stronger, narrower, and located closer to the bar crest than at high tide (Figure 5). The reason for the tidal changes in the longshore current structure is unknown, however tidal changes in the wave forcing are surely important. Clearly more quantitative work is necessary. The observed variation in the cross-shore structure of the longshore current across a tidal cycle is a robust feature (see also Figure 12 of *Thornton and Kim*, (1993)), and one step in the verification of a roller model would be to reproduce qualitatively the observed tidal variation of the longshore current. Finally, although the magnitude of the effects of longshore bathymetric inhomogeneities is not known, there are cases where they dominate the longshore current (Figure 9).

Acknowledgments

The array of current meters, sonar altimeters, and pressure sensors was deployed and maintained by staff from the Center for Coastal Studies. Britt Raubenheimer and Edith Gallagher helped collect the data. Excellent logistical support was provided by the FRF. We thank Edith Gallagher for providing sonar-altimeter based depth profiles and Rob Holman for providing the video images. This research was supported by ONR and the NSF CoOP program. Falk Feddersen received trainee support from the National Sea Grant College Program, NOAA, U.S. Department of Commerce.

CHAPTER 284

THREE-DIMENSIONAL HYDRODYNAMICS ON A BARRED BEACH

Tae-Myoung Oh¹ and Robert G. Dean²

ABSTRACT

Results are described from fixed bed wave tank tests to examine the generation and existence of three-dimensional flows on a barred beach. All tests were carried out with the use of two-dimensional and three-dimensional bar, which represented periodic forms parallel to the coast superimposed on a linear sloping beach. For these tests, wave heights and wave direction fields within and adjacent to the surf zone were documented to calculate the wave-induced horizontal torque based on mean vorticity and momentum equations. The circulation pattern clearly demonstrated that rip currents were stable on a three-dimensionally barred beach. It was found that the individual component including the depth gradients in the longshore direction, i.e., the effects of the bar morphology, tended to stabilize the bar-induced cellular circulation on the three-dimensional beach morphology although increased momentum fluxes of waves in the area with opposing currents induced by the bar tended to exert a counter force against them. It appeared that the mass transport over the more elevated portions of the bar tended to return to offshore through the deeper portions of the bar, where the depth gradients in the longshore direction existed. The cause is believed to be due to the greater hydraulic efficiency of flows through deeper portions of the profile.

INTRODUCTION

There are several proposed mechanisms to explain the presence of three-dimensional forms that are fairly regular and generally associated with rip currents, which range from the relatively simple to the complex, including: (1) Instability between the hydrodynamics and sedimentary systems (Hino, 1974; Deigaard, 1990), (2) Interaction between waves and currents (Dalrymple and Losano, 1978), (3) Interaction between synchronous edge waves and incident waves (Bowen, 1969; Bowen and Inman, 1969), (4) Intersecting wave trains (Dalrymple, 1975), and (5) Structural controls by natural and/or constructed features (Gourlay, 1976; Wind and Vreugdenhil, 1986). Some of those mechanisms (Hino, 1974; Dalrymple and Losano, 1978) contended that rip currents in nature could be explained by the reinforcement of three-dimensional flows over two-dimensional morphology. However, previous laboratory investigations (Dean and Oh, 1994) suggested that rip currents were neither self-reinforcing nor stable on two-dimensional topography due to the stabilizing wave-induced torque associated with the increased momentum fluxes in the vicinity of seaward mass return flow; hence, substantial rip currents could not occur without the presence of a rip channel.

This paper comprises the results of a series of fixed bed wave tank experiments conducted on a barred beach to examine the effects of three-dimensional bar morphology on the tendency for cellular circulation inside the surf zone, thus discussing the questions including: (1) Rip currents of significant strength can form on a barred beach, and (2) Whether the interaction between rips and incident waves causes increased or decreased wave heights at the location of the rip current with the presence of the rip channel.

Before presenting the experiments, it is helpful to discuss theoretical background governing three-dimensional circulation inside the surf zone. Primary emphasis is focused on the driving forces (torques) of the three-dimensional flows rather than the details of the hydrodynamics.

DRIVING FORCES OF THE THREE-DIMENSIONAL FLOWS

Consider a Cartesian coordinate system, where the y -axis is located at the still water line and the x -axis is directed seaward. Assuming horizontal flows, wave-induced circulation inside the surf zone is usually formulated based on depth-integrated, time-averaged continuity and momentum equations (Phillips, 1977). After neglecting the lateral shear stress coupling,

Continuity Equation

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}[U(h + \bar{\eta})] + \frac{\partial}{\partial y}[V(h + \bar{\eta})] = 0 \quad (1)$$

Momentum Equations

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} = -g \frac{\partial \bar{\eta}}{\partial x} + D_x + B_x \quad (2)$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} = -g \frac{\partial \bar{\eta}}{\partial y} + D_y + B_y \quad (3)$$

where, t is the time, (U, V) the mean horizontal velocity components in the x - and y -direction respectively, $\bar{\eta}$ the mean water level measured from the still water level, h the still water depth, g the gravitational acceleration, and (B_x, B_y) are the shear stress components. The driving force components (D_x, D_y) are expressed in terms of the gradients of the radiation stresses.

$$D_x = -\frac{1}{\rho(h + \bar{\eta})} \left(\frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} \right) \quad (4)$$

$$D_y = -\frac{1}{\rho(h + \bar{\eta})} \left(\frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right) \quad (5)$$

in which,

$$S_{xx} = E[n(\cos^2 \theta + 1) - \frac{1}{2}] \quad (6)$$

$$S_{xy} = E n \sin \theta \cos \theta \quad (7)$$

$$S_{yy} = E[n(\sin^2 \theta + 1) - \frac{1}{2}] \quad (8)$$

where, E is the total wave energy per unit surface area and n is the ratio of the group velocity C_g to the wave celerity C .

Mean Vorticity Equations

Mean vorticity equation is obtained by cross-differentiating Equations (2) and (3) such that the set-up terms are eliminated.

$$\frac{\partial \bar{\omega}}{\partial t} + \frac{\partial}{\partial x}(U\bar{\omega}) + \frac{\partial}{\partial y}(V\bar{\omega}) = \frac{\partial D_y}{\partial x} - \frac{\partial D_x}{\partial y} + \frac{\partial B_y}{\partial x} - \frac{\partial B_x}{\partial y} \quad (9)$$

where, the mean vorticity, $\bar{\omega}$, is defined as

$$\bar{\omega} \equiv \frac{\partial V}{\partial x} - \frac{\partial U}{\partial y} \quad (10)$$

Sometimes, this time-averaged and depth-integrated vorticity equation is helpful since the contribution of set-up term to wave-induced current system is considered only indirectly through the total mean water depth $(h + \bar{\eta})$, thus making it possible to neglect $\bar{\eta}$ by assuming that $\bar{\eta}$ is small relative to the still water depth.

Vorticity Driving Torque based on Mean Vorticity Equation

The local vorticity driving torque, T_V , can be obtained directly from the mean vorticity equation presented in Equation (9):

$$T_V = \frac{\partial D_y}{\partial x} - \frac{\partial D_x}{\partial y} \tag{11}$$

in which D_x and D_y are given in Equations (4) and (5). Since D_x and D_y include the contributions by S_{xx} , S_{yy} and S_{xy} , the local torque T_V can also be expressed as the sum of three contributions: (1) $(T_V)_1$ by S_{xx} , (2) $(T_V)_2$ by S_{yy} , and (3) $(T_V)_3$ by S_{xy} .

$$T_V = (T_V)_1 + (T_V)_2 + (T_V)_3 \tag{12}$$

where,

$$(T_V)_1 = -\frac{1}{\rho(h + \bar{\eta})^2} \frac{\partial(h + \bar{\eta})}{\partial y} \frac{\partial S_{xx}}{\partial x} + \frac{1}{\rho(h + \bar{\eta})} \frac{\partial^2 S_{xx}}{\partial x \partial y} \tag{13}$$

$$(T_V)_2 = \frac{1}{\rho(h + \bar{\eta})^2} \frac{\partial(h + \bar{\eta})}{\partial x} \frac{\partial S_{yy}}{\partial y} - \frac{1}{\rho(h + \bar{\eta})} \frac{\partial^2 S_{yy}}{\partial x \partial y} \tag{14}$$

$$(T_V)_3 = \frac{1}{\rho(h + \bar{\eta})^2} \left[\frac{\partial(h + \bar{\eta})}{\partial x} \frac{\partial S_{xy}}{\partial x} - \frac{\partial(h + \bar{\eta})}{\partial y} \frac{\partial S_{xy}}{\partial y} \right] - \frac{1}{\rho(h + \bar{\eta})} \left[\frac{\partial^2 S_{xy}}{\partial x^2} - \frac{\partial^2 S_{xy}}{\partial y^2} \right] \tag{15}$$

Assuming that waves encounter the coast with nearly normal incidence (i.e., $\theta \cong \pi$), and using the shallow water asymptotes ($n = 1$), then the radiation stress terms can be written as

$$\begin{aligned} S_{xx} &= \frac{3}{16} \rho g H^2 \\ S_{xy} &= \frac{1}{8} \rho g H^2 (\theta - \pi) \\ S_{yy} &= \frac{1}{16} \rho g H^2 \end{aligned} \tag{16}$$

Assuming further that $\bar{\eta}$ is small relative to still water depth, i.e., $(h + \bar{\eta}) \rightarrow h$ (this assumption will not be valid near the still water shoreline where $h = 0$), then vorticity driving torque components $(T_V)_1$, $(T_V)_2$ and $(T_V)_3$ can be written as follows:

$$(T_V)_1 = \frac{g}{16h} \left[-\frac{3}{h} \frac{\partial h}{\partial y} \frac{\partial H^2}{\partial x} + 3 \frac{\partial^2 H^2}{\partial x \partial y} \right] \quad (17)$$

$$(T_V)_2 = \frac{g}{16h} \left[\frac{1}{h} \frac{\partial h}{\partial x} \frac{\partial H^2}{\partial y} - \frac{\partial^2 H^2}{\partial x \partial y} \right] \quad (18)$$

$$(T_V)_3 = \frac{g(\theta - \pi)}{8h} \left[\frac{1}{h} \frac{\partial h}{\partial x} \frac{\partial H^2}{\partial x} - \left(\frac{\partial^2 H^2}{\partial x^2} - \frac{\partial^2 H^2}{\partial y^2} \right) \right] + \quad (19)$$

$$\frac{g}{8h} \left[\frac{1}{h} \frac{\partial h}{\partial x} H^2 \frac{\partial \theta}{\partial x} - H^2 \left(\frac{\partial^2 \theta}{\partial x^2} - \frac{\partial^2 \theta}{\partial y^2} \right) \right] - \frac{g}{4h} \left[\frac{\partial \theta}{\partial x} \frac{\partial H^2}{\partial x} - \frac{\partial \theta}{\partial y} \frac{\partial H^2}{\partial y} \right]$$

Hence, if the distributions of wave height and local wave directions are known, the local vorticity driving torque induced on the surf zone can be calculated. It should be noted here that the torque T_V has dimensions of $[1/sec^2]$, which is not actual dimensions of torque, $[\text{force} \times \text{length}]$.

Vorticity Driving Torque based on Momentum Equations

Another expression for the vorticity driving torque, T_M , can be obtained by integrating local torque about a reference point over the entire surf zone.

$$T_M = \iint \rho(h + \bar{\eta}) [(x - x_o)D_y - (y - y_o)D_x] dx dy \quad (20)$$

where, (x_o, y_o) represent the coordinate of the reference point about which the total driving torque is to be calculated. Here, T_M has dimensions of torque, $[\text{force} \times \text{length}]$.

Using the radiation stress expressions given in Equation (16) with the assumption that $\bar{\eta}$ is small, T_M also can be written as the sum of three contributions: (1) $(T_M)_1$ by S_{xx} , (2) $(T_M)_2$ by S_{yy} , and (3) $(T_M)_3$ by S_{xy} , as follows:

$$T_M = (T_M)_1 + (T_M)_2 + (T_M)_3 \quad (21)$$

where,

$$(T_M)_1 = \iint (y - y_o) \frac{\partial S_{xx}}{\partial x} dx dy = \frac{3\rho g}{16} \iint (y - y_o) \frac{\partial H^2}{\partial x} dx dy \quad (22)$$

$$(T_M)_2 = -\iint (x - x_o) \frac{\partial S_{yy}}{\partial y} dx dy = -\frac{\rho g}{16} \iint (x - x_o) \frac{\partial H^2}{\partial y} dx dy \quad (23)$$

$$(T_M)_3 = \iint [-(x - x_o) \frac{\partial S_{xy}}{\partial y} + (y - y_o) \frac{\partial S_{xy}}{\partial x}] dx dy \quad (24)$$

$$= \frac{\rho g}{8} \iint [(y - y_o) \frac{\partial \{H^2(\theta - \pi)\}}{\partial y} - (x - x_o) \frac{\partial \{H^2(\theta - \pi)\}}{\partial x}] dx dy$$

Hence, T_M also can be calculated if the distributions of the radiation stresses, i.e., the distributions of wave heights and wave incidence angle, are known.

EXPERIMENTS

All experiments were conducted in a wave tank of the Coastal and Oceanographic Engineering Laboratory of the University of Florida. This tank is approximately 20 m long, 1.5 m high and 0.6 m wide, and is equipped with a piston type wavemaker and has glass panels on both sides of the tank. The water depth was 0.40 m in the horizontal section of the tank. Two types of regular waves of 3 cm and 9 cm heights were used while the wave period was fixed at 1.43 sec during the experiments. The bathymetry was configured to represent a bar morphology by superimposing two-dimensional and three-dimensional wood bars parallel to the coast on a uniform slope of 1:20. The two-dimensional bar extended to the whole width of the tank, while the three-dimensional bar extended from one wall to two-thirds of the tank width. These bars were installed approximately at the surf line, which depends on wave height condition. All four tests (two waves and two bars) were carried out to document the wave heights and wave direction distribution within and adjacent to the surf zone. The details are described in Oh (1994).

Wave heights and direction fields were measured to document and interpret the interaction of the waves and bar-induced currents. Figures 1 and 2 present the isolines of wave heights in the presence of the three-dimensional bar for the small waves and for the large waves, respectively. For the small waves, as shown in Figure 1, wave crest lines were almost uniform in the longshore direction even in the presence of the three-dimensional bar, which implied that the return flow due to the three-dimensional bar was weak to modify the wave fields. It is seen from Figure 2 that waves were much higher in the vicinity of the seaward return flow than those near the bar area. Much higher waves appeared to be caused by increased return current induced by the three-dimensional bar. However, it should be noted that the breakerline was not significantly influenced by the return flow. [It was observed by Dean and Oh (1994) that the breakerline was significantly displaced seaward near the return current during the circulation tests with the jet present on a prismatic beach.] Uniform breakerline with the three-dimensional bar morphology appeared to be due to both relatively weak return current induced by the three-dimensional bar and deeper water depth at the return current area than the area over the bar, and it was agreed with the field observations by Sonu (1972).

RESULTS AND DISCUSSIONS

Vorticity Driving Torque based on Mean Vorticity Equation

Considering that waves encounters the coast with normal incidence ($\theta = \pi$), Equations (17), (18), and (19) can be expressed as the combinations of different individual components depending on the wave height gradients and water depth near the bar area, as follows:

Figure 1: Wave Height Distributions in the Presence of Three-Dimensional Bar when $H_o = 3\text{ cm}$. Wave heights are given in cm . A dark area represents the area covered by the three-dimensional bar. Note that wave fields are not greatly influenced by the return flow induced due to the presence of the three-dimensional bar, resulting in more or less uniform breakerline.

Figure 2: Wave Height Distributions in the Presence of Three-Dimensional Bar when $H_o = 9\text{ cm}$. Wave heights are given in cm . A dark area represents the area covered by the three-dimensional bar. Note that wave fields are substantially influenced by the return flow induced due to the presence of the three-dimensional bar. Note also almost uniform breakerline due to deeper water depth at the area of return flow than the area over the bar.

$$\begin{aligned}
 (T_V)_1 &= 3 (II - VI) \\
 (T_V)_2 &= I - II \\
 (T_V)_3 &= 0
 \end{aligned}
 \tag{25}$$

where,

$$I = \frac{g}{16h^2} \frac{\partial h}{\partial x} \frac{\partial H^2}{\partial y} \tag{26}$$

$$II = \frac{g}{16h} \frac{\partial^2 H^2}{\partial x \partial y} \tag{27}$$

$$VI = \frac{g}{16h^2} \frac{\partial h}{\partial y} \frac{\partial H^2}{\partial x} \tag{28}$$

The marginal distributions of individual components are presented in Figure 3 for the large waves. When the three-dimensional bar is installed, the vorticity driving torque is mainly contributed by Component VI, which includes the gradients of water depth in the y -direction, $\frac{\partial h}{\partial y}$, and is confined in the vicinity of the three-dimensional bar area. With the two-dimensional bar present, in which case $\frac{\partial h}{\partial y}$ is zero, the magnitude of the Components I and II are negligible. It is noted for the large wave tests in the presence of the three-dimensional bar that Component I increases up to a comparable magnitude to Component VI, as shown in Figure 3(b). This effect might be due to the increase in the gradients of wave heights in the y -direction. Due to space limitations, the results for the small wave condition will not be presented here; however, it was found that the results were consistent with those for the large waves.

The marginal distributions of the total torque are shown in Figure 4 for the large wave condition in the presence of the three-dimensional bar. Positive circulations occur within the surf zone and in the area seaward of the bar region but the magnitudes of these circulations are smaller than and overshadowed by the negative circulation near the bar area. Hence, it would be necessary for future experiments to simulate the more realistic and smooth bar morphology which could avoid these exaggerated effects of the depth gradients in the y -direction. However, these results clearly demonstrate that rip currents are stable on a three-dimensional barred beach although increased momentum fluxes of waves in the area with opposing currents induced by the bar tend to work against rip currents. It appeared that the water mass transported over the bar tended to return to offshore through deeper area in the bar morphology.

(a) Components I, II and VI with 2-D Bar

(b) Components I, II and VI with 3-D Bar

Figure 3: Marginal Distributions of Individual Components along x -axis in cm/sec^2 when $H_o = 9\text{cm}$: (a) Components I, II and VI in the presence of the two-dimensional (2-D) bar and (b) Components I, II and VI in the presence of the three-dimensional (3-D) bar

Figure 4: Marginal Distributions of Total Torque and the Contributions of Radiation Stresses Components along x -axis in cm/sec^2 when $H_o = 9cm$ in the Presence of the Three-Dimensional Bar. Note that torque by S_{xx} is dominant over the torque contributed by S_{yy} . Note also the positive values within the surf zone and in the area seaward of the bar. Hence, positive circulation occurs within the surf zone, which tends to suppress the bar-induced circulation.

Vorticity Driving Torque based on Momentum Equation

Marginal distributions of the total torque and the contributions by S_{xx} and S_{yy} were calculated based on the momentum equations, as presented in Equations (21) to (24), and the results are presented in Figure 5 for the large waves ($H_o = 9cm$) in the presence of the three-dimensional bar. For these calculations, the reference point was selected as the centerline point at the same x -location as the location of the bar crest. The contribution by S_{yy} dominates over the contribution by S_{xx} within the whole area of interest except the area over the bar, where the contribution by S_{xx} is dominant since $(x - x_o)$ is small in this area. The total torque changes from negative values near the shoreline to positive values within the surf zone and again to negative values over the bar, and demonstrates oscillating patterns beyond the breakerline. This figure clearly exhibits the opposing effects of waves to the bar-induced circulation, thus tending to stabilize the surf zone.

Table 1 summarizes the total torque induced on the area of interest from the shoreline to offshore. The positive values of the total torque T_M demonstrate that the wave-induced torque is in opposition to the three-dimensional bar-induced circulation (flowing from the bar area, i.e. shoals, to the base of return current, i.e. the embayments). The opposing wave effects appeared to be due to the increased momentum fluxes associated with higher waves in the vicinity of the return flow.

Table 1: Summary of Total Vorticity Driving Torque based on the Momentum Equation.

Item	Unit	$H_o = 3cm$		$H_o = 9cm$	
		2-D Bar	3-D Bar	2-D Bar	3-D Bar
$\sum \sum D_x$	N	-0.98	-1.29	-8.08	-8.40
$\sum \sum D_y$	N	0.049	0.011	0.23	-4.04
$(T_M)_1$ by S_{xx}	$N - m$	-0.002	-0.005	-0.001	0.035
$(T_M)_2$ by S_{yy}	$N - m$	0.015	0.036	0.376	1.103
Total torque, T_M	$N - m$	0.013	0.031	0.375	1.138

SUMMARY AND CONCLUSIONS

A series of fixed bed tests was carried out to investigate the generation and existence of three-dimensional flows on a barred beach. The bar morphology represented periodic forms parallel to the coast superimposed on a linear sloping beach. For these tests, wave heights and wave direction fields within and adjacent to the surf zone were documented to calculate the wave-induced horizontal torque.

It was found for the large wave condition ($H_o = 9cm$) that three-dimensional circulations occurred due to the effect of the three-dimensional bar morphology and flowed from the bar area (shoals) to the return channel (embayments), thus

Figure 5: Marginal Distributions of Total Torque and the Contributions of Radiation Stresses Components based on Momentum Equations along x -axis in $N-m/m$ when $H_o = 9\text{ cm}$ with the Three-Dimensional Bar. Note that the contribution by S_{yy} is dominant term over the whole area of interest except over the bar area, where the contribution by S_{xx} is dominant. Positive circulation occurs within the surf zone, resulting in opposing effects of waves on the three-dimensional bar-induced circulation.

modifying the wave fields such that waves were higher in the vicinity of the return current. However, the breakerline was not significantly influenced by the return flow since the return current induced by the three-dimensional bar was weak and the water depth in the vicinity of the return current was deeper than that in the area over the bar, which was agreed with the field observations.

When waves were small ($H_o = 3m$), the resulting circulation pattern was the same as that for the large waves; however, the circulation was too weak to modify the wave fields. These results could indicate that rip currents need the wave height larger than a lower limit to form even with the bar morphology, which was observed in the field.

When individual components of the vorticity driving torque was calculated based on the mean vorticity equation, the component which included the depth gradients in the longshore direction demonstrated the largest contribution.

The marginal distributions of the total torque for the large wave tests with the three-dimensional bar present show positive circulations within the surf zone and in the area seaward of the bar region; hence, these results clearly demonstrated that rip currents were stable on three-dimensionally barred beach although increased momentum fluxes of waves in the area with opposing currents induced by the bar tended to exert a counter force against them. It appeared that the water mass transported over the bar tended to return to offshore through deeper area in the bar morphology, where the depth gradients in the longshore direction existed.

When the vorticity driving torque was calculated based on the momentum equations for the large wave condition tests in the presence of the three-dimensional bar, the contribution by S_{yy} dominated over the contribution by S_{xx} within the whole area of interest except the area over the bar. The total torque changed from negative values near the shoreline to positive values within the surf zone, which clearly demonstrated the opposing effects of waves to the bar-induced circulation, thus tending to stabilize the surf zone. The opposing wave effects appeared to be due to the increased momentum fluxes associated with higher waves in the vicinity of the return flow.

In aggregate, these studies suggest that rip currents are stable on three-dimensionally barred beach although increased momentum fluxes of waves in the area with opposing currents induced by the bar tended to exert a counter force against them. It appeared that the water mass transported over the bar tended to return to sea through deeper area in the bar morphology. This cause is believed to be due to the greater hydraulic efficiency of flows through deeper portions of the profile, which leads to a hydraulic/sedimentary instability which causes development of a vestigial channel.

CHAPTER 285

Rip Current Generation on a Plane Beach

D.A. Suriamihardja¹ and Yoshito Tsuchiya², Member, ASCE

ABSTRACT: In order to establish a wave-current interaction model for rip currents, a set of first-order linearized governing equations describing the 2-D nearshore circulation is derived from the equations of nearshore currents by the perturbation method. Wave refraction induced by the generated currents is fully considered. The solutions to the field equations of rip currents both in the surf zone and shoaling zone are obtained, and expressed in the form of Gaussian hypergeometric functions and modified Bessel functions, respectively. The matching condition of the solutions at the breaking point determines the spacing of the rip currents. Comparison of the computed rip current spacing, circulation pattern, and rip current discharge, with laboratory and field data shows a satisfactory agreement especially in the so-called instability region of the surf similarity parameter.

INTRODUCTION

The change in momentum flux of incoming waves can be described by the offshore and longshore gradients of the radiation stresses which act as the driving forces in the nearshore circulation system. Therefore to formulate the driving forces in the momentum equations for the generation of nearshore currents is of importance (Dingemans, Radder and De Vriend, 1987). Two main causes of the driving forces are the so-called wave-current interaction, and structural interaction (Dalrymple and Lozano, 1978).

The first investigation of nearshore currents as 2-D horizontal circulation generated by the interaction between the incoming waves and the resulting rip currents was by Le Blond and Tang (1974), whose theory applies to a plane beach and normally incident waves. Similar to their work, Iwata (1976) developed a theory which assumed the nonuniformity of bottom friction between surf and shoaling zones. However, these two theories still failed in obtaining the nondimensional alongshore spacing of rip currents as an eigenvalue of the governing equations. Iwata further attempted to find

¹Lecturer, Department of Physics, Faculty of Mathematics and Natural Sciences, Hasanuddin University, Ujung Pandang 90245, Indonesia.

²Professor Emeritus, Kyoto University, and Professor, Meijo University, Kani 509-02, Japan.

currents as an eigenvalue of the governing equations. Iwata further attempted to find an asymptotic solution for both the surf and shoaling zones. Finally, he obtained the real eigenvalue from the characteristic equation which is derived by matching conditions at the breaking point, and found that its value is a function of a parameter determined by the bottom friction coefficient, the surf zone width and the breaker height.

Mizuguchi (1976) also attempted to obtain the eigenvalues from the characteristic equation without using any approximation such as asymptotic solution as in Iwata's work, by considering both the uniformity and nonuniformity of the bottom friction. However, no eigenvalue was obtained. He concluded that this failure occurred due to the exclusion of lateral mixing in the governing equation, and because the contribution of the bottom friction was not sufficient to represent the dissipative effect in the nearshore current. Consequently, he reformulated the bottom friction term to be a function of the distance from the shoreline, similar to the lateral mixing. Dalrymple and Lozano (1978) argued that no reason exists to justify this formulation, so that the real eigenvalue obtained as a function of a parameter proportional to the so-called surf zone similarity parameter and inversely proportional to the bottom friction was invalid.

Dalrymple and Lozano (1978) presented two wave-current interaction models. One was similar to the theory of Le Blond and Tang (1974), in which changes in local wave length due to currents were considered. However, their assumption of an extremely small refraction angle, which implied that no longshore variation in wave orthogonals was allowed, resulted in no rip-current formation. In the second model, the wave-current interaction effect was considered through wave refraction due to current, and the formation of longshore periodic nearshore circulation cells was calculated numerically. The obtained eigenvalue was a function of a parameter expressed by the ratio of beach slope to bottom-friction coefficient. The relationship between the eigenvalue and this parameter showed that the rip-current spacing increases as the parameter increases and vice-versa. Comparison with the rip current spacing of Balsillie (1975) obtained by field measurement showed a good agreement in the region of small values of the parameter, which implied that the theoretical eigenvalue of Dalrymple and Lozano was partly suitable for the prediction of rip-current spacings generated by the incidence of infragravity waves, as it was stated by Balsillie that almost all of the data are categorized into this type of waves. However, when compared with the field measurements collected by Sasaki (1977), which were made in wider regions such as the regions of instability and edge waves, the theoretical spacing showed a lower value than that of field measurements.

The present study investigates the steady-state nearshore circulation on a plane beach based on the interaction between normally-incident waves and the resulting rip currents. A mathematical formulation of the governing field equations for rip currents on a plane beach is made by means of the wave-current interaction model, including the formulation of the driving forces. The governing equations of 2-D nearshore currents on the plane beach are first established by employing the conservation laws for mass, momentum and wave action. The so-called mild slope equation (MSE), which is able to calculate wave transformation due to interaction with the nearshore currents, such as wave refraction, is applied to formulate the driving forces in the momentum equations. Nevertheless, to simplify the analysis without sacrificing the

generality of the theory, the lateral mixing terms are omitted. Using a perturbation method for a small parameter of beach slope, the field equations of rip currents are formulated. At the first order of approximation, the field equations of rip currents are obtained in both the surf and shoaling zones, where the wave refraction due to currents is fully considered. With some additional assumptions, solutions to the field equations are obtained both in the surf and shoaling zones in terms of the Gaussian hypergeometric function and the modified Bessel function, respectively. The matching condition for these solutions at the breaking point makes it possible to determine the eigenvalues of the characteristic equation of the derived field equations.

The theoretical results of the rip current characteristics such as the rip current spacing and flow patterns, are compared with both the previous theoretical results, laboratory and field data. The comparison of the theoretical rip current spacings and those of field data showed a satisfactory agreement. Current patterns in a nearshore circulation cell are also calculated numerically through the determination of integration constants in the stream function based on energy budgeting at the breaking point, which resulted in a reasonable value of rip discharge, both at laboratory and field scales.

THE BASIC EQUATIONS OF NEARSHORE CURRENTS

The MSE derived by Kirby (1984) which includes an additional wave energy dissipation term, $i\omega_r W\Phi$, is employed to formulate the driving forces. The terms in the MSE of Kirby are as follows: W is the ratio of the wave energy dissipation rate D to the total wave energy E , C is the wave celerity, C_g is the group velocity, where both values are assumed to be nearly equal due to the shallow water approximation, and D/Dt is the Lagrangian derivative. By introducing velocity potential of linear wave theory, $\Phi = \phi \exp(-i\omega t)$, and $\phi = (ga/i\omega_r) \exp(iS)$, where S is the phase function, into the MSE of Kirby in the steady state condition, the MSE is written as:

$$\left\{ \frac{\partial}{\partial x_j} \left(C C_g \frac{\partial}{\partial x_j} \right) + 2i\omega U_j \frac{\partial}{\partial x_j} \right\} \phi = - \left\{ i \left(\omega \frac{\partial U_j}{\partial x_j} + \omega_r W \right) + \left(\omega^2 + k^2 C C_g - \omega_r^2 \right) \right\} \phi \quad (1)$$

Following lengthy algebraic procedures using the expressions for the radiation stresses by Dingemans, Radder and De Vriend (1987), and for the depth-integrated mass transport by Crapper (1984) (see Tsuchiya and Suriamihardja, 1989), the driving force F_i can be obtained as:

$$F_i = \frac{\rho \omega_r}{2g} \frac{\partial S}{\partial x_i} W \phi \phi^* - \frac{\rho}{4g} d \frac{\partial}{\partial x_i} \left(\phi \phi^* \frac{\omega_r^2}{d} \right) + \frac{\rho \omega_r}{2g} \phi \phi^* \frac{\partial S}{\partial x_j} \left(\frac{\partial U_i}{\partial x_j} - \frac{\partial U_j}{\partial x_i} \right) - \frac{\rho}{4g} C C_g \frac{\partial}{\partial x_i} \left(\frac{\phi \phi^* \partial^2 A}{A \partial x_j^2} \right) \quad (2)$$

where ϕ^* is the complex conjugate of ϕ . The first term in the right side of (2) is the rotational term, and is the contribution from the dissipation of wave energy. The second is the irrotational term, and the third term describes the interaction between wave-induced mass transport and currents. The fourth term represents the additional effect resulting from the diffraction of waves. Dingemans, Radder and De Vriend (1987) demonstrated that only these rotational terms are able to generate non-zero depth-averaged current velocities. For simplicity, the horizontal components of the nearshore current are assumed to be independent of depth. Therefore the conservation laws to be employed in this study are presented in depth-integrated form (For example, Phillips, 1966; Dolata and Rosenthal, 1984; and Crapper, 1984). Neglecting the wave diffraction effect and assuming the shallow water condition, the steady state mass and momentum equations can finally be reduced to

$$\frac{\partial}{\partial x_j}(\rho U_j d) = 0 \tag{3}$$

$$U_j \frac{\partial U_i}{\partial x_j} + R_i = -g \delta_{ij} \frac{\partial \bar{\eta}}{\partial x_j} + \frac{D}{\rho \omega_r d} \frac{\partial S}{\partial x_i} - \frac{\partial}{\partial x_i} \left(\frac{E}{2\rho d} \right) + \frac{E}{\rho \omega_r d} \frac{\partial S}{\partial x_i} \left(\frac{\partial U_i}{\partial x_i} - \frac{\partial U_i}{\partial x_j} \right) \tag{4}$$

where $R_i = \frac{1}{\rho d} \left\{ \frac{\partial}{\partial x_j} (\rho d \tau_{ij}) + f_{ij} U_j \right\}$ $E = \frac{1}{2} \rho g \omega_r^2 \phi \phi^*$

in which U_i are the vertically-averaged horizontal current velocity components, τ_{ij} are the lateral mixing terms, η is the mean water level, ρ is the density of water, d is the water depth, g is the acceleration of gravity, t is time, x_j are the horizontal coordinates x and y for $j = 1$ and 2 , and f_{ij} are the bottom friction coefficients following Iwata's (1976) formulation in the case of normal incidence and are written as

$$\left. \begin{aligned} \begin{pmatrix} f_{xx} & 0 \\ 0 & f_{yy} \end{pmatrix} \begin{pmatrix} U \\ V \end{pmatrix} &= \frac{2}{\pi} K_* \sqrt{gd} \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} U \\ V \end{pmatrix}, & x \leq x_B \\ \begin{pmatrix} f_{xx} & 0 \\ 0 & f_{yy} \end{pmatrix} \begin{pmatrix} U \\ V \end{pmatrix} &= \frac{2}{\pi} K_* \sqrt{gd_B} \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} U \\ V \end{pmatrix}, & x \geq x_B \end{aligned} \right\} \tag{5}$$

where $K_* = 1.41 (\gamma / k \cdot k_e)^{2/3}$ in which k_e is the bottom roughness, k is the wave number and γ is the ratio of wave amplitude to local water depth, and suffix B stands for the position of wave breaking and indices x and y represent the seaward x and alongshore y directions. The conservation of wave action, which can be derived directly from (1), and wave number conservation which is equivalent to the irrotationality condition for wave number, are written as:

$$\frac{\partial}{\partial x_j} \left\{ \frac{E}{\omega_r} (U_j + C_j) \right\} + \frac{D}{\omega_r} = 0; \quad \frac{\partial k_j}{\partial x_i} = \frac{\partial k_i}{\partial x_j} \tag{6}$$

THE FIELD EQUATION OF RIP CURRENT

Perturbation Scheme

Before ordering the equations using the perturbation method, it is convenient to nondimensionalize them. The water depth d_B at the breaking point is selected as the representative length to facilitate the nondimensionalization. The process is defined as:

$$\left. \begin{aligned} (x, y, \bar{\eta}, d) &= d_B(x^*, y^*, \bar{\eta}^*, d^*) & (U, V, C) &= \sqrt{gd_B}(U^*, V^*, C^*) \\ (\omega, \omega_r) &= \sqrt{g/d_B}(\omega^*, \omega_r^*) & (k, k_x, k_y) &= d_B^{-1/2}(k^*, k_x^*, k_y^*) \end{aligned} \right\} \quad (7)$$

where an asterisk represents the dimensionless quantities.

The beach slope s is selected as a parameter of perturbation in ordering the equations, and the series expansion, in which asterisks have been dropped for convenience, are given as:

$$d = s(d_0 + s\zeta_1 + s^2\zeta_2 + \dots) \quad ; \quad a = s(a_0 + sa_1 + s^2a_2 + \dots) \quad (8a)$$

$$U = s^{1/2}(0 + sU_1 + s^2U_2 + \dots) \quad ; \quad V = s^{1/2}(0 + sV_1 + s^2V_2 + \dots) \quad (8b)$$

$$\mathbf{k} = (k_{0x} + sk_{1x} + s^2k_{2x} + \dots) \mathbf{i} + (0 + sk_{1y} + s^2k_{2y} + \dots) \mathbf{j} \quad (8c)$$

$$\omega_r = s^{1/2}\{k_{0x}C_0 + s(k_{1x}C_0 + k_{0x}C_1) + \dots\}; \quad S = (S_0 + sS_1 + s^2S_2 + \dots) \quad (8d)$$

$$C = s^{1/2}(d_0 + s\zeta_1 + s^2\zeta_2 + \dots)^{1/2} \sqrt{(\tanh kd_B)/(kd_B)} \quad (8e)$$

Figure-1 The coordinate system and geometry for nearshore current vectors U , V , and wave number k .

The Conservation of Wave Number

The normally-incident waves refract due to their interaction with rip currents. This may mean that the wave number direction intersects the beach obliquely. Therefore, based on Figure 1 the wave number can be given as:

$$\mathbf{k} = -(|\mathbf{k}| \cos \theta) \mathbf{i} - (|\mathbf{k}| \sin \theta) \mathbf{j} \quad (9)$$

where $|\mathbf{k}|$ is the magnitude of vector \mathbf{k} . Equation (9) can be expanded with respect to

the perturbation parameter ϵ , and as was mentioned above that the group velocity is to be nearly equal to the wave celerity in the surf zone, it was assumed to be in the same direction as the wave number vector. Consequently, it can also be expanded by the perturbation parameter. The conservation equation for the wave number is finally formulated for each order of the perturbation parameter (see Tsuchiya and Suriamihardja, 1989) as:

$$\left. \begin{aligned} O(s^0) &\equiv \frac{\partial k_{0x}}{\partial \bar{y}} = 0 \\ O(s^1) &\equiv \frac{\partial k_{1x}}{\partial \bar{y}} = \frac{\partial k_{1y}}{\partial \bar{x}} \Rightarrow \frac{\partial}{\partial \bar{y}}(C_1 - U_1) = -\frac{\partial}{\partial \bar{x}}(V_1) + \frac{1}{\bar{x}} V_1 \end{aligned} \right\} \quad (10)$$

where $\bar{x} = m(x + x_s) = d_0$; $\bar{y} = my$; $m = (1 + d\zeta_0/d\bar{x})$

m is the slope of mean water level, and x_s is the maximum run-up position.

Zeroth-order equations and their solutions

The leading terms of the governing equations produced by the perturbation expansion are given for the surf zone and shoaling zone, respectively. In the surf zone, the zeroth order equations of momentum and wave action conservation are given respectively as:

$$d_0 \left(\frac{d\zeta_0}{dx} \right) = \frac{D_0}{\omega_{0r}} \frac{dS_0}{dx} - d_0 \frac{d}{dx} \left(\frac{E_0}{2d_0} \right); \quad -\frac{d}{dx}(E_0 C_0) + D_0 = 0 \quad (11)$$

In order to solve the above equations, the wave amplitude a_0 in the surf zone is assumed to be proportional to the local depth to leading order: $a_0 = \gamma d_0$ where γ is an empirical constant. This formulation is employed in surf zone models. The wave energy dissipation term D is hypothesized as:

$$D = (5\gamma^2/4) \left\{ md_0^{\frac{3}{2}} + s \left(3md_0^{\frac{1}{2}} \zeta_1 / 2 + d_0^{\frac{3}{2}} (\partial \zeta_1 / \partial x) + \dots \right) \right\} \quad (12)$$

where D_0 in (11) is equal to $(5\gamma^2 m/4) d_0^{3/2}$

The wave amplitude in the shoaling zone is obtained from the leading order of the equation of wave action conservation as $a_0 = B_0^{1/2} d_0^{-1/4}$, where B_0 is an integration constant. The wave set-up is obtained from (11) (see Tsuchiya and Suriamihardja, 1989) as:

$$\zeta_0(x) = -\left\{ \left(\frac{3}{2} \gamma^2 \right) x + x_s \right\} m \quad (13)$$

where $m = (1 + \frac{3}{2} \gamma^2)^{-1}$; $x_s = \gamma^2 \left\{ \frac{3}{2} - \frac{1}{4} \left(1 + \frac{3}{2} \gamma^2 \right) / \left(1 - \frac{3}{2} \gamma_B^2 \right) \right\} x_B$, and $\gamma_B = B_0 x_B^{-3/4}$ and x_B is the distance from the shoreline to the breaking point.

The first-order equations of rip currents in the surf zone

The mass conservation equation is given from the first equation of (3), considering (8)

for its expansion and using variables defined from mass conservation, of which the stream function can be defined as follows:

$$\frac{\partial}{\partial \tilde{x}}(\tilde{x} U_1) + \frac{\partial}{\partial \tilde{y}}(\tilde{x} V_1) = 0 \Rightarrow (\tilde{x} U_1) = \frac{\partial}{\partial \tilde{y}}(\Psi) \text{ and } (\tilde{x} V_1) = -\frac{\partial}{\partial \tilde{x}}(\Psi) \quad (14)$$

The approximation may be made to the wave dispersion relation, to evaluate C_1 . It is necessary, of course, to obtain a simple relation between C_1 and ζ_1 in order to reduce higher-order differentiation terms. The simple relation can be derived from the established set of four equations. In order to approximate the relation along with the four equations, however, the x-direction of the first order of momentum equation (4) can be used by considering the most effective terms, thus:

$$C_1 = q\tilde{x}^{-\frac{1}{2}}\zeta_1; \quad q = \frac{1}{2}\sqrt{(\tanh kd_B)/(kd_B)} \quad (15)$$

if the other non-leading terms are neglected, q may equal to 1/2 which is equivalent to that of Darlymple and Lozano's approximation. However, based on this approximation, the value of q might be somewhat less than 1/2.

When the horizontal mixing terms remain in (4), the field equation of rip currents may become a fourth-order partial differential equation. Without loss of generality in the formation of rip currents, as previously treated in theoretical approaches to the formation of rip currents, the horizontal mixing terms are neglected, but the bottom friction terms are included. By use of the four equations using (15) to replace C_1 the first-order equation of momentum can finally be obtained (see Tsuchiya and Suriamihardja, 1989 for the detailed reduction) as:

$$\begin{pmatrix} M_{xx}^{\kappa} & 0 \\ 0 & M_{yy}^{\kappa} \end{pmatrix} \Psi = \begin{pmatrix} \beta & 0 \\ 0 & \alpha \end{pmatrix} \frac{\partial^2}{\partial \tilde{x} \partial \tilde{y}} (\tilde{x}^{\frac{3}{2}} \zeta_1) - \frac{5\gamma^2}{4} \begin{pmatrix} (1+2q) & 0 \\ 0 & q\kappa \end{pmatrix} \frac{\partial}{\partial \tilde{y}} (\tilde{x}^{\frac{1}{2}} \zeta_1) \quad (16)$$

where

$$\begin{cases} M_{xx}^{\kappa} = \left\{ \frac{1}{4} \gamma^2 \frac{\partial}{\partial \tilde{x}} \left(\tilde{x} \frac{\partial^2}{\partial \tilde{y}^2} \right) - \frac{15}{8} \gamma^2 (1-\kappa) \tilde{x}^{-1} \frac{\partial}{\partial \tilde{x}} - \frac{7}{8} \gamma^2 \left(1 + \frac{20\kappa}{7} \right) \frac{\partial^2}{\partial \tilde{y}^2} \right\} \\ M_{yy}^{\kappa} = \left\{ \frac{1}{4} \gamma^2 \frac{\partial}{\partial \tilde{x}} \left(\tilde{x} \frac{\partial^2}{\partial \tilde{y}^2} \right) - \frac{5}{2} \gamma^2 (1-\kappa) \tilde{x}^{-1} \frac{\partial}{\partial \tilde{x}} + \frac{3}{8} \gamma^2 \left(1 - \frac{10\kappa}{3} \right) \frac{\partial^2}{\partial \tilde{y}^2} \right\} \end{cases}$$

and $\alpha = \left\{ 1 + \left(\frac{3}{8} + \frac{1}{4}q \right) \gamma^2 \right\}; \quad \beta = \left\{ 1 + \left(\frac{13}{8} + \frac{1}{4}q \right) \gamma^2 \right\}; \quad \kappa = \frac{4K}{5\gamma^2 ms}$

By eliminating ζ_1 from (16), the first-order field equation of rip currents can finally be obtained as:

$$\left(\hat{P} \frac{\partial^2}{\partial \tilde{x}^2} - \hat{Q} \frac{\partial^2}{\partial \tilde{x}^2} \frac{\partial^2}{\partial \tilde{y}^2} - \hat{R} \frac{1}{\tilde{x}} \frac{\partial}{\partial \tilde{x}} - \hat{S} \tilde{x} \frac{\partial}{\partial \tilde{x}} \frac{\partial^2}{\partial \tilde{y}^2} - \hat{T} \frac{\partial^2}{\partial \tilde{y}^2} \right) \Psi = 0 \quad (17)$$

where

$$\hat{P} = \left\{ 1 + 2q \left(1 - \frac{\beta\kappa}{2\alpha} \right) \right\} \left\{ q(1-\kappa) + \left(q - \frac{1}{2} \right) \right\} + \frac{3q}{2} \left(\frac{4\beta}{3\alpha} - 1 \right) (1-\kappa)$$

$$\hat{Q} = \frac{q}{5} \left(\frac{\beta}{\alpha} - 1 \right)$$

$$\hat{R} = \left\{ 1 + 2q \left(1 - \frac{\beta\kappa}{2\alpha} \right) \right\} \left\{ 2 \left(q - \frac{1}{2} \right) + \frac{3q}{2} (1-\kappa) \right\} + \frac{9q}{4} \left(\frac{4\beta}{3\alpha} - 1 \right) (1-\kappa)$$

$$\hat{S} = \frac{3q}{5} \left(\frac{2}{3} + \frac{\beta}{\alpha} \right) + 2\kappa q \left(1 - \frac{\beta}{2\alpha} \right)$$

$$\hat{T} = \left\{ 1 + 2q \left(1 - \frac{\beta\kappa}{2\alpha} \right) \right\} \left\{ q(1-2\kappa) - \frac{1}{2} \right\} + \frac{q}{4} \left(1 + \frac{\beta}{\alpha} \right) + q\kappa \left(1 - \frac{\beta}{2\alpha} \right)$$

The first-order equation of rip currents in the shoaling zone

In the shoaling zone the governing equations differ from the surf zone equations principally in the wave energy dissipation term and in the formulation of the bottom-friction stresses. In this zone, the driving forces are presented in irrotational form, which may be incapable of generating currents of the first order. The remaining terms in the cross-differentiated equations originate from the friction terms. Consequently, the momentum equations in the shoaling zone play an important role in the decay of currents produced in the surf zone. As was previously indicated in (14), a stream function in the shoaling zone can be equally defined. The momentum equations in the x and y directions and cross-differentiated momentum equations are given respectively by

$$\begin{pmatrix} \frac{2\kappa}{s^2 \tilde{x}} & 0 \\ 0 & \frac{2\kappa}{s^2 \tilde{x}} \end{pmatrix} \begin{pmatrix} U_1 \\ V_1 \end{pmatrix} = - \left(1 - \frac{3\gamma_B^2}{8} \right) \begin{pmatrix} \frac{\partial}{\partial \tilde{x}} \\ \frac{\partial}{\partial \tilde{y}} \end{pmatrix} \left(\zeta_1 - \frac{B_0}{4} \tilde{x}^{-\frac{1}{2}} \zeta_1 + \frac{B_0^{\frac{1}{2}}}{2} \tilde{x}^{-\frac{1}{2}} a_1 \right) \quad (18)$$

$$\left(2 \frac{\partial^2}{\partial \tilde{y}^2} + \frac{\partial^2}{\partial \tilde{x}^2} - \frac{2}{\tilde{x}} \frac{\partial}{\partial \tilde{x}} \right) \Psi = 0 \quad (19)$$

THE SOLUTIONS OF THE FIELD EQUATIONS OF RIP CURRENTS

The solution in the surf zone

The solutions to (17) for the surf zone and (19) for the shoaling zone can be obtained by means of the method of separation of variables. The stream function Ψ to be solved for can be expressed by $\Psi(\tilde{x}, \tilde{y}) = \Xi(\tilde{x})Y(\tilde{y})$. Substituting this expression into

(17), the equation can be transformed into two equations as

$$\left\{ \begin{aligned} & \left[\left\{ 1 + \frac{\hat{Q}}{\hat{P}} (\lambda \tilde{x}^c)^2 \right\} \frac{d^2}{d\tilde{x}^2} + \left\{ \frac{\hat{S}}{\hat{P}} (\lambda \tilde{x}^c)^2 - \frac{\hat{R}}{\hat{P}} \right\} \frac{1}{\tilde{x}} \frac{d}{d\tilde{x}} - \frac{\hat{T}}{\hat{P}} \lambda^2 \right] \Xi(\tilde{x}) = 0 \\ & \left(\frac{d^2}{d\tilde{y}^2} + \lambda^2 \right) Y(\tilde{y}) = 0 \end{aligned} \right. \quad (20)$$

where λ is the separation constant which is the eigenvalue corresponding to the number of rip currents. Introducing the new variable

$$\xi = \{1 + \widehat{Q}(\lambda \tilde{x})^2 / \widehat{P}\}^{-1} \tag{21}$$

into the first equation of (20) yields

$$\left[\xi^2(1-\xi) \frac{d^2}{d\xi^2} - \{(\hat{a} + \hat{b} - 1)\xi + (2 - \hat{c})\xi^2\} \frac{d}{d\xi} + \hat{a}\hat{b} \right] \Xi(\xi) = 0 \tag{22}$$

where $(\hat{a}, \hat{b}) = \left\{ (\widehat{S}/\widehat{Q} - 1) \pm \sqrt{(\widehat{S}/\widehat{Q} - 1)^2 + 4\widehat{T}/\widehat{Q}} \right\} / 4$; $\hat{c} = (\widehat{S}/\widehat{Q} + \widehat{R}/\widehat{P})$

The general solution of this equation can be expressed as a Gaussian hypergeometric function in the form

$$\Xi_{\text{surf}} = A_1 \xi^{\hat{a}} \widehat{F}(\hat{a}, 1 + \hat{a} - \hat{c}; 1 + \hat{a} - \hat{b}; \xi) + A_2 \xi^{\hat{b}} \widehat{F}(\hat{b}, 1 + \hat{b} - \hat{c}; 1 + \hat{b} - \hat{a}; \xi) \tag{23}$$

where A_1 and A_2 are the integration constants to be determined, and the suffix "surf" represents the surf zone. To solve for regular rip-current spacing as an eigenvalue problem of the equation, a maximum point for (23) must exist in the surf zone. The solutions should have a finite value and a maximum point within $0 < \xi < 1$.

This behaviour can be examined through the following conditions:

$$\Xi(\xi) \Big|_{\xi=0} = 0 \quad ; \quad \frac{\partial}{\partial \xi} \Xi(\xi) \Big|_{\xi_B \leq (\xi - \xi_m) \leq 1} = 0 \quad ; \quad \frac{\partial^2}{\partial \xi^2} \Xi(\xi) \Big|_{\xi_B \leq (\xi - \xi_m) \leq 1} < 0 \tag{24}$$

where B indicates the breaking point. It is also confirmed by numerical calculation, that for $A_2=0$, the conditions will be fulfilled.

The solution in the shoaling zone

The solution in the shoaling zone can be obtained by solving (19) using the method of separation of variables. Introducing the new variables

$$\varphi(\tilde{x}) = \tilde{x}^{-\frac{3}{2}} \Xi(\tilde{x}) \quad ; \quad \tilde{x} = \lambda \tilde{x} \sqrt{2} \tag{25}$$

Equation (19) is reduced to

$$\left\{ \frac{\partial^2}{\partial \tilde{x}^2} + \frac{1}{\tilde{x}} \frac{\partial}{\partial \tilde{x}} - \left(1 + \frac{9}{4\tilde{x}^2} \right) \right\} \varphi(\tilde{x}) = 0 \quad ; \quad \left(\frac{\partial^2}{\partial \tilde{y}^2} + \lambda^2 \right) Y(\tilde{y}) = 0 \tag{26}$$

The solution to (26) can be expressed using modified Bessel functions of the first and second kinds. By use of (25) the solution can finally be written as

$$\Xi_{\text{shoal}}(\tilde{x}) = B_1 \tilde{x}^{\frac{1}{2}} I(\lambda \tilde{x} \sqrt{2}) + B_2 \tilde{x}^{\frac{1}{2}} K(\lambda \tilde{x} \sqrt{2}) \tag{27}$$

where B_1 and B_2 are integration constants to be determined, and the suffix "shoal" represents the shoaling zone. To fulfill the condition that $\Xi_{\text{shoal}} \rightarrow 0$ far offshore,

therefore, B_1 should be zero.

The boundary conditions and characteristic equation

The eigenvalues can be determined by the matching condition at the breaking point, that is:

$$\frac{d}{dx} \Xi_{\text{surf}}(x) \Big|_{\tilde{x}=\tilde{x}_B} = \frac{d}{dx} \Xi_{\text{shoal}}(x) \Big|_{\tilde{x}=\tilde{x}_B} ; \quad \Xi_{\text{surf}}(x) \Big|_{\tilde{x}=\tilde{x}_B} = \Xi_{\text{shoal}}(x) \Big|_{\tilde{x}=\tilde{x}_B} \quad (28)$$

where B indicates the breaking point.

The real and positive eigenvalues λ which satisfy the matching conditions (28) can be determined if the stream functions in both the surf and shoaling zones are decreasing monotonically in the offshore direction, the characteristic equation is given by

$$\frac{\hat{F}(-\hat{b}, \hat{c} - \hat{b}; 1 + \hat{a} - \hat{b}; \hat{\xi}_B)}{\hat{F}(1 - \hat{b}, \hat{c} - \hat{b}; 1 + \hat{a} - \hat{b}; \hat{\xi}_B)} = \left(\frac{\hat{P}}{\hat{a}\hat{Q}} \right) \left\{ \frac{(1 - \hat{\xi}_B)/\hat{\xi}_B}{1 + \sqrt{2\hat{P}(1 - \hat{\xi}_B)/\hat{Q}\hat{\xi}_B}} \right\} \quad (29)$$

By numerical solution of this characteristic equation, the eigenvalues λ can be determined. The eigenvalues λ directly correspond to rip spacing along the shore line.

Determination of the integration constants in the stream functions

The integration constant of the stream function A_{surf} in the surf zone can be determined from the steady-state wave power conservation in the shoaling and surf zones. The wave energy dissipation rate immediately after breaking is different from that in the inner region. This is revealed by the different wave-elevation decay rates. Therefore, the ratio of wave amplitude to local water depth should be taken into consideration in wave energy budgeting. This difference in the rate of wave energy dissipation is responsible for the structure of the nearshore current. Consequently, the wave power contribution to the generation of the nearshore current initiates at the breaking point. The change in wave power occurring in the region from just before to just after the breaking point can be expressed by:

$$\left(\frac{1}{2\pi} \right)^{\frac{1}{2}} \left(\frac{H'_{\infty}}{d_B} \right)^{\frac{1}{2}} \left(\frac{L'_{\infty}}{d_B} \right)^{\frac{1}{2}} \left(\frac{d_B}{d_{0B}} \right)^{\frac{1}{2}} = s^{\frac{1}{2}} [H_{0B}^{*2} C_{0B}^* + s \{ 2H_{0B}^* H_{1B}^* C_{0B}^* + H_{0B}^{*2} (C_{1B}^* - U_{1B}^*) \} + \dots]^{\frac{1}{2}} \quad (30)$$

Kimura, Goto, and Seyama's (1988) experimental work suggests the condition $\gamma_B > \gamma$.

Based on this fact, the first-order approximation of (30) is reduced to:

$$\frac{1}{s} \left(\frac{\gamma_B}{\gamma} - 1 \right) x_B \cong \left\{ \frac{a_{1B}}{\gamma} + \frac{1}{2} (C_{1B} - U_{1B}) x_B \right\} \Rightarrow \gamma_B = \frac{1}{2} \left(\frac{1}{2\pi} \right)^{\frac{1}{2}} \left(\frac{H'_{\infty}}{d_B} \right)^{\frac{1}{2}} \left(\frac{L'_{\infty}}{d_B} \right)^{\frac{1}{2}} \quad (31)$$

Using (31), the integration constant A_{surf} can immediately be evaluated, and the stream function Ψ can finally be expressed as

$$\left. \begin{aligned} \Psi(\xi, y^*) &= A_{\text{surf}} \xi^{\hat{a}} \hat{F}(\hat{a}, 1 + \hat{a} - \hat{c}; 1 + \hat{a} - \hat{b}; \xi) \cos(\lambda y^*) \\ \Psi(x^*, y^*) &= \text{Re} \left\{ (-1)^{-\hat{a}} \frac{\Gamma(\hat{c}) \Gamma(\hat{b} - \hat{a})}{\Gamma(\hat{c} - \hat{a}) \Gamma(\hat{b})} \Psi(\xi, y^*) \right\} \end{aligned} \right\} \quad (32)$$

The depth-integrated rip current velocity at first-order is now ready to be expressed numerically as:

$$Q(\bar{x}, \bar{y}) = \bar{i} dU(\bar{x}, \bar{y}) = \bar{i} (s\bar{x})s^{\frac{1}{2}} \{0 + sU_1(\bar{x}, \bar{y}) + s^2U_2(\bar{x}, \bar{y}) + \dots\} \quad (33)$$

Theoretical Results And Comparison With Field Data

A theory of the steady nearshore horizontal circulation cells induced by normally-incident waves on a plane beach has been proposed in this paper. The theoretical results predict two main characteristics of rip currents, i.e. the alongshore spacing and the depth-integrated velocity distribution in the seaward direction. The obtained rip current spacing is compared with the theoretical curve of Dalrymple and Lozano (1978) and the field data of Sasaki (1977) and other investigators where the surf similarity of the waves are categorized into instability region. To compare the theoretical results with the field data of Sasaki (1977) and other investigators, their values of the parameter q at the breaking point should be evaluated using their wave characteristics data, and their values of κ should be evaluated using bottom roughness k_e , bottom slope s , and wave length data at the breaking point, then the results are plotted over the theoretical curves. In the evaluation of κ , Kajiura's expression for bottom friction coefficient was used, as Dalrymple and Lozano used and assumed the bottom roughness as $k_e = 0.4$ mm.

Figure 2. Theoretical curves of dimensionless rip spacing (Y_r/x_B) in terms of Dalrymple number A_D for q -values of 0.40, 0.45, and 0.50 including Dalrymple & Lozano's curve (1978) and rearranged field data of rip currents generated by waves having surf similarity parameter of the instability region.

In comparing the results of this study with those of Dalrymple and Lozano, the parameter κ , which has been previously defined, is transformed into Dalrymple and Lozano's number $A_D = 0.4 / \kappa$. Figure 2 shows the curve of dimensionless rip spacing as a function of Dalrymple parameter A_D . The present curves ($q=0.5, 0.4, \text{ and } 0.3$) rapidly increase as A_D becomes less than 1, while Dalrymple's curve decreases as A_D goes to 0. The present theoretical results and those of Dalrymple and Lozano differ particularly at small values of A_D . In the course of deriving the characteristics equation in the present eigenvalue problem, the dimensionless rip spacing depends on the values of κ and q . It was defined that q corresponds to wave characteristics and beach slope s , and κ depends on the bottom roughness and wave length at the breaking point. Therefore, we conclude that the dimensionless rip spacing is determined by incoming wave characteristics, i.e. wave height H and wave length L , and morphological characteristics, i.e. beach slope s and bottom surface roughness k_e .

Figure 3. Seaward distribution of rip discharge, where beach slope $s = 0.05$ and dimensionless rip spacings of 3.12 ($\kappa = 0.30$), 4.21 ($\kappa = 0.45$), and 7.70 ($\kappa = 0.70$) are used.

Figures 3 illustrate the distribution of depth-integrated rip current velocity or seaward rip discharge as a function of seaward distance. The illustrations have dimensionless rip spacings of 7.70, 4.21, and 3.12, a beach slope of 0.05, and q of 0.50. The breaking point is located at 20 meters from run-up line. By using γ_B of 0.50, the numerical value of A_{surf} gives values of rip discharges with reasonable values at both laboratory and field scales.

CONCLUSIONS

In this study a new mathematical model for steady-state horizontal nearshore circulation has been developed, in which the wave-current interaction is taken into consideration. The basic equations consist of the depth-integrated equations for conservation of mass, momentum, wave action, and wave number. The wave-current interaction includes not only wave refraction due to currents but also the work done by radiation stresses against the mean current.

The basic equations are decomposed into the leading order and the instability order using the beach slope as a perturbation parameter. The leading order gave the solution for wave set-up in the surf zone and wave set-down in the shoaling zone. The instability order gave linearized field equations of nearshore currents. It is found that the nearshore circulations were generated by the rotational driving forces in the momentum equation. The solutions were characterized by boundary conditions at a shore line, a breaking line, and far offshore. In the surf zone, the solution was represented by the Gaussian hypergeometric function. In the shoaling zone, the solution was represented by the modified Bessel function. The eigenvalues which correspond to the dimensionless rip spacing are obtained from the characteristics equation extracted from the matching condition at the breaking point.

The present theoretical results for the dimensionless rip spacing were consistent with the scatter of the field data of Sasaki in terms of surf similarity parameter of the region of instability. The curves suddenly increase in the range $A_D < 1.0$, and tend to be a constant value for larger values of A_D . The field data on dimensionless rip spacings caused by infragravity waves are difficult to predict by this theory. Outside of this range, the theory gives reasonable predictions for rip spacing caused by wave-current interactions.

Rip discharge is illustrated with exact numerical values, using an integration constant which is obtained from energy budgeting at the breaking point. This budgeting was applied at the suggestion of Kimura et.al, that the wave energy dissipation rate immediately after breaking is larger than the dissipation rate in the inner region. The resulting value is within the range of data at both laboratory and field scales.

Acknowledgments

This work was completed while the first author was a fellow at the Coastal Disaster Section, Disaster Prevention Research Institute, Kyoto University, Japan. Most of this work was completed while the first author was a postgraduate student under the supervision of the second author at the same university. The authors' appreciations are expressed to Professor T. Takayama, Head of the Section, for his support in executing this work, Associate Professor T. Yamashita for his crucial advice and arrangement to make this work possible, Dr. Gary Watson, Visiting Research Fellow, for his kindness in critical correction of the draft, and Dr. H. Yoshioka for his cooperation during the execution this work at the Institute.

CHAPTER 286

NEARSHORE PLACEMENT OF SAND

By Scott L. Douglass¹, Member ASCE

ABSTRACT:

A methodology that evaluates the influence of depth on the rate of onshore migration of sand placed in the nearshore is presented. The results appear appropriate for the Atlantic and Gulf coasts of the United States. Migration rate is found to be extremely dependent, to the 4th or 5th power, on the water depth. This implies that doubling the rate of migration requires placement in only about 15% less depth. It is argued that accounting for the net shoreward bottom stress due to the velocity asymmetry under finite-amplitude waves is the appropriate way to model the fate of nearshore placed sands.

BACKGROUND

Nearshore placement of sand is becoming a more popular option in two related types of coastal engineering projects; beach nourishment and inlet dredging. "Nearshore" is defined rather loosely here as beyond the day-to-day surf zone but within the depths that are disturbed by storm waves. Nearshore placement is an alternative to direct placement on the beach that has been called "profile nourishment" or "shoreface nourishment" since the placement is farther out on the beach profile than the dry beach.

Placing the sand in the nearshore instead of directly on the beach can reduce costs and improve the overall cost-benefit ratio of a beach nourishment project (Lastrup, et al. 1996). There may also be a perception that construction-related aesthetic and environmental impacts to the beaches are improved with nearshore placement instead of direct beachfill because the sand moves ashore in the form of migrating sand bars instead of being placed there by construction equipment.

Nearshore placement of sand is also an option in navigation dredging projects for similar reasons. First, it may be less expensive than other dredged material disposal options such as hauling to offshore disposal. Second, there may be a recognition that inlet sand transfer is required for the long-term maintenance of the downdrift beaches. The goal of nearshore placement of sand in this case would be to keep the sand resource in the littoral system for the least cost.

The primary question is, "what is the fate of sands placed in the nearshore?" More specific questions are:

1. does the sand move?
2. If so, which way does it move?
3. How fast does it move?
4. What is the influence of depth on this fate?

Depth is one of the primary parameters that the design engineer can specify.

Several tools to answer these questions have been developed in the United States as part of the Corps of Engineers Dredging Research Program in the last decade. Hands and Allison (1991) and Hands (1991) developed an empirically based answer to the first question concerning movement. The stability of bathymetric features (mounds or bars) constructed with dredged sands at eleven locations discussed in the American literature is summarized. A method based on combining extreme wave statistics and Hallermeier's estimates of the limits of sand movement successfully discriminates between mounds that moved and mounds that did not move.

Larson and Kraus (1992) suggest using empirical estimates of surf zone sand bar migration and beachface accretion/recession for estimating the direction of movement of sand placed in the nearshore. A design option is to place the sand in a long, linear, shore-parallel bathymetric feature that is similar to natural sand bars. They validate their method by comparison to the onshore migration of a constructed bar feature at Silver Strand, California (Andrassy 1991).

Scheffner (1991, 1996) suggests combining a hydrodynamic model with a

sediment transport model for evaluating the fate of sand placed in the nearshore. The influence of waves on the bottom friction factor is considered, but mean currents provide the transport mechanism for the sand movement. The migration of a mound south of Dauphin Island, Alabama (Hands and Allison 1991) is used for validation.

The answer to the primary question concerning the fate of sands placed in the nearshore is tied to a broader, underlying question that has been the focus of much research in the nearshore oceanography community for the past decade: "What moves sand in these depths beyond the day-to-day surf zone but within the influence of storm waves?" Considering the rich variations in sediment transport processes such as bed and suspended load, ripple and dune migration, sheetflow, and bed-ventilation; combined with the varying time-scales of the hydrodynamic forcing conditions and our limited understanding of the near-bottom boundary layer of the fluid column under real waves, the answer is only marginally understood at this time. Solving applied problems requires the use of that part of the available science that is considered to be the most important of the geophysical processes for the problem.

One concept for modeling surf zone sand bars is a balance between the cross-shore movement of sand due to the velocity asymmetry of waves and the undertow (Stive 1986, Roelvink and Stive 1989). Simplistically, the waves drive the sand bar landward and the undertow drives it seaward. Considering that the location of constructed mounds is offshore of the location of the typical sand bar, the undertow should be reduced and the wave asymmetry mechanism should dominate. This is the fundamental concept used in this paper.

Douglass (1995) briefly proposed a model for estimating migration of sand mounds constructed in the nearshore. The model assumes that landward migration is due primarily to the net landward transport by the velocity asymmetry of finite-amplitude waves. Conservation of sand considerations in the cross-shore direction lead to the classical convection-diffusion model equation. The "convection" and "diffusion" coefficients are functions of the wave conditions and depth and are based on the wave and transport theory, not traditional concepts of convection and diffusion. The model produced results which were in reasonable agreement with measured migration directions and rates at both Silver Strand and Dauphin Island. The implication of the diffusion is that mounds should spread out while moving landward. This type of behavior has been noticed to different degrees in many of the monitoring reports on mounds (Hands and Allison 1991; Andrassy 1991; Bodge 1994; Foster, et al. 1996; Mesa 1996) and is shown schematically in Figure 1.

Figure 1. "Typical" migration of sand placed in the nearshore.

This present paper briefly discusses the results and implications of a study of the near-bottom current field at a nearshore sand placement site. The Douglass (1995) model is further developed. Modifications include the use of a calibration coefficient and a simple adjustment for wave breaking when using WIS wave climatology data as input. Results for a few locations on the Atlantic and Gulf coasts of the United States are presented. The implications of the dependence of migration on depth of placement are discussed. Some of the practical limitations of the model as well as the theoretical problems are briefly discussed. The implications concerning the important geophysics dominating the problem are discussed. The conclusion is that some form of modeling based on the influence of wave asymmetry is probably appropriate concerning the fate of sand placed in the nearshore.

DAUPHIN ISLAND, ALABAMA NEAR-BOTTOM CURRENT STUDY

The fate of sand mounds constructed in about 6 m depths south of Dauphin Island, Alabama in 1987 was monitored extensively by the US Army Corps of Engineers. A number of reports by Mr. Edward Hands and other co-authors documented the movement of these nearshore mounds (e.g. Hands and Bradley 1989, Hands and Allison 1991). Repetitive bathymetric surveys showed that the mounds moved landward.

Instantaneous, near-bottom currents were measured, along with waves, at the site. These near-bottom currents were examined in detail by Douglass, et al. (1995).

A number of possible mechanisms for mound migration; including mean currents, large wave correlation with mean currents, and mound-induced differences in current fields; were not able to satisfactorily explain the observed shoreward direction of mound migration. Douglass, et al. (1995) concluded that some unknown mechanism that moves the bottom back towards its equilibrium shape may be responsible for the landward migration of mounds and that the velocity asymmetry of storm waves might be part of such a mechanism. These finding played a role in the development of this work.

WAVE-BASED MODEL OF MOUND MIGRATION RATE

Assuming that wave-induced near bottom velocity asymmetries are the dominant mechanism for the net transport of sand in the depths of interest, net sand transport can be expressed as (Douglass 1995),

$$Q = \frac{9\pi^2}{64} \frac{\rho g C_f \epsilon_b}{(\rho_s - \rho) a' \tan^2 \phi} (\tan \phi - \tan \beta) \frac{H^4 T}{L^3} \operatorname{sech}^2 \left(\frac{2\pi h}{L} \right) \operatorname{csch}^4 \left(\frac{2\pi h}{L} \right)$$

where Q =net volumetric transport rate, ρ = density of water, ρ_s =sand density, C_f =a friction coefficient, ϵ_b = Bagnold's efficiency of transport coefficient, ϕ = angle of internal friction of the sediment, β = angle of slope of the bottom, a' =ratio of total volume to volume of solids, H =wave height, T =wave period, L = wave length, and h =water depth. This is an expression for cross-shore bedload transport rate using Stokes wave theory in Bailard and Inman's (1981) form of Bagnold's (1963) bedload transport equation assuming all motion is in the cross-shore direction.

It can be assumed that transport due to irregular waves with a spectral significant wave height, H_{m0} , with a period corresponding to the peak of the energy density spectrum, T_p , will be proportional to transport due to the corresponding monochromatic conditions. Also, given that several of the empirical coefficients, in particular ϵ_b , have typical values based on limited tests, it seems logical to modify this transport equation with an empirical coefficient that can be used to fit the results to observed data specific to the migration problem. Therefore another empirical coefficient, A , has been added to

the above transport equation modified to use the spectral estimates of wave climate:

$$Q = A \frac{9\pi^2}{64} \frac{\rho g C_f \epsilon_b}{(\rho_s - \rho) a' \tan^2 \phi} (\tan \phi - \tan \beta) \frac{H_{mo}^4 T_p}{L_p^3} \operatorname{sech}^2 \left(\frac{2\pi h}{L} \right) \operatorname{csch}^4 \left(\frac{2\pi h}{L} \right)$$

where L_p = wave length corresponding to T_p computed with linear wave theory. The A will be used to fit the results to observed migration rate data below.

Considering conservation of sand in the cross-shore direction,

$$\frac{\partial h}{\partial t} - \frac{\partial Q}{\partial x} = 0$$

where t = time and x = the cross-shore direction.

Substitution of the above transport equation into the conservation equation results in a form of the convection-diffusion equation (Douglass 1995):

$$\frac{\partial h}{\partial t} + C \frac{\partial h}{\partial x} - D \frac{\partial^2 h}{\partial x^2} = 0$$

where

$$C = A \frac{9\pi^3}{16} \frac{\rho g C_f \epsilon_b}{(\rho_s - \rho) a' \tan^2 \phi} \frac{H_{mo}^4 T_p}{L_p^4} \left\{ 2 \operatorname{csch}^5 \left(\frac{2\pi h}{L} \right) \operatorname{sech} \left(\frac{2\pi h}{L} \right) + \operatorname{csch}^3 \left(\frac{2\pi h}{L} \right) \operatorname{sech}^3 \left(\frac{2\pi h}{L} \right) \right\}$$

$$D = A \frac{9\pi^2}{64} \frac{\rho g C_f \epsilon_b}{(\rho_s - \rho) a' \tan^2 \phi} \frac{H_{mo}^4 T_p}{L_p^3} \operatorname{sech}^2 \left(\frac{2\pi h}{L} \right) \operatorname{csch}^4 \left(\frac{2\pi h}{L} \right)$$

C has the role of the "convection" coefficient and D has the role of the "diffusion"

coefficient. The expressions for C and D originated from the consideration of conservation of sand with the wave theory and transport model and not on physical concepts of convection or diffusion. The equation implies that the form of a submerged mound will "convect" or move at speed C while it diffuses. Similar behavior of constructed bottom mounds has been observed (Hands 1991, Bodge 1994, Foster et al. 1996, Mesa 1996).

The equations outlined above can be used as a planning and design tool when combined with an estimate of wave climate at a specific site. The equations predict the behavior of a mound under a given, specified sea state. To apply it to a non-constant sea state, either the time history of sea must be estimated or a statistically valid estimate of the overall wave climate must be evaluated in terms of an "expected value of migration." Given a tabular estimate of the onshore portion of the wave climate, the expected value of mound movement in any given depth, $E[C(h)]$, can be estimated with C, the "convection" coefficient as

$$E[C(h)] = \sum p(H, T) C(H, T, h)$$

where the summation is across all (H,T) bins, $p(H,T)$ = probability or percentage of time that the wave height and period is of that magnitude.

APPLICATION

The migration rate equation above can be roughly calibrated by matching the predictions to the observed migration of constructed mounds. The "expected value" of the migration rate can be estimated with an estimate of the "expected" wave climate such as the US Army Corps of Engineers Wave Information Study (WIS) wave hindcast data for the Atlantic and Gulf coasts of the United States (Hubertz, et al. 1993). Using WIS data provides a consistent estimate of wave climatology when comparing different locations.

WIS data is given at specific depths. Since this methodology evaluates migration rate at varying depths, some form of transformation of wave climatology is needed. For the purposes of this study, a very simple, depth-induced, wave height reduction was used. It was assumed that the maximum spectral significant wave height in any depth of water was half of the water depth, i.e. $(H_{m0})_{max} = 0.5 h$. Wave heights were reduced to

that level to evaluate migration for the shallower depths. A more sophisticated wave transformation scheme could be used.

The first comparison is for the mounds constructed in around 6 m depth off the Alabama coast in 1987-88. Hands and Allison (1991) showed survey data that indicated the mounds moved roughly 30 m/yr initially. The methodology outlined above with the WIS climatology for that location matches this expected value when the calibration coefficient is $A=0.5$.

The second comparison is for a disposal mound created in about 6 m depth off Cocoa Beach in the Cape Canaveral area in 1992. Bodge (1994) found that mound moved roughly 30 m to 45 m landward in the first six months. Most of this movement occurred during and immediately after construction. By the time of the second post-construction survey at six months, the peak of the constructed mound had been flattened to the extent that there was not a clear crest, i.e. the bottom elevation profile had no significant decrease in depth in the offshore direction. Apparently the top of the mound moved about 60 m/yr to 100 m/yr during the first 6 months and then slowed down as the mound or bar-like feature was lost. The methodology presented here with the WIS data for Cape Canaveral, matches this expected migration rate when the calibration coefficient is $A=0.2$ to 0.33 .

Based on these two comparisons, A (using WIS data) can be set to roughly $A=0.3$ with a reasonable expectation that it may vary from $0.1 < A < 1$. The use of observed migration rates for comparison to expected migration rates is not optimum since the observations are based on much less time than the overall WIS estimate of wave climate, 20 years. The waves would be expected to be larger or smaller than typical for any 6-month to one-year time spans because of the natural variability in wave climate. The observed migration rates were due to the actual waves for that time period and not the long-term wave climate.

Any calibration of this methodology is probably dependent on the wave climatology estimate used. For example, wave climatology based on long-term, in-situ wave gages will probably have different calibration coefficients.

Figure 2 shows the results of this methodology at three locations with very different wave climates. The calibration coefficient was set to $A=0.3$ for Figure 2. Alabama is on the Gulf of Mexico and has a relatively mild wave climate. Cape Canaveral on the Atlantic coast of Florida has a moderate wave climate. Cape Hatteras has one of the more severe wave climates on the Atlantic coast of the United States. Figure 2 shows that the model estimates migration rates that vary significantly, up to an order of magnitude, for these three locations. For a given depth, migration rate estimates

Figure 2. Expected migration rate at three U.S. locations

are higher for the Atlantic sites than for Alabama. Such variation would be expected for any process based on wave climate. In particular, wave lengths are typically significantly longer for the Atlantic Ocean than the Gulf of Mexico. For deeper depths, Cape Hatteras migration rates are higher than Cape Canaveral. The estimates for the two Atlantic sites become close to each other in shallower depths. This closeness is due to the depth-induced, wave height reduction employed to transform the data into shallower water as discussed above. The infrequent, largest waves at Hatteras are more influential in the deeper depths but are less so after breaking as the depths decrease.

Interestingly, Figure 2 shows a similar general shape and dependence with depth at the three locations. This similar shape apparently is a function of the model equations. The same general shape has been found using wave climatology based on wave gages for the Santa Anna River, California nearshore placement of sand (Mesa, personal communication, 1996). This dependence with depth has practical value for planning and design. The results shown on figure 2 can be fit to a simple power relation:

$$E[C] = ah^{-b}$$

where $E[C]$ = expected value of migration rate (m/yr), a =coefficient, b =exponent, and h =depth (m). For most of Figure 2 and all of the deeper depths at each location, the best fit for the exponent is $b=5$. These are the depths where the wave height decay due

to depth ($(H_{mo})_{max} = 0.5 h$) was small. This was all of the depths shown for the Alabama site, most of the depths for Cape Canaveral, and the deeper depths for Cape Hatteras. In the portion of Figure 2 where the depth reduced the largest waves in the climatology, the depth dependence exponent is $b=4$. Thus, this methodology implies that migration rate is dependent on depth to the 4th or 5th power.

DISCUSSION

Implications of influence of depth on migration

The depth dependence of migration rate outlined above provides some useful concepts for planning and design of nearshore placement. The above equation implies that migration is extremely sensitive to depth at any specific site. Doubling the depth of placement will decrease the rate of migration by a factor of 16 to 32. Considering it another way, to double the migration rate, it is necessary to place the sand in only 13-16% shallower depth. This guidance should be of value in evaluating the cost vs. depth-of-placement issues typical of nearshore placement of sand.

The extreme sensitivity to depth implied by this methodology has not been verified by observations. Verification would require placement at different depths at the same general location and time with adequate monitoring.

Theoretical limitations

There are a number of theoretical limitations to the methodology presented here. First, many of the physical mechanisms that influence sediment transport in these depths including the effects of suspended sediment load, wave groups, ripple and dune migration, sheetflow, bed-ventilation, wave grouping, undertow, wind, bottom streaming and other bottom boundary layer complexities have been ignored. Second, the one physical mechanism modeled, the influence of wave asymmetry on net bedload sand transport could be modeled in a more sophisticated manner. A primary limitation is the use of Stokes 2nd order theory - particularly in shallow water. It was used because it is the lowest order theory with asymmetry. Better representations of the actual velocities should be used. Thus, this methodology can be considered as a rough first attempt at applying such a model to the problem at hand. Its abilities, in spite of this serious limitation, are encouraging in that they indicate the proper physics may be included.

Practical limitations

One serious practical limitation of this methodology is the use of a single depth

for modeling migration rate. Nearshore placement in a mound-like feature implies that different parts of the feature are in different depths. More importantly, the equations given above are extremely sensitive to depth. This presents a practical problem in specifying the single, appropriate depth for the use of this model. For this work, that single depth was chosen as the pre-existing depth at the middle of the feature. Conceptually, the top, or shallower portion, of the feature should move fastest and be flattened out by landward movement of sand into the deeper depth shoreward. There is evidence at many observed mounds that this has occurred (Bodge 1994, Mesa 1996, Hands and Bradley 1990, Foster et al. 1996).

Appropriate physics for modeling migration

The implication of the observations and the results presented here is that a net sand transport equation that is dependent on depth could be used with the conservation of sand equation to model the fate of nearshore disposed sands. More specifically, the use of a model that accounts for the influence of velocity asymmetry on sand transport is recommended for modeling the fate of nearshore placed material. Such models have been proposed by Stive (1986) and several of the investigators in the European Nourtec project (Houwman and Ruessink 1996, Roelvink, et al. 1996, Hoekstra, et al. 1996). The results presented in this paper and the detailed simulation of the behavior of the Silver Strand, California mound shown in Douglass (1995) imply that such modeling is an appropriate approach. The use of some form of Bailard's model (Bailard and Inman 1981) is common to all of these approaches. This present work does not endorse the use of Bailard's model specifically. Other approaches that explicitly account for the effect of net onshore bottom stress due to wave asymmetry should also be considered.

Other existing American methods

The other existing American methods for estimating the fate of nearshore placed sand are not explicitly based on this physical mechanism (wave asymmetry) although it may be implicitly included through the empiricism. The Hands and Allison (1991) method for movement or non-movement is essentially empirical and does not attempt to explain migration direction. The Hands and Allison method is based on extreme wave heights and a sand movement initiation criterion, and thus is really is not incompatible with the wave asymmetry mechanism proposed here. The Hands and Allison method may be successful because it adequately captures the wave asymmetry mechanism through the empiricism.

The Larson and Kraus (1994) method is purely empirical so the same argument could be made. However, that method is based on empirical expressions for surf zone sand bars and beaches. It does not seem likely that the dominant physical mechanisms in the inner surf zone occur in the same relative proportions in the offshore depths for a number of obvious reasons. Any skill shown by methods based on inner surf zone empiricism may be due to fortune as much as physics.

The physical mechanism modeled by Scheffner (1991, 1996), the sediment response to the mean currents with transport rate modified by the presence of waves, seems relatively unimportant to the migration of nearshore placed sand. The evidence from the Mobile, Alabama site demonstrates the fundamental problem with a model based on mean currents. Douglass, et al. (1995) found that the measured mean near-bottom currents in the area were shore-parallel during the time that the mounds migrated shoreward. Shore-parallel mean currents are consistent with expectations for tidal currents near the coast, i.e. along the bathymetric contours. The cross-shore component of the mean near-bottom current was offshore during the time the mounds migrated landward! This offshore dominance was more pronounced during times of large waves, presumably due to downwelling due to onshore wind stress during storms. It appears that Scheffner (1991, 1996) was only able to verify his model at the Mobile, Alabama site by the explicit specification of shoreward mean currents. This was apparently based on a numerical, tidal simulation of a selected seven month period. Given that the actual measured, mean near-bottom currents at the site were in the other direction, Scheffner's method seems incorrect.

Diffusion concept

The diffusion coefficient, D , presented above has also been investigated. It is notable that the diffusion coefficient does not have any free parameters. It has the same coefficient, A , that is in the C equation. No results are presented here for two reasons. One, the methodology estimated more diffusion was observed at Cape Canaveral. Other mounds; such as Mobile, Alabama and Perdido Pass, Florida; have shown less diffusion than the one at Cape Canaveral. The primary reason for not focussing on the diffusion portion of the model is conceptual. The "diffusion" term results directly from the way that bottom slope, $\tan \beta$, is included in the Bagnold/Inman and Bailard formulation for quasi-instantaneous transport. It accounts for influence of gravitational effects to pull sand down-slope. None of the observed mounds have shown a tendency for sand to move offshore down the slope, only onshore down the slope.

CONCLUSIONS

A design and planning tool for the nearshore placement of sand that estimates the expected onshore migration rate is presented. The results appear appropriate for the Atlantic and Gulf coasts of the United States. For any specific wave climate, the results indicate an appropriate way to evaluate the influence of depth on migration rate. Specifically, doubling the depth of placement will decrease the rate of migration by a factor of 16 to 32. Doubling the rate of migration requires placement in 13-16% shallower depths.

The physical basis for the model is the velocity asymmetry of large waves. This is consistent with observations reported in the literature and the findings of a field study off the Alabama coast that eliminated several other potential physical mechanisms for controlling mound migration. This model is limited by several theoretical and practical shortcomings. Its abilities, however, indicate that a wave-based model that accounts for the net onshore transport or shear stress under finite-amplitude wave is the appropriate way to model the fate of nearshore placed sands.

CHAPTER 287

Influence of Nearshore Berm on Beach Nourishment

Paul A. Work¹, A.M. ASCE, and Emre N. Otay²

Abstract

The influence of a large ($3.0 \times 10^6 \text{ m}^3$) nearshore berm on a large ($4.1 \times 10^6 \text{ m}^3$) beach nourishment project at Perdido Key, FL, is addressed via a monochromatic, numerical wave transformation model. Two years of post-placement survey data indicate that the nearshore berm, placed at a depth of 6 m with a relief of 1-1/2 m, did not migrate during this time period. Wave model results suggest that the berm influences the beach nourishment project via refraction, but breaking and diffraction effects are not significant. The berm causes wave transformation and leads to zones of wave energy focusing (and corresponding de-focusing) that affect longshore sediment transport rates in the lee of the berm. For a typical wave condition, predicted high-energy regions correlate well with observed erosional areas. The findings indicate the relative importance of project-induced wave transformation that should be considered during the design process for nearshore berm projects.

Project Background

The beach nourishment project at Perdido Key, FL, adjacent to Pensacola Pass, was initiated in late 1989. Pensacola Pass serves as an access channel to a major naval port; the beach nourishment material was generated by dredging of the entrance channel to 19 m. The region is characterized by diurnal tides with a very small range (mean tide range = 34 cm; spring range = 58 cm) and a relatively mild wave climate. The mean value of the significant wave height measured over 4 years

as a part of this study near the 6 m contour is 0.6 m. The mean value of the wave period at which the peak of the energy spectrum is found is 6 sec for the same time interval.

The beach nourishment aspect of the project involved widening the dry beach by 140 m over a length of 7 km and required a volume of 4.1 million m^3 . This was completed in September, 1990. Construction of an offshore berm then commenced. The offshore berm was completed in 1991. The placed berm was 4 km (longshore) by 300-800 m (cross-shore) and included 3.0 million m^3 of sand. The bathymetry in the region where the berm was placed was quite flat (slope of 1:1000). Water depth averaged 6 m, and the berm relief is nominally 1.5 m, leaving 4.5 m of water above the berm. Figure 1 indicates the site location, and Figure 2 shows cross-sections through the berm at different times.

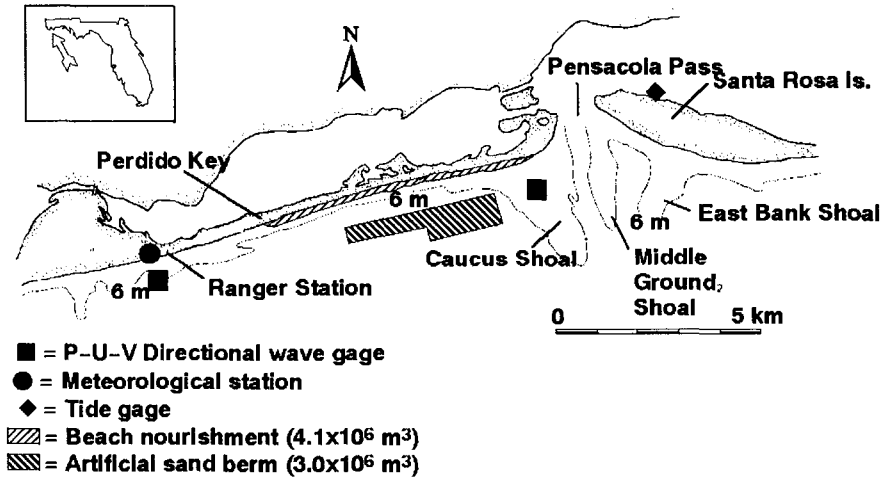

Figure 1. Site location and monitoring plan.

A monitoring program from 1989-1994 yielded a data set that is useful for assessment of hydrodynamics and sediment transport at Perdido Key, including annual bathymetric survey data and long-term wave and current data. Details of the monitoring program may be found in Work (1992), Otay (1994), and Work and Dean (1995).

Figure 2. Cross-section through berm near midpoint.

Survey data indicate that the berm has not migrated since placement, although it has been smoothed slightly (Figure 2). But due to the 25% reduction in water depth that it introduces over a large area, it is expected that the berm will exert some influence on the waves that pass over it, and therefore modify nearshore sediment transport. The purpose of this paper is to investigate this effect and assess its significance.

A nearshore berm can provide at least two benefits, depending on its behavior:

- 1) Nourish the beach as sediment moves onshore.
- 2) Shelter the beach in the lee of the berm.

Berms are sometimes favored over beach nourishment because of the reduction in cost due to the relative ease of placement. But correct assessment of the benefits requires accurate prediction of both any migrational tendency and any effect on adjoining areas.

Bathymetry

A numerical grid of depths at the site was created for wave modeling. The grid represents a combination of measurements taken as a part of the monitoring study and digitized nautical charts. Depths at the offshore boundary are not uniform and the grid does not extend to deep water, posing some problems for wave modeling that are addressed below.

A second grid was created by artificially stripping out the berm from the first grid. A detail of the two grid files is shown in Figure 3. Some “scalping” of the nearshore contours is evident in the no-berm plot. This is due to limitations of the contouring routine when there are “stripes” of data (in this case due to surveying beach profiles at 300 or 600 m intervals along the beach), a common problem. This will lead to some overestimation of the effects of wave transformation.

Figure 3. Bathymetry with and without offshore berm. Contour interval 1 m, with the addition of 3.5, 4.5, and 5.5 m depth contours. x -axis points onshore, y -axis in longshore direction. Pensacola Pass at right near $y = 10$ km.

Hydrodynamic Modeling

Measurements of wave energy spectra and mean currents are available at two locations at the site (Figure 1). A finite element hydrodynamic model (RMA-2, Norton, King, and Orlob, 1973, Thomas and McAnally, 1990) was employed to predict tidal currents. The friction factor in the model was adjusted until modeled currents agreed with published values for predicted tidal currents in the inlet throat (U.S. Dept. of Commerce, 1994). Results were then compared to measurements at the two wave gage locations for maximum ebb and maximum flood conditions. The model typically underpredicted currents slightly, not surprising due to the omission of wind- and wave-driven currents in the model. Figure 4 illustrates the results for maximum ebb tide.

Figure 4. Predicted tidal currents (from RMA-2 model) for maximum ebb tide through Pensacola Pass. Note that flow is concentrated between shoals to either side of navigation channel.

Wave Modeling

A monochromatic, finite difference wave transformation model (REF/DIF 1, Kirby and Dalrymple, 1994) was used to investigate wave transformation at the site. The monochromatic model was selected for two reasons: 1) ease of use, compared to a spectral model, and 2) to assess the viability of a monochromatic model for such a situation. Ease and speed of use become major factors when long-term simulations (years) will be performed.

Since neither bathymetry grid extended to deep water for most of the wave conditions to be modeled, an iterative procedure was developed to estimate wave conditions at the offshore boundary, given wave conditions at the western wave gage, where the bathymetric contours are relatively straight and parallel (Work and Kaihatu, in press). This allows one to drive the model with data from one nearshore wave gage (a common situation) and predict wave conditions anywhere else in the domain.

A large number of model runs have been performed with the real (berm) bathymetry at the site, using data from the western wave gage to drive the model. The monochromatic model, on average, yields a reasonable prediction of wave height at the other gage, although there is a large amount of scatter (the average value of the ratio of model to measured wave heights is 0.99; standard deviation of this

ratio is 0.34). The model is not a good predictor of wave direction at the other gage, in part because of the fact that the contours run nearly perpendicular to the nominal shoreline orientation at the eastern wave gage, which sits near a shoal. Figure 5 shows results for one simulation near this shoal.

Figure 5. Wave vectors near Caucus Shoal, immediately west of Pensacola Pass. Conditions at western wave gage: $H_{mo} = 0.6$ m, $T_p = 6$ sec, shore-normal incidence.

Wave model results indicate that tidal currents at the site do not exert any significant influence on wave conditions outside of the inlet channel. Thus bathymetric gradients are the primary cause of wave transformation. This simplifies modeling efforts substantially.

Hypothetical cases were simulated to isolate the influence of wave period, tide stage, and incident wave height and direction, on wave conditions in the lee of the nearshore berm. Figure 6 compares the wave heights for the two bathymetric grids for the “typical” case ($T_p = 6$ sec, shore-normal waves with height $H_{mo} = 0.6$ m at western wave gage). Figure 7 shows the difference between the two results, normalized by the incident wave height. Some findings:

- Tide stage has minimal influence on the wave height differences (berm vs. no berm). This is largely due to the very small tide range at the site.

- Dependence on wave period is as expected: as period increases, refraction becomes more pronounced, and differences between the two results increase.
- Dependence on wave height is weak until the incident wave height is increased to the point where waves begin to break on the nearshore berm ($H_{mo} > 3.5$ m). The largest significant wave height measured during the 4-year wave monitoring program was 2.9 m, in August, 1992, while Hurricane Andrew was in the Gulf of Mexico. This event also yielded the largest measured wave period ($T_p = 13$ seconds). In summary, wave breaking on the berm has occurred rarely, if at all.
- Dependence on incident wave direction is relatively strong. Greatest differences between the berm and no-berm cases were observed for nearly shore-normal waves.

Figure 6. Wave model results with typical wave conditions ($H_{mo} = 0.6$ m, $T_p = 6$ sec, shore-normal incidence, at western wave gage), with and without berm. Contours indicate depth at 1 m intervals. Shade indicates wave height relative to wave height at western wave gage.

Figure 7. Difference between no-berm and berm wave model results shown in Figure 6. Normalized by no-berm results. Shade indicates percent difference in wave height. Positive values indicate percent increase in wave height in absence of berm, negative indicate percent reduction.

The maximum difference between the berm and no berm wave height fields, for the region behind the berm, is 30%. Because there is typically a minimal difference in energy dissipation between the berm and no berm cases, the total energy reaching the shoreline is the same whether or not the berm is present. The berm acts to redirect energy and leads to zones of focusing and de-focusing. If depths over the berm were less, breaking would occur on the berm and the shoreline behind the berm would be more sheltered. Figure 8 compares the wave height fields for large vs. small incident wave heights, both over the berm bathymetry, to illustrate this effect.

Limited tests were also performed with a spectral version of the same wave model (REF/DIF S, Ozkan and Kirby, 1993). This model essentially consists of superimposing many results from the monochromatic model for different frequencies. Results with the spectral model were similar to the monochromatic model results, but more muted. The presence of additional frequency components leads to less pronounced focusing of wave energy. One example is provided in Figure 9.

Figure 8. Small wave height ($H_{mo} = 0.6$ m, $T_p = 6$ sec, shore-normal at western wave gage) vs. large ($H_{mo} = 3.0$ m) wave height results over berm bathymetry. Shade indicates wave amplification. Contours indicate depth at 1 m intervals.

Figure 9. Monochromatic model (REF/DIF 1) vs. spectral model (REF/DIF S) results for conditions corresponding to Figure 6. Shade indicates percent difference in wave height. Positive values indicate percent increase in wave height in absence of berm, negative indicate percent reduction.

Shoreline Change

Redistribution or reduction of wave energy reaching the shoreline will affect sediment transport. Figure 9 shows the measured changes in shoreline planform, relative to the pre-nourishment condition. This is a classic signature for a beach nourishment project: the waterline moves back, rapidly at first, due to cross-shore sediment transport, since the as-built beach profile slope is much steeper than natural slopes. The “shoulders” (ends) of the project erode more rapidly due to the high rate of sediment diffusion in the longshore direction induced by strong planform gradients.

Figure 10. Measured change in shoreline position, relative to pre-nourishment condition. Nominal distance between survey ranges is 300 m, Pensacola Pass at right limit of figure.

Another means of investigating the evolution of a nourishment project is to calculate the volumetric changes per unit length of beach, i.e. the change in the cross-sectional area of the beach profile. Doing so allows one to integrate out the effects of cross-shore sediment transport: all observed changes are due to longshore redistribution of sediment arising from longshore gradients of longshore sediment transport. This requires assumption of a depth beyond which there is no cross-shore sediment transport. For the Perdido Key beach nourishment project, it is quite clear that there is negligible sediment transport beyond the 5.5 m contour (Work and Dean 1995).

Figure 11 shows the computed longshore gradient of longshore sediment transport, which is equal in magnitude (but opposite in sign) to the change in cross-sectional area of the beach profile per unit time. Positive values indicate erosion and

negative indicate accretion. The question is then whether these zones of erosion and accretion can be predicted by the numerical wave model. A definitive answer to this question would require that the wave model be run for every measured wave event to calculate a four-year time series of breaking wave height and direction. These time series could then be used to drive a shoreline change model.

Unfortunately it is not possible to model wave transformation for every measured wave event. There are many measured wave directions which are highly oblique (> 45 degrees) to the shoreline. The chosen wave model (and any other similar model which employs a parabolic approximation to the elliptic governing equation) has a limitation on the incident wave angle. If the incident wave angle exceeds a certain value (the value of which depends on details of the model formulation), the model will yield erroneous results or no results at all. In addition, the method developed to estimate wave conditions at the offshore boundary of the grid, given wave conditions at one nearshore wave gage, similarly will not work for highly oblique waves. In practice, it was possible to model only about one-half of the measured wave conditions.

A “typical” wave condition was therefore chosen for comparison of wave height fields and observed shoreline changes. Noteworthy regions are indicated by the arrows on Figure 11. Several features stand out:

- There is consistent focusing predicted (both with and without the berm, for nearly all wave conditions) at the eastern limit of the nourishment project. This is indicated by the arrow at the extreme right of Figure 11. A strong erosional trend is also observed there. This is erosion of the end of the beach nourishment project, enhanced by the focusing of wave energy.
- Placement of the berm reduced, for the “typical” wave condition, the wave heights near the midpoint of the beach nourishment project, where a switch from erosional to stable behavior is observed (middle arrow in Figure 11). A similar switch occurred near the western end of the nourishment project, where placement of the berm reduced wave heights, and a switch from a stable shoreline to accretion occurred (left arrow).

Figure 11. Longshore gradient of longshore sediment transport, calculated from surveyed beach profiles. Equivalent in magnitude to change in cross-sectional area of beach profile. Nominal spacing between ranges is 300 m, Pensacola Pass to right.

Project Performance

Volume of sand remaining within the nourished region was computed as a measure of project performance. Three years after placement of the beach nourishment material, 84% of the initial volume remains (Figure 12). If the entire monitored area is considered, the value is 82%. Some of the nourishment material has been deposited into the inlet, and some has moved westward due to the predominant wave conditions.

Figure 12. Volume changes for project. Nourished region is a subset of the monitored region.

Conclusions

Nearshore berms can and have been placed with the goal of gradual beach nourishment through onshore migration. Existing predictive capability with regard to rate and even direction of migration (onshore or offshore) is still limited. A berm can also exert a sheltering effect on the beach in its lee. The presence of the berm can either merely redistribute wave energy, or, if it induces additional dissipation through breaking over the crest of the berm, reduce wave energy reaching the shoreline. The effect of the berm on the shoreline behind it should be considered as part of the design process.

Data for two years after placement of a berm at Perdido Key, FL, indicate the berm did not migrate during this time. It has been slightly smoothed but its volume unchanged. Numerical wave model results indicate that the berm does exert some influence on the breaking wave climate by redistributing energy alongshore. This occurs even in the absence of waves breaking on the berm. Changes in nearshore wave heights which occur as a result of the berm are reflected in the measured shoreline signature, for a typical incident wave.

It was not possible to model all wave events with the chosen numerical wave transformation model. Waves which deviate significantly from shore-normal occur frequently at the site but could not be modeled. Improvements in wave modeling techniques will eventually remove this constraint.

CHAPTER 288

ACCURACY OF SAND VOLUMES AS A FUNCTION OF SURVEY DENSITY

Jennifer L. Irish¹, W. Jeff Lillycrop², and Larry E. Parson³

ABSTRACT

Hydrographic surveys are the primary tool for calculating beach nourishment project volumes. With costs for beach-quality sand as high as \$30 US per cubic meter, miscalculating project design volumes can result in significant cost differentials. Because conventional bathymetry and topography of beach projects are collected along shore-normal profile lines spaced anywhere from 30 m to 300 m, calculation of project volumes relies heavily on the assumption that there is little along-shore variability from one profile to another. In most cases, however, the beach and nearshore are highly irregular and this assumption is violated. With the development of high-resolution bathymeters, such as the SHOALS airborne lidar system, it is now feasible to collect accurate, high-density beach surveys. These types of data sets create a highly accurate, quantitative measurement of beach and nearshore conditions. This paper describes the SHOALS system and lidar technology and presents a comparison of volumes calculated using high-density lidar data and conventional nearshore profile surveys. Volumes are calculated to compare differences for beaches on the Atlantic Ocean, the Gulf of Mexico, and the Great Lakes.

1.0 INTRODUCTION

Cost for a cubic meter of sand placed on a beach ranges from \$5 US to \$30 US, depending on many geographic and engineering factors. Beach nourishment projects range in size from several thousands of cubic meters, such as the 1993 project at St. Joseph, Michigan of 39,000 m³, to millions of cubic meters, such as the project at Miami Beach, Florida of 12 million m³. Underestimated project design volumes can result in cost overruns or a reduced amount of sand being placed on the beach, while overestimated project design volumes can result in excessive budgeting and planning. Hydrographic surveys are the primary tool for calculating project

1) Hydraulic Engineer, 2) Research Physical Scientist, 3) Research Hydraulic Engineer, US Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA

volumes. Conventional survey techniques use shore-normal wading depth surveys matched with offshore acoustic surveys, spaced at intervals along the beach ranging from 30 m to 300 m.

Calculation of project volumes relies on the assumption that there is little topographic or bathymetric variability from one profile line to the next, or that if there is variability, it averages out over the project limits. However, beach and nearshore topography are highly three-dimensional as a result of sub-aerial sand dunes, nearshore bars, hard-bottom outcrops, seawalls, and groins. At profile spacings typically on the order of 300 m, these assumptions are often violated. With the development of lidar (LIght Detection And Ranging) hydrographic systems, such as the US Army Corps of Engineer's (USACE) Scanning Hydrographic Operational Airborne Lidar Survey (SHOALS) system, it is now economically feasible to collect accurate, high-resolution beach and nearshore surveys.

The following discusses the SHOALS system and its technology and discusses the benefits of high-resolution bathymetry and topography. Four beach projects surveyed with SHOALS are presented and analyzed to determine sand volume computation sensitivity to survey density.

2.0 SHOALS SYSTEM

In 1994, the USACE introduced a new airborne hydrographic survey system capable of remotely collecting high-resolution, accurate bathymetry. The SHOALS system is an airborne-lidar system operating from a Bell 212 helicopter (Figure 2.1). The system uses state-of-the-art lidar technology to measure water depths (Guenther, 1996). A laser-transmitter/receiver is housed inside a pod mounted underneath the aircraft. As the laser pulses at 200 Hz, it is scanned in an arc producing a swath width equal to approximately one-half the aircraft altitude. This yields a uniform sounding spacing, nominally 4-m by 4-m. The laser pulse travels from the airborne platform to the water surface where part of the energy reflects back to the receiver (Figure 2.2). The remaining energy penetrates the water column and reflects off the sea bottom. The time differential between these two returns indicates the water depth (Lillycrop et al., 1996).

Figure 2.1 The SHOALS system

Table 2.1 gives SHOALS current performance specifications. SHOALS has a vertical accuracy of ± 15 cm and a horizontal accuracy of ± 3 m and meets the USACE Class I, dredge payment, performance specifications (Riley, 1995). Operating at a nominal speed and altitude of 30 m/s and 200 m, SHOALS surveys 8 km² per hour. In optically clear water, SHOALS records to depths of 40 m. Since early 1995, SHOALS also records accurate topographic

elevations of adjacent beaches allowing full mapping of both the beach and nearshore. To date, SHOALS surveyed over 80 USACE projects totaling 2,000 km².

3.0 SITE DESCRIPTIONS

Because SHOALS collects very dense bathymetry, typically 120,000 soundings per square kilometer, it is an ideal tool for monitoring the beach and nearshore in dynamic, irregular areas. For a particular stretch of beach, SHOALS data provides detailed bathymetry and adjacent beach topography allowing accurate identification of high-erosion areas and complex nearshore features. The four data sets presented herein include Longboat Key on the Gulf of Mexico, Island Beach State Park on the Atlantic, and St. Joseph and Presque Isle on the Great Lakes. Each of these sites is characterized by irregular cross-shore and/or along-shore variation in topography.

3.1 Longboat Key

Longboat Key, Florida is on the east shore of the Gulf of Mexico and is situated between Longboat Pass, to the north, and New Pass, to the south. Over 2 million cubic meters of beach-quality sand were placed on the southern-most 8.5 km of the key in 1993 to protect the shoreline from further erosion. SHOALS surveyed the area 5 times since March 1994 to monitor the nourishment project (Irish and Truitt, 1995). The high-resolution SHOALS bathymetry collected in November 1995 reveal a complex sand-bar system in the nearshore (Figure 3.1). The dual-bar system merges together and separates as it parallels the shoreline. At the southern end of the key, the seaward bar diverges into the ebb shoal of New Pass. Conventional profile data are regularly collected along profiles spaced 300 m apart and outline the dual-bar system; however,

Figure 3.1 Longboat Key, Florida, November 1995: a) representative section of SHOALS bathymetry, b) simulated profile bathymetry at 300-m spacing. All depths are in meters referenced to NGVD.

these data sets do not reflect local complexities in the nearshore. The southern-most 3.4 km were analyzed in this investigation.

3.2 Island Beach State Park

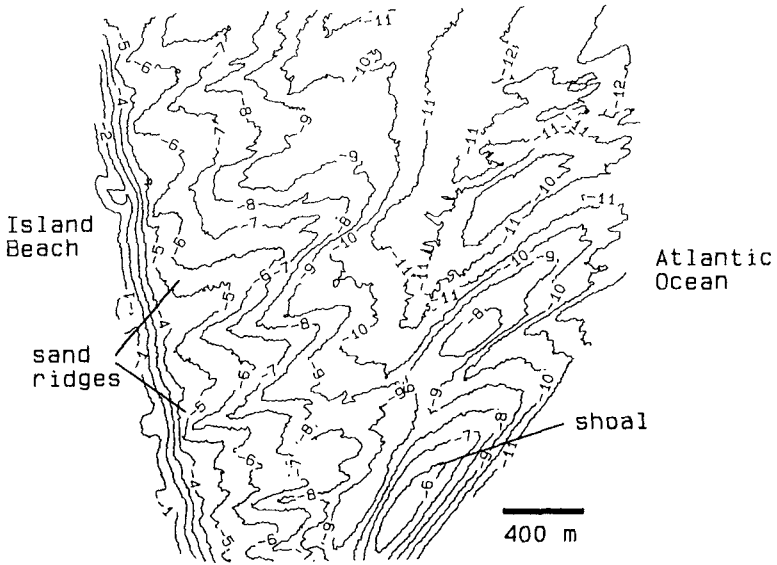

A 2.5-km stretch of Island Beach State Park, New Jersey, just north of Barnegat inlet was surveyed with SHOALS in 1994. The park is directly exposed to the Atlantic Ocean and is characterized by shore-perpendicular sand ridges stretching from the dry beach through the nearshore. Because the area is a state park, no man-made alterations are permitted. However, Barnegat inlet, which is jettied on both its north and south sides, does impact Island Beach. SHOALS surveyed the southern-most 2.5 km of Island Beach in June 1994 (Figure 3.2). The survey details the beach's three-dimensionality quantifying the sand formations and the shoaled areas formed by inlet processes.

3.3 St. Joseph

St. Joseph, on the southeastern shore of Lake Michigan, was authorized as a Federal beach nourishment project in 1976. In 1903, two jetties were constructed to stabilize the St. Joseph River entrance. These jetties interrupt the natural southerly longshore transport of 84,000 m³ per year, and as a consequence, the downdrift beach experienced erosion and the lake bed suffered downcutting (Parson and Smith, 1995). Since 1976, the USACE annually places dredged material from the maintenance dredging of St. Joseph Harbor south of the entrance to form a feeder beach to replenish 6 km of shoreline. Additionally, coarser material from an upland source is periodically placed. Typically, bathymetric and topographic data are collected along survey lines spaced 152 m apart through the fill area and 800 m apart south of the fill area. In August 1995, SHOALS surveyed the project collecting nearly 400,000 soundings (Figure 3.3). The SHOALS data quantify areas of severe lake-bed downcutting and identified a previously undiscovered headland feature with a 2-m relief. The entire 6-km project was analyzed in this investigation.

3.4 Presque Isle

Presque Isle Peninsula is on the south shore of Lake Erie at Erie, Pennsylvania. The peninsula historically tends to migrate easterly causing erosion of the lake-side beach. Occasionally the area breaches causing dangerous navigation conditions in Erie Harbor, situated between the peninsula and the mainland. The USACE has taken several measures to prevent erosion including beach nourishment and the construction of groins (Grace, 1989). In 1992, the USACE installed 55 breakwaters offshore of Presque Isle. Each breakwater is 47.5-m long and is separated by a 106.7-m gap. Additionally, 285,000 m³ of beach fill material were placed initially and renourishment occurs annually (Mohr, 1994). Ongoing project monitoring of the performance of the breakwater system includes bathymetry and topography collected annually along profiles spaced 300 m to 600 m apart. In August 1995, SHOALS surveyed this breakwater system detailing the salient and tombolo formations shoreward of the structures and the fairly uniform bottom seaward of the structures (Figure 3.4). The entire 9.9-km long project was used in this investigation.

4.0 COMPARISON PROCEDURE

To evaluate the importance of data density on beach nourishment volume calculations, profile data along spacings varying from 5 m to 300 m were simulated from the SHOALS bathymetry using a commercially available CAD and engineering package, TERRAMODEL™. First, profile alignments spaced every 5 m were created along the project length. A digital terrain model (DTM) of the SHOALS data was created to represent it mathematically. The SHOALS depths, as represented by the DTM, were then projected onto the profile lines at 4-m intervals. The resulting bathymetric contours for the simulated profiles at 300-m spacing are in Figures 3.1b, 3.2b, 3.3b, and 3.4b illustrating the loss of detail with such a wide spacing.

Figure 4.1 Cross-sectional area

To simplify calculations, volumes were computed between the horizontal plane representing a mean water vertical datum and the bottom topography as represented by the simulated profiles (Figure 4.1). Volumes were computed using the well-known area-end method for each profile spacing. When employing the area-end method, the cross-sectional area between the bathymetry and mean water at

each profile location was first calculated. (Only the area below the mean water vertical datum was computed.) The calculated area at one profile location (A_1) is then averaged with that of the next consecutive profile (A_2). The product of this averaged area and the length between the two consecutive profiles (L) gives the volume (V) between the profiles:

$$V = \frac{A_1 + A_2}{2} \cdot L$$

The total volume for the entire project is then equal to the summation of the volumes. The computed results are presented in Table 4.1 as volume difference between the highest resolution set, 5-m spacing, and the stated spacing, in cubic meters per meter length of beach. Positive differences indicate that the stated spacing resulted in a volume larger than the 5-m spacing volume while negative differences indicate a smaller volume.

5.0 DISCUSSION

The results, in general, show that as the spacing between survey profiles increases, so too does the error in computed volumes. Figure 5.1 gives a plot of

Table 4.1 Computed volume differences

Profile spacing	Volume difference (m ³ /m)			
	Longboat Key	Island Beach	St. Joseph	Presque Isle
5	0.0	0.0	0.0	0.0
10	-0.4	0.1	0.0	1.2
25	0.0	-0.1	-0.4	1.9
30	-1.8	0.1	0.2	0.8
50	0.2	-0.3	-1.7	3.3
60	-3.1	0.2	2.3	0.9
100	-1.6	-1.9	-3.3	6.1

200	2.2	5.3	-18.5	0.8
250	-6.6	-15.9	8.4	4.2
300	12.3	-19.8	-5.3	-9.8

Figure 5.1 Measured volume error

absolute deviation from the 5-m volume (volume error) versus profile spacing for all four sites. In general, the volume error becomes more random and larger in magnitude as profile spacing increases. This is consistent with the findings of Saville and Caldwell (1952). In their investigation, the use of average profiles at spacings varying from 120 m to 2,800 m to represent lengths of a fairly uniform beach were analyzed for accuracy in evaluating engineering volumes. The spacing error, defined as the accuracy measurement of a particular profile in representing a section of beach, was evaluated by comparing the selected profile with the average profile for that section. The spacing error was then translated into a volume error, defined as the total volume difference over the project length. Their conclusions state that the volume error increases nearly linearly as profile spacing increases. Saville and Caldwell's results do not indicate a randomness in volume error; however, the results from this investigation do. This is most probably attributed to the irregularities in the bathymetry evaluated herein.

Of the four sites, the bathymetry at Longboat Key shows the least along-shore variation. This is reflected in the results where the volume error at Longboat Key is within $5 \text{ m}^3/\text{m}$ for profile spacings as great as 200 m. However the area is still highly three-dimensional, and the volume error when using 200-m, 250-m, and 300-m spacings continually increases and is as much as $12.3 \text{ m}^3/\text{m}$. The calculations for Island Beach indicated similar findings. Here, the volume error is small for profile spacings less than 200 m, and as the spacing increases beyond 200 m, the measured volume error increases. In contrast to Longboat Key, the bathymetry at Island Beach is highly variable along-shore with shore-normal sand ridges occurring every 400 m to 500 m. This investigation indicates that bathymetric variations associated with these large features do not impact volume computations until the profile spacing exceeds 200 m.

The analysis at St. Joseph shows that profile spacings larger than 100 m result in significant volume error. Differing from Longboat Key and Island Beach, as the profile spacing is increased at St. Joseph, the volume error does not continually increase. The measured volume error at St. Joseph when a 250-m spacing is used is significantly lower than that measured when a 200-m spacing is used. However, all spacings greater than 100 m result in volume errors larger than $5 \text{ m}^3/\text{m}$.

Of the four projects, Presque Isle is most affected by survey spacing changes between 5 m and 50 m, and volume computations deviate significantly with spacings greater than 50 m. Of the spacings evaluated at Presque Isle, the volumes computed using 150-m spacing yielded the largest error, $10.4 \text{ m}^3/\text{m}$. When the spacing is increased to 200 m, the volume error dramatically decreases. Because of the uniform repetition of salient formations every 155 m corresponding to the breakwater field, it is probable this decrease in volume error is a result of these features. By chance, the profile locations at the 200-m spacing were such that the volume error between consecutive profiles averaged out over the project length.

The economic impact of profile spacing is evident in Figure 5.2 where the cost error, or absolute cost difference per cubic meter per unit length of beach, for the Presque Isle project is displayed. The lower and upper cost error boundaries were calculated using a cost per cubic meter of beach-quality sand equal to \$5 US and \$30 US, respectively. Even at profile spacings as small as 50-m, the cost error is as great as \$100 US/m. As the profile spacing increase to 100 m or greater, the cost error

Figure 5.2 Cost error at Presque Isle, Pennsylvania

becomes as great as \$325 US/m, translating to a total project cost difference well over \$3 million US. With renourishment at \$22 US to \$26 US per cubic meter occurring annually at Presque Isle, higher density surveys are certainly warranted. Typical monitoring at profile spacings of 300 m or greater may result in cost differentials around \$2.5 million US over the project length.

Similar cost impacts may be observed at the other three projects. At Longboat Key, a 300-m profile spacing results in cost differentials between \$ 200,000 US and \$1.2 million US over the 8.5-km project length. At Island Beach and St. Joseph, profile spacings greater than 150 m may result in cost errors in excess of \$75 US/m. At all four projects, the economic benefits of higher density bathymetry are obvious.

Hydrographic surveys serve as the base for engineering planning and design of beach nourishment projects. Usually, a fixed budget for a particular project is developed from volume calculations between the design profile and the collected bathymetry. If design volumes were computed using sparse data, a fixed budget may result in too little, or too much, sand placement at the site. Ultimately, project performance is affected: an under-designed project will not adequately protect against further shoreline erosion.

6.0 CONCLUSIONS

This investigation clearly indicates the economic and planning benefits of high-resolution bathymetry for beach nourishment along irregular beaches. Low density data may result in gross miscalculation of fill volumes ultimately impacting project performance and financial management. The conclusions of this analysis are based on

engineering volumes computed with respect to the below-water portion of the profile and only reflect underwater bathymetric irregularities. However, initial design, maintenance, and monitoring of beach nourishment projects also encompasses the above-water portion of the profile. There are commonly occurring irregularities on the above-water portion as well including sand dunes and features associated with man-made structures. Based on the findings herein, inclusion of the above-water portion of the profile should result in even greater inaccuracies in engineering volumes when wide profile spacings are used.

Data density for a particular hydrographic survey mission should be governed by the degree of along-shore variability and the intended engineering application of the data set rather than the capability of the survey instrument. For example, high-density data may not be required when monitoring long-term regional coastal evolution; however, high-density data are required when preparing plans and specifications for a beach nourishment project in an area with irregular bathymetry. High-density bathymetry are also valuable when evaluating the performance of erosion-control structures such as groins or detached breakwaters.

The findings herein prompted several new investigations including the expansion of this study to include the above-water portion of the project. Furthermore, studies are ongoing to optimize profile locations to best represent a project while minimizing data collection requirements. Finally, similar investigations are evaluating the impacts of data density on other engineering computations, such as dredging volumes.

With complete coverage, accurate bathymetry now available at costs nearly two-thirds that of conventional methods, engineers can more accurately and cost-effectively plan, design and monitor beach nourishment projects. Furthermore, future research will provide new guidance for determining necessary survey densities for accurate engineering computations.

CHAPTER 289

Shoreline Analysis Using Digital Photogrammetry

Margery F. Overton¹
John S. Fisher²

Abstract

This paper discusses the application of digital photogrammetry to the analysis of shoreline change with examples from Holden Beach, NC. Beach cross sections are generated from a three dimensional stereo image. These profiles are then used to determine shoreline position and erosion rates. The paper compares these rates of shoreline change with those determined from the more traditional methodology based on the two dimensional interpretation of the wet-dry line. The paper also illustrates the improved accuracy obtained by using survey grade GPS as opposed to USGS topographic maps to establish ground control.

Introduction

Coastal engineers are always seeking better tools to analyze shoreline changes. These changes include the result of long-term erosion or accretion and short-term impacts of severe storms. The two most frequently used methods to record shoreline change are directly from field surveys and remotely from aerial photographs. Both methods have advantages and disadvantages.

¹ Associate Professor, NCSU-Kenan Natural Hazards Mapping Program, Department of Civil Engineering, NCSU, Raleigh, NC, USA, 27695.

² Professor, NCSU-Kenan Natural Hazards Mapping Program

Field surveys provide detailed information regarding the topography and bathymetry of the beach and shoreline. These surveys are relatively expensive. In addition, they can not be used to determine long-term change if no historical surveys have been conducted.

Alternatively, the interpretation of shoreline change from aerial photographs permits one to perform a historical analysis when such photographs are available. Unlike field surveys, traditional methods for analyzing shoreline change from aerial photographs do not generally furnish the three dimensional data provided by a field survey. Three dimensional data can be obtained from aerial photographs, however, if one utilizes photogrammetric techniques including the analysis of pairs of overlapping photographs.

Until recently, few coastal engineering projects have included the application of three dimensional photogrammetric techniques to analyze shoreline change, simply because traditional photogrammetry relies upon complex analytical stereoplotters. These devices do not lend themselves to routine use outside of the highly specialized photogrammetry laboratory.

The difficulties of using photogrammetry for shoreline change analysis have been significantly reduced by the introduction of the new computer based digital techniques. Digital photogrammetry replaces the analytical stereoplotter with a three dimensional image that has been generated by a computer coupled with a high resolution scanner. A pair of photographs is scanned, the two images merged and viewed on the terminal as a single three dimensional image with the use of special glasses worn by the operator. In addition to reducing the difficulty in generating a three dimensional image, the technique supplies an image in digital format. This greatly expands the opportunities for data manipulation and analysis.

This paper describes our experience with the application of digital photogrammetry to the analysis of shoreline change along the coast of North Carolina. While we are still learning, it is already clear that this technology has greatly expanded our abilities to make accurate measurements of erosion rates and the impacts of severe storms on the beach.

Project Study Area

The Holden Beach project described in the paper is located in Brunswick County, on the southernmost portion of the North Carolina coast, Figure 1. The study area is a typical barrier island separated from the mainland by a narrow estuary (the Intracoastal Waterway). Most of the beaches in Brunswick County are developed with low density single family houses as is typical for the mid-Atlantic coast. Long-term shore erosion is on the order of 2 to 4 ft/yr. The occasional severe storm, including both hurricanes and northeasters, coupled with the effects of long-term erosion has led to the loss of oceanfront houses and a general need to be able to make reasonable estimates for the future changes in shoreline position.

The analysis of the rates of shoreline change at Holden Beach is part of a larger study of the area being undertaken for the North Carolina Department of Emergency Management through a grant from the Federal Emergency Management Agency. The larger study is intended to develop new techniques for natural hazard identification through the use of digital photogrammetry.

Project Description

The analysis presented in this paper focuses on the measurement of the change in position of the shoreline. In this context the shoreline is defined as the interface between the wet and dry beach as seen from aerial photographs. This interface has been used by many investigators (e.g., Dolan, et al. 1978) as the shoreline, and is often referred to as the high water line in the literature. Strictly speaking it is not the high water line, but rather a time average of this line. This line is not fixed in space; it moves up and down the beach face depending upon the tide, beach slope, and to some extent the wave climate (Fisher and Overton, 1994).

Our laboratory utilizes both hardware and software developed by Intergraph Corporation. The photogrammetric grade scanner with a maximum scanning capability of 3386 dpi is a key feature of the system. It provides the digital resolution needed to achieve the accuracy desired in the data analysis. Figure 2 illustrates a typical digital photogrammetric project work flow. Two or more photographs are scanned (at a typical scanning resolution of 1693 dpi) and used to build a stereo image.

Standard photogrammetric procedures including interior and relative orientation correct for camera distortion and tilt.

One of the most important steps in this work flow is to establish an accurate set of ground control points. These points determine the absolute position of objects seen on the photographs. In order to maximize the ultimate accuracy of the project we have elected to use survey grade GPS equipment for this ground control.

Ideally the ground control should be established at the time of the aerial photographs. However, in many cases this is not possible, and we frequently have to establish ground control after the fact. For example, control points can be established from features that are visible in the photography and which can be surveyed accurately. Using photography from the last five years, this procedure has allowed us to establish control points with approximately 3 ft accuracy.

Once the control has been established, the computer can then generate a three dimension image of the beach. As noted above, the operator must be wearing a special set of glasses to view this image, much like one would do in a theater when viewing a 3-D movie.

The operator, using the stereo image, can next proceed to create a digital terrain model, or DTM. This model is developed by the operator "placing" the computer cursor on ground at multiple locations. This process requires a certain amount of training and experience, and therefore the quality of the DTM depends upon the skill of the photo analyst. Once the DTM has been created, a number of different digital products can be produced, depending upon the specific application and interest. Examples include orthophotos, triangulated irregular networks (TINs), grids, and draped images.

Shoreline Change Measurements

Figure 3 is a digital orthophoto for a portion of the study area for June 1992. A digital orthophoto is a computer generated 2-dimensional image which has been corrected for distortion. Accurate measurements can be made directly from this orthophoto. Because of the digital format it is possible to zoom in on a portion of the photo as shown by the inset in this figure. The shoreline (wet-dry line) has been identified by the operator as indicated by the line drawn on the beach. As noted above,

this shoreline is dependent upon the waves and tide at the site at the instant in time when the photograph was taken.

When analyzing shoreline change it is necessary to look at two dates. In addition to the 1992 date shown in Figure 3, we chose a set of photographs taken in 1955 as the second date. Figure 4 shows a pair of orthophotos at the same site for 1992 and 1955. The development that has taken place between these dates is clearly evident. In addition, the 1955 orthophoto was taken less than 12 months after Hurricane Hazel struck this coastline. Hazel (prior to Hurricane Fran in 1996) was the most severe storm to impact this shoreline in memory. The extremely wide overwash penetration shown on this photograph is due to that single storm. It is important to note that the absence on the 1955 photograph of most of the man-made features shown on the 1992 photograph makes it difficult to establish reasonable control for the earlier date.

Once we have identified the wet/dry line for the two different dates it is a relatively easy task to determine shoreline change. We use a technique developed by Dr. Robert Dolan (Dolan, et al. 1978). This technique uses an imaginary, shore parallel off-shore baseline as a reference line. The distance from this baseline to the shoreline is measured along an orthogonal drawn between the shoreline and the baseline. In our work we set these orthogonals at 150 ft intervals. Once the distance between the baseline and the shoreline is known for the two dates in question, it is a simple matter to compute the erosion/accretion rate.

Prior to our use of the digital orthophotos we used the more widely practiced techniques described by Dolan and others which depend upon less accurate corrections for the aerial photographs. In this prior method, ground control points for the photographs were identified using USGS topographic maps. Figure 5 illustrates the difference in erosion rates we found between these two methods at the study site. The difference is about 1 ft/yr. At this site, where the average erosion rate is about 3 ft/yr, this is a significant difference. Depending upon the site, this difference can be important when one attempts to use these data for shoreline management and construction permit programs.

The method to determine shoreline change described above is an essentially 2-dimensional technique. Since the digital image is stored in the computer as an 3-dimensional object, it is interesting to consider how one could determine shoreline change from this latter data. In this case

we work from a computer generated TIN. The TIN is a three dimensional wire diagram of the stereo image, as shown in Figure 6. The triangles connect points of known elevation.

From the TIN the software can generate cross-sections normal to the shoreline at any location. Figure 7 illustrates two such profiles, for 1955 and 1992. As an alternative to measuring the change in position in the wet/dry line, one can now measure the change in position of a specific elevation contour. For comparison, the wet/dry lines are also shown on this figure. Of course, the use of beach profiles to determine rates of shoreline change is not new. This is the normal procedure when working from field survey data. However, the ability to generate these profiles from digital historical aerial photographs is a relatively new procedure, and one worthy of future development.

Figure 8 illustrates the difference in erosion rates determined by these two methods. For this site the change in position of the wet/dry line between 1955 and 1992 yields a higher erosion rate than the method which is based upon the change in position for the 3 ft contour for these same dates. Note that the general trend in the data is consistent between the two methods. All things being equal, we feel that the erosion rate based upon the contour is preferable because it reduces the influence of the waves and tides on the data.

We are continuing to explore the pros and cons of the two methods to measure shoreline change. A rigorous test with field survey data is needed prior to making any conclusions regarding the preference of one over the other.

Draped Images

The discussion above has focused on the use of digital photogrammetry for measuring shoreline change. Another important use for this technology is the ability to generate realistic looking computer images of the beach. One way to generate such an image is to "drape" the orthophoto over the TIN, as shown in Figure 9. This image (shown here with a 5x vertical distortion) enables us to visualize the topography and see clearly the dunes, roads, houses, and vegetation. Such pictures are valuable both to the analyst as well as the general public. In the latter case these images can be used to help explain a problem, proposed solution, or probable impact. Again, since this is a digital image, it is

possible to easily change the scale, angle of viewing, and distortion as needed. We are currently working with these draped images to prepare a report which identifies areas most vulnerable to damage from severe storms.

Conclusions

While the application of digital photogrammetry to coastal engineering is new, it is already clear that this technology will provide important improvements to the field. In particular, the ability to generate orthophotos from historical aerial photographs will allow us to make more accurate determinations of rates of shoreline change. In addition, the computer generated images will create new tools for both shoreline managers as well as the general public to understand the nature of shoreline change.

Acknowledgments

The authors are greatly for the support this research has received from the Kenan Institute for Science and Technology, the NC Division of Emergency Management, the NC Division of Coastal Management, the NC Department of Transportation, the Federal Emergency Management Agency, and the Intergraph Corporation. In addition, we greatly appreciate the help from our research support staff, including Cheryl Hapke, Roger Grenier, Rob Hardy, Brian Joyner, and Beth Judge. Dr. Robert Dolan at the University of Virginia has been a valuable colleague in our work on this and related projects.

CHAPTER 290

Application of Satellite Images to the Detection of Coastal Topography

Ji Wu¹ and Jea Tzyy Juang²

Abstract

Taking advantage of the high resolution visible images from the remotely sensed data of SPOT, the phenomenon of waves in the coastal area of Taichung was analyzed and its changing characteristics were studied. Changes of wave direction are affected by coastal topography; therefore, the changes of water depth can be detected by waves characters. In this study, the P band image data of SPOT of Taichung coast taken on 8th December 1993 was used. After dividing the area from deep to shallow into several blocks, each with 128x128 pixels, the wave images were transformed into two dimensional wave number spectra by ways of Fourier Transform. After that, the wave direction and the wave length were calculated. Results show that the shallower the water depth, the shorter the wave length; and the wave rays tend to approach shore normally. The phenomenon coincides with the theorem of wave dispersion. At last, based on the Snell's Law and the theory of shoaling, the average depth of each block was calculated. The results are encouraging.

Introduction

Remote sensing techniques have been developing rapidly since 1970. Since then, the LANDSAT, SEASAT and the SPOT satellites, have been launched and operated. The earth resources satellite receiving station in Taiwan was also installed in 1993.

² Deputy Director, Institute of Harbour & Marine Technology
No.83, Lin-Hai Rd., Wuchi, Taichung District, Taiwan, R.O.C.

In recent years, many researchers are using this new techniques to solve problems in the field of Oceanography, J. Populus (1991) used SPOT data to do the wave analysis. P.N. Bierwrith (1993) tried to detect depths on shallow water by studying the radiance of sea bottom reflectance. SPOT satellite is a sun-synchronous satellite with an average orbit height of 832 km. It passes Taiwan at 10:45 A.M. and reappears at the same track every 26 days. Since SPOT has the ability of inclined scan, we are able to get information of the same area every 3~5 days. The XS band image has a spatial resolution of 20 meters, and P band image has a spatial resolution of 10 meters. This study try to detect water depth at intermediate depth zone by using the characteristics of wave propagation.

Background Theory

The Dispersion equation states that

$$C^2 = \frac{g}{k} \tanh kh \quad (1)$$

where C : wave celerity
 σ : the angular frequency
 k : wave number
 g : gravitational acceleration
 h : depth

During the propagation of waves from deep sea to shallow water zone, wave height, wavelength and wave direction undergo changes due to changes of water depth. In region with intermediate water depth, we have

$$L = L_0 \tanh kh \quad ; \quad C = C_0 \tanh kh \quad (2)$$

where L_0, C_0 = wavelength & wave celerity in deep water

The irrotationality condition of wave number k yields

$$\frac{\partial(k \sin \theta)}{\partial x} - \frac{\partial(k \cos \theta)}{\partial y} = 0 \quad (3)$$

where θ is the angle between wave ray and the normal of coastline.

For a coast with straight and parallel contours, the changes of the wave direction obey the Snell's law :

$$\frac{\sin \theta}{c} = \frac{\sin \theta_0}{c_0} \quad (4)$$

By using all the above equations and the data from satellite image, the variations of the water depths at different locations can be estimated.

Techniques Used

Although the wave patterns are visible roughly in the satellite image, its real direction and wavelength can not be measured by eyes. Therefore, certain techniques of wave-number spectrum analysis using the two-dimensional Fourier transform are required. From the satellite image, we obtained the wave-number spectrum $S(k) = S(k_x, k_y)$. If $I(x, y)$ stands for the spatial intensity of the image, then the wave-number spectrum can be obtained by using the two-dimensional Fourier transform as

$$S(k_x, k_y) = \iint I(x, y) e^{-jk_x x - jk_y y} dx dy \quad (5)$$

When the spectrum peak was calculated, the wavelength and wave direction in each subregion can be determined as follows :

$$\frac{2\pi}{L} = k = \sqrt{k_x^2 + k_y^2} \quad ; \quad \theta = \tan^{-1}(k_x / k_y) \quad (6)$$

where k_x, k_y = the wave number components of the peak position on the spectrum diagram; θ = the angle between the wave direction and the Y-axis.

The above method is suitable for cases where wave phenomenon is simple and significant. If there is noise on the image scene, for example, a boundary of different water colors exists. We'll get a confused spectrum. In such cases we have to use special techniques, such as top-hat transform, to reduce the influence of noise. Fig.1 & Fig.2 show the comparison of the original image scene and the image after using Top-hat transformation, a detail flow chart of processing is shown in Fig.3.

Fig. 1 Original image scene of the sea

Fig. 2 Image scene after using Top-hat transformation

Fig. 3 Detail flow chart of processing

Fig. 4 Satellite images off Taichung Coast

Results

In this study, the Pan Band image data off Taichung Harbour on 8th December, 1993 were used (Fig.4), it covers an area of 18km x 12.5km. Taichung Harbour was built on 1970's, locate at the central western coast of Taiwan. From September to March, the winter monsoon season, the strong wind always blows from north. Therefore, the waves travel from the upper to the lower in Fig.4. The upper left corner is 9 kms away from coast and the depth is about 50 meters. The lower left corner is the outlet of Da-Du River and is quite shallow. Therefore we can observe the phenomenon of waves shoaling. After selecting and dividing some scope in the left part area from deep to shallow water and labelling them as A, B, ... S, with each block having 128x128 pixels, the wave image is then transformed into the wave-number spectrum.

Two example diagrams of the wave-number spectrum at block E (in deep water) and S (in shallow water) are shown in Fig.5 and Fig.6 respectively. In these figures, the longer the distance of the bright spot to the original point, the larger the wave number, which means shorter the wavelength.

Fig. 5 Wave image & wave number spectrum at block E

Fig. 6 Wave image & wave number spectrum at block S

From Table 1, we can see that the wavelength is decreasing and wave direction changes from 15° at block E to 350° at block S also. Fig.7 shows the variation of wavelength with wave direction from block E to block S.

Table 1 Results of water depth computation

Block	Wavelength	Wave direction 0° for N: clockwise	c/c_0	k	dp(m)	dr(m)
C	107	16	0.99	0.059	44	---
E	101	15	0.98	0.062	41	43
G	101	14	0.97	0.062	40	46
I	92	6	0.94	0.068	26	30
K	88	3	0.92	0.071	22	20
M	83	0	0.90	0.076	19	19
O	81	356	0.86	0.078	17	17
Q	75	353	0.83	0.083	14	15
S	68	350	0.80	0.092	12	10

Finally, the Snell's law of wave refraction and the small amplitude wave formula were used to compute the ratio of wave celerity from deep to shallow water and to predict the water depth at each block individually. Comparison of the predicted water depth (dp) and the measure's (dr) was also shown in Table 1 and Fig.8. The results are encouraging.

Fig. 7 Variation of wavelength with wave direction

Fig. 8 Comparison of the predicted water depth and the measure's

Conclusions and Discussions

1. From the satellite image of the sea, we can get direct information of wave propagating from deep to shallow water, such as refraction, diffraction and reflection. It has the advantages of wide spatial information and lower cost, when compared to traditional field survey.
2. By combining Snell's law, dispersion relationship and spectral results, the bottom topography are easily derived. The results are encouraging.
3. The method used here takes the assumption of straight and parallel offshore contours; therefore the range of water depths can be estimated is within intermediate depth, i.e., from $L/2$ to $L/20$, where L is the wave length.
4. Block size influences the analyses. Larger block size provides better spectral resolution while causing more uncertainty due to shoaling effect. On the other hand, small block size has the problem of insufficient details. The present study uses a 128x128 pixel block size.
5. Effects of water color on the image may yield confusing in the detection of spectra. The top-hat transformation is used to reduce the influence of this factor.
6. SPOT Pan band images are used in the present spectral analyses. In comparison with most of the earlier works where SAR images were used, these images generally provides higher space resolution and lesser non-linear effects.

CHAPTER 291

SEDIMENT TRANSPORT IN SWASH ZONE UNDER OBLIQUELY INCIDENT WAVES

Toshiyuki Asano¹

ABSTRACT

Time dependent calculations on two-dimensional sediment transport are carried out. The swash wave front is treated as a moving boundary which can reproduce non-vanishing sediment transport rate even for landward region of the still water shoreline. Meanwhile, experimental investigations on this subject are conducted by florescent sand tracer method. By comparing the present and existing experimental results with the numerical ones, the sediment transport mechanism in the swash zone is discussed.

1. INTRODUCTION

Recently, swash zone has received much attention because the sediment process in this zone provides an important boundary condition for the entire beach evolution. And also, recent studies have reported that the alongshore sand transport takes bimodal distribution with maxima at the swash zone as well as near the breaking point(White-Inman (1986), Bodge-Dean (1987)). Under obliquely incident waves, sediment near shoreline moves in a zig-zag way which results in the inherent alongshore transport in the swash zone. Intensive turbulence generated in uprush and backwash waves causes a large volume of sediment in suspension. However, these mechanisms have not been sufficiently understood.

The author proposed a horizontally two-dimensional shallow water wave model for predicting the free surface elevation and fluid velocities in the swash and surf zone under obliquely incident waves (Asano, 1994). The

¹ Associate Professor, Dept. of Ocean Civil Engrg., Kagoshima Univ., 1-21-40, Korimoto, Kagoshima, 890, JAPAN

sediment movement in swash zone should be described in a time dependent way because the bed is immersed and dried alternatively corresponding to run-up and run-down motion. The objective of this work is to improve the understanding of sediment transport in the swash zone by numerical analysis as well as experimental investigations focusing on the alongshore transport rate.

2. NUMERICAL ANALYSIS

(a) Two dimensional velocity fields in swash zone

The author has presented the numerical model for the two-dimensional velocity field in a swash zone (Asano, 1994). The outline of the calculations is as follows:

Two dimensional coordinate system is considered where x- and y- axis is chosen to be in the normal and the parallel direction to the shoreline, respectively. The z-axis is taken positive upward with z=0 at the still water shoreline. The beach slope *S* is herein restricted to be uniform and its contour is straight and parallel to the shoreline. The incident monochromatic waves with straight parallel crests are assumed to arrive at the seaward boundary with an angle θ_B .

The basic equations are two-dimensional shallow water equations with a moving boundary at the front of wave runup. Ryrie's(1983) method is applied in order to obtain simplified equations. That is, the wave crest is straight parallel and bottom topography does not vary in y-direction, the observed wave motion moving along the alongshore direction at the speed $C/\sin\theta$ becomes independent in the y-direction. By introducing pseudo-time $\hat{t} = t - (\sin\theta_B / C_B)y$ to unify two independent variable t and y, and assuming the incident wave angle θ_B is small enough to be used as a small parameter, the basic equations are decoupled into independent equations both for longshore motion and cross shore motion.

(b) Particle trajectory in swash zone

Instantaneous behavior of a single spherical particle placed on a uniform slope is simulated under two-dimensional swash motion calculated in the above mentioned model. The momentum equation for the particle is given by

$$\begin{aligned}
 (\rho_s/\rho + C_A)A_3d^3\dot{u}_s = & \frac{1}{2}C_D A_2 d^2 |\mathbf{u} - \mathbf{u}_s| (\mathbf{u} - \mathbf{u}_s) \\
 & + (1 + C_A)A_3d^3\dot{u} - (\rho_s/\rho - 1)A_3gd^3 \sin S \\
 & - (\rho_s/\rho - 1)A_3gd^3 \tan \phi \cos S \dots\dots\dots (1)
 \end{aligned}$$

in which, *g*: gravitational acceleration, ρ and ρ_s : specific gravity of water and sediment, *d*: sediment particle diameter, A_2, A_3 : 2- and 3- dimensional shape factor of sediment particle, ϕ : internal friction angel, C_A, C_D : added

mass and drag coefficient, u , u_s : fluid and sediment particle velocity vector, respectively.

Since the fluid velocity u has been obtained at every calculation grid, interpolation is needed to calculate u at the point sediment particle locates. The instantaneous position of the particle can be calculated by integrating sediment particle velocity u_s with a time increment of $1/1000$ of the wave period.

Fig. 1 shows one example of the calculated trajectories of a single particle placed on a relatively steep slope $S=0.4$ to emphasize the gravitational effect. Here, x - and y - axis is chosen to be in the normal and parallel direction to the shoreline, respectively. The results reproduce the zig-zag transport under which a particle is conveyed onshore with a certain angle to the shoreline, then transported offshore with greater angle due to the gravity.

Fig. 1

Trajectories of a sediment particle
in a swash zone

(c) Sediment Transport Rate

Instantaneous sediment transport rate was calculated based on Kobayashi's (1982) bed load formula, which accounts for the effect of a slope explicitly. In the model, the composing forces acting on a spherical particle are the submerged weight, frictional force, fluid drag and lift forces. An inertia force acting on the particle was neglected in the model for simplicity.

To illustrate the external force of a sediment particle, the temporal variations of on-offshore velocity at the still water shoreline $x=0$ are shown in Fig. 2. The parameter of Fig. 2 (a) and (b) is the wave period T and the slope steepness S , respectively. The results show that each velocity fluctuation in swash zone rapidly increases at a passage of bore-like crest, and has long lasting backwash motion. Even though the incident wave height is same in the figures, the breaking wave height H_b will change by the parameter T and S , and that leads to different set-up height at the still water shoreline. The magnitude of the backwash flow is found to be large because the precedent onshore mass flux should be returned through a thin backwash flow. These figures show greater integrated areas in the offshore direction than those in the onshore direction.

The variations of sediment transport rate reflect the velocity variations shown above. Fig. 3(a),(b) illustrates the instantaneous on-offshore transport rates q_s/wd (w : sediment fall velocity) at the still water shoreline $x=0$. At the limit of horizontal bed, Kobayashi's formula yields that the sediment

transport rate is proportional to the Shields number $\Psi(t)$ to the power of 1.5 (3rd power of the instantaneous fluid velocity). As a result, the curves of sediment transport rate in Fig. 3 show steeper peaks than those in Fig. 2. Fig. 3(b) shows the results with a slope steepness S as a parameter. The steeper the bottom slope, the sharper the onshore transport fluctuations and the greater and the longer the offshore transport fluctuations.

Fig. 4 depicts the instantaneous alongshore transport rate q_y . The alongshore transport is generated mainly during wave up-rush under mild slope condition. Meanwhile, under steep slope condition, a large amount of alongshore transport is observed during down-rush.

Fig. 2 Temporal variations of on-offshore velocity at $x/x_0 = 0$

Fig. 3 Temporal variations of on-offshore sediment transport rate at $x/x_0 = 0$

Fig. 4 Temporal variations of alongshore sediment transport rate at $x/x_0 = 0$

Fig. 5 and Fig. 6 depicts spatial variations of time averaged on-offshore and alongshore sediment transport rates Q_x, Q_y , respectively. The positive direction of the abscissa is taken in the onshore direction from S.W.S.L.. It is recognized that substantial values both for Q_x and Q_y are observed even in the onshore region of the shoreline. The time dependent calculation treating the swash wave front as a moving boundary is able to reproduce non-vanishing transport rates both Q_x and Q_y in the region $x/x_0 > 0$. These figures show that Q_x are offshore direction except for the mildest case $S=1/20$, and Q_y decreases monotonously toward the onshore direction, hence, no bi-modal peak around the shoreline is obtained.

(d) Comparison with Conventional Experimental Data

Kamphuis(1990) conducted three-dimensional mobile bed experiments, and investigated alongshore sediment transport rate in swash zone as well as surf zone. Most distributions of his data exhibited bimodal with one peak close to the breaking zone and another in the swash zone. One example of his data is shown in Fig. 7. The ratio of suspended load and bed load throughout his tests showed roughly constant for the entire region, even near the breaking point where suspend load is expected to be predominant.

Fig. 5 Spatial variations of time averaged on-offshore sediment transport rate

Fig. 6 Spatial variations of time averaged alongshore sediment transport rate

Comparisons with the present calculation under the same input condition of Kamphuis's experiment have revealed that his results were 2 order greater than the calculated results. Fig. 7 shows one of the results where the transport rate Q_y at still water shore line $x=0$ for the bed load was around 17kg/m/hr in its immersed weight. Converting into a non-dimensional transport rate Q_y/wd , this amount corresponds to 1.06, while the calculated rate is 0.029.

Sunamura(1984) measured on-offshore sediment transport rate focusing on the swash zone in a two-dimensional wave tank. Based on the results, he proposed a transport rate formula for the swash zone. Comparisons between the calculated on-offshore sediment transport rates Q_x at $x=0$ with those of Sunamura's empirical formula are shown in Fig. 8, in which the parameter H_0, T, d is the incident wave height, wave period and sediment diameter, respectively.

Qualitative agreements are fairly good in all the figures, but some discrepancies are found. In Fig. 8(a), Sunamura's formula predicts positive Q_x values for small wave height, which implies onshore sediment transport corresponding accretional beach formation. Meanwhile the calculated Q_x also decreases to zero with decreasing of wave tractive force but the direction is still offshoreward.

The present calculations deal only with bed load transport under non-breaking waves. Large amount of sediment will be suspended by the vortex when the backwash collides with the incoming bore. The discrepancy from the empirical formula suggests the significant contribution of the generated vortex.

Fig. 7 Distributions of alongshore sediment transport rate (Kamphuis, 1991)

Fig. 8 Comparison of calculated on-offshore sediment transport rate with Sunamura's(1984) formula

3. EXPERIMENTAL STUDY

(a) Experimental Apparatus

The wave tank used here was 26.7m long, 13m wide and 1.2m deep wave basin in Dept. of Ocean Civil Engrg., Kagoshima Univ.(Fig. 8). In this section, the x-axis is taken positive in the offshore direction with the origin $x=0$ at the still water shoreline. The y-axis is taken in the alongshore direction. A uniform concrete slope of gradient $S=1/7.5$ was set up at an angle $\theta=15^\circ$ with a wave generator equipped at the other end of the basin. The uniform water depth in the offshore region was kept at constant 79cm throughout the experiments.

Ten capacitance type wave gauges were used, one for the offshore waves, and nine were set in an array on the slope from 210cm offshore to 40cm onshore of the still water shoreline(S.W.S.L.), which covered the surf and swash zone. The wave gauges were inserted into slit holes, which were ditched in order to maintain small water depth even when the bed was dried up at the downrush phase.

A 10mm thick sand layer extending 1.0m width by 3.2m length was laid on the mortar bed. The sand used here was clastic sediment particle originated from igneous rock, of which diameter d was 0.9mm and specific gravity s was 2.96.

Table-1 Test conditions

	H_i (cm)	T (s)	x_b (cm)	W_w (cm)	ξ
CASE-5	6.4	2.5	-70	85	1.65
CASE-6	7.9	2.0	-60	70	1.19
CASE-7	3.3	3.0	-70	100	2.75
CASE-8	7.5	1.5	-65	65	0.91

(b) Experimental Procedures

Measurements using the florescent sand tracer were conducted at 16 points with 15cm intervals in the range between $x=150$ cm offshore and $x=-75$ cm onshore of S.W.S.L. First, natural undyed sand was laid and leveled its surface accurately. Then, using a core sampler of 36mm inner-diameter and a thin spatula, a cylindrical sand mass was removed. Instead of this, a cylindrical plug of florescent colored sand was buried. After one minute wave action on the sand bed, core samples were collected at 16 points each for two concentric circles of 20cm and 40cm radius.

The samples were evaporated in a drying oven, then, weighed on a precision balance. Meanwhile, the weight

Fig. 8 Wave tank

of dyed sand was estimated by the number which was determined by visual counting under ultraviolet illumination. For this conversion, a calibration curve between the number of particles and its weight was determined beforehand. The final results were arranged in volumetric concentration; the occupation ratio of dyed sand against the whole sand.

Assuming advection is predominant, the sediment transport velocity was estimated in the following way. If a particle initially located at the center moves to the position (r, θ) after Δt time, the traveling velocity for on-offshore and alongshore direction u_s, v_s will be given by $r \cos \theta / \Delta t, r \sin \theta / \Delta t$, respectively. The representative sediment transport velocity was estimated by spatial averaging as follows:

$$\begin{aligned}
 u_s &= \frac{\iint c(r, \theta) \frac{r \cos \theta}{\Delta t} dS}{\iint c(r, \theta) dS} = \frac{\int_0^\infty \int_0^{2\pi} c(r, \theta) \frac{r \cos \theta}{\Delta t} r d\theta dr}{\int_0^\infty \int_0^{2\pi} c(r, \theta) r d\theta dr} \\
 v_s &= \frac{\iint c(r, \theta) \frac{r \sin \theta}{\Delta t} dS}{\iint c(r, \theta) dS} = \frac{\int_0^\infty \int_0^{2\pi} c(r, \theta) \frac{r \sin \theta}{\Delta t} r d\theta dr}{\int_0^\infty \int_0^{2\pi} c(r, \theta) r d\theta dr} \quad (2)
 \end{aligned}$$

However, the number of the measuring points was restricted as 16 for each concentric circle, 32 in total, thus the estimation for u_s, v_s was actually carried out by the following equations.

$$\begin{aligned}
 u_s &= \frac{\sum_{i=1}^{16} c_i \frac{r_1^2 \cos \theta}{\Delta t} + \sum_{j=1}^{16} c_j \frac{r_2^2 \cos \theta}{\Delta t}}{\left(\sum_{i=1}^{16} c_i \right) r_1 + \left(\sum_{j=1}^{16} c_j \right) r_2} \\
 v_s &= \frac{\sum_{i=1}^{16} c_i \frac{r_1^2 \sin \theta}{\Delta t} + \sum_{j=1}^{16} c_j \frac{r_2^2 \sin \theta}{\Delta t}}{\left(\sum_{i=1}^{16} c_i \right) r_1 + \left(\sum_{j=1}^{16} c_j \right) r_2} \quad (3)
 \end{aligned}$$

The test conditions are summarized in Table-1, in which H_i is the incident wave height in uniform depth region, x_b is the location of breaking wave, and W_u is the maximum run-up distance on the slope obtained by eye-measurements.

(c) Wave characteristics on a slope

Fig.9 shows the water surface fluctuations at each measuring point from offshore to onshore. From the fluctuation records, the following parameters were defined to describe the sediment transport; wave height, skewness (asymmetry in respect of horizontal level), asymmetry (asymmetry in respect of center line).

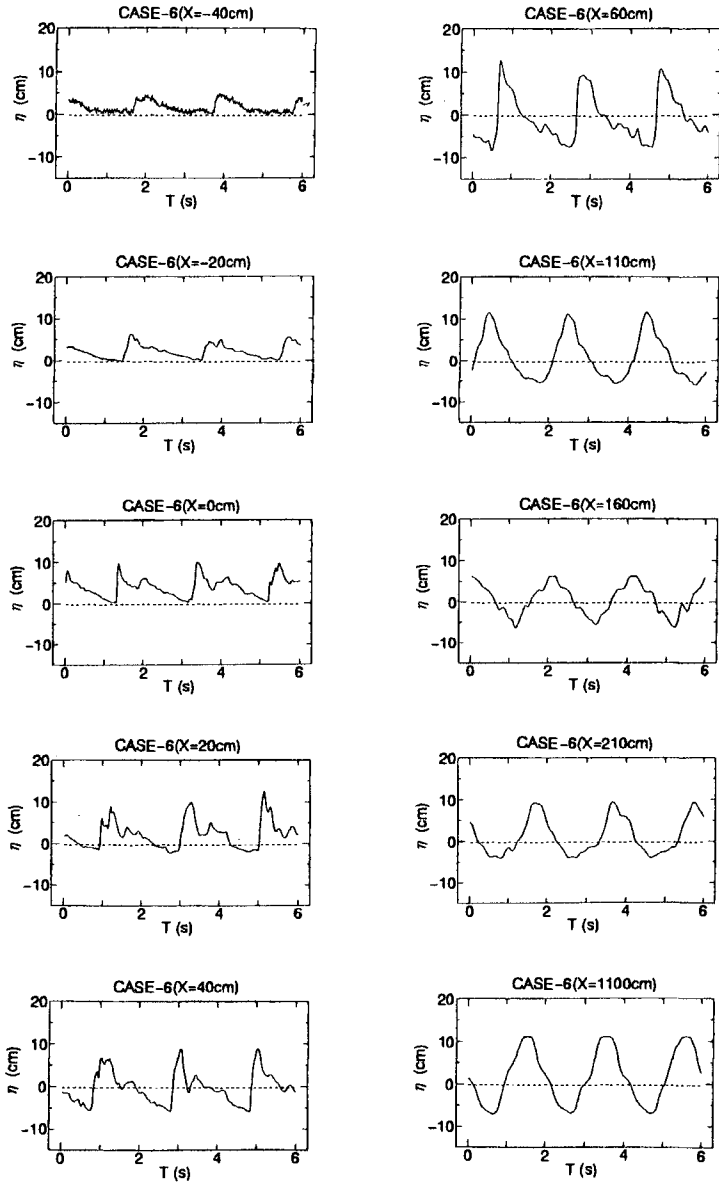

Fig. 9 Measured water surface fluctuations

The definitions of skewness $H(\text{cm})$ and asymmetry are given by

$$\text{skewness} = \frac{1}{\eta_{rms}^3} \overline{(\eta - \bar{\eta})^3}$$

$$\text{asymmetry} = (t_{peak} - t_0) / T$$

in which, η : water surface fluctuation, η_{rms} : root mean square of η , t_0 : time at the lowest water surface fluctuation, t_{peak} : time at the succeeding fluctuation peak.

Fig. 10 Spatial variations of wave profile properties

Fig. 10 illustrates that *skewness* becomes small in the swash zone where the water surface fluctuation shows bore-like variation. Meanwhile, *asymmetry* monotonously decreases toward onshore. This sudden increase of wave profile will cause significant onshore-ward sediment transport in the swash region.

(d)Transport velocity determined by tracers

Fig. 11 shows an example of directional distribution of florescent sand concentration. Onshore transport predominance in the offshore region of the breaking point(in this case;x=70cm), alongshore transport in the surf region, and onshore transport around still water shoreline (x=0) are observed. Large scattering was found in the surf zone, where not only advection but diffusion contributes the tracer transport.

The sediment transport velocities estimated from Eq. (3) are plotted in a vector form(Fig. 12). In the figure, the solid vector indicates the data where more than 10 florescent sands were sampled, the dotted vector points out the data where 6 ~ 10 florescent sands were found (less reliable). Following characteristics are obtained:

In the offshore region of the breaking point(B.P) sediment is transported onshore because the velocity fluctuations are skewed in the onshore direction.

In the region between the breaking point and still water shoreline, alongshore transport is predominant. This is due to generated longshore current in this region. For on-offshore transport, the onward sediment transport due to the skewness of velocity fluctuation may be almost canceled by offshore transport due to an undertow generated near the bottom.

In the swash zone, the transport direction is offshore (except for CASE-7). Since water mass running up on a slope will be returned in a thin layer flow, the velocity of the return flow becomes large enough to transport the sediment offshore in averaging over a period.

The result of CASE-7 is slightly different from others especially in the swash zone, it could be because the wave period was the longest among all the cases, so the breaking type became collapsing (surf similarity parameter in this case $\xi = 2.75$) which breaks suddenly close to the shoreline.

(e) Comparison with the calculated transport velocity

In order to check the validity of the experimental results, calculations based on Kobayashi's formula are performed under the same input condition as the experiments. The results are illustrated in Fig. 13. All of the on-offshore components of transport velocity vector direct offshore. This directional property agrees with the experiment in the swash zone, but disagree in the surf zone and offshore zone.

The comparison also shows the discrepancy in the magnitude of transport velocity. For the experiment, most of the results ranges 0.3 ~ 0.4cm/s, and maximum is 0.66cm/s, which is so small compared to the calculation. In terms of a ratio to the generated longshore current velocity, the data were not so small, but agreed with existing field data. Nadaoka et al.(1981) reported that the sand transport velocity was less than 1.0cm/s, which corresponded to 1 ~ 2 % of the observed longshore velocity.

Several reasons can be considered to explain the difference. One would be due to the large grain size. In this experiment, relatively coarse sand $d=0.9\text{mm}$ was used. This might be beyond the applicability of Kobayashi formula which calibrated with existing data using medium and fine sand. The run-up waves propagate on a slope with generating much turbulence at the front. In the numerical model, the velocity field is treated as uniform and no-turbulence, the predictability of sediment transport in the swash zone is severely restricted.

4. CONCLUSIONS

- (1) Analysis on single particle trajectory reproduces the zig-zag sediment movement, which is inherent transport mechanism in the swash zone.
- (2) The time dependent analysis treating the swash wave front as a moving boundary enable the calculation to reproduce the swash zone sediment transport. Non-vanishing transport rates both for on-offshore and alongshore directions have been obtained even for the onshore region of the still water shoreline.
- (3) From the experiments using florescent sand tracers, the sediment transport in the swash zone is comparable in the magnitude with those in the surf zone, and to be directed generally offshore. The offshore transport can be explained due to the strong backwash flow prevailing over the onshore flow generated at a passage of bore-like front.

- (4) The present model postulates uniform velocity distribution and no turbulence. Quantitatively, the model could not reproduce the sediment transport rate in the existing and present experiments. For improving model to describe sediment transport in a swash zone, vortex and turbulence roles for sediment stirring up mechanism should be included.

CHAPTER 292

Sheet Flow Modelled as Pure Convection

Stephen Clark¹
Peter Nielsen²

Abstract

A considerable amount of experimental data regarding the transport of sand under violent wave conditions (specifically the sheet flow regime) has been gathered in recent years. Historically, modelling of the concentration distributions of the suspended sediments immediately above the sheet flow layer has been undertaken using the diffusion equation. A physically more appropriate model is the combined convection diffusion approach. However, analysis of the experimental results to date indicate that a pure convection which is far simpler than either of the other two is adequate.

Introduction

The transport of sand under violent wave conditions with Shield's parameter values greater than one is often described by the term sheet flow because no bedforms survive through the wave cycles and a layer (sheet) of sand, many grain diameters thick, can be seen to move back and forth with the wave motion.

A considerable amount of experimental details of the process have been gathered in recent years by Ribberink and co-workers (1992). However, modelling of the process is still inadequate. This paper concentrates on the "upper" or suspended part of the sediment distribution. Traditionally, concentration distributions have been modelled using forms of the diffusion equation. As will be presented below, analysis of experimental results indicates that a combined

¹ Senior Engineer, Lawson & Treloar, PO Box 115, Ashgrove, Queensland, Australia 4060.

² Reader, Dept of Civil Engineering, University of Queensland, Australia, 4072.

convection diffusion model or in some cases a pure convection model appears to be adequate.

Experimental Data

A series of experiments have been conducted in the Large Oscillating Water Tunnel (LOWT) of Delft Hydraulics which have focussed on both time averaged and time dependant near bed and within bed sediment concentrations and sediment transport rates.

Flow conditions investigated have ranged from purely sinusoidal to regular, asymmetric waves over both rippled and plane beds. Sediments investigated have been predominantly sands with a $D_{50} = 0.2$ mm. An additional set of experiments have been conducted using a finer sand $D_{50} = 0.12$ mm.

Figure 1 provides an example of the results obtained through this procedure (Ribberink et al, 1992).

Figure 1: Experiment C8 Results

Suspended Sediment Distribution Models

Natural suspended sediment processes are a combination of both convective and diffusive processes. The process by which sediment (heavier than water) is driven upward has traditionally been described in terms of pure gradient diffusion. This process is due to driven by vertical mixing and consists of a large number of small, random vertical steps. Alternatively, the scale over which this mixing takes place is much smaller than the scale of the concentration profile.

Analysis of recent experimental data indicates that the pure gradient diffusion model is inadequate and that in many cases, a larger scale or convective process is reflected by many suspensions as well. These results reflect a process whereby the mixing scale is of the same order as the concentration profile.

Considering a horizontally uniform sediment concentration field $c = c(z, t)$ and a correspondingly uniform sediment velocity field $u_s = u_s(z, t)$, the vertical sediment flux $q = c u_s$ is considered to consist of three components. These components are a downward component $-w_0 c$ due to gravitational settling and an upward flux which can be of convective (subscript C) or diffusive (subscript D) nature or a combination of both. This process is illustrated in Figure 2 (Nielsen, 1992).

The total vertical flux is thus written as:

$$q_z = -w_0 c + q_D + q_C$$

enabling the conservation equation to be written as

$$\frac{\partial c}{\partial t} = w_0 \frac{\partial c}{\partial z} - \frac{\partial q_D}{\partial z} - \frac{\partial q_C}{\partial z}$$

The forms of convective and diffusive functions considered for this paper are as below:

$$\text{Convective Flux, } q_c(z, t) = p\left(t - \frac{z}{w_c}\right)F(z)$$

$$\text{Diffusive Flux, } q_D(z, t) = -\epsilon_s \frac{\partial c}{\partial z}$$

The pickup function $p(t)$ is a non-negative function describing the instantaneous pick up rate at the bed and the dimensionless convective distribution function $F(z)$ determines the fraction of the entrained sand which travels (convectively) beyond the level z above the bed.

Analytical Solution - Pure Convection

The vertical convective sediment flux, q_c is generally written in the following form

$$q_c(z, t) = p\left(t - \frac{z}{w_c}\right)F(z)$$

where w_c is the average vertical velocity with which the sand is convected upwards.

Assuming that the distribution function $F(z)$ is an exponential of the form

$$F(z) = e^{-z/L}$$

the general form of the time dependant sediment concentration equation may be expressed in terms of periodic functions as:

$$c_n(z, t) = C_n f(z) e^{im\omega t}$$

becoming

$$c_n(z, t) = C_n e^{-\beta_n z/L} e^{im\omega t}$$

where

$$C_n = \frac{P_n}{w_0} \frac{1 + im\omega L / w_c}{1 + im\omega L / w_c + im\omega L / w_0}$$

and

$$\beta_n = 1 + \frac{im\omega L}{w_c}$$

If the real portion of c_n is considered, have

$$\text{Re}\{c_n(z, t)\} = \text{Re}\{C_n\} e^{-z/L}$$

Analytical Solution - Pure Gradient Diffusion

As with the pure convection description, with the general form of the time dependant sediment concentration equation as

$$c_n(z, t) = C_n f(z) e^{in\omega t}$$

for the pure gradient diffusion solution, this becomes

$$c_n(z, t) = C_n e^{-\alpha_n z w_0 / \epsilon_s} e^{in\omega t}$$

where

$$C_n = \frac{P_n}{w_0 \alpha_n}$$

and

$$\alpha_n = \frac{1}{2} + \sqrt{\frac{1}{4} + \frac{in\omega \epsilon_s}{w_0^2}}$$

Note that for the pure gradient diffusion solution, the length scale, L of the convective solution is replaced by the sediment diffusivity over the still water settling velocity ϵ_s / w_0 .

There are two important differences between the analytical solutions for pure gradient diffusion and pure convection. Firstly, all the harmonic concentration components decay as $e^{-z/L}$ for the convective solution and secondly, the phase lag relative to the pick up function grows at the same rate for all frequencies. This indicates that in a process dominated by convection, defined concentration peaks will travel upwards through the water column at a constant rate. However, for a process dominated by diffusion, the phase lags will grow with elevation above the bed, leading to "blurring" of successive peaks.

Data Analysis

The experimental results previously illustrated may be expressed in terms of simple periodic functions via a Fourier Analysis. This has been carried out on the available data to the tenth harmonic. It has been found to date that six harmonics provide an appropriate level of accuracy.

Figure 3 provides an example of the relative magnitudes of the primary harmonics obtained for the data set presented in Figure 1. From these results, parameters representing the mixing length (pure convection solution) and diffusivity (pure gradient diffusion solution) can be derived.

Figure 4 presents the results of this process. Note that the length scale (corresponding to pure convection) is approximately constant across all harmonics. However, the diffusivities show an increasing “drift” as the harmonic number increases. As could be expected, this is more pronounced for the sand of larger grain size.

Conclusions

The primary conclusion which may be drawn from this analysis is that the experimental results analysed are more appropriately represented by a purely convective model. This is convenient as computationally, the solution of the equations corresponding to pure convection is much more straightforward than for the second order partial DE for the pure diffusion (and combined convection diffusion) equation.

CHAPTER 293

A TRANSPORT RATE FORMULA FOR MIXED-SIZE SANDS

Mohammad Dibajnia¹ and Akira Watanabe²

Abstract

Experiments were conducted on the transport of mixed grain size sands due to nonlinear waves, over both rippled and flat beds. The sand mixture was composed of a fine sand with median diameter of 0.2 mm and a coarse sand with median diameter of 0.87 mm. Conditions for the initiation of sheet flow were investigated and transport rates were measured. It was found that the transport rate of fine sand is significantly reduced by the existence of the coarse sand, whereas the coarse sand behaved almost as if there were no other sand present. A transport rate formula for mixed sands was presented and verified by using the measured data.

1. Introduction

Sandy beaches are the focus of many attentions because of their role in preserving the coastal environment, their ability in reducing disasters, and their attractiveness for recreational activities. They are, however, subjected to erosion problems due to the action of natural forces or artificial impacts. As a counter-measure, beach nourishment is one of the most acceptable methods for protecting sandy beaches. The grain size of the sand used for filling the beach is, however, decided by the available sources of material and in many cases does not coincide with the grain size of the native sand. Also, using a sand coarser than the native sand is in general more desirable because it can better stabilize the beach.

¹Associate Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

²Professor, ditto.

Figure 1: Oscillatory/steady flow water tunnel and its test section.

Needless to mention that even the grain size of the native sand itself may be nonuniform. Therefore, estimation of the transport rates of mixed-size sands is of crucial importance in predicting the behavior of both natural and artificial beaches.

In this study experiments were conducted on the transport of mixed grain size sands due to nonlinear waves over rippled and flat beds. The transport rate formula of Dibajnia and Watanabe (1992), which has originally been derived for 0.2 mm sand, was first generalized to cover the transport of granular sediments with other grain sizes and densities. A method was then presented to apply this formula to estimating the transport rate of mixed size sands. Conditions for the initiation of sheet flow were also investigated.

2. Experiments

The present experiments were carried out in a loop-shape oscillatory flow water tunnel at the University of Tokyo. The tunnel and its test section are shown in Fig. 1. Two kinds of sand, fine and coarse, were mixed together. The fine sand had a median grain size of 0.2 mm and the fall velocity of 2.3 cm/s. For the coarse sand these values were 0.87 mm and 8.7 cm/s, respectively. The percentage of the weight of each sand in the total weight of a mixed sample was defined as the percentage of that sand, P_i . Three types of mixed sands with percentages of fine sand, $P_{0.2}$, equal to 25%, 50%, and 75% were prepared. The oscillatory velocity profiles generated in the tunnel were calculated by the first

order Cnoidal wave theory. Two wave periods, $T = 3$ and 5 s and one nonlinearity index $u_{max}/\hat{u} = 0.7$ (see Fig. 2) were selected. By changing the velocity amplitude, transport of sands over rippled beds as well as under sheet flow conditions were observed and net transport rates were measured. The experimental conditions for which transport rates were measured are summarized in Table 1. In this table, d_0 and T are the excursion length of water particle and the period of oscillation, respectively. Conditions for initiation of sheet flow were also investigated. The present experimental data have originally been reported in Suzuki *et. al* (1994) and Inui *et. al* (1995).

3. Initiation of Sheet Flow

For a uniform sand, the transport mode usually changes from the bedload transport over an initial flat bed to the suspended load transport over the ripples and, as the velocity amplitude continue to increase, to the sheet flow transport over the reflattened bed. Several experiments were performed to observe the

Figure 3: Occurrence of different transport modes.

behavior of mixed sand beds. The procedure was to start each experiment from a flat bed and see whether ripples appear or not. The results for $T = 3$ s were summarized in Fig. 3. It is interesting to see that for mixed sands, sheet flow occurs under lower velocities than those required for uniform sands. However, this was the case when the bed has initially been flat. Additional few experiments were performed with an initially rippled bed. As shown in Fig. 4, it was found that a higher velocity than that in the case of uniform sand is required to wash out the ripples from the mixed sand bed. It was thus concluded that the mixture of fine and coarse sand provides a firm structure which is not deformed as easily as uniform sands are.

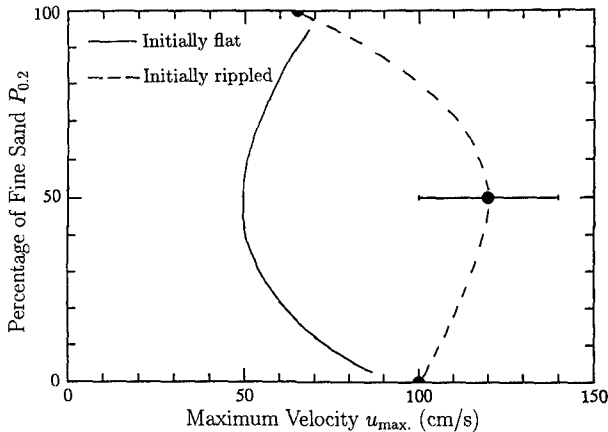

Figure 4: Dependence of the initiation of sheet flow on the initial bed form.

4. Generalized Transport Rate Formula

A transport rate formula involving unsteady aspects of the sand transport phenomenon has been presented by Dibajnia and Watanabe (1992) for estimating the sheet flow sand transport rates. The formula has later been extended by them (Dibajnia *et. al*, 1994) to cover suspended load over ripples as well as bed load transports. Their formula, however, is based on the experimental data obtained by using a sand with median grain size of 0.2 mm only, and needs further verification for sands of other sizes before it is applied to the transport of mixed sands.

In their experiments on sheet flow, Dibajnia and Watanabe (1992) noticed that once there was a positive velocity (Fig. 2) large enough to raise up sand particles to such a level that they could not reach the bottom before the negative velocity occurred, then these particles tended to be carried to the negative direction. Dibajnia and Watanabe (1992), therefore, defined a dimensionless parameter, Γ , as

$$\Gamma = \frac{u_c T_c (\Omega_c^3 + \Omega_t^3) - u_t T_t (\Omega_t^3 + \Omega_c^3)}{(u_c + u_t) T} \quad (1)$$

and assumed the net transport rate to be a function of Γ . For the dimensionless net transport rate, Φ , Dibajnia (1995) proposed

$$\Phi = \frac{q_{\text{net}}(1 - \epsilon)}{Wd} = 0.0023 \cdot \text{sign}(\Gamma) \cdot |\Gamma|^{0.5} \quad (2)$$

In the above relations q_{net} is the net volumetric transport rate, ϵ the sediment porosity, d the sediment grain size, W the sediment fall velocity, and u_c and u_t are representative velocity amplitudes for the positive and negative portions of the velocity profile, respectively, as

$$u_c^2 = \frac{2}{T_c} \int_0^{T_c} u^2 dt, \quad u_t^2 = \frac{2}{T_t} \int_{T_c}^T u^2 dt \quad (3)$$

In Eq. (1) Ω_c' represents the amount of suspended sand remaining from the positive half cycle, to be carried by the negative velocity. Similarly Ω_t' stands for the amount of sand still in suspension after the negative half cycle, which will be transported to the positive direction. On the other hand, Ω_c represents that amount of sand which is entrained and carried only by the positive velocity; and Ω_t indicates the amount of sand entrained, transported, and settled during the negative half cycle. Values of Ω were estimated in terms of another parameter, ω , equal to the ratio of the time required for a sand particle, suspended during a half cycle, to reach the bottom to the time duration of that half cycle. The reader is referred to the original paper for more details.

Now consider the simple case of sheet flow sand transport under half of a sinusoidal cycle. In this condition, Eq. (1) reduces to

Table 2: Transport rate data of Sawamoto and Yamashita (1986)

$$\Gamma = \Omega^3 \quad (4)$$

which means that a method to evaluate Ω can best be verified by using averaged transport rates measured under half cycle of sinusoidal oscillations. Such data have been reported by Sawamoto and Yamashita (1986) for sheet flow sand transport, and are shown here in Table 2. The data are for quartz sands of three different sizes (0.2, 0.7, and 1.8 mm) and for coal dust with density of 1.58. According to Dibajnia and Watanabe (1992), Ω may be evaluated as

$$\begin{aligned} \Omega_j &= \omega_j \cdot \frac{WT_j}{d} = \frac{1}{2} \frac{u_j^2}{sgWT_j} \cdot \frac{WT_j}{d} \\ &= \frac{1}{2} \frac{u_j^2}{sgd} = \Theta \quad : \quad \text{Mobility number} \end{aligned} \quad (5)$$

Figure 5: Comparison of calculated half cycle averaged transport rates with measurements (previous method).

where $s = (\rho_s - \rho) / \rho$ in which ρ and ρ_s are the densities of water and sediment, respectively, g is the acceleration of gravity, and the subscript j should be replaced by either c or t . Figure 5 shows the comparison between measured and calculated transport rates when Eq. (5) was applied. In this figure $Q = q(1 - \epsilon)$ where q is the half cycle averaged transport rate. The proportionality coefficient in Eq. (2) is not considered. It is seen that each sediment type defines a different line of agreement. This indicates that the proportionality coefficient should depend on the grain size and density of sediment whenever the transport rate is assumed to be a function of either Mobility or Shields numbers.

Sawamoto and Yamashita (1986) found that the half cycle averaged sheet flow transport rate is proportional to the third power of the ratio of the friction velocity to the sediment fall velocity. Considering this, a new way to evaluate Ω is as follows.

$$\begin{aligned} \Omega_j &= \omega_j \cdot T_j \sqrt{\frac{sg}{d}} = \frac{1}{2} \frac{u_j^2}{sgWT_j} \cdot T_j \sqrt{\frac{sg}{d}} \\ &= \frac{1}{2} \frac{u_j^2}{W \sqrt{sgd}} \propto \left(\frac{u_j}{W}\right)^2 \end{aligned} \tag{6}$$

Figure 6 shows the results after applying Eq. (6). All the data follow the same line of agreement, indicating that the new method for calculating Ω is valid for granular sediments with different grain sizes as well as different densities. The proportionality constant in Fig. 6 is about 0.0035, and is valid for half cycle averaged transport rates. For the net transport rate, original data of Dibajnia and Watanabe (1992) were used ($d = 0.2$ mm) to obtain the value of the constant.

Figure 6: Comparison of calculated half cycle averaged transport rates with measurements (new method).

The generalized transport formula was thus obtained (Takasawa *et. al*, 1996) as

$$\Phi = \frac{q_{net}(1 - \epsilon)}{Wd} = 0.0015 \cdot \text{sign}(\Gamma) \cdot |\Gamma|^{0.5} \quad (7)$$

$$\left\{ \begin{array}{l} \text{if } \omega_j \leq \omega_{cr} \\ \text{if } \omega_j > \omega_{cr} \end{array} \right\} \left\{ \begin{array}{l} \Omega_j = \omega_j \cdot T_j \sqrt{\frac{sg}{d}} \\ \Omega'_j = 0 \\ \Omega_j = \omega_{cr} \cdot T_j \sqrt{\frac{sg}{d}} \\ \Omega'_j = (\omega_j - \omega_{cr}) \cdot T_j \sqrt{\frac{sg}{d}} \end{array} \right. \quad (8)$$

$$\omega_j = \frac{1}{2} \frac{u_j^2}{sgWT_j} \quad (9)$$

where Γ should be obtained as before from Eq. 1. In order to verify the above formulation, net sand transport rate data for grain sizes other than 0.2 mm are required. The only such a data set available to the authors was that reported by Watanabe and Isobe (1990), giving the net sand transport rate over ripples under nonlinear waves for sands of 0.2 and 0.87 mm median diameter. Value of ω_{cr} in Eq. (8) is equal to 1 for sheet flow. In presence of ripples, ω_{cr} is equal to 0.03 for 0.2 mm sand and equal to 0.05 for 0.87 mm sand. Threshold velocity should also be considered. Comparison between measured and calculated nondimensional net transport rates for the experiments of Watanabe and Isobe (1990) is shown in Fig. 7. In this figure, the transport rates of the 0.87 mm sand are multiplied by a factor of ten to be more visible. Satisfactory agreement is observed.

Figure 7: Comparison of calculated net transport rates over ripples with measurements.

5. Transport Rate of Mixed Sands

Let us first assume that the transport of each of the sands in a mixture, is not affected by the existence of the other sand. Then the transport rate of each sand could be obtained by using the following formulation.

$$\Phi_i = \frac{M_i}{(\rho_s - \rho)W_i d_i} = 0.0015 \text{ sign}(\Gamma) \cdot |\Gamma|^{0.5} \cdot P_i \tag{10}$$

$$\left\{ \begin{array}{l} \text{if } \omega_j \leq \omega_{cr} \\ \text{if } \omega_j > \omega_{cr} \end{array} \right\} \left\{ \begin{array}{l} \Omega_j = \omega_j \cdot T_j \sqrt{\frac{sg}{d_i}} \\ \Omega'_j = 0 \\ \Omega_j = \omega_{cr} \cdot T_j \sqrt{\frac{sg}{d_i}} \\ \Omega'_j = (\omega_j - \omega_{cr}) \cdot T_j \sqrt{\frac{sg}{d_i}} \end{array} \right. \tag{11}$$

$$\omega_j = \frac{1}{2} \frac{u_j^2}{sgW_i T_j} \tag{12}$$

In the above relations M is the immersed weight of sand corresponding to Φ , subscript i is to address each grain size, and it is assumed that sands have the same density ρ_s . The above formulation was applied to the present experimental data. The results were compared with the measurements as shown in Fig. 8. The dash line in this figure is to separate sheet flow data from those obtained over ripples, and the solid line is the line of perfect agreement. The coarse sand data are again multiplied by a factor of ten for clarity. It is noticed that the fine sand

Figure 8: Calculated net transport rates of mixed sand (Eq. 10) compared with measurements.

Figure 9: Calculated net transport rates of mixed sand (Eq. 10) compared with measurements for $P = 0.75\%$.

Figure 10: Calculated net transport rates of mixed sand (Eq. 10) compared with measurements for $P = 0.50\%$.

Figure 11: Calculated net transport rates of mixed sand (Eq. 10) compared with measurements for $P = 0.25\%$.

data lay below the solid line, whereas the data for coarse sand are located above this line. This simply means that while the transport rate of fine sand has in fact been reduced, the coarse sand has kept its activity. The data were separated according to the percentage of sand and plotted again in Figs. 9, 10, and 11. For $P = 75\%$, *i.e.* when each sand has occupied the major part of the mixture, the data more or less follow the solid line of agreement. Interesting results are observed for $P = 25\%$, where measured transport rates of coarse sand show much larger values than those estimated. Despite the fact that coarse sand amounted only to 25% of the mixture, it has behaved as if it were alone; a clear indication of the armouring phenomenon.

The reduction in the transport rate of fine sand was explained by assuming that a percentage of the total flow energy equal to the percentage of fine sand is consumed to carry the fine sand. In the present formulation, ω is the parameter involving the flow kinetic energy. In general, Eqs. (10) and (12) may be rewritten as

$$\Phi_i = \frac{M_i}{(\rho_s - \rho)W_i d_i} = 0.0015 \operatorname{sign}(\Gamma) \cdot |\Gamma|^{0.5} \quad (13)$$

$$\omega_j = \frac{1}{2} \frac{u_j^2}{sgW_i T_j} \cdot P_i^{\frac{1}{\alpha_i}} \quad (14)$$

where α is expected to depend on the ratio of the mean diameter of each sand to that of the other sand. For the present sand mixture it was found that $\alpha_{0,2} = 1$

Figure 12: Comparison of net transport rates of mixed sand, calculated by the presented method, with measurements.

and $\alpha_{0.87} = 4$ are appropriate. Equations (1), (3), (11), (13), and (14) were thus applied to estimating the net transport rates of the present experiments. Calculated transport rates reasonably agreed with the measurements as shown in Fig. 12.

6. Concluding Remarks

The transport rate formula of Dibajnia and Watanabe (1992) was generalized to cover the transport of uniform granular sediments of any size and density.

Experiments were performed on transport of mixed-size sands. It was shown that fine and coarse sands when mixed together may make a firm structure and thus the bed may not be deformed as easily as in the case of uniform sands. Measurements of transport rate showed that armouring of fine sand by the coarse sand causes a significant reduction in the transport rate of the fine sand. But the transport rates of the coarse sand itself were almost unaffected by the presence of the fine sand. A method to apply the above generalized transport formula to estimating the transport rate of mixed sands was presented. Application of this method to beach profile simulation will be presented in a separate paper.

In the present experiments, the oscillatory velocity amplitude had to be limited because of the limited length of the test section (maximum velocity was about 95 cm/s) and higher velocities could not be tried. Therefore, further experiments under sheet flow conditions but with higher velocities are required to confirm whether the armouring function of the coarse sand will persist or not.

Coastal Engineering 1996

Proceedings of the
twenty-fifth international conference

September 2-6, 1996
The Peabody Hotel
Orlando, Florida

Held under the auspices of the
Coastal Engineering Research Council of the
American Society of Civil Engineers

Edited by Billy L. Edge

Published by the

ASCE *American Society
of Civil Engineers*

345 East 47th Street
New York, New York 10017-2398

Abstract:

This proceedings contains over 370 papers presented at the 25th International Conference on Coastal Engineering which was held in Orlando, Florida, 2-6 September, 1996. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation, erosion and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering.

CONTENTS

Part I Characteristics of Coastal Waves and Currents

CHAPTER 1	
Experimental Study of Breaking Waves over a Shoal	2
<i>Arun Chawla, H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 2	
A Method for Estimating Standardized Bimodal Directional Spectra	16
<i>Ryuichi Fujiwara, Masahiko Isobe</i>	
CHAPTER 3	
The Effects of Currents on Estimations of Directional Wave Spectra	30
<i>Yasuyuki Nakagawa, Hiroichi Tsuruya, Noriaki Hashimoto</i>	
CHAPTER 4	
A Method for Estimating Directional Spectra in a Field of Incident and Reflected Waves	43
<i>Hiromune Yokoki, Masahiko Isobe</i>	
CHAPTER 5	
Active Absorption of Multidirectional Waves	55
<i>Hemming A. Schaffer, Jesper Skourup</i>	
CHAPTER 6	
Time-Averaged Wave Field Evolution in Coastal Zone	67
<i>Jianlu Xu, Rodney J. Sobey</i>	
CHAPTER 7	
Quality Control of GEOSAT Wave Data for Engineering Applications	81
<i>M. Siddabathula, Vijay G. Panchang</i>	
CHAPTER 8	
Boussinesq Type Equations with High Accuracy in Dispersion and Nonlinearity	95
<i>P.A. Madsen, B. Banijamali, H.A. Schaffer, O.R. Sorensen</i>	
CHAPTER 9	
Wave Kinematics Computations Using Boussinesq Models	109
<i>J. Bosboom, G. Klopman, J.A. Roelvink, J.A. Battjes</i>	
CHAPTER 10	
Effects of Mode Truncation and Dissipation on Predictions of Higher Order Statistics ..	123
<i>James M. Kaihatu, James T. Kirby</i>	
CHAPTER 11	
Field Observation of Movement of Sand Body Due to Waves and Verification of Its Mechanism by Numerical Model	137
<i>Takaaki Uda, Yoshimichi Yamamoto, Naoki Itabashi, Kosuke Yamaji</i>	

CHAPTER 12	
Wave Groups in the Surf-Zone: Model & Experiments	151
<i>J. Veeramony, I. A. Svendsen</i>	
CHAPTER 13	
Simulation of Propagating Nonlinear Wave Groups	165
<i>Paul de Haas, Maarten Dingemans, Gert Klopman</i>	
CHAPTER 14	
Cross-Shore Momentum Flux Due to Shear Instabilities	175
<i>Ad Reniers, Jurjen A. Battjes</i>	
CHAPTER 15	
Modelling Post-Wave Breaking Turbulence and Vorticity	186
<i>T.C.D. Barnes, M. Brocchini, D.H. Peregrine, P.K. Stansby</i>	
CHAPTER 16	
A Turbulent Flow Model for Breaking Waves	200
<i>Nguyen The Duy, Tomoya Shibayama, Akio Okayasu</i>	
CHAPTER 17	
Turbulence Structures in the Surf Zone	214
<i>T.R. Haydon, D.B. Hann, P. Davies, C.A. Greated, T.C.D. Barnes</i>	
CHAPTER 18	
Experiments on Design Wave Height in Shallow Water	221
<i>J. William Kamphuis</i>	
CHAPTER 19	
Time-Dependent Quasi-3D Modeling of Breaking Waves on Beaches	233
<i>Entin A. Karjadi, Nobuhisa Kobayashi</i>	
CHAPTER 20	
Models of Wave Height and Fraction of Breaking Waves on a Barred Beach	247
<i>Yoshiaki Kuriyama</i>	
CHAPTER 21	
A Parametric Model for Random Wave Deformation by Breaking on Arbitrary Beach Profiles	261
<i>Hyuck-Min Kweon, Yoshimi Goda</i>	
CHAPTER 22	
Generation Characteristics of Wave Sounds as a Factor of Beach Amenity	275
<i>Hitoshi Murakami, Sadahiko Itoh, Yoshihiko Hosoi, Hideo Araki and Tsuyoshi Koyabu</i>	
CHAPTER 23	
Measurements of Wave Breaking in the UK Coastal Research Facility	286
<i>Howard N. Southgate, Stuart Stripling</i>	
CHAPTER 24	
A New Type Breaker Forming a Giant Jet and Its Decaying Properties	300

CHAPTER 25	
Wave Climate Cycles and Coastal Engineering Practice	314
<i>Douglas L. Inman, Scott A. Jenkins, M. Hany S. Elwany</i>	
CHAPTER 26	
Stability of Design Wave Estimates	328
<i>Jan Rossouw, Josep R. Medina</i>	
CHAPTER 27	
An Evaluation of Two Wave Forecast Models for the South African Region	340
<i>M. Rossouw, D. Phelp</i>	
CHAPTER 28	
A Comprehensive Wind, Wave, and Current Measurement Program in the South China Sea	354
<i>Jagat N. Sharma, S. Tryggestad, J. Bian</i>	
CHAPTER 29	
Wave Height and Period Distributions from Long-Term Wave Measurement	368
<i>Chung-Chu Teng, Ian M. Palao</i>	
CHAPTER 30	
Interference of Small Structures in the Vicinity of Large Structures	380
<i>Subrata K. Chakrabarti, Sumita Chakrabarti</i>	
CHAPTER 31	
Wave Dynamics at Coastal Structures: Development of a Numerical Model for Free Surface Flow	389
<i>Zoheir A. Sabeur, N. William H. Allsop, Robert G. Beale, John M. Dennis</i>	
CHAPTER 32	
Scale Effects in Oxygenation in the Breaker Zone of Coastal Structures	403
<i>V.K. Tsoukala, C.I. Moutzouris</i>	
CHAPTER 33	
Wave Actions on a Vertical Cylinder in Multi-Directional Random Waves	415
<i>Yu-xiu Yu, Ning-chuan Zhang, Qun Zhao</i>	
CHAPTER 34	
Wind/Wave Relation and the Pressure Gradient Effect	429
<i>Spiros M. Gouloumis</i>	
CHAPTER 35	
Non-Reflected Multi Directional Wave Maker Theory and Experiments of Verification ..	443
<i>Kazunori Ito, Hidehiro Katsui, Masashi Mochizuki, Masahiko Isobe</i>	
CHAPTER 36	
Fifty Years of Wave Growth Curves	457
<i>Paul C. Liu</i>	

CHAPTER 37	
Development of a Third Generation Shallow-Water Wave Model with Unstructured Spatial Meshing	465
<i>Michel Benoit, Frederic Marcos, Francoise Becq</i>	
CHAPTER 38	
New Optimization Method for Paddle Motion of Multi-Directional Wavemaker	479
<i>Akira Matsumoto, Minoru Hanzawa</i>	
CHAPTER 39	
Generation of Second-Order Long Waves by a Wave Group in a Laboratory Flume and Its Control	493
<i>M. Mizuguchi, H. Toita</i>	
CHAPTER 40	
Kinematic Predictions in Large Shallow Water Waves	502
<i>Susan Smith, Christopher Swan</i>	
CHAPTER 41	
Fetch Limited Spectral Evolution in Finite Depth Water	516
<i>I.R. Young, L.A. Verhagen</i>	
CHAPTER 42	
Measurement of Breaking Waves Using Particle Image Velocimetry	527
<i>Kuang-An Chang, Philip L.-F. Liu</i>	
CHAPTER 43	
Computation of the Near-Bottom Kinematics of Shoaling Waves	537
<i>Luc Hamm</i>	
CHAPTER 44	
Formulation and Validation of Vertically 2-D Shallow-Water Wave Model	551
<i>Bradley D. Johnson, Nobuhisa Kobayashi, Daniel T. Cox</i>	
CHAPTER 45	
Particle Velocity Distribution in Surface Waves	565
<i>Geir Moe, Oivind A. Arntsen</i>	
CHAPTER 46	
A Comparison of Analysis Methods for Wave Pressure Data	575
<i>Murray Townsend, John D. Fenton</i>	
CHAPTER 47	
A Nonlinear Model for Wave Propagation	589
<i>Ting-Kuei Tsay, Philip L.-F. Liu, Nan-Jing Wu</i>	
CHAPTER 48	
Application of a Digital Particle Image Velocimetry (DPIV) System to Breaking Waves in the Surf Zone	602
<i>Kenneth R. Craig, Robert J. Thieke</i>	

CHAPTER 49	
Wave Gauging Networks Worldwide - An Overview616
<i>J. Michael Hemsley</i>	
CHAPTER 50	
Improvement of Submerged Doppler-Type Directional Wave Meter and its Application to Field Observations629
<i>Noriaki Hashimoto, Masao Mitsui, Yoshimi Goda, Toshihiko Nagai, Tomoharu Takahashi</i>	
CHAPTER 51	
Comparison of Directional Wave Data Quality from Two Different Monitoring Systems ..	.643
<i>Lihwa Lin, Sidney Schofield, Hsiang Wang</i>	
CHAPTER 52	
The Digital Simulation of Non-Linear Random Waves657
<i>Kyungmo Ahn</i>	
CHAPTER 53	
The “SWAN” Wave Model for Shallow Water668
<i>N. Booij, L.H. Holthuijsen, R.C. Ris</i>	
CHAPTER 54	
Generation Depths from Water Wave Data677
<i>J. Ernest Breeding, Jr.</i>	
CHAPTER 55	
Wave Climate Assessment in the South Aegean Shelf689
<i>Spiros Christopoulos, Christos Solomonidis</i>	
CHAPTER 56	
Sea State Parameterisation Using Empirical Orthogonal Functions703
<i>Witold Cieslikiewicz, Jerzy Graff</i>	
CHAPTER 57	
Fully Nonlinear Properties of Periodic Waves Shoaling over Slopes717
<i>Stephan T. Grilli, Juan Horrillo</i>	
CHAPTER 58	
Water Wave Fluctuations Induced by Irregular Bathymetry731
<i>Lulin Guo, Robert A. Dalrymple</i>	
CHAPTER 59	
Integral Control Data Assimilation in Wave Predictions743
<i>L.H. Holthuijsen, N. Booij, M. van Endt, S. Caires, C. Guedes Soares</i>	
CHAPTER 60	
Two-Dimensional Analysis of Wave Transformation by Rational-Approximation-Based, Time-Dependent Mild-Slope Equation for Random Waves754
<i>Toshimasa Ishii, Masahiko Isobe, Akira Watanabe</i>	

CHAPTER 61	
Nonlinear Wave Transformation Due to a Submerged Breakwater	767
<i>Masahiko Isobe, Akira Watanabe, Shogo Yamamoto</i>	
CHAPTER 62	
Observed and Modeled Wave Results from Near-Stationary Hurricanes	781
<i>Charles L. Vincent, Robert E. Jensen</i>	
CHAPTER 63	
Estimation of Persistence Statistics of the Waves Observed on Japanese Coast in the Light of Recent Studies	794
<i>Hajime Kato, Hisamichi Nobuoka</i>	
CHAPTER 64	
Probabilistic Modeling of Long-Term Wave Climate	808
<i>V.M. Leyden, W.R. Dally</i>	
CHAPTER 65	
Monte Carlo Simulation for Nearshore Wave Statistics in Southern California	822
<i>Chia-Chi Lu, R. Rea Strange III</i>	
CHAPTER 66	
Bottom Friction Dissipation in the Belgian Coastal Regions	836
<i>Weimin Luo, Jaak Monbaliu, Jean Berlamont</i>	
CHAPTER 67	
Weakly non-Gaussian Model of Wave Height Distribution for Nonlinear Random Waves ..	850
<i>Nobuhito Mori, Takashi Yasuda</i>	
CHAPTER 68	
An Attempt at Applying the Chaos Theory to Wave Forecasting	864
<i>Takao Ohta, Akira Kimura</i>	
CHAPTER 69	
Transition of Stochastic Characteristics of Waves in the Nearshore Zone	878
<i>David J. Robillard, Michel K. Ochi</i>	
CHAPTER 70	
Monitoring and Modelling on Shallow Water Wave Propagations in “El Saler” Beach ..	889
<i>Jose C. Santos, Jose M. de la Pena, Jose Lozano</i>	
CHAPTER 71	
Intercomparison of Parameter Estimation Methods in Extremal Wave Analysis	900
<i>Masataka Yamaguchi</i>	
CHAPTER 72	
Influences of Spectral Shapes on the Statistical Properties of Simulated Random Waves ..	914
<i>John Z. Yim, M.-Y. Lai</i>	
CHAPTER 73	
Second-Order Interaction between Random Wave and Submerged Obstacle	927

CHAPTER 74	
A Uniform Mild-Slope Model for Waves over Varying Bottom	941
<i>Libang Zhang, Billy L. Edge</i>	
CHAPTER 75	
Bragg Reflection of Shallow-Water Waves on a Sloping Beach	955
<i>Yong-Sik Cho, Jong-In Lee, Jong-Kyu Lee</i>	
CHAPTER 76	
Reflection Analysis with Separation of Cross Modes	968
<i>John Gronbech, Thomas Jensen, Henning Andersen</i>	
CHAPTER 77	
Wave Runup on Beaches	981
<i>John P. Ahrens, William N. Seelig</i>	
CHAPTER 78	
Field Study on Wave Run-Up on Seadykes	994
<i>Joachim Grune</i>	
CHAPTER 79	
Wave Run-Up on Revetments with Composite Slopes	1008
<i>Zeya Wang, Joachim Grune</i>	
CHAPTER 80	
Landward Transport of Spray Generated from a Wave Absorbing Sea Wall	1022
<i>Misao Hashida, Nobuhiro Matsunaga, Isao Irie</i>	
CHAPTER 81	
Irregular Wave Kinematics from a Pressure Record	1034
<i>Christopher H. Barker, Rodney J. Sobey</i>	
CHAPTER 82	
Nonlinear Refraction-Diffraction of Surface Waves over Arbitrary Depths	1048
<i>Serdar Beji, Kazuo Nadaoka</i>	
CHAPTER 83	
Boussinesq Equations with Improved Doppler Shift and Dispersion for Wave/Current Interaction	1060
<i>Qin Chen, Per A. Madsen, Ole R. Sorensen, David R. Basco</i>	
CHAPTER 84	
The Propagation of Water Waves in Prismatic Channels	1074
<i>Li Li, Robert A. Dalrymple, Jeffrey M. Mlynarski</i>	
CHAPTER 85	
A Statistical Approach for Modeling Triad Interactions in Dispersive Waves	1088
<i>Y. Eldeberky, V. Polnikov, J. A. Battjes</i>	

CHAPTER 86	
A Fully Nonlinear 3D Method for the Computation of Wave Propagation	1102
<i>Andrew B. Kennedy, John D. Fenton</i>	
CHAPTER 87	
A Fourth Order Boussinesq-Type Wave Model	1116
<i>Mauricio F. Gobbi, James T. Kirby</i>	
CHAPTER 88	
Fast Methods for Computing the Shoaling of Nonlinear Waves	1130
<i>J.D. Fenton, A.B. Kennedy</i>	
CHAPTER 89	
Structure of Frequency Domain Models for Random Wave Breaking	1144
<i>James T. Kirby, James M. Kaihatu</i>	
CHAPTER 90	
A Hamiltonian Model for Nonlinear Water Waves and Its Applications	1156
<i>A.K. Otta, M.W. Dingemans, A.C. Radder</i>	
CHAPTER 91	
The Role of Wave-Induced Shear Stresses in the Momentum Balance Equations	1168
<i>Francisco J. Rivero, Agustin S.-Arcilla</i>

CHAPTER 97	
Spectral Modelling of Current Induced Wave-Blocking	1247
<i>R.C. Ris, L.H. Holthuijsen</i>	

Part II Long Period Waves, Storm Surges and Wave Groups

CHAPTER 98	
Uncertainties in the Validation of Harbor Wave Models	1256
<i>Zeki Demirbilek, Bingyi Xu, Vijay Panchang</i>	
CHAPTER 99	
Field Measurements and Numerical Modeling of Harbor Oscillations During Storm Waves	1268
<i>W.M. Jeong, J.W. Chae, W.S. Park, K.T. Jung</i>	
CHAPTER 100	
Performance of a Resonator Designed by the Wave Filter Theory - Applicability to a Harbor	1280
<i>Takayuki Nakamura, Hitoshi Mochizuki, Satoshi Morita</i>	
CHAPTER 101	
The Generation of Waves by a Landslide: Skagway, Alaska - A Case Study	1293
<i>Fredric Raichlen, Jiin Jen Lee, Catherine Petroff, Philip Watts</i>	
CHAPTER 102	
Laboratory Experiment on Long Wave Generation by Time-Varying Breakpoint	1307
<i>Satoru Nagase, Masaru Mizuguchi</i>	
CHAPTER 103	
Laboratory Experiments on Generation of Long Waves in the Surf Zone	1321
<i>Akio Okayasu, Teruki Matsumoto, Yasuyuki Suzuki</i>	
CHAPTER 104	
Generation of Infragravity Waves	1335
<i>A. R. van Dongeren, I.A. Svendsen, F.E. Sancho</i>	
CHAPTER 105	
Responses of Coastal Topography to Sea-Level Rise	1349
<i>Nobuo Mimura, Eiichi Kawaguchi</i>	
CHAPTER 106	
Numerical Study of Low Frequency Surf Zone Motions	1361
<i>H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 107	
Neptune - An Integrated Approach to Determining NW European Coastal Extremes ...	1375
<i>Jerzy Graff, Witold Cieslikiewicz</i>	
CHAPTER 108	
A Stochastic Typhoon Model and Its Application to the Estimation of Extremes of Storm Surge and Wave Height	1389
<i>Yoshio Hatada, Masataka Yamaguchi</i>	

CHAPTER 109	
Design of Vertical Walls Against Storm Surge	1403
<i>A. Kortenhaus, C. Miller, H. Oumeraci</i>	
CHAPTER 110	
Nearshore, Wave and Topographic Effects in Storm Surges	1417
<i>Gary Watson, Takao Yamashita</i>	
CHAPTER 111	
The Swash Zone: A Focus on Low Frequency Motion	1431
<i>Adam M. Shah, J. William Kamphuis</i>	
CHAPTER 112	
The Development of an On-Line, Interactive, Tsunami-Information Resource	1443
<i>Benjamin Cook, Catherine Petroff</i>	
CHAPTER 113	
Long Wave Runup on Coastal Structures	1452
<i>Utku Kanoglu, Costas Emmanuel Synolakis</i>	
CHAPTER 114	
Offshore Tsunami Profiles Observed at the Coastal Wave Stations	1465
<i>Toshihiko Nagai, Noriaki Hashimoto, Kazuyoshi Shimizu, Fujio Kitamura</i>	
CHAPTER 115	
A Realistic Model for the 1992-96 Tidal Waves	1478
<i>Srinivas Tadepalli, Costas Emmanuel Synolakis</i>	
CHAPTER 116	
Long-Period Oscillations in a Harbour Caused by Typhoon	1491
<i>Wataru Kioka</i>	
CHAPTER 117	
Estimation of Wave Groups Parameter from Wave Climate Statistics	1503
<i>Satoshi Nakamura</i>	

Part III Coastal Structures

CHAPTER 118	
Reflection Coefficients of the Step-Shaped Slit Caisson on the Rubble Mound	1516
<i>Sung Mo Ahn, Ryuichi Fujiwara, Hiroshi Matsunaga, Katsuhiko Kurata, Shohachi Kakuno</i>	
CHAPTER 119	
Berm Breakwater Trunk Exposed to Oblique Waves	1528
<i>A. Alikhani, G.R. Tomasicchio, J. Juhl</i>	
CHAPTER 120	
Interaction Between Main Armour and Toe Berm Damage	1542
<i>P. Aminti, A. Lamberti</i>	

CHAPTER 121	
Stability of Artificial Roughness Elements and Run-Up Reduction	1556
<i>M. Klein Breteler, K.W. Pilarczyk</i>	
CHAPTER 122	
Wave Induced Velocities at a Rubble Mound Breakwater	1569
<i>Bruno Brunone, Giuseppe R. Tomasicchio</i>	
CHAPTER 123	
Natural Periods of Armor Stones	1583
<i>Fred E. Camfield</i>	
CHAPTER 124	
Reliability Based Optimal Design of Vertical Breakwaters Modelled as a Series System of Failure	1589
<i>E. Christiani, H.F. Burcharth, J. Dalsgaard Sorensen</i>	
CHAPTER 125	
Overall Slope Stability Analysis of Rubble Mound Breakwaters	1603
<i>Julien De Rouck, Luc Van Damme</i>	
CHAPTER 126	
Interactions in the Stability of Toe-Berm and Main-Armour for Rubble-Mound Breakwaters: An Experimental Study	1617
<i>Philippe Donnars, Michel Benoit</i>	
CHAPTER 127	
Potential Uses for the Rapidly Installed Breakwater System	1631
<i>Jimmy Fowler, Donald Resio, Michael Briggs, Cheryl Pollock</i>	
CHAPTER 128	
Stability of Reshaping Breakwaters with Special Reference to Stone Durability	1640
<i>P. Frigaard, T. Hald, H.F. Burcharth, Sigurdur Sigurdarson</i>	
CHAPTER 129	
Field Investigations on Wave-Dissipating Concrete Blocks Covering Vertical Wall Breakwater	1652
<i>Michio Gomyoh, Kazuhiko Sakai, Tomotuka Takayama, Kojiro Suzuki, Shigeo Takahashi</i>	
CHAPTER 130	
New Stability Formula for Wave-Dissipating Concrete Blocks Covering Horizontally Composite Breakwaters	1665
<i>Minoru Hanzawa, Hirokazu Sato, Shigeo Takahashi, Kenichiro Shimosako, Tomotsuka Takayama, Katsutoshi Tanimoto</i>	
CHAPTER 131	
Breakwater Stability under Regular and Irregular Wave Attack	1679
<i>Thomas Jensen, Henning Andersen, John Gronbech, Etienne P.D. Mansard, Michael H. Davies</i>	
CHAPTER 132	
Roundhead Stability of Berm Breakwaters	1693

CHAPTER 133	
Improvement of Composite Breakwater on Solid Bottom Against Severe Tsunamis1707
<i>Yoshiaki Kimura, Hideo Kondo, Shinji Kuwabara, Akira Kawamori</i>	
CHAPTER 134	
Hydraulic Stability Analysis of Leaside Slopes of Overtopped Breakwaters1721
<i>M.D. Kudale, N. Kobayashi</i>	
CHAPTER 135	
Influence of the Core Configuration on the Stability of Berm Breakwaters1735
<i>Nikolay Lissev, Alf Torum</i>	
CHAPTER 136	
Model Study of Reservoir Riprap Stability1748
<i>Etienne P. D. Mansard, Michael H. Davies, Octave Caron</i>	
CHAPTER 137	
Prototype Measurements of Wave Pressures on a Wave Screen: Comparison to Physical and Analytical Models1762
<i>F.L. Martin, M. A. Losada, C. Vidal, J.L. Diaz Rato</i>	
CHAPTER 138	
Velocity Field Measurements over Breakwater Heads under 3D Waves1776
<i>Yoshiharu Matsumi, Akira Kimura, Kenichi Ohno</i>	
CHAPTER 139	
Wave Climate Simulation and Breakwater Stability1789
<i>Josep R. Medina</i>	
CHAPTER 140	
Incipient Motion of Breakwater Armor Units1803
<i>J. A. Melby, N. Kobayashi</i>	
CHAPTER 141	
Overtopping Reduction in Crownwall Design1816
<i>Jose Luis Monso, Alfonso Vidaor, Cristina Cadevall, Cristina Garcia</i>	
CHAPTER 142	
Stable Profiles of Reshaping Breakwaters with a Berm Below the Water Level1826
<i>C.I. Moutzouris</i>	
CHAPTER 143	
Experiments on a Non-Wave Overtopping Type Seawall1840
<i>Keisuke Murakami, I. Irie, Y. Kamikubo</i>	
CHAPTER 144	
A Condition and Performance Rating System for Breakwaters and Jetties1852
<i>John Oliver, Don Plotkin, John Lesnik, Douglas Pirie</i>	

CHAPTER 145	
Wave Overtopping and Stability of Armor Units under Multidirectional Waves	1862
<i>T. Sakakiyama, R. Kajima</i>	
CHAPTER 146	
Numerical Modeling of Breach Growth in a Sanddike	1876
<i>Gaus S. Stelling, Willem T. Bakker, Christine van Kuik, Christel Somers</i>	
CHAPTER 147	
Aging and Stability of Placed Block Revetments	1888
<i>Theo Stoutjesdijk, Hans Johanson, Mark Klein Breteler</i>	
CHAPTER 148	
Experimental Analysis of the Settlement Failure Mechanism Shown by Caisson-Type Seawalls	1902
<i>Shigeo Takahashi, Kojiro Suzuki, Katsumasa Tokubuchi, Ken-ichiro Shimosako</i>	
CHAPTER 149	
Full Scale Measurements of Wave Attenuation Inside a Rubble Mound Breakwater ...	1916
<i>Peter Troch, Marc De Somer, Julien De Rouck, Luc van Damme, Dierik Vermeir, Jean-Pierre Martens, Conan van Hove</i>	
CHAPTER 150	
Numerical Modelling of Wave Interaction with Dynamically Stable Structures	1930
<i>Marcel R.A. van Gent</i>	
CHAPTER 151	
Monitoring of Zeebrugge Breakwaters	1944
<i>Luc van Damme, Julien de Rouck</i>	
CHAPTER 152	
Influence of Rock Shape and Grading on Stability of Low-Crested Structures	1957
<i>Jentsje W. van der Meer, W.H. Tutuarima, G. Burger</i>	
CHAPTER 153	
Toe Stability of Rubble Mound Breakwaters	1971
<i>Ton van der Meulen, Gerrit J. Schiereck, Kees d'Angremond</i>	
CHAPTER 154	
Seawall Effects on Historically Receding Shorelines	1985
<i>Bryan N. Jones, David R. Basco</i>	
CHAPTER 155	
Control of Wave Propagation Angle by Tapered-Submerged Breakwater	1998
<i>Satoshi Takewaka, Isao Irie</i>	
CHAPTER 156	
Multidirectional Wave Loads on Vertical Breakwaters	2008
<i>Claudio Franco, Jentsie W. Van der Meer, Leopoldo Franco</i>	

CHAPTER 157	
Modelling the Impact of Detached Breakwaters on the Coast	2022
<i>K.J. Bos, J.A. Roelvink, M.W. Dingemans</i>	
CHAPTER 158	
Evaluation of Beach Modelling Techniques Behind Detached Breakwaters	2036
<i>Philip Axe, Suzana Ilic, Andrew Chadwick</i>	
CHAPTER 159	
Numerical Modelling of Bed Evolution Behind a Detached Breakwater	2050
<i>Philippe Pechon, Charles Teisson</i>	
CHAPTER 160	
Combined Diffraction and Transmission of Water Waves around a Porous Breakwater	
Gap	2063
<i>Xiping Yu, Hiroyoshi Togashi</i>	
CHAPTER 161	
Prediction of Wave Reflection from Rock Structures: An Integration of	
Field & Laboratory Data	2077
<i>Mark A. Davidson, Paul A.D. Bird, David A. Huntley, Geoff N. Bullock</i>	
CHAPTER 162	
Performance Evaluation of Buoy-Membrane Wave Barriers	2087
<i>M.H. Kim, B. L. Edge, S.T. Kee, L. Zhang</i>	
CHAPTER 163	
An Improved Design Method for the Riprap of Earthfill Dams of Large Reservoirs ...	2101
<i>Jean-Pierre Tournier, Pierre Dupuis, Raymond Ares</i>	
CHAPTER 164	
Geotextile Systems in Coastal Engineering - An Overview -	2114
<i>Krzysztof W. Pilarczyk</i>	
CHAPTER 165	
Groynes on the East Frisian Islands: History and Experiences	2128
<i>Hans Kunz</i>	
CHAPTER 166	
Permeable Pile Groins	2142
<i>Thomas Trampenau, Frank Goricke, Arved J. Raudkivi</i>	
CHAPTER 167	
The Effect of Groundwater on Scour Near Structures	2152
<i>John H. Loveless, Geoffrey T. Grant, Robert I. Karlsson</i>	
CHAPTER 168	
Abrasion of Steel Pipe Piles by Sediment Motion in Coastal Zones	2166
<i>Gaku Matsuoka, Shinichi Ito, Toshihiko Yamashita, Hiroshi Saeki, Yoshihisa Kariyazono, Koichi Sato</i>	

CHAPTER 169	
A Viscous Rotational Model for Wave Overtopping over Marine Structure	2178
<i>Fei Zhuang, Jiin-Jen Lee</i>	
CHAPTER 170	
Overtopping of Waves at a Wall: A Theoretical Approach	2192
<i>M. Jervis, D.H. Peregrine</i>	
CHAPTER 171	
Wind Effects on Runup and Overtopping of Coastal Structures	2206
<i>Donald L. Ward, Jun Zhang, Christopher G. Wibner, Charles M. Cinotto</i>	
CHAPTER 172	
Wave Overtopping of Vertical Structures Including Wind Effect	2216
<i>Johannes P. de Waal, Patrick Tonjes, Jentsje W. van der Meer</i>	
CHAPTER 173	
Bridge Pier Scour Assessment for the Northumberland Strait Crossing	2230
<i>C.D. Anglin, R.B. Nairn, A.M. Cornett, L. Dunaszegi, J. Turnham, G.W. Annandale</i>	
CHAPTER 174	
Wave Setup at River Entrances	2244
<i>David J. Hanslow, Peter Nielsen, Kevin Hibbert</i>	
CHAPTER 175	
Scour at Coastal Inlet Structures	2258
<i>Steven A. Hughes, J. William Kamphuis</i>	
CHAPTER 176	
Probability Distribution of the Maximum Wave Height along a Sea Wall with Finite Width	2272
<i>Akira Kimura, Takao Ohta</i>	
CHAPTER 177	
Beach Response in Front of Wave-Reflecting Structures	2284
<i>Roy C. Seaman, Tom O'Donoghue</i>	
CHAPTER 178	
Fundamental Characteristics of Wave Transformation around Artificial Reefs	2298
<i>Toshio Aono, Eric C. Cruz</i>	
CHAPTER 179	
Performance of a Submerged Breakwater for Shore Protection	2312
<i>Albert E. Browder, Robert G. Dean, Renjie Chen</i>	
CHAPTER 180	
Nonlinear Wave Transformation over a Submerged Triangular Breakwater	2324
<i>Lifen Dong, Akira Watanabe, Masahiko Isobe</i>	
CHAPTER 181	
Breaking Limit, Breaking and Post-Breaking Wave Deformation Due to Submerged	

Structures	2338
<i>Koichiro Iwata, Koji Kawasaki, Do-Sam Kim</i>	
CHAPTER 182	
Italian Experience on Submerged Barriers as Beach Defence Structures	2352
<i>Alberto Lamberti, Alessandro Mancinelli</i>	
CHAPTER 183	
Resonant Reflection and Refraction-Diffraction of Surface Waves Due to Porous Submerged Breakwaters	2366
<i>Hajime Mase, Akira Kimura, Hiroshi Sakakibara</i>	
CHAPTER 184	
BEM-FEM Combined Analysis of Nonlinear Interaction between Wave and Submerged Breakwater	2377
<i>N. Mizutani, W.G. McDougal, A.M. Mostafa</i>	
CHAPTER 185	
Regulation of Nearshore Circulation by Submerged Breakwater for Shore Protection ..	2391
<i>Hisamichi Nobuoka, Isao Irie, Hajime Kato, Nobuo Mimura</i>	
CHAPTER 186	
Submerged Breakwaters for the Defence of the Shoreline at Ostia - Field Experiences, Comparison	2404
<i>Ugo Tomasicchio</i>	
CHAPTER 187	
Wave Transmission of Low-Crested Structures	2418
<i>Kees d'Angremond, Jentsje W. van der Meer, Rutger J. De Jong</i>	
CHAPTER 188	
Effect of Submerged Breakwater on Profile Development	2428
<i>Martin D. Groenewoud, Jan van de Graaff, Edward W.M. Claessen, Stephan C. van der Biezen</i>	
CHAPTER 189	
Cause and Characteristics of Impact Pressure Exerted by Spilling and Plunging Breakers on a Vertical Wall	2442
<i>Seyed Ali Azarmsa, Takashi Yasuda, Hidemi Mutsuda</i>	
CHAPTER 190	
Dynamic Response of Vertical Elastic Walls to Breaking Wave Impact	2456
<i>Masatato Hattori, Nobuaki Tsujioka</i>	
CHAPTER 191	
Wave Transmission Past Vertical Wave Barriers	2470
<i>David L. Kriebel, Chad A. Bollmann</i>	
CHAPTER 192	
Physical Study of the Nature of High Peak Wave Pressures	2484
<i>Jordan Marinski</i>	

CHAPTER 193	
A Design Short-Crested Wave Force Model for Vertical Deep-Water Breakwaters	2494
	<i>S.-Y. Tzang, S.-R. Liaw</i>
CHAPTER 194	
New Design Methods for Wave Impact Loadings on Vertical Breakwaters and Seawalls . .	2508
	<i>N.W.H. Allsop, J.E. McKenna, D. Vicinanza, T.T.J. Whitaker</i>
CHAPTER 195	
Scale Effects of Wave Impact Pressures on Cob Armour Units	2522
	<i>M.W. Howarth, N.W.H. Allsop, A.M. Vann, R.J. Jones, J.P. Davis</i>
CHAPTER 196	
Wave Impact Loading of Vertical Face Structures for Dynamic Stability	
Analysis - Prediction Formulae -	2534
	<i>P. Klammer, A. Kortenhaus, H. Oumeraci</i>
CHAPTER 197	
Analysis on the Interaction of Waves with Flexible Floating Structure	
by BE-FE Combined Method	2548
	<i>Xiaodong Liu, Shigeki Sakai</i>
CHAPTER 198	
Design Wave Height Related to Structure Lifetime	2560
	<i>Zhou Liu, Hans F. Burcharth</i>
CHAPTER 199	
Wave Impact Beneath a Horizontal Surface	2573
	<i>D.J. Wood, D.H. Peregrine</i>
CHAPTER 200	
Wave Impulse Prediction for Caisson Design	2584
	<i>Michael J.A. Walkden, Peter J. Hewson, Geoffrey N. Bullock</i>
CHAPTER 201	
Wave Overtopping Rate and Reflection Coefficient for Obliquely Incident Waves	2598
	<i>Yoichi Moriya, Masaru Mizuguchi</i>
CHAPTER 202	
Sediment Transport and Wave Reflection near a Seawall	2612
	<i>Jonathon R. Miles, Paul E. Russell, David A. Huntley</i>

Part IV Coastal Processes and Sediment Transport

CHAPTER 203	
Wave Energy Dissipation in Kelp Vegetation	2626
	<i>Alfonse Dubi, Alf Torum</i>
CHAPTER 204	
Experimental Study on the Effect of Gravity Drainage System on Beach Stabilization . .	2640
	<i>Hiroi Kanazawa, Fumihiko Matsukawa, Kazumasa Katoh, Iwao Hasegawa</i>

CHAPTER 205	
Field Experiment on the Effect of Gravity Drainage System on Beach Stabilization . . .	2654
	<i>Kazumasa Katoh, Shin-ichi Yanagishima</i>
CHAPTER 206	
On the Change of Velocity Field in Nearshore Zone Due to Coastal Drain and the Consequent Beach Transformation	2666
	<i>Michio Sato, Tadahiro Fukushima, Ryuichiro Nishi, Masahiko Fukunaga</i>
CHAPTER 207	
Evaluation of a Beach Dewatering System: Nantucket, USA	2677
	<i>William R. Curtis, Jack E. Davis, Ian L. Turner</i>
CHAPTER 208	
Sediment Transport Processes at Ocean Beach, San Francisco, California	2691
	<i>Robert T. Battalio, Dilip Trivedi</i>
CHAPTER 209	
Two Treatments of Shore Erosion in Extreme Floods on U.S. Great Lakes	2705
	<i>Robert J. Hallermeier</i>
CHAPTER 210	
Long-Term Beach Response to Shore Stabilization Structures on the Oregon Coast . . .	2718
	<i>G.E. Hearon, W.G. McDougal, P.D. Komar</i>
CHAPTER 211	
Profile Volumes as a Measure of Erosion Vulnerability	2732
	<i>Timothy W. Kana, Ram Krishna Mohan</i>
CHAPTER 212	
Breach Growth: Experiments and Modelling	2746
	<i>Harry de Looff, Henk J. Steetzel, Arie W. Kraak</i>
CHAPTER 213	
The Impact of an Extreme Event on the Sediment Budget: Hurricane Andrew in the Louisiana Barrier Islands	2756
	<i>Jeffrey H. List, Mark E. Hansen, Asbury H. Sallenger, Jr., Bruce E. Jaffe</i>
CHAPTER 214	
Beach Maintenance Strategies, a Comparison for a Recreational Beach	2770
	<i>M. Pluijm, G. Kant, R. Noltén, A.P. de Looff</i>
CHAPTER 215	
Littoral Impact of Ocean City Inlet, Maryland, USA	2779
	<i>Julie Dean Rosati, Bruce A. Ebersole</i>
CHAPTER 216	
Extreme Water Levels, Wave Runup and Coastal Erosion	2793
	<i>P. Ruggiero, P.D. Komar, W.G. McDougal, R.A. Beach</i>

CHAPTER 217	
A Morphological “Mixed-Type” Model for the Ebro Delta Coast	2806
<i>Agustin Sanchez-Arcilla, Jose A. Jimenez</i>	
CHAPTER 218	
Sea Dike Erosion and Coastal Retreat at Nam Ha Province, Vietnam	2820
<i>Ton That Vinh, G. Kant, Nguyen Ngoc Huan, Z. Pruszk</i>	
CHAPTER 219	
Beach Profile Analysis around Indian River Inlet, Delaware, U.S.A	2829
<i>Kirk F. Bosma, Robert A. Dalrymple</i>	
CHAPTER 220	
Improved 3-D Beach Evolution Model Coupled with the Shoreline Model (3D-SHORE)	2843
<i>Takuzo Shimizu, Takahiro Kumagai, Akira Watanabe</i>	
CHAPTER 221	
Evaluation of Shoreface Nourishments by Line Modelling	2857
<i>Martin D. Groenewoud, Willem T. Bakker, Jan van de Graaff, Ruud Spanhoff, Christian Laustrup</i>	
CHAPTER 222	
Beach Monitoring Program of Valencia (Spain)	2871
<i>Jose Serra, Josep R. Medina</i>	
CHAPTER 223	
Bar Migration and Duneface Oscillation on Decadal Scales	2884
<i>Marcel J.F. Stive, Jorge Guillen, Michele Capobianco</i>	
CHAPTER 224	
Morphological Development of the Terschelling Shoreface Nourishment in Response to Hydrodynamic and Sediment Transport Processes	2897
<i>P. Hoekstra, K.T. Houwman, A. Kroon, B.G. Ruessink, J.A. Roelvink, R. Spanhoff</i>	
CHAPTER 225	
Justification for Beach Nourishment	2911
<i>John G. Housley</i>	
CHAPTER 226	
Beach Nourishment Versus Shore Protection Structures	2918
<i>Alexander Khabidov, Yuri Bazhenov, Marina Glodenis, Nadya Ivanova, Liya Kaskevitch, Oleg Rybak, Valery Savkin, Anatoly Trizno, Grigory Zelensky, Veniamin Yedapin</i>	
CHAPTER 227	
Comparison of Beach and Shoreface Nourishment Torsminde Tange, Denmark	2927
<i>Christian Laustrup, Holger Toxvig Madsen, Per Sorensen, Ida Broker</i>	
CHAPTER 228	
Mathematical and Physical Modeling of Beach Nourishment Projects	2941
<i>W. Eric Rogers, Paul A. Work</i>	

CHAPTER 229	
Coastal Zone Dynamics during Artificial Nourishment	2955
<i>Elzbieta Zawadzka</i>	
CHAPTER 230	
Dune Damage Curves and Their Use to Estimate Dune Maintenance Costs	2969
<i>David R. Basco, Cheol S. Shin</i>	
CHAPTER 231	
Hurricane Opal Induced Changes on Natural and Nourished Beaches, West-Central Florida	2982
<i>Richard A. Davis, Jr., Ping Wang</i>	
CHAPTER 232	
Modelling Sand Transport and Profile Evolution on Macrotidal Beaches	2994
<i>Paul R. Fisher, Tim J. O'Hare</i>	
CHAPTER 233	
Beach Evolution Under Random Waves	3006
<i>Patrick Holmes, Thomas E. Baldock, Ray T.C. Chan, M. Ahmad L. Neshaei</i>	
CHAPTER 234	
Beach Profile Surveys Along the U.S. Pacific Coast 1945-1947	3020
<i>Nicholas C. Kraus, Robert L. Wiegel, Willard N. Bascom</i>	
CHAPTER 235	
Mechanism and Calculation of Sand Dune Erosion by Storms	3034
<i>Ryuichiro Nishi, Nicholas C. Kraus</i>	
CHAPTER 236	
Simulation of Coastal Profile Development Using a Boussinesq Wave Model	3048
<i>K.A. Rakha, R. Deigaard, P.A. Madsen, I. Broker, J.K. Ronberg</i>	
CHAPTER 237	
Cross-shore Sediment Transport and Beach Deformation Model	3062
<i>RattanapitikonWinyu , Tomoya Shibayama</i>	
CHAPTER 238	
Experimental Study on Sediment Transport in Surf and Swash Zones Using Large Wave Flume	3076
<i>Takao Shimizu, Masaaki Ikeno</i>	
CHAPTER 239	
The Influence of Long Waves on Macrotidal Beach Morphology	3090
<i>David J. Simmonds, Tim J. O'Hare, David A. Huntley</i>	
CHAPTER 240	
Mathematical Models for Waves and Beach Profiles in Surf and Swash Zones	3104
<i>Akira Watanabe, Mohammad Dibajnia</i>	

CHAPTER 241
Comparisons of Erosion Models for Storms at Ocean City, Maryland3115
Jie Zheng, Robert G. Dean

CHAPTER 242
Measurements of Wave Generated Bedforms3129
Christopher D. Jette, Daniel M. Hanes

CHAPTER 243
Field Measurement of Bed Roughness for Waves on an Offshore Reef3143
Raymond C. Nelson

CHAPTER 244
Effect of Wave-Induced-Pressure on Seabed Configuration3155
Tetsuo Sakai, Hitoshi Gotoh

CHAPTER 245
The Measurement of Bed Form Shapes in Hydraulic Models3169
Ian E. Shepherd

CHAPTER 246
Asymmetric Boundary Layer Flow above Sand Ripples under Progressive Waves3183
Takao Toue, Kazuo Nadaoka, Hidehiro Katsui

CHAPTER 247
Undertow Profiles in the Bottom Boundary Layer under Breaking Waves3194
Daniel T. Cox, Nobuhisa Kobayashi

CHAPTER 248
A Comparison of Field Observations and Quasi-Steady Linear Shear Instabilities of the Wave Bottom Boundary Layer3207
D.L. Foster, A.J. Bowen, R.A. Beach, R.A. Holman

CHAPTER 249
Wave Boundary Layer Flows and Pore Pressures in Permeable Beds3219
H.H. Hwang, K.S. Hwang, B.H. Lee

CHAPTER 250
Backfilling of Trenches Exposed to Waves3231
Jacob Hjelmager Jensen, Jorgen Fredsoe

CHAPTER 251
A Closed-Form Solution for Turbulent Wave Boundary Layers3244
Magnus Larson

CHAPTER 252
Observed Suspended Sediments in Storm Conditions3257
J.J. Williams, C.P. Rose, P.D. Thorne, L.E. Coates, J.R. West, P.J. Harcastle, J.D. Humphery, S.P. Moores, D.J. Wilson

CHAPTER 253	
Ebb Tidal Delta Evolution of Coastal Inlets	3270
<i>Michael R. Dombrowski, Ashish J. Mehta</i>	
CHAPTER 254	
Adjustments toward Equilibrium of a Large Flood -Tidal Delta after a Major Dredging Program, Tauranga Harbour, New Zealand	3284
<i>Terry Healy, Joseph Mathew, Willem de Lange, Kerry Black</i>	
CHAPTER 255	
Laboratory Mobile Bed Model Studies on Ebb Tidal Shoal Evolution	3295
<i>Xu Wang, Lihwa Lin, Hsiang Wang</i>	
CHAPTER 256	
Interaction of the Colorado River Project, Texas, with Longshore Sediment Transport ..	3309
<i>Daniel J. Heilman, Billy L. Edge</i>	
CHAPTER 257	
A Comprehensive Field Study of Tidal Inlet Processes at Ponce de Leon Inlet, Florida ..	3323
<i>Gary L. Howell</i>	
CHAPTER 258	
Transport of Fluid Mud Generated by Waves on Inclined Beds	3337
<i>Thijs van Kessel, C. Kranenburg, J.A. Battjes</i>	
CHAPTER 259	
Wave on Pebble Beach and Deformation of Pebble Beach	3349
<i>Ichiro Deguchi, Masanobu Ono, Toru Sawaragi</i>	
CHAPTER 260	
Wind-Induced Waves and Currents in a Nearshore Zone	3363
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroshi Kawakami</i>	
CHAPTER 261	
Predicting Large-Scale, Cross-Shore Sediment Movement from Orbital Speeds	3378
<i>Edward B. Hands, John P. Ahrens, Donald T. Resio</i>	
CHAPTER 262	
Small-scale Morphology Related to Wave and Current Parameters Over a Barred Beach	3391
<i>A.F. Garcez Faria, E.B. Thornton, T.P. Stanton</i>	
CHAPTER 263	
Prediction of Shoreline Change Considering Cross-Shore Sediment Transport	3405
<i>Yoshimichi Yamamoto, Kiyoshi Horikawa, Katsutoshi Tanimoto</i>	
CHAPTER 264	
The Influence of Rollers on Longshore Currents	3419
<i>Daniel A. Osiecki, William R. Dally</i>	

CHAPTER 265	
Velocity Field Measurements in a “Coastal Buffer Zone”	3431
<i>Hiroshi Yagi, Hirofumi Hinata, Kazuo Nadaoka</i>	
CHAPTER 266	
Development of Underwater Beach Profile by Monochromatic and Random Waves . . .	3442
<i>Karsten Peters, Jurgen Neue, Hans-H. Dette</i>	
CHAPTER 267	
Turbulent Stresses in the Surf-Zone: Which Way Is Up?	3453
<i>John W. Haines, Guy Gelfenbaum</i>	
CHAPTER 268	
Asymmetric and Irregular Wave Effects on Bedload: Theory Versus Laboratory and Field Experiments	3467
<i>Leszek M. Kaczmarek, Rafal Ostrowski</i>	
CHAPTER 269	
Kinematics and Shear Stresses from Combined Waves and Longshore Currents in the UK Coastal Research Facility	3481
<i>Richard R. Simons, Ruairi D. MacIver, Wameidh M. Saleh</i>	
CHAPTER 270	
Movable Bed Roughness in the Flow of Irregular Waves and Currents Over Movable Beds	3495
<i>Zai-Jin You, Peter Nielsen</i>	
CHAPTER 271	
Seabed and Foundation Response to Wave Loading	3507
<i>Michael H. Davies</i>	
CHAPTER 272	
Interannual Shoreline Variations at Duck, NC, USA	3521
<i>Nathaniel Plant, Rob Holman</i>	
CHAPTER 273	
Long Term Behaviour of the Sediment Volume inside a Tidal Basin after Poldering . . .	3534
<i>Ernst Schroeder, Roland Goldenbogen, Hans Kunz</i>	
CHAPTER 274	
Wave Groups in a Barred Nearshore	3546
<i>B. Boczar-Karakiewicz, W. Romanczyk, J.L. Bona, B. Greenwood</i>	
CHAPTER 275	
Coastal Morphodynamic Instabilities	3560
<i>Albert Falques, Amadeu Montoto, Vicente Iranzo</i>	
CHAPTER 276	
On Validation of a Sand Waves and Sand Banks Model	3574
<i>Suzanne J.M.H. Hulscher</i>	

CHAPTER 277	
Transverse Bars in Duck, North Carolina	3588
<i>Kathryn M. Konicki, Rob A. Holman</i>	
CHAPTER 278	
On the Systematic Offshore Decay of Breaker Bars	3600
<i>Kathelijne M. Wijnberg</i>	
CHAPTER 279	
Longshore Bed-Load Transport	3614
<i>Jesper S. Damgaard, Richard L. Soulsby</i>	
CHAPTER 280	
Design Capacity of a Longshore Current Recirculation System for a Longshore Sediment Transport Laboratory Facility	3628
<i>David G. Hamilton, Julie D. Rosati, Jimmy E. Fowler, Jane M. Smith</i>	
CHAPTER 281	
Influence of Nearshore Hardbottom on Regional Sediment Transport	3642
<i>Paul C.-P. Lin, R. Harvey Sasso</i>	
CHAPTER 282	
Improvement of the Most Accurate Longshore Transport Formula	3652
<i>J.S. Schoonees, A.K. Theron</i>	
CHAPTER 283	
Cross-shore Structure of Longshore Currents during Duck94	3666
<i>Falk Feddersen, R.T. Guza, Steve Elgar, T.H.C. Herbers</i>	
CHAPTER 284	
Three-Dimensional Hydrodynamics on a Barred Beach	3680
<i>Tae-Myoung Oh, Robert G. Dean</i>	
CHAPTER 285	
Rip Current Generation on a Plane Beach	3694
<i>D.A. Suriamihardja, Yoshito Tsuchiya</i>	
CHAPTER 286	
Nearshore Placement of Sand	3708
<i>Scott L. Douglass</i>	
CHAPTER 287	
Influence of Nearshore Berm on Beach Nourishment	3722
<i>Paul A. Work, Emre N. Otay</i>	
CHAPTER 288	
Accuracy of Sand Volumes as a Function of Survey Density	3736
<i>Jennifer L. Irish, W. Jeff Lillycrop, Larry E. Parson</i>	
CHAPTER 289	
Shoreline Analysis Using Digital Photogrammetry	3750

CHAPTER 290	
Application of Satellite Images to the Detection of Coastal Topography	3762
<i>Ji Wu, Jea Tzyy Juang</i>	
CHAPTER 291	
Sediment Transport in Swash Zone under Obliquely Incident Waves	3770
<i>Toshiyuki Asano</i>	
CHAPTER 292	
Sheet Flow Modelled As Pure Convection	3784
<i>Stephen Clark, Peter Nielsen</i>	
CHAPTER 293	
A Transport Rate Formula for Mixed-Size Sands	3791
<i>Mohammad Dibajnia, Akira Watanabe</i>	
CHAPTER 294	
Modelling of 3D Sediment Transport in the Surf Zone	3805
<i>Berry Elfrink, Ida Broker, Rolf Deigaard, Erik Asp Hansen, Peter Justesen</i>	
CHAPTER 295	
A Numerical Model of Sheet Flow Sediment Transport	3818
<i>Sadakazu Katori, Masaru Mizuguchi, Akira Watanabe</i>	
CHAPTER 296	
Numerical Modeling of Nearshore Morphological Changes under a Current-Wave Field	3830
<i>Taerim Kim, Hsiang Wang</i>	
CHAPTER 297	
An Analysis of Particle Saltation Dynamics	3846
<i>Michael R. Krecic, Daniel M. Hanes</i>	
CHAPTER 298	
Sediment Movement and Stress Condition in Sea Bed	3860
<i>Yoshihiko Maeno, Motoyasu Ishikawa, Koza Bando, Yoshinobu Akiyama, Kouichi Yabe</i>	
CHAPTER 299	
Application of the Depth of Closure Concept	3874
<i>Robert J. Nicholls, William A. Birkemeier, Robert J. Hallermeier</i>	
CHAPTER 300	
Numerical Modeling of Sediment Transport for Various Mode	3888
<i>Masanobu Ono, Ichiro Deguchi, Toru Sawaragi</i>	
CHAPTER 301	
Nearbed Sediment Concentration from Tracer Studies	3901
<i>Zbigniew Pruszk, Ryszard Wierzchnicki, Andrzej Owczarczyk, Ryszard B. Zeidler</i>	

CHAPTER 302	
A Sloping Duct for the Study of Sediment Transport	3913
<i>Jesper S. Damgaard, Richard J.S. Whitehouse, Richard L. Soulsby</i>	
CHAPTER 303	
Sediment Dynamics and Profile Interactions: DUCK94	3921
<i>Donald K. Stauble, Mary A. Cialone</i>	
CHAPTER 304	
A Study on Flow Structure and Suspended Sediment Concentration over Seaweed Bed ..	3935
<i>Gozo Tsujimoto</i>	
CHAPTER 305	
An Energetics Approach for Suspended Sand Transport on Macrotidal Ridge and Runnel Beaches	3948
<i>George Voulgaris, Travis Mason, Michael B. Collins</i>	
CHAPTER 306	
Field Tests of Suspended-Load Transport Theories Used in Numerical Models	3962
<i>Thomas E. White</i>	
CHAPTER 307	
Shore Protection Studies for Ras-Elbar Area, Egypt	3976
<i>John B. Herbich, Abd-Elfattah Elfiky, Abd-Elmohsen Elmongy; Ali Elbahrawy, Gamal Elsaeed</i>	
CHAPTER 308	
Stabilizing Beaches Downcoast of Harbor Extensions	3986
<i>John R.C. Hsu, Richard Silvester</i>	
CHAPTER 309	
Observation of Nearshore Currents and Beach Changes around Headlands Built on the Kashimanada Coast, Japan	4000
<i>K. Saito, T. Uda, K. Yokota, S. Ohara, Y. Kawanakajima, K. Uchida</i>	
CHAPTER 310	
Nourished Beach Control Between Balis and Arenys Harbours (Spain)	4014
<i>F. Javier Escartin, Alfonso Vidaor, A.M. Castaneda, Nuria Lupon</i>	
CHAPTER 311	
Numerical Simulation of Shoreline Change with Longshore Sand Waves at Groins	4024
<i>Hans Hanson, Michelle M. Thevenot, Nicholas C. Kraus</i>	
CHAPTER 312	
Erosive Waves in Shoreline Change Due to the Reduction of a River Delta	4038
<i>Yoshito Tsuchiya</i>	
CHAPTER 313	
DELILAH, DUCK94 & SandyDuck: Three Nearshore Field Experiments	4052
<i>William A. Birkemeier, Charles E. Long, Kent K. Hathaway</i>	

CHAPTER 314	
Eulerian Mean Velocities under Non-Breaking Waves on Horizontal Bottoms	4066
	<i>Peter Nielsen, Zai-Jin You</i>
CHAPTER 315	
Reynolds Stress and Small-Scale Morphology Measurements during DUCK94	4079
	<i>Timothy P. Stanton, Edward B. Thornton</i>
CHAPTER 316	
Studies on the Suspended Concentration in the Surf Zone	4088
	<i>Ching-Her Hwang, Li-Hung Tsai, Po-Ching Lin, Chin-Chi Tsai</i>
CHAPTER 317	
Suspended Sediment Mixing in the Surf Zone	4098
	<i>Jose A. Jimenez, Francisco J. Rivero, Agustin Sanchez-Arcilla, Vicente Gracia, Andres Rodriguez</i>
CHAPTER 318	
Sand Suspension Events and Intermittence of Turbulence in the Surf Zone	4111
	<i>R.D. Kos'yan, H. Kunz, S.Yu. Kuznetsov, N.V. Pykhov, M.V. Krylenko</i>
CHAPTER 319

CHAPTER 294

MODELLING OF 3D SEDIMENT TRANSPORT IN THE SURF ZONE

by

Berry Elfrink¹, Ida Brøker¹, Rolf Deigaard², Erik Asp Hansen¹ and Peter Justesen¹

ABSTRACT

The three-dimensional sediment transport in the surf zone has been investigated using two different approaches for modelling of the flow pattern. The first approach is based on the integrated momentum concept for the turbulent wave-current boundary layer, see Fredsøe (1984), the second approach is based on the k-model, as described in Deigaard et al. (1991). The k-model allows for a more consistent description of the time and space varying eddy viscosity than the integrated momentum approach, but demands considerably more computation effort. The driving forces are calculated according to the formulations of Deigaard et al. (1991) and Deigaard (1993). The model based on the integrated momentum equation is able to reproduce the details of the flow satisfactorily. The presence of a longshore current increases the turbulence near the bed. This results in a decreased offshore directed flow velocity near the bed and an increase in the sediment concentration. Comparisons with field measurements show good agreement.

INTRODUCTION

When waves break turbulent kinetic energy is produced at the water surface. This energy is partly dissipated in the surface roller and partly transported downwards into the water column. The radiation stress gradients, associated with the wave breaking, are balanced by the pressure gradient originating from the wave setup and the mean bed shear stress.

In case of uniform conditions along the shore, the net discharge in the mean cross shore flow must balance the fluid mass transported in the surface roller and the discharge associated with the asymmetric wave motion and streaming in the bottom boundary layer. The zero mass flux in the cross shore direction is achieved by a slope of the mean water level. The vertical variation of the cross shore flow velocity is therefore characterized by offshore directed velocities near the bed (the undertow) and onshore velocities further away from the bed.

¹ Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark

² Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, 2800 Lyngby, Denmark

In the longshore direction, the forces associated with the wave breaking can only be balanced by a mean bed shear stress which drives the wave induced longshore current.

The interaction of the turbulence originating from wave breaking with the turbulence generated in the bottom boundary layer is of great importance in the description of the sediment transport in the surf zone, see Justesen et al. (1986). Due to the higher level of turbulence more sediment can be kept into suspension under breaking waves than under non-breaking waves.

In the present work, the flow conditions along the shore are assumed to be uniform, see figure 1. The waves approach the coast under an angle α and are assumed to be long crested and monochromatic.

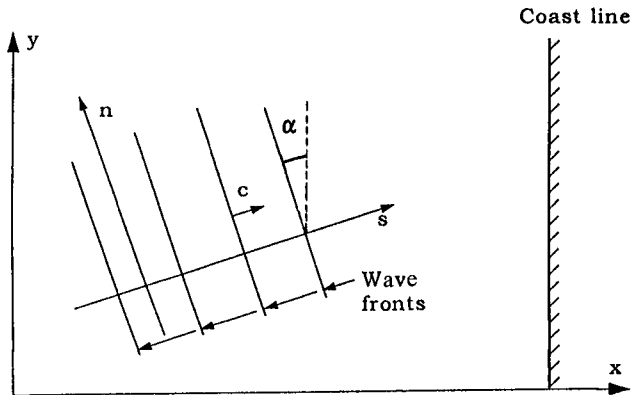

Figure 1 : plan view

VERTICAL VARIATION OF THE DRIVING FORCE

Deigaard and Fredsøe (1989) determined the time mean shear stress in normally incident breaking waves. It was found that the vertical transfer of horizontal momentum gives a significant contribution to the momentum balance. Deigaard (1993) derived expressions for the time mean shear stress in case of oblique waves by considering the momentum balance for the surface rollers. The surface shear stress is given as :

$$\overline{\tau_s} = \left(-\frac{g}{8c} \frac{dH^2c}{ds} - \frac{dAc}{ds} \frac{1}{T} \right) \begin{pmatrix} \cos\alpha \\ \sin\alpha \end{pmatrix} \quad (1)$$

where H=wave height, s=direction of wave propagation, A=surface roller cross section, c=wave celerity, α =wave angle, g=gravitational acceleration and T=wave period.

The cross shore and longshore components of the time mean bed shear stress are determined by the gradients in the radiation stress and the mean water surface slope, the wave set-up, in the cross shore direction, Justesen et al. (1994) :

$$\frac{\bar{\tau}_{b,x}}{\rho} = -\frac{g}{8} \frac{dH^2}{dx} \cos^2 \alpha - \frac{g}{16} \frac{dH^2}{dx} - \frac{d}{dx} \left(\frac{Ac}{T} \right) \cos^2 \alpha - gDs_s \tag{2}$$

$$\frac{\bar{\tau}_{b,y}}{\rho} = -\frac{g}{8} \frac{dH^2}{dx} \cos \alpha \sin \alpha - \frac{d}{dx} \left(\frac{Ac}{T} \right) \cos \alpha \sin \alpha \tag{3}$$

Here, s_s is the slope of the water surface, and x and y are the cross shore and longshore coordinate, respectively. The shear stress varies linearly across the water column. The vertical distribution of the time mean shear stress is illustrated in figure 2.

Figure 2 : Illustration of the time mean shear stress in the cross shore and longshore direction.

In both models, the wave orbital motion was calculated from linear wave theory, but any potential wave theory could be used here. If a non-linear wave description is used, the mean bed shear stress associated with the wave motion is non-zero. In the model based on the integrated momentum equation, the wave motion outside the boundary layer is described by potential theory. In order to fulfil the requirements of potential theory, the mean bed shear stress due to the wave motion must be zero. Brøker-Hedegaard et al. (1991) showed that a perfect force balance can be obtained by adding a small constant velocity to the orbital motion. This additional velocity is found iteratively by the requirement of zero mean bed shear stress, see Elfrink et al. (1993). In the K-model, this velocity is found automatically.

In case of progressive waves, a small net shear stress is generated due to the non-uniformity of the wave boundary layer. Brøker-Hedegaard (1985) showed that this streaming induced shear stress at the bed can be expressed as :

$$\tau_{str.} = \frac{\rho}{c} \overline{U_o U_f} |U_f| \quad (4)$$

where U_o = wave orbital velocity and U_f = instantaneous friction velocity.

THE INTEGRATED MOMENTUM APPROACH

In this model the instantaneous velocity profiles and eddy viscosity profiles inside the boundary layer are assumed to be given by a logarithmic and a parabolic distribution, respectively. The interaction of the undertow, the longshore current and the waves is taken into account by superposing the wave by a steady current and solving the turbulent boundary layer for the combined wave/current motion. The total mean eddy viscosity has contributions from the wave breaking, from the bottom layer and from the mean current. The eddy viscosity due to the mean current outside the boundary layer is calculated by applying the mixing length concept. The equations are solved by the assumption that the net flux perpendicular to the shoreline is zero. It is noted that the integrated momentum approach is by far the most computationally efficient.

The time-averaged flow velocity distribution is calculated from the vertical distribution of the driving forces (eq. 1 - 4) and the mean eddy viscosity :

$$\frac{d\bar{U}}{dz} = \frac{\bar{\tau}}{\rho\nu_t} \quad (5)$$

The three contributions to the eddy viscosity are calculated independently from each other. The contribution from the wave boundary layer is calculated from the boundary layer model of Fredsøe (1984). The contribution from the mean flow is modelled by applying a mixing length concept, see Justesen et al. (1994) and the eddy viscosity due to wave breaking is calculated from the transport equation for turbulent kinetic energy, see Deigaard et al. (1986).

THE K-EQUATION MODEL

The k-model approach in the present work is an extension of the model developed by Deigaard et al. (1991) for the case of normally incident waves.

The driving force in the unsteady motion is composed of a steady part as given in eqs. 1 - 4 and an oscillatory part which is given by the periodically varying horizontal pressure gradient associated with the wave motion. The flow equations, neglecting convective terms, read :

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho} \left[\frac{\partial \tau_{zx}}{\partial z} - \frac{\partial \bar{\tau}_{zx}}{\partial z} \right] \quad (6)$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \frac{1}{\rho} \left[\frac{\partial \tau_{zy}}{\partial z} - \frac{\partial \bar{\tau}_{zy}}{\partial z} \right] \quad (7)$$

where u =cross shore flow velocity, v =longshore flow velocity, x =cross shore coordinate, y =longshore coordinate, z =vertical coordinate, p =pressure gradient associated with the wave motion, ρ =density of water, τ_{zx} and τ_{zy} = cross shore and longshore components of the shear stress respectively, t = time.

$$\tau_{zx} = \rho \nu_t \frac{\partial u}{\partial z} ; \quad \frac{1}{\rho} \frac{\partial p}{\partial x} = -\frac{\partial U_o}{\partial t} \quad (8)$$

$$\tau_{zy} = \rho \nu_t \frac{\partial v}{\partial z} ; \quad \frac{1}{\rho} \frac{\partial p}{\partial y} = -\frac{\partial V_o}{\partial t} \quad (9)$$

The eddy viscosity, ν_t , is calculated from the diffusion equation for turbulent kinetic energy, see Justesen et al. (1994) :

$$\nu_t = l\sqrt{k} ; \quad \frac{\partial k}{\partial t} = -\frac{\partial}{\partial z} \left(\nu_t \frac{\partial k}{\partial z} \right) + \frac{1}{\rho} PROD - c_l \frac{k^{3/2}}{l} \quad (10)$$

PROD = production term, which consists of contributions from wave breaking , as expressed through the gradient in wave energy flux, E_f , and from the shear stress in the model.

$$PROD = \tau_{zx} \frac{\partial u}{\partial z} + \tau_{zy} \frac{\partial v}{\partial z} - \frac{\partial E_f}{\partial x} \quad (11)$$

SEDIMENT TRANSPORT

The sediment transport is calculated according to Fredsøe et al. (1985) and Deigaard et al. (1986). Here the bed load transport model of Engelund and Fredsøe (1976) is used, where the bedload transport is calculated from the instantaneous bed shear stress. The vertical variation of the suspended sediment concentration is calculated from the vertical diffusion equation for suspended sediment.

The omission of the convective terms in the diffusion equation is alleviated by adding the lagrangian flow velocity times the mean concentration to the time averaged product of instantaneous velocity and concentrations.

COMPARISON OF THE 2 MODELS

Figs 3 and 4 show the mean cross shore and longshore flow velocities for the 2 models for varying wave angles. The wave height in this example was taken as 0.6 m and the period as 6 s. The water depth was 1 m and the bed roughness 0.5 mm. The energy dissipation, the surface roller volume and the cross shore gradient of the surface roller were calculated by using a wave height gradient of -0.015 and a bed slope of 0.033. The sediment grain size was taken as 0.2 mm.

It can be seen that the agreement between the two models is good. In the lower part of the water column, the gradients in the velocity profiles are somewhat steeper for the k-model than for the integrated momentum approach, which indicates slightly higher values of the eddy viscosity for the latter.

Figure 3 : Time averaged cross shore flow velocities for the two models.
 a = integrated momentum approach , b = k-model.

Figure 4 : Time averaged longshore flow velocities for the two models.
 a = integrated momentum approach , b = k-model.

The time variation of the cross shore and longshore components of the friction velocity are shown in figs. 5 and 6. For low angles of wave incidence, the cross shore friction velocities are slightly lower under the wave crest for the integrated momentum approach than for the k-model, but generally the agreement is good.

Figure 5 : Time variation of the cross shore component of the shear velocity. a = integrated momentum approach, b = k-model.

Figure 6 : Time variation of the longshore component of the shear velocity. a = Integrated momentum approach, b = k-model.

In this example, the cross momentum exchange of horizontal momentum, associated with the gradients in the longshore current velocity across the shore has been neglected. This causes unrealistically high values of the calculated longshore current velocities and friction velocities. Usually, the mean bed shear stress is calculated from a surf zone model which

includes this momentum exchange. However, this has no importance in the context of intercomparing the two different models.

In both models, the suspended sediment transport is calculated as the product of the instantaneous flow velocities and the instantaneous sediment concentration :

$$q_s = \frac{I}{T} \int_0^D \int_0^D (uc) dz dt \quad (12)$$

In the calculation of the sediment transport in the surf zone, the vertical variation of the suspended sediment concentration is important. Deviations in the time averaged suspended sediment concentrations may occur due the phase difference between the flow in the wave boundary layer and the outer flow. In the k-model, this phase difference is included, whereas the boundary layer in the integrated momentum approach is assumed to be in phase with the outer flow. Figs. 7 and 8 show the time averaged vertical variation of the suspended sediment fluxes for the two models in the cross shore and longshore direction. The agreement is seen to be good for all examined wave angles.

A number of comparisons were performed where the hydrodynamic parameters (e.g the wave height, period, angle of incidence and energy dissipation) were varied systematically. Also different grain sizes were analyzed. The integrated momentum approach tends to give slightly higher transport rates for high levels of turbulence, associated with wave breaking. This is due to the different techniques in determining the turbulence originating from the boundary layer, the mean flow and wave breaking. Generally the agreement is good.

Figure 7 : Vertical variation of the time averaged cross shore sediment flux.
a = Integrated momentum approach, b = k-model.

Figure 8 : Vertical variation of the time averaged longshore sediment flux.
 a = Integrated momentum approach, b = k-model.

It can be concluded that the integrated momentum approach gives results very similar to the more complete k-model in determining the mean flow, the time variation of the bed shear stress and the sediment transport.

THE INTERACTION OF UNDERTOW AND LONGSHORE CURRENT

The presence of a longshore current will affect the undertow and the resulting cross shore sediment transport. The interaction of the longshore current with the undertow is important in the determination of the cross shore profile evolution. The longshore current causes higher levels of turbulence near the sea bed, this affects the vertical shape of the cross shore velocity as the vertical velocity gradients decrease due to the higher eddy viscosity. This results in a reduction of the near bed cross shore flow velocity. At the same time, the higher levels of turbulence allow higher concentrations of suspended sediment.

A test was performed with the model based on the integrated momentum equation for a situation with and without the presence of a longshore current of 0.5 m/s. In the present example, a wave height of 0.7 m and a period of 5 s was used. The water depth is 1.5 m and the energy dissipation corresponds to the energy loss in a hydraulic jump. Figure 9a shows the simulated time averaged cross shore velocity profile with and without a longshore current. In both cases, the mean flow under the wave crest balances the mass transport in the surface roller and the wave drift. It can be seen that the near bed offshore directed velocities are lower in case of a longshore current. Consequently, the velocities in the vicinity of the water surface are slightly higher.

The bed concentrations for both cases are shown in figure 9b. The main difference is that the bed concentration does not vanish at the flow reversal ($t/T \approx 0.05$, and $t/T \approx 0.45$) in case of a longshore current. The bed concentrations are lower under the wave crest ($t/T < 0.5$) than under the trough ($t/T > 0.5$) because the wave orbital motion and the undertow counteract each other, whereas they both are directed offshore under the wave trough. The maximal bed concentration is slightly higher in case of a longshore current. The vertical variations of the time-mean sediment concentration for the two examples are shown in figure 9c. The increased eddy viscosity and the higher mean bed concentration result in a higher mean concentration in case of a longshore current. The combined effect of lower offshore velocities near the bed and the higher sediment concentrations result in an increased cross shore sediment transport in case of a longshore current in this example as shown in figure 9d.

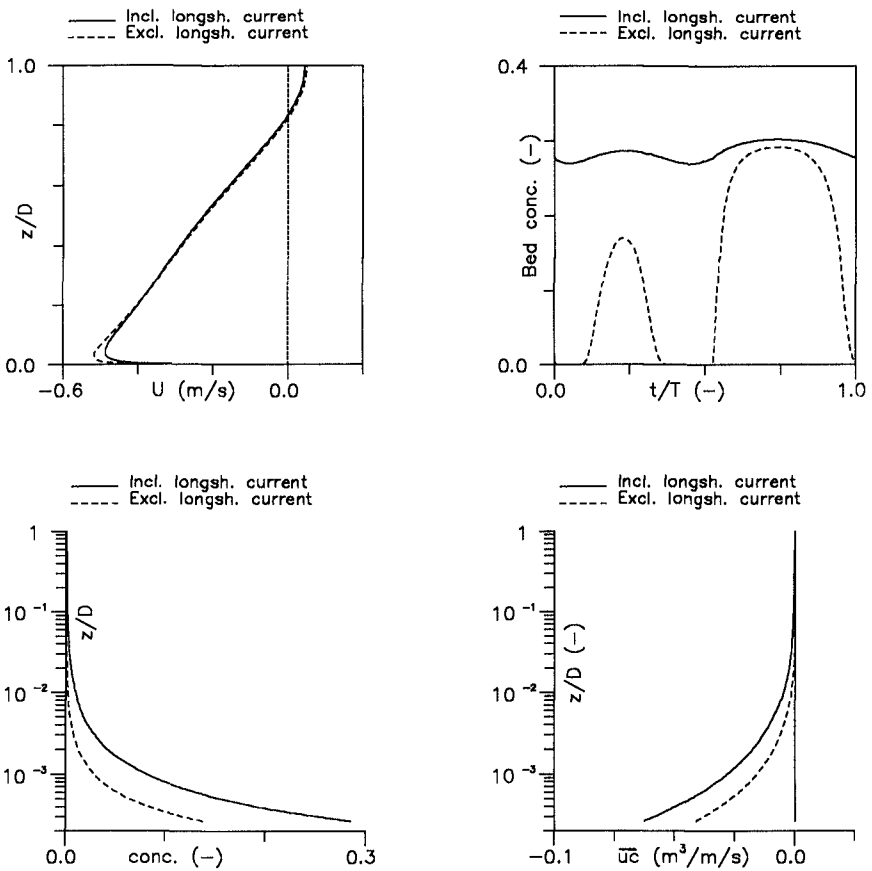

Figure 9 : Interaction of the undertow with a longshore current. a: Mean cross shore flow, b: time variation of the bed concentration, c: time-mean sediment concentration d: time-mean sediment flux.

COMPARISON WITH FIELD MEASUREMENTS

A comparison was made with measured flow velocity profiles at the Ebro delta, Spain, which were reported in Rodriguez et al. (1994). The comparison was made for three levels of calibration. First, the mean cross shore flow velocities were calculated without any calibration. In these simulations, a fully developed roller, where the associated energy dissipation corresponds to the energy loss in a stationary hydraulic jump was assumed.

Figure 10 : Comparison of the present model with field measurements from Rodriguez et al. (1994). Three levels of calibration were applied :
 1 - uncalibrated, 2 - rotated, 3 - adjusted roller volume.

secondly, the uncalibrated flow velocity profiles were rotated such that the calculated depth averaged velocity matched the measured values. This adjustment accounts for possible 2D

effects, e.g. the coast is not perfectly uniform in the longshore direction. Thirdly, a calibration was performed by determining the volume of the surface rollers from the measured mean cross shore flow velocity and the estimated wave drift, which was calculated from sinusoidal wave theory. In all cases the waves were assumed to be unidirectional and regular. The wave orbital motion was calculated by using 1st order Stokes theory. The results for the mean cross shore flow are shown in figure 10. Generally the agreement is satisfactorily. The uncalibrated model underestimates the measured velocities near the bed slightly. The rotation of the coordinate system improves the agreement to a limited degree. The agreement is worst for the sample point located at a cross shore coordinate of approximately 80 m. For the present test, this corresponds to the outer surf zone. The calibrated velocity profiles match the velocity gradients better than the uncalibrated model.

CONCLUSIONS

A numerical model was developed for the flow and the sediment transport under oblique incident waves in the surf zone. The model is based on the integrated momentum equation for the wave boundary layer of Fredsøe (1984). The eddy viscosity consists of contributions from the wave boundary layer, the mean flow and wave breaking. These contributions are calculated separately.

The model based on the integrated momentum equation gives very similar results compared to a more complete turbulence model. For engineering purposes, the integrated momentum approach is recommended because it is able to reproduce the details of the flow and the sediment transport and is very efficient in computing time.

In case of a longshore current the level of turbulence near the bed is increased compared to a situation without current. This results in lower near bed velocities of the undertow and an increased concentration of suspended sediment.

Comparison of the simulated mean cross shore and longshore flow velocities show good agreement with field measurements.

ACKNOWLEDGEMENT

This work was supported by the Danish Technical Research Council (STVF) under the program "Marin Teknik".

The authors would like to express their gratitude to Andres Rodriquez for supplying the data of the field measurements at the Ebro delta.

CHAPTER 295

A Numerical Model of Sheet Flow Sediment Transport

Sadakazu Katori,¹ Masaru Mizuguchi² and Akira Watanabe³

Abstract

Governing equations are derived for a numerical model to simulate the sediment motion under sheet flow condition. They consist of equations for the conservation of the horizontal momentum, the turbulence energy and the sediment mass. Values of coefficients in the governing equations are determined using the experimental results of Horikawa *et al.* (1982). The mean sediment transport rates during half a period of sinusoidally oscillatory flow are calculated and the computed values agree well with the experimental results of Sawamoto and Yamashita (1986). Computations are also made for the net transport rate in unsinusoidally oscillatory flow with and without superposed steady flow, showing a good agreement with the measurements of Dibajnia and Watanabe (1992). Finally the thickness of the sheet flow moving layers is computed and related to grain-flow parameters.

Introduction

The first author conducted a detailed experiment on the sheet flow sediment transport in an oscillatory flow tank with sinusoidal velocity variations, measured the velocity as well as concentration of the sediment, and evaluated the mean transport rate during half a period of sinusoidal flow (Horikawa *et al.*, 1982). After this experiment that remarkably advanced our understanding of the sheet flow transport, many studies have been performed until now. According to recent studies on the sediment transport, it has been widely recognized that the sheet flow predominates in the surf zone not only during storms but also even under moderate waves in the field (e.g., Watanabe *et al.*, 1991, Dibajnia *et al.*, 1994).

²Professor, Department of Civil Engineering, Chuo University.

³Professor, Department of Civil Engineering, University of Tokyo.

Hence not a few numerical models for the sheet flow sediment movement have been presented so far, but the validity and applicability of most of them are not sufficient enough.

This study aims to develop governing equations and a numerical model that can reproduce time-space changes in the velocity and concentration of the sediment as well as the net transport rate under the sheet flow condition.

Governing Equations Derived for A Numerical Model

Equations (1) to (3) are newly proposed to describe the sheet flow sediment motion.

For the conservation of the horizontal momentum:

$$\begin{aligned} \partial u / \partial t &= (\rho_w / \rho) [\partial U / \partial t + \partial (K_u \partial u / \partial z) / \partial z] & (1) \\ K_u &= \begin{cases} \nu + \kappa_{ul} d k^{1/2} + \kappa_{uc} \nu F(c) & (-\infty < z < z_5) \\ \nu + [\kappa_{ul} d + \kappa_{uh} (z - z_5)] k^{1/2} + \kappa_{uc} \nu F(c) & (z_5 < z < \infty) \end{cases} \\ F(c) &= [1 + 0.183c / (1 - 0.878c)]^2 \text{ - - - - - (Eilers, 1941)} \end{aligned}$$

For the conservation of the turbulence energy:

$$\begin{aligned} \partial k / \partial t &= K_{kp} (\partial u / \partial z)^2 + \partial (K_{kd} \partial k / \partial z) / \partial z - \varepsilon & (2) \\ K_{kp} &= \begin{cases} 0 & (-\infty < z < z_5) \\ [\nu + \kappa_{kp} (z - z_5) k^{1/2}] (c_5 - c) & (z_5 < z < \infty) \end{cases} \\ K_{kd} &= \begin{cases} 0 & (-\infty < z < z_{10}) \\ (\nu + \kappa_{kd} d k^{1/2}) (1 - c) & (z_{10} < z < z_5) \\ \{ \nu + [\kappa_{kd} d + \kappa_{kdh} (z - z_5)] k^{1/2} \} (1 - c) & (z_5 < z < \infty) \end{cases} \\ \varepsilon &= \kappa_{ke} g F(c) k^{1/2} \end{aligned}$$

For the conservation of the sediment mass:

$$\begin{aligned} \partial c / \partial t &= \partial (K_c \partial c / \partial z) / \partial z + \partial (w c) / \partial z & (3) \\ K_c &= \begin{cases} \nu + \kappa_{cl} d k^{1/2} |_{z=z_5} & (-\infty < z < z_5) \\ \nu + [\kappa_{cl} d + \kappa_{ch} (z - z_5)] k^{1/2} & (z_5 < z < \infty) \end{cases} \\ w &= w_0 (1 - c) \end{aligned}$$

Here U is the main flow velocity, u the velocity of the fluid-sediment mixture, k the turbulence energy, c the volumetric sediment concentration ($0 \leq c \leq 1.0$), t the time, z the vertical distance measured upward from an initial bed surface, ρ_w the fluid density, ρ the density of the fluid-sediment mixture, ν the fluid kinematic viscosity, d the sediment grain size, w_0 the free fall velocity of sediment particles, z_5 and z_{10} are z where $c = c_5 = 0.5$ and $c = 0.99$, respectively, and g is the acceleration of gravity. All the coefficients κ with subscripts are constants.

Equation (1) is a turbulence model for the conservation of the horizontal momentum in the bottom boundary layer. Here it is assumed that the fluid and sediment move together with the same horizontal velocity u . The density of the fluid-sediment mixture $\rho(z, t)$ is defined as

$$\rho = (1-\lambda)c\rho_s + [1-(1-\lambda)c]\rho_w \tag{4}$$

where λ is the porosity of the fluid-sediment mixture at $c=1.0$, ρ_s the density of the sediment particles. A main point of Eq. (1) is how to express the eddy viscosity K_u . According to Kolmogorov (1941) and Prandtl (1945), K_u is determined as $K_u \sim \ell k^{1/2}$, where ℓ is the length scale of turbulence and k is the turbulence energy. As observed in one of the experimental results of Horikawa *et al.* (1982) in Fig. 1, the vertical distribution of concentration has an inflection point around the vertical distance z_5 where concentration c is c_5 . This implies that the length scale in the inner layer is very different from that in the outer layer. Then we assume that the length scale in the inner layer is governed by the grain size d , because the concentration in this layer is very high. On the other hand, the length scale in the outer layer will be set as $z - z_5$, because more free turbulence field is formed in this layer. The grain size d , $z - z_5$, and the turbulence energy k are thus included in the expression of the eddy viscosity K_u . In addition, we employ an equation proposed by Eilers (1941) to describe the chaotic collision of grains.

Fig. 1 Distribution of sediment concentration.

($d=0.2\text{mm}$, $T=3.64\text{s}$, $\hat{U}=127\text{cm/s}$, $\theta = 90^\circ$, i.e., $U=\hat{U}$)

Equation (2) shows that time change in the turbulence energy k is determined by three terms; the production, diffusion and dissipation. Regarding coefficients K_{kp} and K_{kd} in Eq. (2), similar formation is made in terms of $\nu, z - z_5, k$ and d for the same reasons mentioned above. A main difference is that there are layers where no production or diffusion of the turbulence energy takes place. This assumption is acceptable, because the concentration in the vicinity of the bed surface is very high and it is nearly impossible for the fluid-sediment mixture with high concentration to form the strong turbulence field. Another point is that the effect of concentration is simply expressed by $(c_5 - c)$ or $(1 - c)$ and that the dissipation rate ε is described in a very simple way. On these assumptions, Eq. (2) becomes a one-equation model of the turbulence energy which is much simpler to solve than two-equation models such as $k-\varepsilon$ models.

Equation (3) for the conservation of sediment mass takes similar formulation except that the diffusion coefficient K_c for the inner layer is determined by the turbulence energy k at $z = z_5$, because sediment particles are expected to diffuse even in the inner layer where the magnitude of turbulence energy is very small. In other words, the reduction of concentration in the inner layer is assumed to take place at the phase of acceleration of the main flow through loosening of the grain arrangement due to shear stresses around $z = z_5$. The reduction rate of fall velocity w with the increase of sediment concentration can be approximately expressed as $(1 - c)$ according to Katori and Homma (1984).

Boundary conditions are

$$\left. \begin{array}{l} u = 0 \\ k = 0 \\ c = 1 \end{array} \right\} \quad \text{at } z < z_{10} \quad \left. \begin{array}{l} u = U \\ k = 0 \\ c = 0 \end{array} \right\} \quad \text{at } z = z_{\infty} \quad (5)$$

Here z_{10} is the vertical distance where $c = 0.99$, and z_{∞} is that of the outer edge of the bottom boundary layer. It has been reported that the thickness of the bottom boundary layer becomes much larger when fluid contains granular sediment particles. For this reason, z_{∞} should be set as large as possible in computation. According to trial and error, $z_{\infty} = 5\text{cm}$ is large enough for grain diameter smaller than several millimeters. In addition it has been found that the concentration around $z = z_{10}$ sometimes exceeds 1.0 at the phase of sediment falling and in the worst cases the computation fails by oscillation or divergence of solutions. We employ the following procedure to avoid such computational failure. At each time step of calculation of the sediment concentration by Eq. (3), we detect the top vertical distance z_B where the concentration becomes or exceeds 1.0 by searching downward from z_{∞} , set the concentration below z_B as 1.0, and make the following adjustment for the upper region so as to maintain the conservation of total sediment mass.

$$c \leftarrow c [(V_o - z_B)/(V_i - z_B)] \quad \text{at } z > z_B \quad (6)$$

$$V_i = \int_{z_{-\infty}}^{z_{\infty}} c \, dz$$

where V_0 is the volume of sediment per unit horizontal area at the beginning of calculation, and $z_{-\infty}$ is the vertical distance of the lower boundary of a calculation domain.

Determination of Coefficients κ

In the governing equations, there are several coefficients κ with subscripts to be determined. These coefficients are determined using the experimental data presented by Horikawa *et al.* (1982). Figure 2 shows another example of their measurements. The experimental conditions are: $d=0.2\text{mm}$, $\rho_s=2.66$, $T=3.64\text{s}$ and $\hat{U}=127\text{cm/s}$. In Fig. 2 the phase θ of the main flow is defined as $\theta = 0^\circ$ for $U = 0$ and $\theta = 90^\circ$ for $U=\hat{U}$. Open circles in Fig. 2 are the measurement data of the horizontal velocity u and concentration c . As for the experimental data of the turbulence energy k , Yamashita *et al.* (1985) measured the velocity by

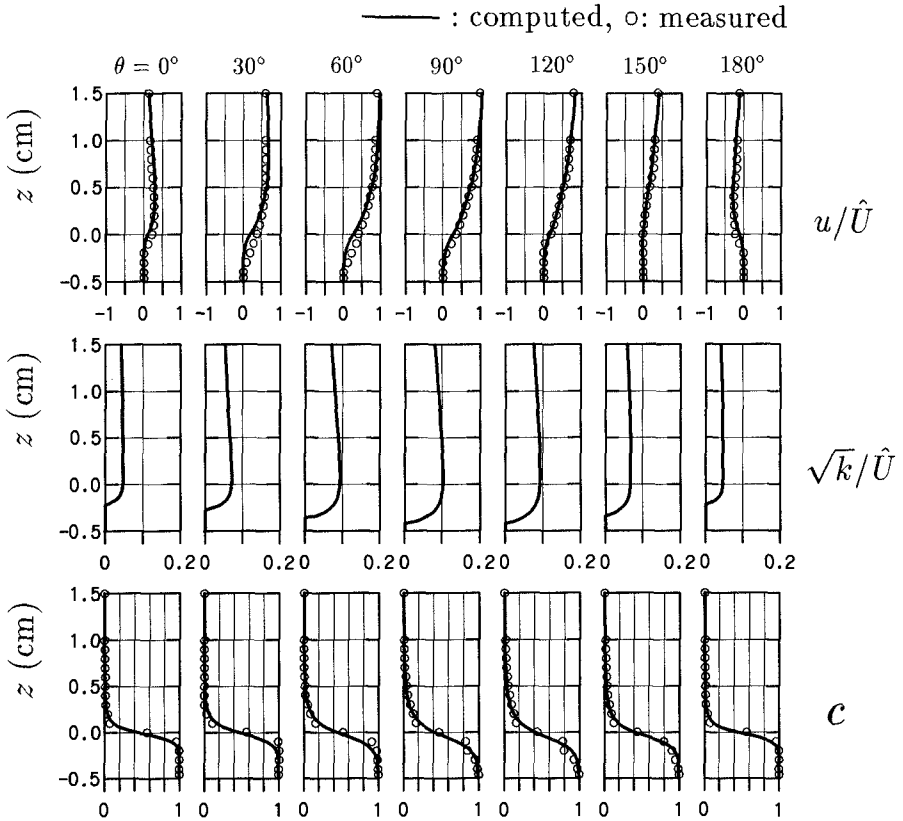

Fig. 2 Comparison of the horizontal velocity u and concentration c between the measurements and the computations.

using an optic fiber velocity meter and reported that the maximum magnitude of square root of the turbulence energy is about 1/10 of the main flow velocity. The computations shown by solid lines in Fig. 2 show a remarkably good agreement with the measurements when we set values of the coefficients κ as follows:

$$\begin{aligned} \kappa_{ul} &= 1.8, & \kappa_{uh} &= 0.045, & \kappa_{uc} &= 10.0 \\ \kappa_{kp} &= 0.984, & \kappa_{kdl} &= 45.0, & \kappa_{kdh} &= 18.0, & \kappa_{ke} &= 0.006 \\ \kappa_{cl} &= 0.833, & \kappa_{ch} &= 0.09 \end{aligned} \quad (7)$$

It should be emphasized that these constants have given a good agreement between the computations and the measurements also for all the other cases of Horikawa *et al.* (1982), and that they will be commonly used in the following calculations.

In the numerical computation the initial conditions are $u=0$, $k=0$, and

$$\begin{aligned} c=0 & & z > 0 \\ c=1 & & z \leq 0 \end{aligned} \quad (8)$$

The time interval Δt and the vertical grid interval Δz are set as follows:

$$\begin{aligned} \Delta t &= T/2400 \\ \Delta z &= \min(\sqrt{2q\Delta t}, d) \end{aligned} \quad (9)$$

where q is the mean sediment transport rate during half a period estimated by the following formulas presented by Sawamoto and Yamashita (1986).

$$\Phi \equiv (1 - \lambda)q/w_0d = 2.2 (u_*/w_0)^3 \quad (10)$$

in which Φ is the nondimensional mean transport rate, u_* the friction velocity, and w_0 the free fall velocity. To estimate the friction velocity u_* , we employ the following wave friction factor f_w proposed by Jonsson (1966).

$$\begin{aligned} \frac{1}{4\sqrt{f_w}} + \log \frac{1}{4\sqrt{f_w}} &= -0.08 + \log(a_m/\xi) & (a_m/\xi > 1.57) \\ f_w &= 0.3 & (a_m/\xi < 1.57) \end{aligned} \quad (11)$$

where a_m is the amplitude of main flow orbital movement, and ξ is the bottom roughness, which is set as $\xi=d$ in this study.

Sediment Transport Rate

Computations of the sediment transport rate are conducted to verify the validity and applicability of the present model. Sawamoto and Yamashita (1986) have carried out a series of experiments in a U-shape tube with a rectangular cross section. In the tube, quasi-sinusoidal flow is generated by releasing the initial imbalance of water heads between the tube ends. The period of the oscillatory flow is fixed to be 3.8s owing to the natural frequency of the fluid motion in the

tube. The range of the amplitude of main flow velocity is 44.3-125.3 cm/s. They have used three kinds of quartz sands and a coal powder as the bed materials to measure their transport rates. Imitation pearl pellets have also been used to observe the sediment motion through a side glass wall. Figure 3 shows the comparison between Φ_{cal} and Φ_{meas} , where Φ_{cal} is the calculated nondimensional mean transport rate during half a period and Φ_{meas} is that of the measurement data by Sawamoto and Yamashita (1986), Horikawa *et al.* (1982) and Abou-Seida (1965). Although a little scatter is observed especially for the case of Abou-Seida, the overall agreement between Φ_{cal} and Φ_{meas} is fairly good.

In addition Sawamoto and Yamashita (1986) proposed a mean transport rate formula during half a period of sinusoidal flow as already shown by Eq. (10). Figure 4 shows that the computed values of Φ shown by symbols agree well with thier formula except for the range of small u_* / w_0 , where the sediment movement approaches to its threshold of sediment motion. Here the computation conditions are almost the same with those of Sawamoto and Yamashita, while the range of main flow velocity amplitude \hat{U} has been extended to 0.2-4.0m/s.

Fig. 3 Comparison between Φ_{cal} and Φ_{meas} in sinusoidally oscillatory flow.

Fig. 4 Relation between Φ_{cal} and u_*/w_0 in sinusoidally oscillatory flow.

Dibajnia and Watanabe (1992) have measured the net rate of sheet flow sediment transport in unisusoidally oscillatory flow with and without superposed steady flow. The experiments have been carried out in a loop-shape oscillatory/steady flow water tunnel. The flow is driven by a piston to be oscillation with arbitrary temporal variations and by a pump to superpose a steady current on the oscillation. The bet material is the sand with a grain diameter of 0.2mm. They have selected five oscillation periods ranging from 1s to 4s and four conditions of the asymmetry index $U_{\text{max}}/\hat{U}=0.5$ to 0.8, where U_{max} is the maximum value of the oscillatory flow velocity U and \hat{U} is the total amplitude of U . In addition the steady flow with four velocities ($\bar{V} \simeq -20, -10, 10, 20\text{cm/s}$) have been superposed on each of the oscillations. In Fig. 5 their data are compared with computations, which shows a good agreement for both the positive and the negative transport rate. Here the results are plotted for the two oscillation periods of 3s and 4s, because the other experimental results for $T=1.0\text{s}, 1.5\text{s}$ and 2.0s show large scatter. The reason for such large scatter is to that Dibajnia and Watanabe have not measured the flow velocities directly in coexistent oscillatory

Fig. 5 Comparison between Φ_{cal} and Φ_{meas} in unsinusoidally oscillatory flow with and without superposed steady flow.

and steady flow. The expected flow conditions may not have been obtained when the period of oscillatory flow is short and the interaction between oscillatory flow and steady flow becomes significant in their water tunnel.

Thickness of Moving Layers

The thickness of moving layers is another major concern about the sheet flow sediment transport. In this study, the moving layer thickness δ_B is defined as the maximum change in the elevation of the bed surface, where the sediment particles never move during the whole period of the oscillatory flow. The quantity δ_B is not only important to be used as a boundary condition for analytical treatment of the sheet flow transport but also useful for rough evaluation of the transport rate. It is possible to make such evaluation by multiplying δ_B by the mean concentration and the mean near-bed velocity. Although experimental studies on δ_B have been performed (e.g., Li *et al.*, 1993, Yamashita *et al.*, 1993), most of them are observations through side glass walls where the movement of sediment particles is greatly affected by the side boundary layer. For this reason, we only

show computations without comparison with the measurements. Figure 6 shows the computed results, indicating a high correlation with grain-flow parameters. The solid line fitted for the computations reads

$$\delta_B / \sqrt{d\nu / \hat{U}} = 230 \Psi^{0.891} \quad (12)$$

where d is the grain size, ν the fluid kinematic viscosity, \hat{U} the amplitude of main flow velocity, $\Psi (=u_*^2 / s d g)$ is the Shield number, and $s = (\rho_s / \rho_w - 1)$ is the immersed specific gravity of sediment.

Conclusions

This paper has presented a numerical model for the sheet flow sediment transport. The model consists of governing equations for the conservation of horizontal momentum, the turbulence energy and the sediment mass. Comparisons have been made between the computations and laboratory measurements for vertical distributions of the horizontal velocity and sediment concentration as well as the

Fig. 6 Relation between $\delta_B / \sqrt{d\nu / \hat{U}}$ and Ψ in sinusoidally oscillatory flow.

sediment transport rate under a variety of main flow conditions, showing a remarkably good agreement for any of them. It should be emphasized that every coefficient in the governing equations has been set to be a constant respectively common for all the computations. These results indicate the validity and applicability of the present model for estimating the net transport rate of the sheet flow as well as time-space changes in its velocity and concentration over a very wide range of conditions.

Acknowledgement

The authors would like to express their appreciation to Assoc. Profs. M. Dibajnia and Y. Kawahara of University of Tokyo, Japan for their helpful discussion and to Assoc. Prof. T. Yamashita of Hokkaido University, Japan for his greatful kindness to provide us with his experimental data.

CHAPTER 296

Numerical Modeling of Nearshore Morphological Changes under a Current-Wave Field

Taerim Kim¹ and Hsiang Wang²

Abstract

This paper presents a time-dependent 3-D nearshore morphological response numerical model which includes the slope effect, undertow current, wave-borne transport, and transition zone effect. These effects are very important but often not estimated in other sediment transport models. By including the cushioning effect in the water column, which prevents the advection of turbulence generated by wave breaking from the surface to the bottom, this model is shown to be able to approach an equilibrium state of sediment transport. The computed cross-shore and longshore sediment transport rates are calibrated based on the large wave tank data, 3-D basin experiments, and available sediment transport formulas. The predicted changes of bottom topography near structures and inlet in physical model are compared for model verification.

Introduction

Prediction of beach response to the engineering activities is important for assessing the impact of coastal structures and to improve their design. It is also useful for evaluating remedial and mitigation measures. Numerical modeling is clearly an attractive alternative for this purpose and is becoming increasingly viable with the advancement of computational facilities and improved understanding on wave mechanics and sediment transport processes.

There have been two types of approach to predict the 3- dimensional morphological changes in the nearshore zone. The so called 3DBEACH (3-dimensional decoupled model of beach change) by Larson et al. (1989) utilizes the profile change model, SBEACH, for calculating storm-induced beach erosion and recovery and the shoreline change model, GENESIS, for calculating long-term change in shoreline position. Since the profile model is based on equilibrium profile, the combined model also maintains

1 Senior Research Engineer, Ocean Engineering Division, KORDI, Ansan, P.O. Box 29, SEOUL 425-600, KOREA

2 Professor, Department of Coastal and Oceanographic Engineering, University of Florida, Gainesville, FL 32611, USA

the ability to approach an equilibrium bottom configuration under steady wave condition. This is difficult to attain in the models of other type. However, since the submodels are all wave driven, combined current wave effect can not be directly addressed. The other approach computes nearshore topographic change based on local sediment flux balance. This approach usually links a hydrodynamic submodel with a sediment transport submodel. Models of this kind with varying degrees of sophistication have been developed. van Rijn et al. (1989) estimated the sediment transport rate by multiplying the wave-averaged mean vertical sediment concentration by the wave-averaged local horizontal velocity. In their model, the wave-borne transport mechanism is not directly addressed. A model developed by Ohnaka and Watanabe (1990), on the other hand, computes the flow field with considerations of current and wave interaction based on coupled mild-slope wave equation and depth-averaged circulation equations. It calculates the rate of sediment transport as the summation of two energetic mechanisms, one due to the mean current and the other due to waves (Watanabe et al., 1986). Recently, the nearshore circulation model was improved by a 3-D approach, which employed a combined depth-integrated current model and a vertical profile model (De Vriend and Stive, 1987). This improvement when incorporated into the sediment transport model enables one to more realistically

represent the 3-D nature both inside and outside the surfzone. Briand and Kamphuis (1993) multiplied the time averaged quasi-3D velocities to a time averaged exponential sediment concentration profile to achieve a 3-D sediment flux. This technique of combining a quasi-3D velocity profile with a vertical distribution of suspended sediment concentrations is a promising step to lead to full 3-D models in the future.

The model developed in this study consists of three submodels for calculation of waves, nearshore currents, and beach changes. At the first step, the initial beach topography and the geometry of the structures for the study area are given as input data. Next, the wave model determines the spatial

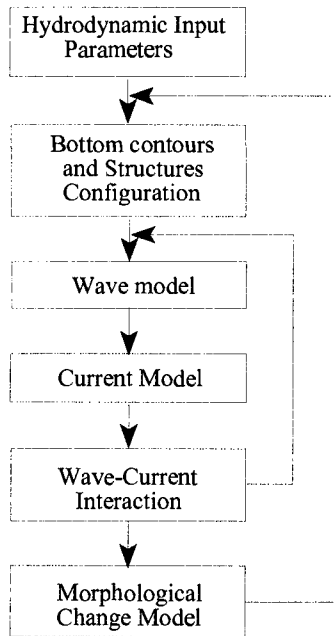

Figure 1 Structure of Nearshore Morphodynamic Model.

distributions of radiation stresses and near-bottom orbital velocities for a given incident wave condition. Then, the circulation model computes the mean water surface level and the depth-averaged mean currents using depth-averaged momentum and continuity equations. Inside the surf zone, mean undertow current, transition zone length, and cushioning effect are calculated based on the wave-current model results. Spatial distribution of sediment transport fluxes are computed in the domain of interest. Finally, bottom topography changes are computed based on sediment mass conservation. The change in bottom topography will modify the flow field. Therefore the hydrodynamic model needs to be updated from time to time. Figure 1 shows the computational flow chart of the model.

Wave and Circulation Models

The flow field in the nearshore is computed by depth integrated 2-D hydrodynamic model developed by Winer(1988). The hydrodynamic model consists of wave and circulation models which are fully coupled through interaction terms. First, the wave model determines the spatial distributions of radiation stresses and near-bottom orbital velocities based on the following parabolic wave equation,

$$\begin{aligned} (C_g \cos\theta + U)A_x + \frac{\sigma}{2} \left(\frac{C_g \cos\theta + U}{\sigma} \right)_x A + VA_y + \frac{\sigma}{2} \left(\frac{V}{\sigma} \right)_y A \\ - \frac{i}{2} k C_g (1 - \cos^2\theta) A - \frac{i}{2} \left[CC_g \left(\frac{A}{\sigma} \right)_y \right] + \frac{W}{2} A = 0 \end{aligned} \quad (1)$$

where, U and V are the depth averaged horizontal velocities in the x (cross-shore) direction and y (longshore) direction, respectively, C is the phase velocity, C_g is the group velocity, σ is the intrinsic angular frequency, A is the complex amplitude, θ is the angle of the wave propagation relative to the x axis, the subscripts x and y denote derivatives in the x and y directions, respectively, W is the energy dissipation coefficient. The coefficient W is related to the energy dissipation due to wave breaking following the work of Dally et al., (1984).

$$D_E = \frac{K}{D} [(E - E_s) C_g] \quad (2)$$

where, D_E is the energy dissipation rate, D is water depth, K is empirical parameter ($K=0.17$), E is the local wave energy density, E_s is the local stable wave energy density that the breaker is striving to attain.

The circulation model computes the mean water surface level and the depth averaged mean currents using depth averaged momentum and continuity equations with the radiation stresses imported from the wave model as the driving force.

The governing equations are given by (Ebersole and Dalrymple, 1979)

$$\begin{aligned} \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + g \frac{\partial \bar{\eta}}{\partial x} + \frac{1}{\rho D} \tau_{bx} - \frac{1}{\rho D} \tau_{sx} \\ + \frac{1}{\rho D} \left(\frac{\partial S_{xx}}{\partial x} + V \frac{\partial S_{xy}}{\partial y} \right) + \frac{1}{\rho} \frac{\partial \tau_l}{\partial y} = 0 \\ \frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + g \frac{\partial \bar{\eta}}{\partial y} + \frac{1}{\rho D} \tau_{by} - \frac{1}{\rho D} \tau_{sy} \\ + \frac{1}{\rho D} \left(\frac{\partial S_{xy}}{\partial x} + V \frac{\partial S_{yy}}{\partial y} \right) + \frac{1}{\rho} \frac{\partial \tau_l}{\partial x} = 0 \end{aligned} \quad (3)$$

and the continuity equation

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}(UD) + \frac{\partial}{\partial y}(VD) = 0 \quad (4)$$

where, t is the time; x and y are the Cartesian coordinates in a horizontal plane; U and V are the corresponding velocity components of the nearshore current; $D = h + \bar{\eta}$; h is the still water depth; $\bar{\eta}$ is the elevation of the mean water level due to wave set up/set down; τ_l is the lateral shear stress due to turbulent mixing; τ_{bx} and τ_{by} are the bottom shear stresses; τ_{sx} and τ_{sy} are the surface shear stresses; and S_{xx} , S_{xy} , and S_{yy} are the radiation stress components which arise from the excess momentum flux due to waves. These equations are obtained by integrating the local x and y momentum equations and the continuity equation over the depth of the water column and then time-averaging the results. The governing equations in the circulation model are solved by a matrix analysis using the alternating direction implicit (ADI) scheme (Winer, 1988). In order to treat the wave-current interaction, waves and currents are calculated alternatively.

Inside the surf zone, the 2-D model is inadequate as the model will yield null current in the cross-shore direction, consequently, zero net cross-shore transport. In reality, the current inside the surfzone is highly three dimensional. Field and laboratory observations of surf zone flow show the existence of current that is directed offshore on the bottom, balanced with the onshore flow of water carried by the breaking waves. This offshore-directed steady current near the bed, commonly referred to as undertow, is known to be the most important mechanism causing profile erosion and bar. The depth-integrated discharge of x component by undertow current, Q_u is expressed as

$$Q_u = \frac{\rho g H^2 k_x}{8\sigma} \quad (5)$$

The mean undertow velocity is simply estimated as $\bar{u} = Q_u / (\eta_c + h)$, which is directed offshore.

Sediment Transport Model

The computed current-wave field is used to drive the sediment model which, in turn, computes the morphological changes by utilizing the equation of conservation of sediment material. In the present study, the sediment transport formula contains two parts, bed load and suspended load. The bed load transport is based on an energetic approach driven by mean current and bottom wave orbital velocity. Owing to the asymmetric wave bottom orbital velocity in a wave cycle, this bed load transport by wave orbital velocity has a net onshore component. The suspended load transport which dominates in surfzone is built upon an undertow current. Here, the suspended sediment concentration is related to breaking wave energy dissipation and the transport velocity is the mean undertow current. This component is always directed offshore. The total transport Q is the sum of bed and suspended loads as followings

$$\begin{aligned} Q &= q_b + q_s \\ q_b &= A_{bc}(\tau_m - \tau_{cr})U_c/\rho g + A_{bw}(\tau_m - \tau_{cr})U_w/\rho g \\ q_s &= A_s \tau_{urb} Q_u \end{aligned} \quad (6)$$

, where ρ is the density of water, g is gravity coefficient, U_c is the integrated depth mean wave induced-current, U_w is the maximum orbital velocity at the bottom, Q_u is the discharge by the undertow, τ_m is the maximum bottom shear stress generated by wave and current, τ_{urb} is the turbulent shear stress generated by waves and mean current, τ_{cr} is the critical shear stress under waves and mean current, A_{bc} , A_{bw} , and A_s are calibrated coefficients.

Sediment transport is influenced by the bottom slope as downslope reduces resistance and upslope increases resistance. The down-slope gravitational transport is the most important mechanism to keep the bed from growing indefinitely and, to enable the coastal profile to reach a dynamic equilibrium state. A basic formulation to express the slope gravitational transport component proposed by Horikawa (1988) assumes the following functional form,

$$\begin{aligned} q_x &= q_x^1 + \epsilon_x |q_x^1| \frac{\partial h}{\partial x} \\ q_y &= q_y^1 + \epsilon_y |q_y^1| \frac{\partial h}{\partial y} \end{aligned} \quad (7)$$

and in which q_x and q_y are the transport components in x and y directions, respectively, q_x^1 and q_y^1 are their equivalents for horizontal bed, h is the water depth and ϵ are empirical coefficients

The zone between the incipient breaking and the plunging point is defined as

transition zone. The transition zone effect on the wave setup, undertow current, and sediment transport is a subject of increased research over recent years. It showed that the inclusion of the transition zone in profile modeling has an important effect on the predicted profiles, particularly for the bar features. Several approaches have been proposed to evaluate the distance and influence of the transition zone based on wave tank experiments (Galvin (1969)). The present model uses the following formula analyzed from the experimental data (O'Shea et al. (1991)).

$$l_t = 0.556 \tan\beta L_b \xi^{-1.465} \quad (8)$$

in which, $\tan\beta$ and L_b are respectively the bed slope and wave length at breaking, and ξ is the surfzone parameter.

Cushioning Effect

Most of the laboratory results as well as field evidence seems to support the concept of beach equilibrium. The profile equilibrium can be reached either when the tangential thrust by fluid is not strong enough to overcome the sand resistance or when the local landward sediment transport is balanced by the local seaward sediment transport. In the latter case, although there could be active sediment movement, the profile remains stable. Including this feature into the model is a difficult subject. One popular approach is to predesignate an equilibrium profile shape. The sediment transport formulas should then be consistent to lead the profile evolution to this equilibrium profile. Kriebel's (1985) storm profile model was of this kind. This type of models can be classified as closed loop model. On the other hand, most sediment transport models do not have a targeted equilibrium profile therefore often fail to reach an equilibrium state. This type of models is known as open loop model. For the open loop model to reach equilibrium, mechanisms must be devised to locally balance the on/offshore transport. The present model is an open loop model. In the formulas presented earlier, inside the surf zone the offshore transport is much too strong to be balanced by the onshore transport component. The reason is that in the formulation, once wave breaks wave breaking-induced turbulence immediately produces a strong bottom stress and the resulting offshore transport is much larger than the onshore transport computed by the bed load transport equation. Clearly, the offshore transport equation needs to be modified. Dally and Dean (1984) pointed out that the expression developed for the sediment concentration profile apparently lacks the "cushioning" effect which the water column provides in reducing the amount of sediment entrainment as breaking wave form and trough evolve. This cushioning effect is especially important in the stabilization of the bar and trough formation. Almost no work has been done for this cushioning effect. The present model attempted to incorporate this cushioning effect into the model based on the ratio of the depth and wave height at the plunging point as follows,

$$C_{us} = \tanh\left(7\frac{H}{D}\right)^{700} \quad (9)$$

where, C_{us} is the cushioning effect, H is the wave height, D is the water depth. Figure 2(a) plots this cushioning coefficient and its effect on sediment transport. As can be seen, when relative water depth increases, the cushioning equation limits the turbulence penetration to the bottom. When wave height is larger than water depth, there is no cushioning effect. However, as the water depth at the trough zone becomes larger, cushioning effect becomes stronger. Finally when water depth reaches 2.5 times the wave height breaking induced turbulence will not reach the bottom. This equation is, of course, purely empirical at this stage with no supporting data. Figure 2(b) shows the effect on sediment transport rate. With the inclusion of this effect, the open loop model presented in this study could reach profile equilibrium without a predetermined profile shape.

Calibration of Sediment Transport Rate

The nearshore sediment transport characteristics under storm wave conditions as predicted by the model are illustrated here. In order to validate the 3-D morphological response model, cross-shore transport rate and longshore transport rate are calibrated separately by using available experiment data or empirical formulas.

a)

b)

Figure 2 a) Distribution of Cushioning Effect.
b) Evolution of Sediment Transport Rate.

Cross-Shore Transport Rate

For the calibration of cross-shore transport rate, two sets of 2-D tank experiment data were used. These included the case of a sand beach backed by a sloping dike tested in the German Big Wave Flume (GWK) and case CE 400 from Saville's large wave tank tests (CE). Comparisons were made between computed values and experimental results both in profile changes and transport rates.

The GWK experiment (Dette and Uliczka, 1986) used sand with a median diameter of 0.33 mm and the test profile was subjected to regular wave attack ($H=1.5$ m, $T=6$ sec). Figure 3 shows the comparison between the predicted profiles and the experimental results at run times of 62, 111, and 273 minutes, respectively. The computed wave height distribution across shore

is also shown. The waves cut back the foreshore to produce a vertical scarp and a bar formed shoreward of the breaking point which grew and moved offshore with continued wave action. The numerical model satisfactorily reproduced the observed foreshore erosion and main breakpoint bar development. Simulated shoreline retreat and bar growth were initially rapid and gradually slowed as the bar moved offshore to reach a location close to that of the observed bar at the end of the run (20 hr). However, the bar trough is less well reproduced. All smaller features inshore of the main breakpoint bar were not reproduced in the simulations. Figure 4 shows the comparison of the cross-shore transport rate between the profile changes in Figure 3. Initially, a high peak appears near the shoreline as beach material slumps down slope into the foreshore zone in this experiment. These material was transported offshore to form the bar. The seaward changes of the peak transport rate explain the offshore movement of the bar. With the exception at the initial stage, the predicted transport rate distribution is in good agreement with the laboratory data. At the initial stage the experimental values were larger than predicted. There are many factors that could contribute to the difference such as slumping effect mentioned earlier. It was also found later in small scale experiments conducted at UF that the profile erosion particularly in the dune region was much more severe in the initial stage if the beach is dry and loosely compacted as opposed to wet and well compacted. The best overall fit of both profile

Figure 3 Comparison between Computed and Measured Beach Profiles for $t=62, 111, 273$ minutes. Data from Dette and Uliczka (1986).

Figure 4 Comparison of Cross-Shore Transport Rates between Experiment and Present Model for $t=62, 111, 273$ minutes. Data from Dette and Uliczka(1986)

and transport rate was obtained by using A_{bw}

in a range from 0.05 to 0.07 and A_s from $1.0 \times 10^{-5} (m^2/N)$ to $1.5 \times 10^{-5} (m^2/N)$. With these determined A_{bw} and A_s values, the model was used to simulate the CE case CE400. Figure 5 shows the comparison of measured and calculated profiles. The test conditions were: initial uniform slope = 1/15; grain size = 0.22 mm; wave height and period of 1.62 m and 5.6 sec. The numerical and test results are shown for simulation times of 1, 3, and 5 hours. In this case, the bar development was also well predicted except at the initial stage. However, the profile change near the shoreline shows very different results between the experiment and the model. In experiment, there was strong erosion at the foreshore region above the water level, but this erosion was limited near the shoreline in the numerical model. The spatial distribution of the transport rate from the CE tests were very different from that of the GWK tests. Here in the CE case, peak transport initially occurred near the breaking point and did not show any onshore transport outside the breaking point (The numerical model results did show a very small onshore transport component). Also, in the CE experiments, the transport in swash zone apparently played an important role to cause shore face erosion. The numerical model does not have an appropriate swash zone transport mechanism. Therefore, it was unable to reproduce the large erosion near the shoreline in the experiment.

Longshore Transport Rate

Longshore sediment transport plays a very important role particularly in long term beach evolution. The longterm evolution of many coastlines is the result of slight gradients in the longshore transport rate. Available data suitable for calibration and verification of longshore transport rate are scarce and mostly limited to 2-D cases. The 2-D data will not yield information on A_{bc} . In this section, the characteristics of longshore transport rate are investigated by comparing with CERC formula and the coefficient A_{bc} was calibrated based on a 3-D basin experiment. The CERC's littoral drift formula (Shore Protection Manual, 1984) has the following form as,

$$Q = \frac{K(EC_g \cos\theta \sin\theta)_b}{\rho g(s-1)(1-p)} \quad (10)$$

where Q is the volumetric longshore transport rate, E is wave energy, C_g is group velocity, s is specific gravity, p is porosity and K is an empirical transport coefficient.

a)

b)

Figure 7 a) Distributions of Longshore Transport Rate in Different Wave Directions
b) Comparison of Longshore Transport Rates between CERC Formula and Present Model in Different Wave Directions.

The formula is based on energetic concept with empirically determined coefficient based on field evidence.

In the present model, the sediment transport formulas as presented are of very different nature. However, for lack of laboratory and/or field data for verification, CERC's formula is used here as a bench mark to test the model. A case of 2-D beach that has an initial profile of a uniform slope (1/20) was used here to compare the characteristics of the present model and CERC's formula. Figure 7(a) shows the longshore transport distribution across the surf zone as calculated by the model at different wave angles under the same wave height of 1.5 m. The transport patterns are all bell-shaped with a uni-modal peak inside the breaking point. This shape is consistent with observations on beaches of more or less uniform slopes excluding the swash zone (dual peaks were common if swash zone is included). It is also shown that the longshore transport rate increases drastically as

wave angle increases. The total transport rate is obtained by integrating the volume under the curves. These total transport rates are compared with the CERC's formula in Figure 7(b) which plots the transport rate vs. wave height for different wave angles. The comparisons are good for wave up to 20° . For larger wave angles, the model yields values slightly higher than the CERC's formula. The coefficient A_{bc} in the transport equation given by Equation (6) is equal to unity and 0.77 was used for the K value of CERC formula in this comparisons. As discussed earlier, most experiments and field measurements were conducted for cross-shore transport, and there is very little information on longshore transport rate. Therefore, a plain beach movable bed physical model was constructed in a wave basin to investigate the sediment transport patterns, specially longshore transport rate. The experiments were performed in the 16x23 m 3-D wave basin of the Coastal Engineering Laboratory of the Department of Coastal and Oceanographic Engineering at University of Florida. The designed initial beach profile consists of a flat backshore, a steep-sloped foreshore, and a mild-sloped offshore, and has simple straight shoreline and parallel offshore contours.

After 80 minutes run time, a total of $0.28 m^3$ sand was collected at the sediment trap channel located in the downdrift boundary. This longshore transported material was used to calibrate the A_{bc} value in the numerical model and to check the K value in CERC's formula. By applying wave height, and angle used in the experiment to the CERC's formula, it was found that $K=0.23$ from the results. This value of the proportionality coefficient obtained in this study is smaller than 0.77 in Komar and Inman's formula and is rather close to the value in Sato and Tanaka (1966)'s formula. It is noted here that many one line models utilizing CERC's formula the K coefficient was adjusted downward to the range of 0.05 - 0.4 based on model calibrations with physical experiment data. Here, the numerical longshore sediment transport is calibrated with measured total longshore transport quantitatively. The best fitting value was found to be $A_{bc} = 0.1$. This value is also smaller than the previous value which gave good agreement with CERC's formula.

Performance Test

The model performance is demonstrated here with two types of man-made structures including shore perpendicular structures (groins) and offshore breakwaters. The purpose is not for model calibration or verification as there is no available data in hand. Rather, model utilizations are illustrated with realistic coastal structures.

Groins

Groins are shore perpendicular structures which are built to intercept littoral transport from updrift. They are used to trap sand locally or as end structures to stabilize sand placed in conjunction with beach nourishment projects. For trapping sand, a series of groins is often used. The presence of groins is generally known to cause accretion on the updrift end and erosion on the downdrift end. The ability to be able to predict morphological changes associated with groin structure is undoubtedly useful in coastal engineering. Perlín and Dean (1985) developed an N-line model using a simple

wave refraction and diffraction scheme and longshore sediment transport equation to modify the topography. Kraus et al.(1994) investigated parameters governing beach response to groins and incorporated them into the so-called GENESIS model that can be used to predict shoreline changes in the presence of groins. In the present model, the presence of a groin is reflected in the boundary conditions. The boundary conditions for the groin in the sediment transport model are given as,

$$\begin{aligned} q_y(I, J_{groin} + 1) &= 0, & \text{if } q_y(I, J_{groin} + 1) > 0 \\ q_y(I, J_{groin} - 1) &= 0, & \text{if } q_y(I, J_{groin} - 1) < 0 \end{aligned} \quad (11)$$

a)

b)

where q_y is the transport rate in y direction and J_{groin} is the J th grid column which has the groin.

Figure 8 shows the morphological changes for the case of a three-groin after 70 days and 140 days, respectively, when wave of 0.5 m, 6 sec approaches the beach at 15 degree angle. It is shown that shoreline and bottom contours advances at the updrift of first groin and retreats at the down drift of the last groin. In each compartment, erosion occurs at the updrift end and accretion takes place at the downdrift end. At present, there is a lack of reliable data especially on the morphological effects of groins to compare with numerical results.

Figure 8 Depth Changes after a)70 days, and b)140 days on the Plain Beach with Three Groins for 0.5 m, 8 sec, and 10 degree Incident Waves.

Breakwater

An offshore breakwater is generally a shore parallel structure designed to protect the beach behind the structure against severe erosion. Behind the breakwater wave

height is reduced and circulation cells are generated which draw sediment into the sheltered area. A salient feature soon appears which grows into a tombolo and sometimes becomes attached to the breakwater. Many numerical models, some based on rather artificial mechanisms are able to produce the described topographic changes. Hanson and Kraus (1990) employed a numerical model (GENESIS) to investigate the various depositional types in the lee of a single detached breakwater. Suh and Hardway (1994) developed a one-line numerical model for predicting shoreline change in the vicinity of multiple breakwaters and compared with the field data. The boundary condition for the breakwater in the present sediment transport model is as follows,

$$\begin{aligned} q_x(I_{break} + 1, J) &= 0, & \text{if } q_x(I_{break} + 1, J) > 0 \\ q_x(I_{break} - 1, J) &= 0, & \text{if } q_x(I_{break} - 1, J) < 0 \end{aligned} \quad (12)$$

where q_x is the transport rate in x direction and I_{break} is the I th grid row which has the breakwater. Figure 9 shows the topographic changes after 2 days and 7 days under the normal incident wave condition with 1 m height and 8 sec period. It is clear that salient

a)

b)

Figure 9 Depth Changes after a) 2 days, and b) 7 days on the Plain Beach with Breakwater for 1 m, 6 sec, and Normal Incident Waves.

feature grows rather rapidly. Shoreline, on the other hand, changes only slightly. The absence of swash transport mechanism might be one of the reasons that shoreline change is so slight.

Inlet Experiment

The sedimentary processes in the vicinity of a tidal inlet present a complex dynamic interaction problem between fluid and sediment motion. There exist water level changes at the shoreline by tide and periodical tidal currents in and out of the inlet. This tidal current interacts with wave and wave induced longshore current. Under the combined effects of waves, longshore current, tidal current and coastal structures, the behavior of the sediment movement and morphological evolution in the inlet region is a very complicated process and the current knowledge is extremely limited. Laboratory

modeling using movable bed-material is still a viable tool despite its limitations such as expensive cost, time consuming, and scale effects (Wang et al., 1992). Numerical model on inlet morphology is at its infancy. An attempt is made here to apply the present model to an inlet beach system. On a separate study(Wang et al., 1995), an inlet-beach physical model was constructed in the wave basin facility in the Coastal and Oceanographic Engineering Laboratory at the University of Florida. The inlet beach model consists of an idealized inlet on a plain beach with profile identical to that in the plain beach model. The inlet has two parallel jetties extending offshore with the updrift jetty twice as long as the downdrift jetty. These jetties are made of concrete blocks and impervious to sediment transport. The experiments were carried out under the condition of 7.5 degree oblique waves. The test conditions are as follows:

Wave condition: 8 cm wave height, 1 sec wave period, 7.5° wave direction

Current condition: 0.14 m/sec ebb current, 0.1 m/sec flood current

Tidal range(between flood and ebb): 3 cm

The flood and ebb tidal conditions were simulated alternatively in the model at every 40 minute intervals by holding the high and low water levels, respectively, and reversing tidal currents in the inlet. Figure 10 shows the changes of the topographies by plotting the difference between the initial contours and the contours after 160 minutes. The numerical model appears to be able to reproduce reasonably well some of the general features found in the physical model, as the locations of erosion and accretion, the position and size of breakpoint bars and the shoreline offset. Detailed topographic comparisons are still difficult and may not be too meaningful owing partly the three dimensional effects produced in the physical model.

Figure 10 Comparison of Bathymetric Changes after 160 minutes between Experiment and Numerical Model for 8 cm, 1 sec, and Oblique Incident Waves.

Results

- 1) The prediction of cross-shore transport from model was compared to the evolution of beach profiles and sediment transport rate distributions in the 2-D German's Big Wave Flume tests and CERC's large tank tests. The model is capable of predicting the growth and movement of main breakpoint bars and beach processes with reasonable reliability.
- 2) The comparison of longshore transport rates between present model and CERC formula shows close agreement for different wave angles when the coefficient $A_{bc} = 1$ is adopted in the model as compatible with $K=0.77$ in CERC's formula. A different calibration using 3-D basin experiments yields $A_{bc} = 0.1$ and $K=0.23$.
- 3) An application of the model to different coastal structures including groins and breakwaters shows the model is capable of producing the general scouring, accretion and erosion features found in nature. The model was tested with inlet beach movable bed physical model experiment. The comparison of depth changes shows reasonable agreement between numerical model and physical experiment.

CHAPTER 297

An Analysis of Particle Saltation Dynamics

Michael R. Krecic¹ and Daniel M. Hanes²

Abstract

A two-dimensional particle saltation model for unidirectional flow is applied to simulate the motion of single particles. The equations of motion include added mass, gravity, drag, shear lift, Basset history, and Magnus or spin lift forces. A sensitivity analysis is performed on the forces, initial lift-off speeds and angles, and for different size particles. The Magnus lift force is found to have a significant effect on a particle's trajectory for coarse sand sized and larger particles. The shear lift and Basset history forces cause particles to saltate farther. Most of the forces vary with particle size. The model predictions compare favorably to observations if appropriate initial conditions are assumed.

Introduction

The term saltation was first used by Gilbert (1914) and comes from the Latin word "saltare" meaning to leap or dance. Saltation is analogous to a ballistic trajectory in the sense that trajectories are smooth and not strongly influenced by turbulent fluctuations. However, hydrodynamic forces such as lift and drag significantly influence the particles' trajectory (Nino, Garcia, and Ayala, 1992).

Fernandez Luque and van Beek (1976) performed experiments in a flume with different bed slopes. They were able to measure the mean critical bed shear stress for the initiation of motion, rate of bedload transport, average particle velocity, and the average length of individual saltations. This was accomplished through the use of high speed photography. Two different sediment types, gravel and magnetite, were studied. When they compared their model results, they concluded that a lift force was needed to explain the observed saltation characteristics.

¹ Research Assistant, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

² Associate Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

There is some debate as to what angles the saltating particles leave the bed. Owen (1964) examined particle saltation in air. Owen suggested that those particles that leave the bed nearly vertically with a certain initial speed will saltate to a higher elevation than those with other initial angles. White and Schulz (1977), in contrast, observed that particles in air eject at angles ranging from 30 to 70 degrees.

Other researchers such as Murphy and Hooshiari (1982), van Rijn (1984), Wiberg and Smith (1985), Nino and Garcia (1992), and Lee and Hsu (1994) have tried to derive a set of equations to describe the motion of a particle in saltation from bed ejection to bed impact based on the fluid forces. This paper focuses on developing a complete equation of motion from a Lagrangian perspective and provides a detailed analysis of the model parameters.

Particle Saltation Model

This model simulates the trajectory of a single saltating sphere in a steady state, unidirectional flow. An equation of motion is developed and evaluated using previous experimental observations. Models based on only drag and gravity proved insufficient, so other forces have been included, as will be described below. Some of these other forces are found to be significant while others can be ignored in certain situations. What follows is a brief description of the relevant forces.

The effect of gravity is usually written as a submerged weight,

$$\mathbf{F}_G = (\rho_s - \rho)gV \quad (1)$$

where V is the volume of the particle. Obviously, this force increases with increasing particle size because of its dependence on the volume of a particle.

The added mass force arises from the relative accelerations of the particle and the fluid. A submerged body induces accelerations on a fluid if the body is moving with an acceleration relative to the surrounding fluid. The particle can be thought of as having an 'added mass' of fluid attached to its own mass when it accelerates relative to the surrounding fluid (Patel, 1989). The added mass force is given by Auton et al. (1988) as

$$\mathbf{F}_A = -\rho C_M V \left(\frac{d\mathbf{u}}{dt} - \frac{Du_f}{Dt} \right) \quad (2)$$

where \mathbf{u} is the particle velocity, u_f is the fluid velocity, and C_M is the added mass coefficient. The added mass coefficient is defined as a ratio of the additional mass of fluid that is accelerated with the particle to the mass of the displaced fluid by the particle. For a sphere, C_M equals 0.5.

A drag force is a net force in the direction of the fluid relative to the body due to pressure and viscous forces on the body. The drag force on a particle may be written as

$$F_D = C_D A \frac{1}{2} \rho V_r^2 \quad (3)$$

where C_D is the coefficient of drag, A is the cross-sectional area of the particle normal to the force, and V_r is the relative velocity (Fredsoe and Deigaard, 1992). The drag coefficient is a strong function of Reynolds number and shape; thus, it is generally not constant. There have been many empirical formulas for C_D such as those found by Graf (1984) and Morsi and Alexander (1972) which provide C_D as a function of particle Reynolds number. The following formula is used for this analysis:

$$C_D = \frac{24}{Re} + \frac{7.3}{1 + \sqrt{Re}} + 0.25 \quad (4)$$

where Re is the Reynolds number, $Re = \frac{V_r d}{\nu}$

In shear flow the particle develops a pressure gradient across it which results in a lift force, which is commonly called the shear lift force. This phenomenon can be attributed to the Bernoulli effect where the lift force acts in the direction of the velocity gradient. The shear lift force may be written as

$$F_L(\text{shear}) = C_L A \frac{1}{2} \rho (u_{\Delta Top}^2 - u_{\Delta Bot}^2) \quad (5)$$

where C_L is the lift coefficient and A is the cross-sectional area of the particle normal to the force. The $u_{\Delta Top}$ and $u_{\Delta Bot}$ are the relative velocities evaluated at the top and bottom of the particle, respectively (Wiberg and Smith, 1985).

The lift coefficient has been related to the drag coefficient by Chepil (1958). He conducted experiments involving evenly-spaced hemispheres and allowed wind to flow over them. He then proceeded to calculate drag, lift, and the ratio of lift to drag for different wind speeds. It was determined that the ratio was approximately equal to 0.85; therefore we assume here that C_L equals 0.85 times C_D .

A. B. Basset (1888) first acknowledged that a particle's history had a role in the present particle path; hence, the Basset history force bears his name. Mei (1995) described the force as

... derived from the diffusion of vorticity generated at the surface of the particle at a rate proportional to the particle's relative acceleration. Since the diffusion rate is finite, this means that the force is dependent on the history of the particle motion.

Consider a sphere in a steady fluid and then instantaneously increasing the flow to some higher value. It takes some time for the boundary layer on the sphere to adjust to the new flow intensity. This time is accounted for through the Basset history force. The Basset force is defined as

$$F_B = 6\rho\sqrt{\pi v} \left(\frac{d}{2}\right)^2 \int_0^{t_s} \frac{d\mathbf{u}}{dt} - \frac{d\mathbf{u}_f}{dt} \frac{dt}{\sqrt{t_s - \tau}} d\tau \tag{6}$$

where \mathbf{u}_f is the fluid velocity, v is the kinematic viscosity, t_s is time, and τ is a dummy variable (Mei, 1994). This force has both a vertical and horizontal component. For steady, shear flow, the fluid acceleration is zero, so the term can be simplified to be a function of the particle acceleration.

In addition to the shear lift force, the Magnus lift force also results from the velocity gradient across the particle. This force, named for Heinrich Magnus who first discovered the phenomenon in 1853, is a pressure force due to the circulation around a spinning sphere (Murphy and Hooshiari, 1982). As a result of viscous effects, angular momentum is supplied to the particle. This force accounts for the different types of pitches in baseball such as the curveball and the slider (Munson, Young, and Okiishi, 1990). The shear flow induces a rotation which causes a particle to saltate higher and further than without the inclusion of this term. If the velocity gradient is positive, the particle will rotate clockwise (cw); hence, an upward lift. If the velocity gradient is negative, the particle will rotate counterclockwise (ccw); hence, a downward lift. For a moving sphere in a shear flow, the force is expressed as

$$F_L(Magnus) = \frac{\pi}{8} d^3 \rho V_r \left(\Omega - \frac{1}{2} \frac{d\mathbf{u}_f}{dz} \right) \tag{7}$$

with Ω as the angular velocity of the particle with units in rad/s (White and Schulz, 1977). This force was developed from the work of Rubinow and Keller (1961). Rubinow and Keller (1961) looked at rotating a moving sphere in a still viscous fluid with low Reynolds numbers only. Based on their analysis, the Magnus force was independent of viscosity. From this they derived the form of the Magnus force and the moment acting on the sphere. The force has been described previously. The moment has the form

$$Moment = I \frac{d\Omega}{dt} = -\pi\mu d^3 \left(\Omega - \frac{1}{2} \frac{d\mathbf{u}_f}{dz} \right) \tag{8}$$

where I is the particle's moment of inertia. This moment equation is solved simultaneously with the equations of motion to constantly adjust the particle rotation to that induced by the fluid. Note that the dynamic viscosity appears in (8). It acts to dampen the effects of the initial particle rotation to that of the fluid. It must be said that the Magnus force and moment equations were derived for small Reynolds numbers. We consider the Magnus force in this shear flow analysis for the purpose of determining whether the effect improves the agreement between experiments and theory.

Applicability of Forces For Different Reynolds Number Ranges

The drag, added mass, shear lift, Magnus lift, and Basset history forces have been formulated as previously published in the literature. The drag force, as defined here, is valid for the entire range of Reynolds numbers encountered. The form of the shear lift force was originally verified for turbulent flow. Also, theoretically a solid sphere in an inviscid fluid has an added mass coefficient value of 0.5; so, the added mass force defined herein is applicable to large Reynolds number flows, too. From Rubinow and Keller (1961), the Magnus force was derived for low Reynolds number flows only. The Basset history force is not well known for low Reynolds number flow (Nino and Garcia, 1992). For analysis purposes, the forces are extended to the entire range of Reynolds numbers. This follows the previous research procedures as done by Wiberg and Smith (1985) and Nino and Garcia (1992) which have yielded satisfactory results.

Equation of Motion

The equation of motion for a saltating particle may be divided into longitudinal and vertical components. The forces acting on a saltating particle are described by the following equations for a steady, horizontal flow.

$$\begin{aligned} \rho_s V \frac{du}{dt} = & -C_D A \frac{1}{2} \rho \sqrt{(u-u_f)^2 + w^2} (u-u_f) - \rho V C_M \frac{du}{dt} - \frac{6\pi\mu \left(\frac{d}{2}\right)^2}{\sqrt{\pi\nu}} \int_0^{T_f} \frac{du}{\sqrt{T_s - \tau}} d\tau \\ & + \frac{\pi}{8} d^3 \rho \sqrt{(u-u_f)^2 + w^2} \left(\Omega - \frac{1}{2} \frac{du_f}{dz} \right) \frac{w}{\sqrt{(u-u_f)^2 + w^2}} + \rho(s-1)gV \sin \beta \end{aligned} \quad (9)$$

and

$$\begin{aligned} \rho_s V \frac{dw}{dt} = & -C_D A \frac{1}{2} \rho \sqrt{(u-u_f)^2 + w^2} (w) - \rho V C_M \frac{dw}{dt} - \frac{6\pi\mu \left(\frac{d}{2}\right)^2}{\sqrt{\pi\nu}} \int_0^{T_f} \frac{dw}{\sqrt{T_s - \tau}} d\tau \\ & - \frac{\pi}{8} d^3 \rho \sqrt{(u-u_f)^2 + w^2} \left(\Omega - \frac{1}{2} \frac{du_f}{dz} \right) \frac{u-u_f}{\sqrt{(u-u_f)^2 + w^2}} \\ & + \frac{\rho}{2} A C_L (u_{\Delta T_{op}}^2 - u_{\Delta B_{ot}}^2) - \rho(s-1)gV \cos \beta \end{aligned} \quad (10)$$

where

$$u_{\Delta T_{op}}^2 = (u - u_{fT_{op}})^2 + w^2 \quad (11)$$

and

$$u_{\Delta B_{ot}}^2 = (u - u_{fB_{ot}})^2 + w^2 \quad (12)$$

The variables, u_{fTop} and u_{fBot} , are the fluid velocities evaluated at the top and bottom of the particle, respectively. The quantities, u and w , are the particle's translational speed parallel and normal to the bed, respectively. All these assume no w -component of fluid velocity. Figure 1 provides a sketch of the particle forces. β is the bed slope as defined in Figure 2.

Figure 1 Force definition sketch of particle saltation

Figure 2 Definition of bed slope

The fluid velocity profile used in the model is the "law of the wall" profile,

$$\frac{\bar{u}}{u_*} = \frac{1}{\kappa} \ln \left(\frac{29.7z}{k_s} + 1 \right) \tag{13}$$

where \bar{u} is the mean fluid velocity, u_* is the fluid friction velocity, κ is Karman's constant, z is height above the "theoretical bed", and k_s is the bed roughness. The "theoretical bed" is located at $z = 0$. Note that the fluid velocity has only a horizontal, or bed-parallel, component.

Boundary Conditions

The "theoretical bed" is assumed to be 0.2 times the particle diameter below the top of the particles as is shown in Figure 3. The initial position of the saltating particle is at one-half a particle diameter above the "theoretical bed". In order to solve the equations of motion given previously, the particle's initial vertical and horizontal velocity components are needed. The values of these components come

from the equations of White and Schulz (1977). They found that the speeds varied from u_* to $2u_*$. In addition, they found that lift-off angles varied from 30 to 70 degrees. When the Magnus force is considered, an initial particle angular velocity is needed. This value is adjusted to yield a best match to a known trajectory.

Figure 3 Saltating particle initial position

Method of Solution

The equations of motion along with the moment equation are defined as first order ordinary differential equations. A fourth order Runge Kutta approach is used to yield a vertical and horizontal particle velocity and an angular velocity. The vertical and horizontal velocity components are numerically integrated with a simple Simpson's Rule approach to obtain a particle trajectory. The model includes some adjustable parameters. The bed roughness can be taken to be any multiple of the particle diameter. The initial velocities, angular velocity and the lift-off angle also may be adjusted.

Sensitivity Analysis

This section looks at the relative effect force combinations and initial conditions have in determining the trajectory of a saltating grain. The parameters that are held constant unless otherwise specified through the force sensitivity test are grain diameter, specific gravity, initial particle velocity, initial angle, and bed roughness. They are 0.18 cm, 2.65, $2u_*$, 45 degrees, and $2d$, respectively. The coefficient of lift was taken to be 85% of the coefficient of drag. These are the values that were either used or observed by Fernandez Luque and van Beek (1976). In addition, it needs to be stated that the bed slope was taken to be zero in this case.

The most basic form of the model contains the drag, added mass, and gravity forces. The shear lift force developed by Wiberg and Smith (1985) and the history force from Basset (1888) are successively added to the model. Figure 4 shows the results. For this case, $u_* = 4$ cm/s with $u_0 = w_0 = 2u_*$. The shear lift force increases the length of the trajectory by about one grain diameter while the Basset history

force appears to have a lesser effect on the trajectory. The results with the shear lift force included are consistent with our intuition. Only a small velocity gradient develops across the grain because of its size. As a result, the shear lift has a relatively small effect. The height is increased by less than one-tenth of a grain diameter while the length increased by approximately one-half grain diameter when the Basset term is included. The increase in length is due to the fact that the grain travels higher into the fluid column and thus attains a greater velocity.

Figure 4 Effect of shear lift and Basset history forces on small particle

We then ran the model with a larger particle size. A diameter of 3.1 cm was chosen, roughly in the gravel regime. The other parameters maintained their same values with the exception of $u_* = 22.84$ cm/s and $\beta = 0.07$ to match the experimental conditions of Nino et al. (1992). Figure 5 shows that the shear lift force had more of an effect than it did with the smaller grain. This result is expected because the velocity gradient is large on a larger particle. The Basset force, however, did not possess the same significance as it did in the other case. This force had little effect on the particle trajectory. The Basset history force had a greater effect on the smaller particle than on the larger particle. This same result was obtained by Nino and Garcia (1992).

Figure 5 Effect of shear lift and Basset history force on a large particle

The next force to consider adding to the formulation is the Magnus lift force. To review, this force results from grain rotation which is caused in two ways. First, a grain may be transferred an angular velocity from the shear flow. Since the fluid velocity is greater at the top of a grain than at the bottom of a grain, a net torque may

be exerted upon the grain. Second, a grain on the bed may obtain an angular velocity from a collision with another grain. The magnitude of the rotation is dependent on the speed and the placement of the blow that the grain striking the bed delivers. Figure 6 displays the trajectories that result by varying the initial angular velocity. The diameter of the particle is 0.18 cm with $k_s=2d$, $C_L=0.85C_D$, $u_* = 4$ cm/s, $u_0=2u_*$, and $w_0=2u_*$. It is obvious and expected that the trajectories should both increase in length and height with increasing initial angular velocity. The effect of the Magnus force on a particle's path is quite significant. This is a somewhat discouraging result because little is known about the angular velocities of saltating grains. A common practice is to match a known trajectory by "tweaking" the initial angular velocity of the particle.

Figure 6 Effect of Magnus force on particle trajectories

The initial angle and velocity of the grain is the next area of interest. Again the grain size used is 0.18 cm. Figure 7 displays the results of varying the take-off angles and maintaining a constant initial velocity. The initial angles are 30, 45, and 60 degrees. The initial longitudinal velocity and initial vertical velocity are both $2u_*$. Figure 8 shows what happens if the velocities are varied and the angles are held constant at 45 degrees. As the lift-off angles increased, the grains saltated farther. Also, the higher the initial velocity, the longer the trajectory. These results are obviously from the fact that the grain attains a higher velocity from the fluid with a larger angle and higher initial velocity.

Figure 7 Trajectory sensitivity to particle take-off angle

Figure 8 Trajectory sensitivity to particle take-off speed

To summarize, the forces acting on the particle vary significantly with grain size. The shear lift force and the Basset history force vary the greatest of the forces examined. The Magnus effect increases saltation length and height greatly as initial angular particle velocity increases. Finally, the larger the initial velocity and angle, the greater the saltation length and height.

Comparison of Model to Data

The Magnus Effect is neglected for the first comparison with a given data set to see if the shear lift force is sufficient. The trajectory data used for the model comparison is provided by Fernandez Luque and van Beek (1976). The grain diameter was 0.18 cm with a friction velocity of 4 cm/s. The initial conditions for the model were $u_0 = 8$ cm/s, $w_0 = 8$ cm/s, $\beta = 0$, $C_L = 0.85C_D$, and $k_s = 2d$. The trajectory is shown as the solid line in Figure 9. It is easily seen that the shear lift force alone does not adequately describe the motion of the particle as observed by Fernandez Luque and van Beek (1976).

Figure 9 Model comparison to Fernandez Luque and van Beek (1976) observations

Figures 10 through 14 show some of the relevant velocities and forces as predicted by the model. The fluid velocity is always in the rough, turbulent range as shown by the Reynolds number. The drag coefficient was between 0.60 and 0.85. Those quantities are graphically shown in Figure 10 and Figure 11. Figure 12 shows how the particle, fluid, and relative velocities varied over the trajectory length of the saltation. The plot reveals that the particle velocity is continuously increasing

Figure 10 Reynolds number simulated saltation trajectory

Figure 11 Drag coefficient for simulated saltation trajectory

Figure 12 Strength of velocities of simulated particle trajectory

Figure 13 Strength of particle accelerations for a simulated particle trajectory

Figure 14 Strength of relevant forces for a simulated particle trajectory

toward that of the fluid velocity. So as a result, the relative velocity is decreasing. This means that the drag and lift forces are both decreasing over the grain trajectory. This is shown in Figure 14. The drag force is represented by the solid line and the shear lift force is represented with a dashed line. The Basset history force is smaller than both the lift force and the drag force for much of the saltation also in Figure 14. These forces in this figure are given relative to gravity. Note that the Basset force continually increases as the particle saltated as a result of the integral nature of the force.

The horizontal acceleration of the particle decreases as the particle velocity approaches the fluid velocity as shown in Figure 13. The vertical acceleration becomes less negative as the particle saltates. The accelerations are non-dimensionalized by multiplying the acceleration by T_s/u_* . The particle decelerates significantly in the rising part of the trajectory and continues to do so until the particle approaches the bed. It accelerates again near the bed because of the aforementioned lift force. This shear lift force is significant when compared to the drag force. It is evident from Figure 9 that the lift force is not providing enough upward thrust for the particle to saltate as observed by Fernandez Luque and van Beek (1976).

The Magnus force was added to the equation of motion to improve the agreement with observations. In addition, the moment equation was added and solved simultaneously with the equation of motion. The initial conditions were maintained with one exception. An initial angular velocity, Ω_0 , of 30 rev/s was added. The model comparison with the data range is displayed in Figure 9. The model now predicts the grain trajectory fairly well and certainly much better than previously. The Magnus force significantly increases the overall lift effect on the particle especially in the rising part of the trajectory according to Figure 15. For this particular case, the Magnus force increased the saltation height by 2.3 grain diameters and the length by 21 grain diameters. Wiberg and Smith (1985) reached a similar conclusion that the Magnus force should be included.

Figure 15 Comparison of shear lift and Magnus forces

Conclusion

The saltation model considered particles from incipient motion through a trajectory and returning to the bed. The saltation model included gravity, added mass, drag, shear lift, Magnus lift, and Basset history forces. The shear lift force is the same as defined by Wiberg and Smith (1985). When the Magnus lift force is applied, the moment equation from White and Schulz (1977) is used to continually update the particle's rotation.

It was found that a particle will saltate farther with increasing take-off speed and angle. The shear lift and Basset history forces vary significantly with particle size. The shear lift force has a greater effect on large particles and Basset history has a greater effect on small particles. The Magnus lift force affects trajectories significantly when included in the model formulation.

The model is able to match observed trajectories from Fernandez Luque and van Beek (1976). It is necessary to include the Magnus lift force to best match their observations. The shear lift force may need further examination. It appears to underpredict the velocity gradient that is expected at the end of a particle's trajectory near bed. These results suggest experiments be conducted to measure the rotation of saltating grains.

CHAPTER 298

Sediment Movement and Stress Condition in Sea Bed

Yoshihiko Maeno¹, Motoyasu Ishikawa², Kozo Bando³,
Yoshinobu Akiyama⁴ and Kouichi Yabe⁵

ABSTRACT

The stress condition in the sea bed such as effective stress and hydrodynamic condition were measured in the surf zone to understand the detailed mechanism of local and temporal sediment movement. Analysis of the measured data suggests that the large effective stress drop and strong flow in the onshore direction when the wave crest passes are the possible cause for the sand movement in the surf zone. It is also found that the sea bottom elevation change can be evaluated from the effective stress in the sand by a simple equation. The effective stress sensor used in the field measurement was proved to be useful in estimating local and temporal sediment transport.

INTRODUCTION

Sediment transport is usually studied in terms of wave condition and characteristics of bed material. However, in order to understand the detailed mechanism of local and temporal sediment movement, it is important to associate the stress condition in sea bed with wave condition and then to relate the stress to sediment transport. For example, Nago (1982) pointed the relation between the pore pressure and fluidization of the bed.

Maeno and Hasegawa(1985) examined the effects of wave-induced pore pressure in sand bed on liquefaction. Maeno and Tokutomi(1989b) indicated the strong correlation between the liquefaction of sand bed and the mechanisms of sediment transport. Maeno (1992) introduced the experimental results on wave-induced liquefaction and sediment transport, and indicated the needs of the further verification by field observation.

Maeno *et al.*(1993) measured the effective stress, pore pressure and wave conditions outside the surf zone, and concluded that liquefaction occurs by the delayed response of the pore pressure to the surface elevation change. In this research, the similar approach was taken, and the bottom elevation change was tried to relate to the effective stress, pore pressure, wave height and current velocity, which were measured in the surf zone.

This research also attempts to examine the performance of a newly developed effective stress sensor (Maeno *et al.*,1992), which may give the local and temporal information that are hard to obtain by the conventional methods; sand trap, surveying, etc.

FIELD MEASUREMENT

Measurement Site

Measurement was made in a beach at Hazaki-cho, Ibaragi Prefecture, Japan (see Figure 1). This beach is a part of 80 km straight sandy coast facing the Pacific Ocean. There is a 427 m long observation pier on the beach owned by Port and Harbour Research Institute, Ministry of Transport, to study sediment transport. This study made use of the pier, from which various data were taken. Two measurement locations were chosen in the surf zone along the pier: one is 230 m offshore from the shoreline and the other is 260 m offshore. Figure 2 illustrates the measurement locations and the bottom profiles under the pier during the measurement period. The water depth at those locations fluctuated in the range of 1 m, but both the locations remained on a large bar.

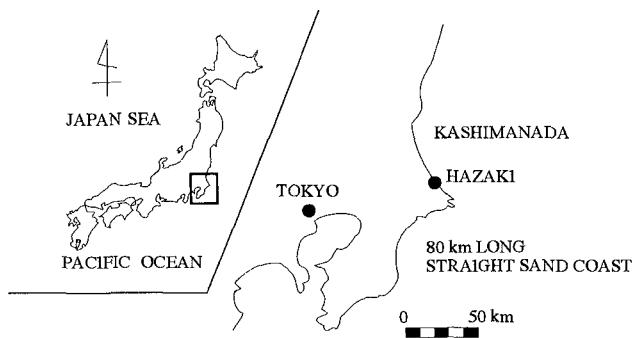

FIG. 1. MEASUREMENT SITE

FIG. 2. MEASUREMENTS OF SEA BOTTOM PROFILE

Instruments

The instruments deployed in the measurement locations are listed in Table 1. To install these instruments, a frame structure was put in sea bed at each location as shown in Figure 3. It held an effective stress sensor and a dynamic pore pressure gauge in the sea bed, a pressure gauge on the sea bed, a current meter, and a wave gauge. The effective stress sensor and dynamic pore pressure gauge were the differential type made of the flexible filter (Maeno and Tokutomi, 1989a). Additional data such as sea surface elevation by acoustic wave gauge, wind data, water depth and ground water level were supplied by Port and Harbour Research Institute, who takes these data at the pier on a regular basis. The measured data were recorded at 10 Hz from June 12th to 26th, 1994 for the location 1 and from June 12th to 15th for the location 2. Data acquisition was terminated by the damage to the measurement system due to the high seas.

MECHANISM OF LIQUEFACTION

From a soil mechanical point of view, the sand can be mobilized when the stress acting on it exceeds its capacity. The sand in the zero or negative effective stress condition, which may be called liquefaction, is certainly the case. How liquefaction takes place outside the surf zone was explained (Maeno *et al.*, 1993), and this study focuses on the condition in the surf zone. The mechanism of liquefaction outside the surf zone is reviewed first, and the mechanism in the surf zone found by analyzing the data measured in the present study is followed.

FIG. 3. INSTALLATION OF INSTRUMENTS

Outside Surf Zone

Generally, the dynamic pore pressure and effective stress in the sea bed follow the sea surface elevation change. However, it was found from close observation of these data taken outside the surf zone (Maeno *et al.*, 1993) that the dynamic pore pressure is slightly lagged behind the change of the sea surface elevation. This yields excessive positive effective stress at crest and negative value after the crest passes to compensate

for the insufficient pore pressure response. The negative part of the effective stress gives rise to the liquefaction of the sand, which can be swept away by the currents near the bed. This process is illustrated in Figure 4. Figure 5 shows the time histories of the stresses measured at a depth of 6 m (Maeno *et al.*, 1993). Sharp peaks are observed in the effective stress record due to the late response of the pore pressure to the surface elevation. The magnitude of the negative peak indicates the thickness of the sand layer that was liquidized, and the difference in the stress level before and after the wave is equal to the thickness of the sand layer that was washed away. In this example, the sand in the top 47 cm thick layer was liquidized and the sand layer in the thickness of about 17 cm was carried away.

FIG. 4. MECHANISM OF LIQUEFACTION OUTSIDE SURF ZONE

FIG. 5. TIME HISTORIES FOR STEEP AND LARGE WAVE HEIGHT

Inside Surf Zone

In this study the similar kinds of data were collected in the surf zone. Figure 6 shows the responses of those stresses collected at location 2, where waves were steep enough to break. In this case there is little time lag in the response of the pore pressure, which is different from the stress response outside the surf zone. The wave action in the surf zone is severer and the top layer of the sand is more likely to be loose so that the pressure exerted on the sea bottom is transmitted instantaneously to inside.

The response of the effective stress is characterized with the sharp and large drops when the wave crests pass. These drops become larger as the wave height increases. The magnitude of this drop is much smaller than that of the pore pressure, and the negative effective stress may be due to the overshooting response of the pore pressure.

The current data at the sea bottom in Figure 6 show the strong flow in the onshore direction when the crests pass and the effective stress is very low. It is surmised that the loose sand in the top layer where the effective stress is nearly zero may be carried

FIG. 6. TIME HISTORY DATA AT LOCATION 2 (6/15/1994 01:17:16)

away by the strong onshore flow. Compared with the condition outside the surf zone, the larger negative effective stress and stronger current due to severer wave action are expected in the surf zone. The condition in the surf zone that large negative effective stress and strong current occur at crest is one of the mechanisms for the sediment movement in the surf zone

ANALYSIS OF FIELD DATA

Wave Condition

The significant wave height and period, and wind information are computed based on 50 minutes-long data to represent the condition at that hour, and are shown in Figure 7. There were two moderate storms with approximately 2 m significant wave height coming in the measuring period: on 15th to 16th and on 19th to 20th. The swells were dominant at the first event, since wind was weak and the wave period was relatively long. On the other hand, the second event was caused by the strong easterly winds.

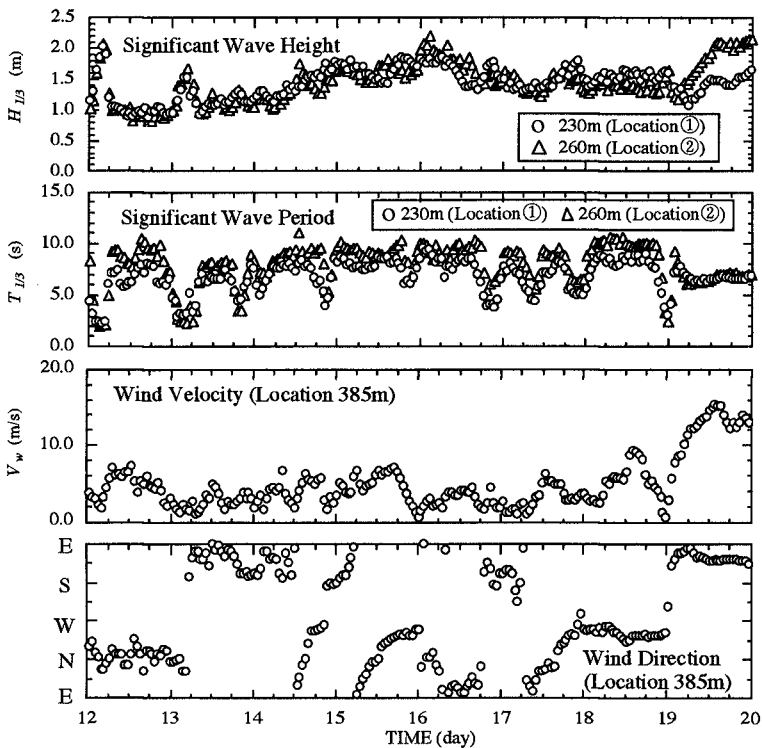

FIG. 7. SIGNIFICANT WAVE HEIGHT AND PERIOD, AND WIND INFORMATION (50 MINUTES-LONG AVERAGED DATA)

Response of Stress in Sand to Wave Action

To compare the stress condition in the sand with the wave condition, the stress data were also processed in the same way as the waves were. Figure 8 illustrates the time histories of the significant pressure, stresses and velocity data. The pressure data can be linearly converted to the sea surface elevation. It is seen that the amplitude of the effective stress change in one wave period becomes larger with the significant wave height. It implies that the effective stress is directly controlled by the wave action.

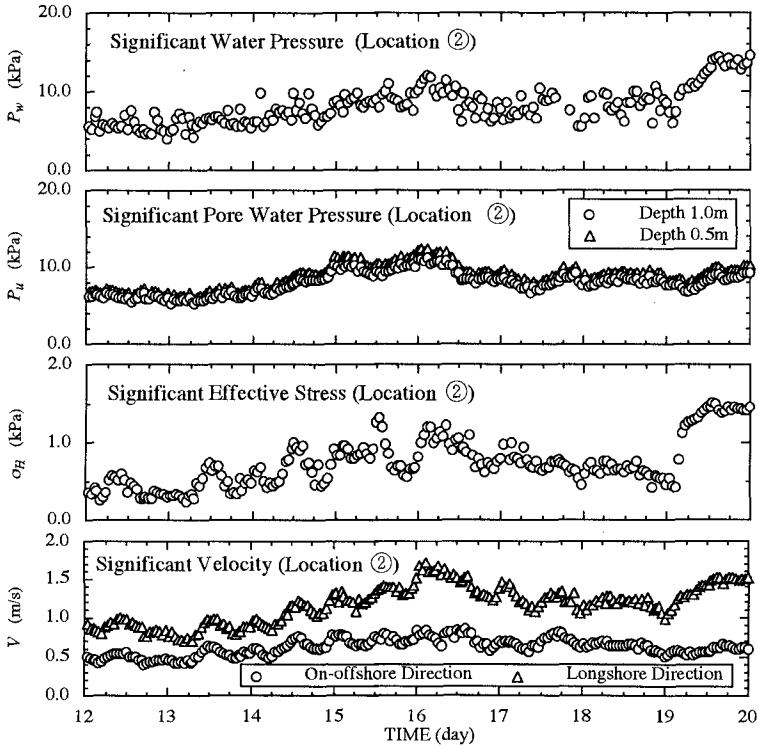

FIG. 8. SIGNIFICANT STRESS AND VELOCITY (50 MINUTES-LONG AVERAGED DATA)

The averaged data are shown in Figure 9. There is a sharp depression everyday in the effective stress data, and it becomes larger with time until 17th. The pore pressure exhibits the similar response but in the positive direction. Then adding them together makes the variation at the time become negligible. It is also seen that the drop in the averaged effective stress occurs at the lowest elevation of the sea surface in each day. Clear cause for these events are not understood, but the non-linearity associated with

shallower water depth may be attributed. Correlation with the wave height is not clear either, since high waves came from 15th evening to 16th morning.

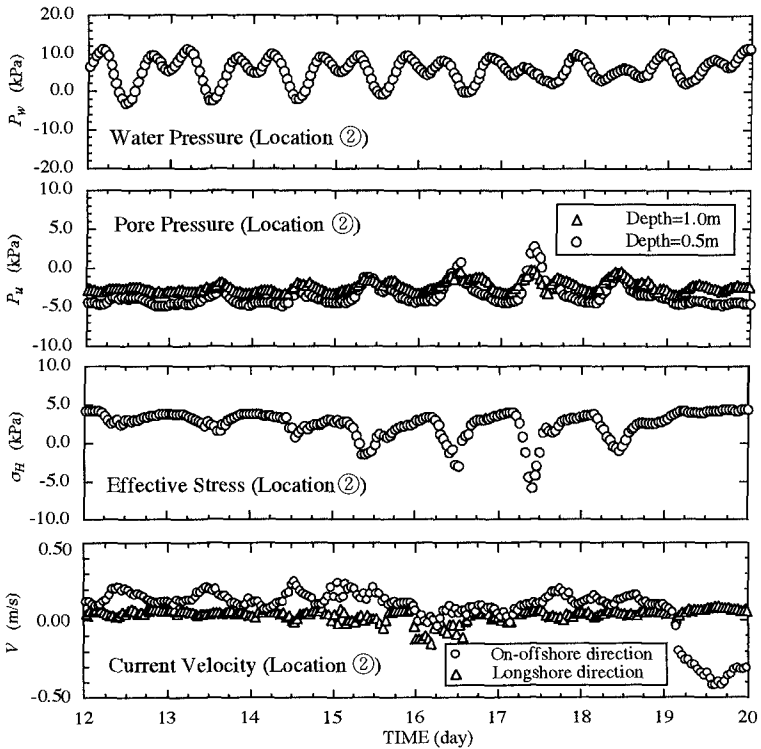

FIG. 9. 50 MINUTES-LONG AVERAGED STRESS AND VELOCITY

Bottom Elevation Change

It is reasonable to assume that the effective stress represents the thickness of the sand above. Then, the vertical location of the effective stress sensor in relation to the sea bottom can be estimated by the following equation (1), and consequently the sea bottom elevation, Δh is evaluated.

$$\Delta h = \frac{\sigma_H}{K_o \{ (1-n)(\rho_s - \rho_w) g \}} \tag{1}$$

where K_o , n , ρ_s , ρ_w and g are coefficient of earth pressure at rest, porosity, density of soil particle, density of sea water and gravity acceleration. The averaged effective stress, σ_H was used in the equation. Note that since there are large drops in the averaged effective stress series as mentioned above, those data was unconsidered. If these data

were converted to the thickness based on equation (1), it turned out to be about 3 m depth change, which is unrealistic. The effective stress change is assumed to be solely by the change of sand layer thickness in equation (1), and those large stress drops are more likely to be caused by other physical factors.

The estimated sea bottom elevation is shown in Figure 10 along with the measured elevation. The estimate appears to oscillate about the measurement. But, considering that the measurement was made only once a day and that the elevation possibly changes within a day, the estimated changes are compared well with the measured data at the corresponding time. This trend is observed both at location 1 and at location 2. Agreement between the measured elevation and the estimate by the effective stress implies that the effective stress is directly related to the sand movement and the sea bed elevation change can be estimated from the information on the effective stress. From this point of view the effective stress sensor employed in this study is found to be one of the most efficient instrument to provide the information on the sediment movement. It also suggests that the bottom elevation may fluctuate in a day and may have to be measured more than once in such a day to understand the actual movement.

FIG. 10. ELEVATION OF BOTTOM SURFACE

Effect of Ground Water

There are some studies indicating connection between ground water and sediment transport (*e.g.*, Grant, 1948). Since the ground water level near the shoreline was

continuously measured by Port and Harbour Research Institute, its effect was attempted to examine. The sea surface level and ground water table changes are compared in Figure 11. There is a long-period variation in the time history of the ground water level, which is similar to the wave height record in the same period; *i.e.*, the ground water level rose as the wave became higher. There is also oscillations with short periods, responding to the tides. Thus, it is clear that the ground water near the shore is influenced by the sea conditions.

FIG. 11. SEA LEVEL AND WATER TABLE ELEVATIONS

Further, this rise and drop of the ground water level due to the sea condition change may affect the stress condition in the sand bed in the surf zone. Especially, the liquefaction and the sand movement on a bar may be affected by the ground water, because rapid pressure change at bottom by surface wave may cause the discontinuity between that pressure and the pressure defined by ground water.

Effects of Non-Linearity

To examine the non-linear effects of the surface waves on the effective stress, skewness and kurtosis were calculated from the measured sea surface elevation data. When those values in Figure 12 are compared with the time histories of the wave height and effective stress, the skewness becomes slightly bigger with the wave height and the kurtosis remains constant. From these observations clear relation between the non-linearity of the surface waves and the effective stress is not recognized.

Effects of Long-Period Component of Waves

From the spectrum computed from the sea surface data, the long period waves are

estimated and shown in Figure 13. In this study, only the components with the period longer than 30 s are picked. The long-period wave had larger height on 15 th and 16th, the duration of which coincides with that of the higher significant wave. The trend of long-period wave height is also found in the time history of the ground water level. It implies that the ground water near the coast can be affected by the longer waves.

FIG. 12. EFFECTS OF NON-LINEARITY

FIG. 13. EFFECTS OF LONG-PERIOD WAVES

Relation between Stresses and Wave Steepness

Using the significant wave height and period, and the corresponding effective stress change, their relation is examined in Figure 14, which exhibits the strong linear relation between them.

FIG. 14. CORRELATION BETWEEN EFFECTIVE STRESS AND WAVE STEEPNESS

CONCLUSIONS

The effective stress and pore pressure in the surf zone were directly measured to study the relation with the stress, and the wave condition and other factors, and to evaluate the bottom elevation change from the effective stress data. Though the data were collected only 10 days because of difficult installation of the instruments in the surf zone and the damage by high waves, there were two moderate storms in the measuring period. From the careful observation and analysis of the measured data during this period the followings are found.

- (1) The pore pressure and effective stress appears to respond to the water surface elevation without any time lag. The measured area is always attacked by breaking waves and the sand there is anticipated to be loose. Then, the pressure on the bottom transmits almost simultaneously to the pore pressure inside the soil.
- (2) The mechanism of liquefaction in the surf zone seems to be different from that outside the surf zone. The large effective stress drop and strong flow in the onshore direction when the wave crest passes are the possible cause for the sand movement in the surf zone.
- (3) The water depth change estimated from the effective stress records agrees well with the measured depth change. This leads to the following three conclusions.
 - (a) The effective stress in sea bed is closely related to liquidization of sand and then to sand movement.

- (b) The sea bottom elevation change can be evaluated from the effective stress in the sand and equation (1).
- (c) The effective stress sensor was proved to be useful in estimating local and temporal sediment transport.
- (4) Both the pore pressure and effective stress show larger variation when the short waves with large wave steepness pass.
- (5) The currents going offshore were observed when the sea level was low. The effective stress varied corresponding to these currents.
- (6) The averaged effective stress over 50 minutes drops sharply at low tide. The shallower water depth may be a possible cause, and the exact reason for this is still being studied.
- (7) The ground water level near the coast is likely to be affected by the long waves and tidal changes.

CHAPTER 299

APPLICATION OF THE DEPTH OF CLOSURE CONCEPT

Robert J. Nicholls, ASCE Associate Member¹,
William A. Birkemeier, ASCE Member², and Robert J. Hallermeier³

ABSTRACT

Using data from Duck NC (a wave-dominated, microtidal, sandy oceanic beach), depth of closure is critically evaluated. A meaningful closure is observed for most erosional events, and annual to 30 month time intervals, supporting the application of this concept within coastal engineering. However, the magnitude of depth of closure is sensitive to the definition and analysis approach utilized and estimates of closure need to be explicitly linked to this information.

The limit depth d_l (Hallermeier, 1981) is found to define a conservative bound to the observations of closure during erosional events and in those annual cases where we have data. This confirms the ability to compute a meaningful limit depth simply using extreme wave conditions. At longer time scales there is evidence of a decoupling of the relationship between d_l and observed depth of closure, the observations increase less rapidly than the predictions of d_l . Understanding how closure evolves from individual erosional events to annual and longer time intervals improves the interpretation of sparse surveys and can assist engineering judgement when applying closure predictions.

INTRODUCTION

Depth of closure (DoC) is a widely-used concept within coastal engineering which describes the seaward limit of appreciable depth change (Hallermeier, 1978; 1981; Nicholls *et al.*, in review). It is based on the observation that repetitive beach-nearshore profiles show a decline in vertical variability with increasing depth. Empirically, a closure depth is observed in most high-quality profile data, corresponding to a pinch-out depth

2. US Army Engineer Waterways Experiment Station, Field Research Facility, 1261 Duck Road, Kitty Hawk, NC 27949.

3. Dewberry & Davis, 8401 Arlington Boulevard, Fairfax, VA 22031.

below which depth changes become small (Figure 1). DoC is often used to infer a seaward limit to significant cross-shore sediment transport, leading to applications such as: (1) estimating coastal sediment budgets (e.g., Hands, 1983); (2) numerical modeling of coastal change (e.g., Kraus and Harikai, 1983) and (3) beach nourishment design (e.g., Stive *et al.*, 1991).

Figure 1. Example of (a) depth of closure produced by single storm, and (b) standard deviation of depth change (SDDC) over a typical year and 12 years. Variability decreases offshore, but increases with time scale. (Profile line 188, Duck, NC).

At sites with repetitive, beach-nearshore profile data, empirical estimates of DoC may be made directly. However, such sites are unusual and DoC is normally estimated using a range of possible indicators (USACE, 1984). The only analytical method to estimate DoC has been proposed by Hallermeier (1978; 1981). Annual DoC is the seaward limit of the littoral zone (depth — d_l) which can be estimated using extreme wave conditions. In a generalized time-dependent form:

$$d_{l,t} = 2.28H_{e,t} - 68.5(H_{e,t}^2/gT_{e,t}^2) \quad (1)$$

where $d_{l,t}$ is the predicted DoC over t years, referenced to Mean Low Water; $H_{e,t}$ is the non-breaking significant wave height that is exceeded 12 hours per t years, $(100/730t)\%$

of the time); $T_{e,t}$ is the associated wave period; and g is the acceleration due to gravity.

The detailed characteristics of DoC, including the validity of Equation 1, have been evaluated (Nicholls *et al.*, in review) using 12 years of profile data collected at the Field Research Facility (FRF) of the U.S. Army Engineer Waterways Experiment Station's, Coastal and Hydraulic Laboratory (formerly the Coastal Engineering Research Center), located in Duck, NC, U.S.A. This paper extends previous analyses, develops additional conclusions, and examines implications for coastal engineering design and practice.

THE DUCK DATA SET

Duck, NC is a wave-dominated, microtidal sandy beach located on the Atlantic Ocean (Birkemeier *et al.*, 1985). The beach-nearshore profile data used in this study were collected to about 8-m depth along four profile lines (58, 62, 188, and 190). On these lines, offshore contours are relatively straight and one or two nearshore bars are usually present. These bars tend to be three-dimensional (Lippmann and Holman, 1990). Surveys are typically collected every two weeks and after most storms, providing pre- and post-storm profiles. Operational survey accuracy is <3 cm (Lee and Birkemeier, 1993).

Wave height and period data were collected every six hours, with hourly measurements during storms. Tidal elevation is also measured on site, with the mean tide range being about 1 m. Mean Low Water (MLW) is 0.42 m below National Geodetic Vertical Datum (NGVD). For more details on the data set see Lee and Birkemeier (1993), Larson and Kraus (1994), Lee *et al.* (1995; in review) and Nicholls *et al.* (in review). All observations of DoC are given relative to MLW as this appears to be an appropriate reference level for DoC estimates based simply on wave dimensions (Hallermeier, 1981; Nicholls *et al.*, in review).

DEFINITION AND INTERPRETATION OF CLOSURE

DoC is a fundamental morphodynamic boundary separating a landward active zone from a seaward less active zone *over the period defined by the profile observations used to define closure*. It is not an absolute cross-shore boundary and some depth change, and hence some cross-shore transport is expected to occur at DoC and further seaward (*cf.* Hallermeier, 1981). The position of DoC depends on several factors, including definition. Time scale is also significant as profile activity increases with time scale and a fixed closure criterion will typically move offshore as time scale increases (*e.g.*, Figure 1(b)). (Note that data accuracy often influences our ability to resolve DoC, but at Duck this is a minor issue). The processes which are observed to control DoC at Duck are the typical annual to decadal storm-accretion processes of the beach-nearshore zone (Lee *et al.*, in review), but at longer time scales, shoreface processes will probably control closure (*cf.* Stive and DeVriend, 1995). Therefore, while the concept of DoC is relatively simple, stating its magnitude at any site as x meters is meaningless without qualification concerning the definition utilized and the pertinent time scale. In some cases, closure may not be susceptible to a practical empirical definition, as observed by Inman *et al.* (1993) in samples of surveys at Oceanside, CA which include major storms in 1982/83.

DoC can be defined for (1) events, such as storms, (2) time-interval (or endpoint) change, which ignore intermediate changes (or in practical terms is equivalent to analysis of a typical sporadic survey program), or (3) time-integrated (or cumulative) change. While events can be related to specific energetic wave conditions and processes (e.g., erosion), time-interval and time-integrated changes are controlled by the balance of erosional processes (rapid offshore transport during high energy wave events) and accretional processes (slow, but continuous onshore transport between erosional events) (Lee *et al.*, in review).

To illustrate and examine the variability of DoC due to different definitions at a site with frequent surveys, annual DoC values from profile lines 62 and 188 at Duck are presented in Table 1. Annual time-interval DoC using three fixed depth change criteria: (6 cm, 10 cm and 15 cm) are considered; In this analysis, profiles are compared proceeding seaward to determine where the profile change consistently declines below the depth change criterion, hence defining closure. Annual time-integrated DoC is measured using the standard deviation of depth change (SDDC) which avoids bias from outliers —

Table 1. Annual closure (m, MLW) derived from three fixed change criteria and from an SDDC analysis, including the annual elevation range shown at closure. Each annual period is July to July (fixed criterion) and July to end June (SDDC). "*" indicates non-closing case.										
Start Year	Profile Line 62					Profile Line 188				
	Fixed Depth -Change Criteria			SDDC		Fixed Depth -Change Criteria			SDDC	
	6 - cm	10- cm	15- cm	Depth (m)	Range (m)	6- cm	10- cm	15- cm	Depth (m)	Range (m)

1992	6.9	6.3	6.0	6.8	0.16	5.2	5.0	4.1	6.0	0.14

the DoC then corresponds to the start of a non-zero tail (Kraus and Harikai, 1983). Note that depth change at DoC is a variable defined by the standard deviation envelope and hence there is more potential for an irregular criterion using this approach. Annual SDDC-defined closures from Profile line 62 are illustrated in Figure 2.

The first observation concerning Table 1 is that annual DoC is not always defined within the surveys (≤ 8 -m depth): the 6-cm fixed criterion defines 58% of closures, while SDDC defines 96% of closures. The largest annual DoC is usually given by the 6-cm change criterion: the 10-cm and 15-cm changes are on average about 90% and 80% of the

Figure 2. Standard deviation of depth change envelopes for 12 annual periods from July 1981 until end June 1993 (Profile line 62). Arrows mark SDDC-derived closure and are labeled with depths in m below MLW.

6-cm changes, respectively. Clearly, DoC defined with any constant depth change criterion is just one of a family of possible DoCs, depending on the depth change criterion selected. The smaller the depth change criterion, the greater the proportion of the active profile which will be defined.

The SDDC-defined boundary defines most annual DoCs, including periods of significant profile accretion when all the fixed change criteria fail. However, these cases are associated with a larger non-zero tail, indicating larger uniform changes to the seaward limit of the profile envelope than in typical years. On average, the SDDC DoC lies between the 10-cm and 15-cm time-interval DoC, but this relationship is not apparent for the non-closing cases using a fixed change criterion. Therefore, it is concluded that while the SDDC approach is a reasonable empirical method to define DoC, at Duck it shows bias towards smaller annual closure when there are uniform profile changes at the seaward ends of profiles. A fixed, standard deviation criterion (e.g., 10 cm) would provide results more consistent with the fixed change criterion.

It is also noted that these annual SDDC analyses differ from Larson and Kraus (1994). Using all the Duck data from 1981 to 1991, they discriminated a boundary at about 3.6 m below MLW (400 m offshore). However, comparing Figures 1 (b) and 2 shows that while the minimum at 400 m is an intriguing aspect of the survey data, it is part of a larger declining trend to greater depths. Therefore, this position should not be considered the start of a non-zero tail in the sense of the results in Table 1.

Clearly, different definitions for DoC yield different depth estimates, so any stated empirical result needs to make the definitions explicit. Closure at Duck due to erosional events and over annual and longer time scales is now examined in more detail.

DEPTH OF CLOSURE DURING EROSIONAL EVENTS

Predictions Using Hallermeier (1981)

DoC during erosional events, defined by consistent offshore bar migration, was measured for 68 events with high waves (>2 m height) (Nicholls *et al.*, in review) and is henceforth referred to as erosional event-dependent (E-D) DoC. Following the rationale behind Equation 1, which defines a depth where most waves will not have experienced shallow water breaking, analysis of DoC during erosion at Duck shows that a 6-cm change criterion is the best indicator of closure. It is also most consistent with the documented survey accuracy. A 6-cm change criterion is used in all subsequent analysis

Equation 1 is found to define a conservative bound to the observations (Figure 3), agreeing with Hallermeier's (1981) original recommendations concerning input parameters. Below this limit, the observations show considerable scatter which is partly explained by the pre-event bar configuration — the largest DoC appear to be associated with the most dissipative profile morphology, namely, single outer bars (bar crest about 300 m offshore). Three erosional events produced observed DoCs which were near the survey limit (8-m depth), while three erosional events did not close within the measured profile. These results do not contradict Equation 1 as $d_f > 8$ m for those cases which close beyond the survey range.

Using an empirical best-fit approach to the data in Figure 3, a typical erosional

event realizes 69% of the change predicted by Equation 1 (>95% confidence) (Figure 3):

$$d_E = 0.69 d_t \quad (2)$$

where d_E = observed E-D DoC. However, Equation 2 is affected by the fact of missing observations and its validity for other sites is uncertain.

Probability Analysis

The 68 available observations of erosional E-D DoC approximately conform to a lognormal probability distribution, *i.e.* plot near a straight line in Figure 4. The observations have been ranked in ascending order from $i = 1$ to 68, then assigned evenly-spaced probabilities of $(i-0.5)/N$, where $N = (68+3)$; this procedure allows for the three presumably higher missing observations noted in the previous section. A lognormal probability distribution arises "when many random quantities cooperate multiplicatively so that the effect of a random change is in every case proportional to the previous value of the quantity" (Sachs, 1984, p. 107). For these nearshore DoC, the controlling variables include wave height and period and pre-event profile geometry (Nicholls *et al.*, in review).

Such well-behaved observations suggest a coherent sample of erosional events at Duck, so that extrapolation to rarer events than those yet recorded at the site maybe meaningful. One approach to extrapolation is to use annual maxima of the erosional E-D DoC, giving observations a direct basis in annual probabilities. Figure 4 also displays the nine observed annual maxima (three missing) in the same basic format, with these values showing fair conformance to a shifted lognormal probability distribution. The median annual extreme corresponds to 50% annual probability, or a recurrence interval of 2 years. Note that a lognormal distribution yields lower extremes than an exponential distribution, which would typically describe wave heights (USACE, 1984).

Empirical evidence in Figure 4 consistently supports the order-of-magnitude

Figure 3. Observed versus predicted depth of closure (averaged alongshore) during 68 storms. The best-fit line (Equation 2) is dashed.

Figure 4. Lognormal distributions of all observed erosional event-dependent cases, comprising all observations (Event), and the nine observed annual extremes estimates for extreme DoC in Table 2. These projections suggest that during more extreme erosional events, advances of DoC into water depths beyond 8- to 9-m depth below MLW are rather rare. This behavior is broadly consistent with (1) the predictions of Equation 1 which suggest that over 12.5 years, DoC during erosional events only exceeded 9-m on four occasions (or 6% of cases), and (2) conclusions about observed DoC in a probabilistic context, derived from an independent analysis of all the Duck survey data from 1981 to 1991 (Larson and Kraus, 1994).

Table 2. Approximate recurrence interval for the annual maximum erosional event-dependent closures based on a probability analysis (see text for more details).					
Closure Depth (m below MLW)	7	8	9	10	11
Approximate Recurrence Interval (years)	2.5	5	12	30	70
Annual Probability (%)	40	20	8	3	1.4

DEPTH OF CLOSURE OVER ANNUAL AND LONGER TIME INTERVALS

This section examines the magnitude of DoC over a range of time intervals (1, 1.5, 2, 2.5, 4 and 8 years), including the applicability of Equation 1. DoC was evaluated using

a time-interval approach (*i.e.*, comparing surveys separated by a fixed time interval, as defined earlier) with a 6-cm change criterion. Surveys three months apart in time over the period July 1981 to October 1993 were selected as the basic data set for analysis. This gave 46 time periods for annual closures, 44 annual time periods for 18-month closure, etc.

Predictions Using Hallermeier (1981)

An important result is that time-interval (T-I) DoC is generally deeper than the largest E-D DoC during the same time period. For the annual case, the residuals (d_t - observed DoC) are about 1 m smaller than the erosional events, as shown in Figure 5. This demonstrates that T-I DoC is an integrated response to both erosional and accretional processes, rather than simply indicating the biggest erosional event during a period. Equation 1 is known to fail under accretional conditions, producing estimates that are generally smaller than the observed DoC (Nicholls *et al.*, in review). Therefore, if erosional processes dominate a period, Equation 1 may have more predictive capability than if accretion dominates the period.

Figure 5. Residuals (d_t - observed DoC) versus d_t for erosional event-dependent closures and annual time-interval closure using a 6-cm change criterion. The dashed line is the best-fit to the erosional data, while the dotted line is the same line offset to pass through the approximate median of the annual time-interval data.

As the time interval between surveys increases, fewer cases close within the surveyed profile range at Duck (≤ 8 -m depth below MLW) — 65% of annual interval cases, 63% of 18-month interval cases, 61% of 2-year interval cases, 51% of 30-month interval cases, 44% of 4-year interval cases and only 3% of 8-year interval cases close. The 8-year intervals always include significant profile movement and hence 6-cm closure is lost, except in one case. In all the non-closing cases, net profile change (>6 cm) is occurring seaward of 8-m depth.

Equation 1 is found to provide a useful conservative bound to those annual DoC which are defined within the survey range, see Figure 6. Using an empirical best-fit approach to the data, over a typical year, 76% of the change predicted by Equation 1 occurs ($>95\%$ confidence):

$$d_{T,1} = 0.76 d_{t,1} \quad (3)$$

where $d_{T,1}$ = observed annual T-I DoC. Note that Equation 3 has a numerical coefficient 10% larger than Equation 2.

Most of the annual cases which do not close are consistent with Equation 1 as $d_{t,1} > 8$ m. However, there are five cases (8%) which are predicted to close but did not within the survey extent. This characteristic is also observed in the 18 month, 2 year and 30 month interval data, comprising 9%, 8% and 17% of cases, respectively. All the time periods where this behavior is observed were characterized by slow near-continuous onshore feed of sand from the upper shoreface (>5 -m depth) (cf. Lee *et al.*, in review). Under these conditions, Equation 1 might be expected to be inapplicable, as already discussed. The large number of missing observations and the scatter in results makes objective assessment of the predictive value of Equation 1 more difficult to assess than for the erosional events.

Figure 6. Observed versus predicted annual depth of closure for individual profiles. The dashed line is the best-fit (Equation 3). Of the 32 cases which are not observed to close, $d_{t,1} > 8$ m for 27 cases.

Sensitivity Analysis

The data were examined considering median values to circumvent the missing values, and annual up to 30 month time intervals. (Longer intervals have too few observations to define medians). The cases with d_{θ} of 11.1 m due to the most energetic wave event of record occurring on 31 October 1991, the "Halloween storm," are disarded as outliers not likely to be observed. The remaining data is divided as near equally as possible into a low and high bin, while retaining the capacity to define observational medians: *i.e.*, a meaningful central tendency for measurements. The median for each bin was then determined, treating all missing values as higher than available observations. The sensitivity of observations to predictions is simply the ratio of the difference in observation medians between the two bins, to the difference between the prediction medians. The sensitivity results are presented in Figure 7. Annual observations appear more strongly related to predictions than the erosional event observations. Above the annual time scale, there is a significant decline in sensitivity to negligible levels at 24- and 30-month time intervals.

This indicates that at time intervals longer than one year, the observed closures are increasing much less rapidly than Equation 1 would suggest — *i.e.* the observations and predictions are decoupling. (Of course, Equation 1 still provides estimates of closure that tend to be larger than the observations, so that its predictions have value as a conservative bound.) From this evidence, Equation 1 is interpreted at Duck as being meaningful up to annual time scales, as originally proposed by Hallermeier (1978; 1981).

Figure 7. Sensitivity of observation to $d_{\theta,t}$ as a function of time interval: from individual events to a 30-month interval.

DISCUSSION

The time-interval behavior of closures in this extensive database appears to validate a common empirical definition of a useful DoC: such analyses usually group all available surveys of a profile, regardless of the time interval between data (*e.g.*, Inman *et al.*, 1993). The results documented here indicate that a closure estimate from such analysis is meaningful for a site, provided that the time interval of available data includes at least one seasonal profile translation. However, Figure 2 shows that profile variation in any one year

may be a poor description of the statistical properties of a profile and more than one annual cycle of profile data is preferred. Further, a practical DoC may not be evident if the time span included exceptionally energetic wave sequences yielding a permanent profile translation (Inman *et al.*, 1993).

Some previous analyses may appear to be a little misleading about the DoC implications of the Duck profile database. Our analyses focusing on isolated energetic episodes have revealed many cases of resolvable and volumetrically significant changes at water depths well beyond the 4-m or 6-m deduced as limits by Larson and Kraus (1994). In addition, our analysis, focusing on intervals of one year clearly established that, within survey limits, an annual DoC is the prevalent situation at Duck, despite an absence of definite DoC over some longer time spans (Inman *et al.*, 1993). For each type of observation, the seaward limits of profile change are related to extreme wave conditions by Equation 1. Previously repeated conclusions about DoC at Duck are empirically supported by particular analyses addressing certain longer time intervals, but the present findings reflect more detailed and intensive examination of the same database. Additions to and analysis of that database continue at present, and a more coherent picture is expected to emerge progressively.

As Equation 1 provides a robust conservative bound for significant cross-shore sediment transport at Duck for individual erosional events up to the annual time scale, simply knowing the extreme wave conditions will allow estimates of closure to be made at similar microtidal, wave-dominated sites. Interestingly, both Equation 3 and the sensitivity analysis indicate a stronger relationship between annual DoC and Equation 1 than erosional DoC and Equation 1. Given that Equation 1 is an event-based formulation (*i.e.*, based on the biggest event in a period), this is a surprising result. Above an annual time scale, the available evidence suggests that DoC increases less rapidly than Equation 1 would predict. This is an important result which disagrees with earlier work (*e.g.*, Stive *et al.*, 1992) and has important implications for application. While we are unsure about applying Equation 1 to a t -year time interval, we are more confident about applying Equation 1 as a conservative bound with known wave conditions during an t -year erosional event. An estimate of how far sand might be carried offshore during extreme events can assist in analysis of a range of problems. In intervening periods between erosional events when Equation 1 may not be applicable, sand is generally being slowly transported onshore at open-coast sites such as Duck (Lee *et al.*, in review) with beneficial effects for the beach-nearshore sediment budget. In more sheltered sites with more limited swell, this may not be the case.

A key question is the specification of the wave information to use in Equation 1. The predictions presented here are based on 12-hour exceeded wave height and period measurements at a waverider buoy, 6-km offshore at a depth of about 18-m. Therefore, the measurements are shallow water, but well seaward of the breaker zone. In many cases such data are unavailable, although other wave measurements or hindcast wave information may be available. Improved guidance on optimum wave inputs to Equation 1 need to be developed.

Another problem is the variation in $d_{q,1}$ at any site due to variations in annual extreme waves. Twelve years of wave data at Duck show that $d_{q,1}$ can vary by more than 2 meters depending on the annual period selected: the 25th percentile is 7.7 m, the median

is 8.7 m and the 75th percentile is 9.2 m below MLW. Given the apparent tendency for overprediction of closure depth, most attention might be focused on the two lower values. Taking beach nourishment as an example, selecting a smaller DoC will result in a lower initial project cost, but it may be prudent to plan for more frequent renourishment. This type of analysis will help to identify the trade-offs when selecting from the range of legitimate DoC estimates.

Despite the apparent decoupling of Equation 1 and observations with increasing time scale, it is apparent that application of DoC requires a more explicit consideration of time scale. At Duck, longer time scales are associated with greater profile variability at depth (*cf.* Figure 1(b)), implying larger DoC for a constant depth change criterion. The surveys define DoC for 95% of erosion episodes and for 65% of annual intervals, but over the 12-year window they have failed to define a seaward limit of the profile envelope. An important lesson is that when designing long-term, high accuracy, beach monitoring programs to define the profile envelope, the distribution of $d_{\ell,t}$ helps to define a realistic *minimum* target depth for routine surveys. At Duck, the surveys considered in this paper typically only reach the 25th percentile of $d_{\ell,t}$, with the maximum depths attained being less than the median $d_{\ell,t}$. With our present knowledge of Duck, occasional surveys to the 75 percentile of $d_{\ell,t}$ would appear a reasonable target depth for Duck and similar sites.

CONCLUSIONS

A meaningful depth of closure is observed at Duck under erosional events and a range of time intervals from 1 year to 30 months. The depth limit $d_{\ell,t}$ is found to be robust and useful for erosional events and annual time intervals. Therefore, with limited environmental information (the event or annual 12-hour exceeded wave height and period), a reliable closure estimate apparently can be made. However, Equation 1 is a conservative bound to the observed closures and results should be applied with this in mind. At longer time scales, the observations and Equation 1 decouple as observed closure appears to increase more slowly than the predictions of $d_{\ell,t}$ would suggest.

Knowing the nature of Equation 1 and how closure evolves with increasing time scale, coastal engineers can make better judgements when interpreting sparse survey data. They can also optimize application of a closure value by considering the trade-offs in selecting from a range of legitimate estimates for a site. Finally, the Duck data indicates our limited understanding of cross-shore sand exchange between the beach and the upper shoreface. To capture more of the change for extreme cases, routine measurements are required to greater depths. Collection and investigation of the Duck data set continues.

CHAPTER 300

Numerical modeling of sediment transport for various mode

Masanobu ONO¹⁾, Ichiro DEGUCHI²⁾ and Toru SAWARAGI³⁾

Abstract

There are various mode of sediment transport on sandy beach. They are bed load, suspended load and sheet flow. Until now, various kinds of numerical model for analyzing these sediment transport have been developed based on the assumption of each mode of sediment transport. Consequently, it is difficult to apply them to different mode of sedimentation.

In this study, we propose a relatively simple numerical model for simulating sediment motion of various mode based on the semi-multi-phase flow model. The applicability of the model to sheet flow transport and suspended load transport is examined by using existing experimental data.

The results show that for the suspended sediment, it is necessary to take into the effect of the vortex to lift up sediment to high position. To construct numerical model for simulating sediment transport phenomena of the various mode, we have to introduce generation, development and disappearance process of bed ripple in this model.

Introduction

Mode of sediment transport continually changes from bed load, suspended load to sheet flow according to the increase in magnitude of agitation force. Until now, various kinds of numerical model for analyzing these sediment transport have been developed. An advection-diffusion equation has been widely used to analyze suspended sediment concentration. Suspended load is expressed as the product of concentration and migration speed of suspended sediment that is assumed to be equivalent to water particle velocity when the concentration is not so high. Concentration of bed load and sheet flow has also been analyzed by solving the advection-diffusion equation and the migration speed is estimated by solving a momentum equation of multi-phase flow. When we analyze sediment motion by these model, we have to know the mode of sediment transport before we determine what kind of model we should use.

1) Research Assoc., and 2) Assoc. Prof., Dept. of Civil Engineering, Osaka University, Yamada-oka, Suita, Osaka, 565, Japan

3) Prof., Dept. of Civil Engineering, Osaka sangyo University, Japan

In this study, we propose a relatively simple numerical model for simulating sediment motion of various mode based on the semi-multi-phase flow model. The applicability of the model to sheet flow transport and suspended load transport is examined by using existing experimental data. The effect of vortex shedding from the rippled bed on the Schmidt number is also investigated numerically.

Numerical simulation method for analyzing sediment transport

(1)Basic equations

Numerical model consists of a horizontal momentum equation of one-phase flow and equations of mass conservation of two-phase flow. There are generally six equations, that is, conservation of mass and conservation of horizontal and vertical momentum flux for sediment phase and fluid phase.

The continuity equations for sediment and water phase are shown by Eq.(1) and Eq.(2).

$$\frac{\partial \rho_s c}{\partial t} + \frac{\partial \rho_s c u_s}{\partial x} + \frac{\partial \rho_s c w_s}{\partial z} = 0 \quad (1)$$

$$\frac{\partial \rho_f (1-c)}{\partial t} + \frac{\partial \rho_f (1-c) u_f}{\partial x} + \frac{\partial \rho_f (1-c) w_f}{\partial z} = 0 \quad (2)$$

where c is volumetric concentration of sediment, ρ_s and ρ_f are the density of sediment and water, u_s and u_f are horizontal velocity of sand and water particle, w_s and w_f are vertical velocity of sand and water particle.

The momentum equations for sediment and water phase are shown by Eqs.(3),(4) and Eqs.(5),(6).

$$\frac{\partial \rho_s c u_s}{\partial t} + \frac{\partial \rho_s c u_s^2}{\partial x} + \frac{\partial \rho_s c u_s w_s}{\partial z} = -c \frac{\partial p}{\partial x} + \frac{\partial r_{xx}}{\partial x} + \frac{\partial r_{zx}}{\partial z} + f_x \quad (3)$$

$$\frac{\partial \rho_s c w_s}{\partial t} + \frac{\partial \rho_s c u_s w_s}{\partial x} + \frac{\partial \rho_s c w_s^2}{\partial z} = -c \frac{\partial p}{\partial z} + \frac{\partial r_{xz}}{\partial x} + \frac{\partial r_{zz}}{\partial z} - \rho_s c g + f_z \quad (4)$$

$$\frac{\partial \rho_f (1-c) u_f}{\partial t} + \frac{\partial \rho_f (1-c) u_f^2}{\partial x} + \frac{\partial \rho_f (1-c) u_f w_f}{\partial z} = -(1-c) \frac{\partial p}{\partial x} - f_x \quad (5)$$

$$\frac{\partial \rho_f (1-c) w_f}{\partial t} + \frac{\partial \rho_f (1-c) u_f w_f}{\partial x} + \frac{\partial \rho_f (1-c) w_f^2}{\partial z} = -(1-c) \frac{\partial p}{\partial z} - \rho_f (1-c) g - f_z \quad (6)$$

where p is pressure, $f_i(i=x,z)$ is the i -th component of interaction force per unit volume between sediment and water, r_{ij} is inter granular stress tensor.

There are six unknowns, p , u_f , w_f , u_s , w_s , and c . However, it is very difficult to get stable numerical results of these equations due to very strong non-linear interaction of each equations, Therefore in our model we use the horizontal momentum equations and mass conservation equations and apply empirical relation for determining vertical velocity of sediment phase.

(2)Numerical simulation method

To construct numerical model we made some assumptions and simplification. One is that the horizontal velocity of moving sand is the same as the horizontal fluid velocity. This implies that we apply single layer model for the sediment larded water and Eqs.(3) and (5) become Eq.(7) as shown below:

$$\begin{aligned} \frac{\partial}{\partial t} \left\{ \rho u - (\rho_s - \rho_f) k_x \frac{\partial c}{\partial x} \right\} + \frac{\partial}{\partial x} \left\{ \rho u^2 - 2u(\rho_s - \rho_f) k_x \frac{\partial c}{\partial x} - (\mu_e + \rho \Omega_x) \frac{\partial u}{\partial x} \right\} \\ + \frac{\partial}{\partial z} \left[\left\{ (1-c) \rho w_f + c \rho_s w_s \right\} u - (\mu_e + \rho \Omega_z) \frac{\partial u}{\partial z} \right. \\ \left. - u(\rho_s - \rho_f) k_z \frac{\partial c}{\partial z} - (\rho_s w_s - \rho_f w_f) k_x \frac{\partial c}{\partial x} \right] = - \frac{\partial p}{\partial x} \quad (7) \end{aligned}$$

where u ($=u_s=u_f$) is the horizontal velocity of sand and fluid particle and μ_e is apparent viscosity of sediment laden water (Savage-McKeown, 1983).

Sediment concentration C is calculated from the continuity equation for the sediment phase Eq. (1) by transforming it into an advection-diffusion equation with diffusion coefficient k_i as follows:

$$\frac{\partial c}{\partial t} + \frac{\partial cu}{\partial x} + \frac{\partial cw_s}{\partial z} = \frac{\partial}{\partial x} \left(k_x \frac{\partial c}{\partial x} \right) + \frac{\partial}{\partial z} \left(k_z \frac{\partial c}{\partial z} \right) \quad (8)$$

Eq.(9) is derived from Eq.(2) by performing the same transform.

$$- \frac{\partial c}{\partial t} + \frac{\partial(1-c)u}{\partial x} + \frac{\partial(1-c)w_f}{\partial z} = - \frac{\partial}{\partial x} \left(k_x \frac{\partial c}{\partial x} \right) - \frac{\partial}{\partial z} \left(k_z \frac{\partial c}{\partial z} \right) \quad (9)$$

The diffusion coefficient is assumed to be proportional to the kinematic eddy viscosity Ω_i by using Schmidt number Sm as follow.

$$k_x = \Omega_x / Sm \quad k_z = \Omega_z / Sm \quad (10)$$

$$\mu_e = 1.2\lambda^2 \mu_0 \quad \lambda = 1 / \left\{ (c_{\max} / c)^{1/3} - 1 \right\} \quad (11)$$

where μ_0 is water viscosity, λ is the Linear concentration, $c_{\max}(=0.65)$ is the maximum possible static concentration of uniform spheres. We used the expression for kinematic eddy viscosity proposed by Nadaoka et al.(1990).

$$\Omega_x = l_{(z)}^2 \left| \frac{\partial u}{\partial x} \right| \quad \Omega_z = l_{(z)}^2 \left| \frac{\partial u}{\partial z} \right| \quad l_{(z)} = \kappa \int_{-\infty}^z (c_{\max} - c) / c_{\max} dz \quad (12)$$

where $l(z)$ is mixing length and κ is Karman constant.

To evaluate the vertical velocity of sediment phase, an empirical expression to relate settling velocity of sand particle and concentration is used.

$$w_s = -w_{s0} \left(1 - c / c_{\max} \right)^{2.3} \quad (13)$$

where w_{s0} is the settling velocity of sand particle in clear water.

Vertical velocity of water particle is calculated by the continuity equation for two phase flow. Eq.(14) is derived from Eqs.(8) and (9).

$$\frac{\partial u}{\partial x} + \frac{\partial}{\partial z} \left\{ cw_s + (1-c)w_f \right\} = 0 \quad (14)$$

Equations (7),(8),(13) and (14) were simultaneously solved by transforming them into finite difference equations. In this model, horizontal phenomena is assumed to be homogeneous in the direction of wave propagation.

(3)Initial and boundary conditions

Z axis is taken upward from the initial sand surface as shown in Fig.1. The up-ward boundary conditions are given by Eqs.(15) and (16) at the boundary layer whose thickness is given by Eq.(17).

$$c w_s + k_z \frac{\partial c}{\partial z} = 0 \quad (15) \qquad u = U_0 \sin(\sigma t) \quad (16)$$

$$\max(D_z) = 4\kappa \max(u^*)/\sigma \qquad u^* = |v_z| \frac{\partial u}{\partial z} \quad (17)$$

The pressure gradient in Eq.(7) is given by the pressure gradient outside the boundary layer using the expression of Eq.(16).

Fig. 1 Coordinate system

Two boundary conditions at the bottom are applied. One is the velocity of sediment laden water is 0 and the other is sediment concentration is $0.99c_{max}$. These are given at assumed initial thickness of sand layer $z=-z_0$. To prevent dispersion of vertical gradient of apparent viscosity near sand surface, we distribute sediment concentration in sand layer from $0.97c_{max}$ to $0.99c_{max}$ between $z=-z_0$ and $z=0$ linearly. Calculations are started from the still water and there is no suspended sediment concentration in the region of z is greater than 0.

The thickness of moving sand layer is determined by using Bagnold's condition as shown by Eq.(21).

$$\mu_e \frac{\partial u}{\partial z} \geq \int_z^{+\infty} (\rho_s - \rho_f) g c \tan \phi dz \quad (21)$$

The friction angle ϕ in Eq. (21) also depends on sediment concentration. When the linear concentration is smaller than 1, there is no resisting force against shear. We assume that the value usually used for ϕ is applicable when the linear concentration is larger than 14. It is said that fluid act as a Newtonian fluid when the linear concentration is smaller than 14. We change the value of ϕ continuously in this region as shown by Eq. (23).

$$\mu_e \frac{\partial u}{\partial z} \geq \int_z^{+\infty} (\rho_s - \rho_f) g c \tan(\alpha\phi) dz \quad (22)$$

$$\alpha = \lambda / \lambda_{14} \quad \lambda \leq 14 (c \leq 0.53)$$

$$\alpha = 1 \quad 14 \leq \lambda (0.53 \leq c) \quad (23)$$

Applicability of the model under sheet flow and suspended sediment conditions

We carried out a series of calculation under various conditions. Here, the calculated results are compared with experimental results under sheet flow condition reported by Horikawa et al.(1982) and experimental results under pure suspension condition given by Nakato et. al.(1977) to examine the applicability of the numerical method. There was not any bottom configuration in the former experiments and there were ripples on the bottom in the latter experiments. Both of the experiments were carried out in oscillatory flow tunnels.

Figures 2 and 3 show the comparisons of calculated and measured horizontal velocity, concentration profile. Fig. 4 is the thickness of moving sand layer under the same experiment (Horikawa et. al.(1982)). In these calculation we assumed that the value of Schmidt number was 10. Measured velocity, concentration and thickness of moving layer are roughly reproduced by the numerical simulation.

Fig. 2 Comparison between Horikawa's experimental results and calculated results under sheet flow condition (Horizontal velocity profile, Schmidt number :Sm=10)

Fig. 3 Comparison between Horikawa's experimental results and calculated results under sheet flow condition (Sediment concentration profile, $Sm=10$)

Fig. 4 Comparison between Horikawa's experimental results and calculated results under sheet flow condition (Thickness of moving layer, $Sm=10$)

We calculate the vertical distribution of purely suspended sediment concentration given by Nakato and others by using the same Schmidt number, that is $Sm=10$. In Figs.5 and 6, some examples of calculated results (shown by solid line) are compared with the measured results. As can be seen from this figure, we could not reproduce the measured distribution by the calculation.

Fig. 5 Comparison between Nakato's experimental results and calculated results under suspended sediment condition (sediment concentration profile ,Case1, $S_m=10$)

Fig. 6 Comparison between Nakato's experimental results and calculated results under suspended sediment condition (sediment concentration profile ,Case2, $S_m=10$)

The reason for this discrepancy was simply because the kinematic eddy viscosity did not diffuse from the horizontal bottom and diffusion coefficient outside the boundary layer become almost 0. To improve our numerical model, we changed the value of Schmidt number from bed load layer to suspended load layer. In the bed load layer, the same value of Schmidt number as the sheet flow is used and for the suspended load layer, the value is reduced to be 0.5 to increase diffusion coefficient. We defined the bed load layer where the concentration is lower than the reference concentration given by Sawaragi et al.(1985).

The calculated results are shown by broken lines in Figs. 7 and 8. The degree of agreement between measured and calculated concentration is improved. This

implies that the flow field, especially structure of turbulence in the sheet flow region and suspended load layer is perfectly different from each other and systematic vortices generated by the ripples play an important role in the purely suspended load layer.

Fig. 7 Comparison between Nakato's experimental results and calculated results under suspended sediment condition (Case1, Suspended load layer : $S_m=0.5$, Bed load layer : $S_m=10$)

Fig. 8 Comparison between Nakato's experimental results and calculated results under suspended sediment condition (Case2, Suspended load layer : $S_m=0.5$, Bed load layer : $S_m=10$)

Diffusion coefficient of suspended sediment on the ripple bed

To investigate flow field and the effect of the systematic generation of vortex on rippled bottom, we calculated vortex flow field on ripple bed by modified vortex

filament method originally proposed by Longuet-Higgins(1981). We used circular vortex instead of vortex filament to avoid velocity from going infinity. Eqs.(24) and (25) are the complex velocity potential of circular vortex used in the analysis.

$$|W - W_n| > Gr \Rightarrow \frac{\Gamma_n}{2\pi i} \ln(W - W_n) \quad (24)$$

$$|W - W_n| < Gr \Rightarrow \frac{\Gamma_n}{2\pi i} \frac{1}{Gr} (W - W_n) \quad (25)$$

where W is the arbitrary point in the interior of the unit circle on the complex number plane, W_n is the position of circular vortex, Γ_n is the circulation of circular vortex, Gr is the radius of circular vortex that will be determined from the comparison of measured and calculated turbulence intensity of horizontal velocity on the ripples. When the distance between W and W_n is longer than Gr , the complex velocity potential becomes the same equation of vortex filament. But when W_n approaches to W , the complex velocity potential converges to 0.

Decay of circulation of separated vortex is reproduced by decreasing circulation of each circular vortex by assuming the following time variation with the damping coefficient α_G :

$$\Gamma_n = \Gamma_{on} \exp(-\alpha_G t_{0n} / T) \quad (26)$$

where Γ_{on} is the initial circulation of n-th circular vortex, t_{0n} is the elapsed time since n-th circular vortex has been released. The damping coefficient will also be determined from the measured time variation of vortex circulation.

Solid lines in Fig.9 show the calculated time variation of circulation under various values of damping coefficient. In the figure, measured time variation of circulation of separated vortex (Horikawa et al.,1992) is also shown. Fig. 11 shows the comparison of measured turbulent intensity of horizontal velocity on the ripples (Sawamoto et al.,1981) and calculated result by giving various values of radius for the circular vortex. The vertical axis z is the distance upward from the ripple crest.

Fig. 9 Time variation of circulation of separated vortex

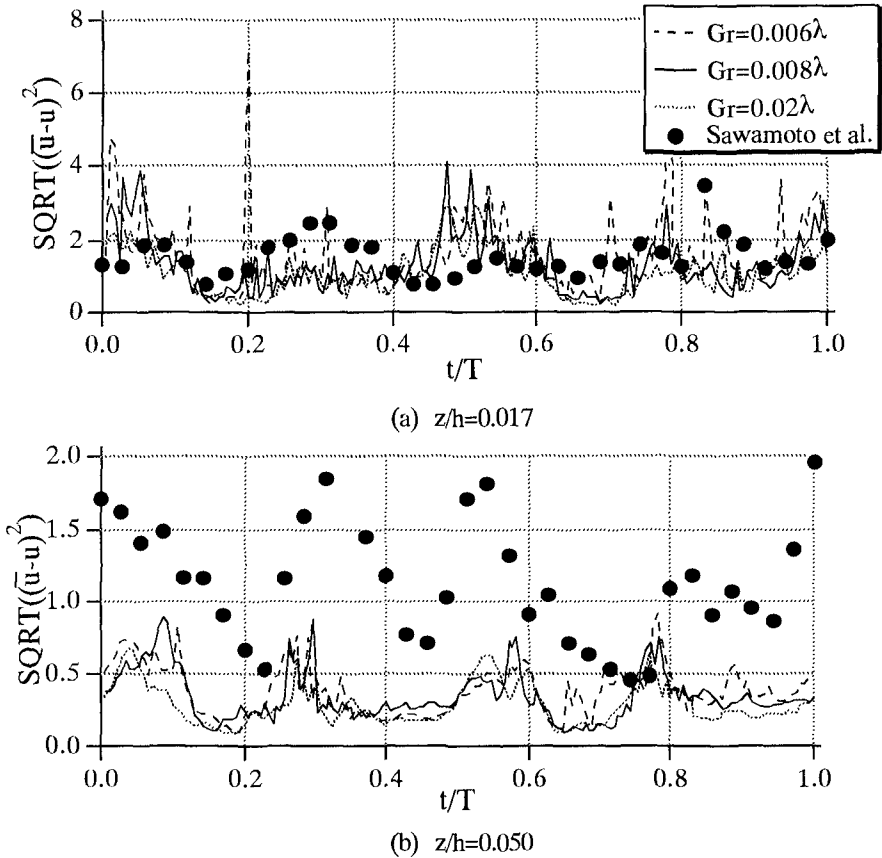

Fig. 10 Vertical distribution of turbulent intensity of horizontal velocity

By comparing calculated and measured result of time decay of circulation and turbulent intensity, circular vortex radius is determined to be 0.8% of ripple length and vortex circulation damping coefficient to be 4.

Calculation of diffusion coefficient of suspended sediment

The motions of suspended sediment are calculated in the flow field obtained on the ripples by an above-mentioned procedure. The governing equations of sediment motion are horizontal and vertical equations of motion as shown in non-dimensional forms by Eqs.(27) and (28) and are solved by using the forth-order Runge-Kutta method.

$$\frac{\partial u_s^*}{\partial t^*} = \frac{3}{4} \frac{1}{\rho_s^* + C_M} C_D K_C |u_f^* - u_s^*| (u_f^* - u_s^*) + \frac{\partial u_f^*}{\partial t^*} \tag{27}$$

$$\frac{\partial w_s^*}{\partial t^*} = \frac{3}{4} \frac{1}{\rho_s^* + C_M} C_D K_C |w_f^* - w_s^*| (w_f^* - w_s^*) + \frac{\partial w_f^*}{\partial t^*} - \frac{\rho_s^* - 1}{\rho_s^* + C_M} g^* \quad (28)$$

$$t^* = t\sigma, (u_s^*, w_s^*) = (u_s, w_s) / w_{s0}, (u_f^*, w_f^*) = (u_f, w_f) / w_{s0},$$

$$\rho_s^* = \rho_s / \rho_f, g^* = g / (w_{s0}\sigma) \quad (29)$$

where $R_e = w_{s0}D/\nu$, $K_C = w_{s0}/D\sigma$, $C_M = 1/2$, g is the gravity acceleration, σ is the angular frequency and C_D is the drag coefficient. The variables with ' in Eqs.(27) and (28) are dimensionless normalized by relation shown by Eq.(29).

To evaluate drag coefficient C_D we adopted the following expression of Molerus and Werther(1968):

$$C_D = \frac{24}{R_e} \left(\frac{1}{|w_f^* - w_s^*|} + \frac{0.152}{\sqrt{|w_f^* - w_s^*|}} + 0.0151R_e \right) \quad (31)$$

Initial positions of sand particles are distributed on the ripples as shown Fig.11. and they are released four cycles after calculation of the flow field where the flow becomes steady and stable. The motion of sand particles is calculated for seven cycles.

Fig. 11 Coordinate system and initial arrangement of sand particles

Diffusion coefficient of suspended sediment is evaluated by the calculated displacement of sand particles by Eq.(32).

$$k_z(t) = \frac{1}{2} \frac{d}{dt} \left\{ \sum_{i=1}^{25} l_i(t)^2 / 25 \right\} \quad (32)$$

where $l(i)$ is relative position vector of sand particles evaluated by Eq.(33).

$$l_i(t) = s_i(t) - S(t) \quad (33)$$

where $s_i(t)$ is the position of i -th sand particle, $S(t)$ is the average position of all sand particles.

Fig.12 shows the comparison of the calculated and measured diffusion coefficient of suspended sediment. Calculated results show good agreement with the measured diffusion coefficient. This means that systematic vortex shedding from the ripple bed plays very important role in sediment suspension. It is not necessary for the sediment movement under the sheet flow condition that takes place on a flat bed to exist such kind of systematic vortex. For the suspended sediment, it is necessary to take into the effect of the vortex to lift up sediment to high position.

Fig. 12 Comparison of measured and calculated diffusion coefficient

Conclusions

We propose a relatively simple numerical modeling of sediment transport for various mode based on the semi-multi-phase flow model and examine the applicability of the model by using existing experimental results of sheet flow and suspended sediment. Although calculated results roughly reproduce the experimental results under sheet flow condition, we could not predict vertical distribution of the concentration of the suspended sediment.

To investigate this reason, we examine the suspended sand particle motion in vortex flow on the ripples. The diffusion coefficient that is evaluated by analyzing sand particle motions on ripples is coincide with the experimental results. This result implies that systematic vortices generated by the ripples lift up suspended sediment to

high position. Therefore to construct numerical model for various mode of sediment transport, we have to introduce generation, development and disappearance process of bed ripple in the model.

CHAPTER 301

Nearbed sediment concentration from tracer studies

Zbigniew PRUSZAK¹, Ryszard WIERZCHNICKI², Andrzej OWCZARCZYK² &
Ryszard B. ZEIDLER¹

ABSTRACT

This paper reports on field investigations, in which the nearbed layer was one of major foci. The study was carried out at the IBW PAN Coastal Research Facility Lubiatowo. The radioactive sand tracer used in the study consisted of iridium glass beads with medium grain diameter D_{50} from 0.2 to 0.25 mm and having physical properties close to their counterparts of natural sand on the Baltic coast of Lubiatowo. Some 150 core samples, each 30 cm long, were taken from the areas where the tracer was set in motion, i.e. bar crests, troughs between bars, and other regions subject to the action of waves and currents. Data analysis shows that sediment movement is characterized by high intermittence reflected in a stratified structure of bedlayer, whereby each sublayer is governed by different forcing factors. For identical external conditions the vertical tracer profiles are different at bar crests and troughs, showing clear diversification of sediment mechanics across the surf zone. Fairly thin sediment sheets, a few millimeters thick, travel at bar crests and troughs, due to high sand speed in one-directional (longshore) movement. The aggregated vertical profile of tracer concentration stems from the superposition of a few quasi-parabolas (close to the injection point) or thin uniform laminas (further away from the tracer source).

1. INTRODUCTION

The surficial layer of seabed is affected by continuous dynamic motion of sea water due to waves and currents. As a result, sediment moves in an unstable and variable moveable layer. Adequate description of the active layer of sediment transport in the sea bed becomes now an urgent but yet controversial problem of coastal dynamics. The thickness of that layer has been assessed in a number of studies to range from a few grain diameters, see Kraus (1984) and Galvin (1987) to several grain diameters (Ingle 1966 and Horikawa et al. 1982) or as much as tens of centimetres (Drapeau et al. 1990). These estimates originate from analyses and investigations having different

¹ Polish Academy of Sciences' Institute of Hydro-Engineering, IBW PAN,
Kościerska 7, 80-953 Gdańsk, Poland

² Institute of Nuclear Chemistry, 16 Dorodna, 03-195 Warsaw, Poland

degree of accuracy, scales and site conditions. Among the conditions bringing about those different estimates of bed layer thickness one can enumerate:

- a) ambiguity of the distinction between bedload and suspended load;
- b) difficulties in determination of real sand grain speed profiles within the entire active layer of sea bed due to variable waves and currents, especially under random field conditions;
- c) problematic delineation of the vertical extension of the movement of single sand grains in sea bed during storms, and controversial singling out individual storm events from aggregated bed thickness due to storm spectrum;
- d) diversified conditions of investigations, analysis and their time and space scales (laboratory versus prototype etc.).

Because of the sophisticated patterns of the transmission of random energy of waves and currents to sea bed and its constituent grains, the problem is complex and highly dependent on scales of the phenomenon. Undistorted relationships between the forces controlling sediment transport stemming from the prototype seem to provide the most reliable and valuable information on the processes investigated here.

This study has aimed at analysing and estimating the bedload thickness in the sea, and its dynamic variability due to random waves and currents.

2. FIELD STUDIES

Our field studies were carried out by the use of radioactive tracers (Ir-192) in the form of iridium glass having geometric and physical properties identical with those of natural sand in the area of investigations (Pruszek & Zeidler 1994).

Some 150 core samples taken from various locations of the cross-shore profile (Fig. 1) were taken all over the area of characteristic coastal features such as sand bars at crests and troughs, under various circumstances created by random waves and currents.

Waves and two components of nearshore currents were measured continuously at two stations D1 and D3 on the cross-shore transect (Fig. 1) every three hours. In addition, wind and sea level oscillations were also recorded every three hours. The results described here stem basically from two measuring series of 23th September to 4th November 93 and 11th May to 30th June 94. Graphical distributions of some hydrodynamic parameters representative of the hydrological background of those situations are shown as examples in Figure 2. The times of core sampling over the area of tracer movement are also indicated on the drawing. Each of the core samples was about 30 cm thick and was subsequently subject to analysis in 2-cm layers with a sensitive apparatus for measurement of low radioactivity.

A special casting box $0.5 \times 0.5 \times 0.25$ m filled up with the radioactive tracer was deployed at the point P1 (Fig. 1). Core samples were taken from that box at intervals of a few hours, in the course of wave and current action. This section of the study was intended as monitoring of the dynamic variability of sea bed in its linkage to changes in the thickness of the active sand layer as a function of time and external factors.

3. ANALYSIS

3.1 TIME AND SPACE CHARACTERISTICS OF THE BEDLOAD LAYER

Geometric characteristics of the variable active layer (primarily its thickness), in the time and space domain, have been analysed by reference to the core samples taken at different locations of the tracer plume. One of the situations tested in area B is illustrated in Figure 3, while the vertical distribution of the tracer concentration, providing insight into the thickness of the active layer with increasing distance from the point of injection, is depicted in Figure 4.

Figure 3. Location of tracer plume in area B during the first series of experiments

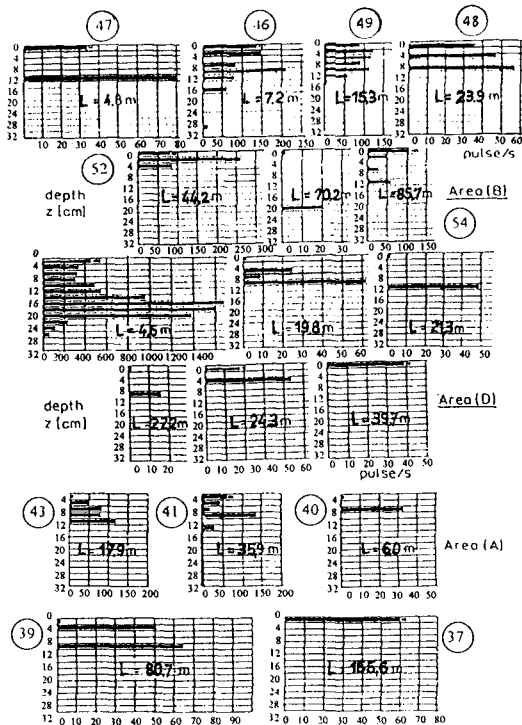

Figure 4. Vertical tracer concentration profiles at various location as a function of spacing L from injection point

Some other vertical profiles, illustrating the wide range of diversity at other locations of the cross-shore transect, are shown in Figure 5. All these results, on the background of the controlling factors have been employed in the determination of characteristic descriptors of the bedload layer.

Figure 5. Exemplary types of vertical tracer concentration profiles

As a result of our analysis of the core samples taken in both measuring series it has turned out that there is no prevailing type of vertical concentration within the bedload layer. Among a few possible general types of distribution one can suggest a quasi-parabolic profile resulting from the superposition of two or even three „moving” parabolas and one or a few thin surface layers on top of those parabolas. The schematic representation of that profile is illustrated in Figure 6. The number of components, thus complexity of the profile, depends on the intensity of changes in wave and current climates at a given location. Since every sublayer of the core sample represents a certain instantaneous random hydrodynamic situation cut out of the complex series of events during the measurements, the storm history is obviously reflected in the configuration of the tracer within the core sample. The higher the diversity of the storm history the more complex the core sample.

Figure 6. Schematic decomposition of the vertical profile of tracer concentration

Clear-cut variability of the vertical tracer profiles in time and space (distance from the injection point) is visible. In the near field of the injection point, the vertical distribution of the tracer is close to the parabolic type, sometimes with an additional thin surficial sublayer. As one moves away from the injection point, the thickness of the tracer layer decreases and the higher activity „moves” from deeper depth to the sea bed surface.

The shape of the vertical bedload profile depends very much on the shape of sea bed itself and its macroforms such as sand bars. Under the same external conditions, at both crests and troughs the tracer travels in a thin surface layer (Fig. 7). The picture is different at bar slopes and in areas without large bed forms; the vertical profiles of tracer concentrations at those locations are less regular, more variable and close to the types depicted in Figures 4, 5 and 6.

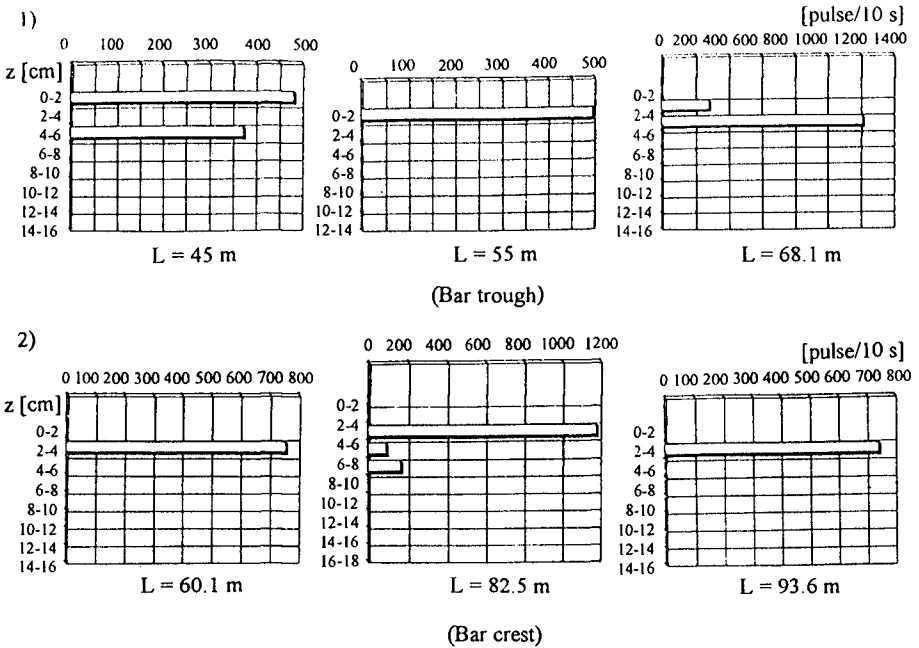

Figure 7. Vertical profile of tracer concentration at bar crests and bar troughs

The core samples tested display a strong nonlinear variability of the bedload thickness as a function of waves and currents. The thickness of each sublayer in the vertical profile, created by various sequences of waves and currents, depends on the intensity and duration of wave motion. Very roughly, it can be described by the general function:

$$a = F(H,t) \approx f(H) \cdot g(b \cdot t/T_{st}) \tag{1}$$

in which T_{st} = time after which stabilisation of the controlling factors takes place and some equilibrium is attained for a given wave situation. This time is estimated as 10 to 100 wave periods T .

The function $f(H)$ stands for the strength of forcing, thus the intensity of sediment transport, while the function $g(b \cdot t/T_{st})$ represents the effect of the time necessary for generation of the bedload layer. After a sufficiently long time $t = T_{st}$ one should get $g(b \cdot t/T_{st}) = 1$ and accordingly $a \approx f(H)$, for a given combination of waves and currents. The vertical profiles of tracer concentration shown in Figures 4 and 5 (or schematically in Figure 6) are thus integrals of the quantity a due to individual segments of the wave and current history.

The thickness a can be estimated from the sediment transport rate $q = (\rho_s - \rho) \cdot v_s \cdot a$ and independent assessments of the average grain speed v_s , both resulting from our

analysis of the tracer movement and core samples. By such procedure one can claim that the thickness a is in the range of 2-4 centimetres during moderate storms.

Theoretical investigations of the bedload layer (Kaczmarek et al. 1995) suggest that the bedload layer thickness a should be smaller. A numerical simulation belonging to those studies is depicted in Figure 8 for the grain diameter D_{50} and wave period T typical of the area of investigation; the thickness a should obviously be a function of wave height and the depth of water.

Figure 8. Theoretical bedload layer thickness for wave period $T=4 \text{ s}$ and variable wave height (H_{rms}) and depth of water h (Kaczmarek et al. 1995)

Upon comparison of the simulated quantities and their prototype counterparts it can be inferred that the bedload layer is about a few millimetres thick, thus by one order of magnitude smaller theoretically than under prototype conditions. This disparity can partly be associated with the laboratory origin of the theoretical outcome. More important, the definitions of the bedload layer are different — Kaczmarek et al. (1995) adhere to the classical few grain diameters above and beneath bedline, while in this study the movable bed layer encompasses sheet flow as well.

The function $f(H)$ can be approximated by $f(H) \approx 0.027H_{br}$, as postulated by Kraus et al. (1982) and Pruszek & Zeidler (1994). On the other hand, the function $g(b \cdot t/T_{st})$ can be estimated once T_{st} is given more accurately, which is however beyond the scope of this study.

3.2 LOCAL VARIABILITY OF ACTIVE SAND LAYER

In order to shed light on local variability of the active sand layer as a function of time and variable forcing by waves and currents, the second series of measurements included a special experiment under prototype conditions. The test box denoted by P1 was situated on a depth $h=1.2$ m, on the seaward slope of the sand bar, some 6 m from the bar crest (Fig. 1). The experiment was initiated at 12:00 on 26th May 1994 at calm weather. The tracer concentration on a depth about 25 cm below original sea bed was constant $c=1500$ pulse/s (Fig. 9). Moderate waves were noted between 12:00 and 14:00 (Table 1).

Table 1. Parameters of water and sediment movement at box P1 (depth = 1.2 m, Fig. 1)

Time (t)	Wind		Wave (m)		Current (m/s) Average/ Max		Sea level change (cm)	Depth of mixing (m)	Rate of depth changes	Remarks

19 ⁰⁰	274°	6.8	0.16	0.48	0.2/0.6	0.01/0.4	+5.0			
22 ⁰⁰	328°	2.4	0.2	0.54	0.2/0.5	0.01/0.4	0.0			
27.05.94 1 ⁰⁰ 4 ⁰⁰	19° 38°	4.9 7.5	0.25 0.35	0.96 1.0	0.3/1.1 0.4/1.2	0.01/0.8 0.02/0.9	+1.0 +6.0	a few	mean value = 10cm/10h	Multiple-point wave breaking
7 ⁰⁰	33°	6.5	0.40	1.17	0.4/1.4	0.02/1.1	+20	cm		
10 ⁰⁰	21°	3.0	0.35	1.0	0.4/1.4	0.02/1.0	+20			

Waves broke in a close vicinity of shoreline, far away from the area of investigations. Although quite small, the waves clearly affected the upper sand layer, reaching some 4 cm below original sea bed line. For similar waves and currents between 14:00 and 18:00 the activity of sand movement in the bedload layer was similar, but its intensity was growing, with the maximum at the surface and linear decrease to the depth $h_d = 4$ cm below sea bed line. The latter value can be regarded as the depth of wave effect on sea bed grains; thus it somehow defines the thickness of the active sea bed layer at given external forcing. Substantially thinner bedload thickness, about a few grain diameters, is typical of that period for the grains belonging to the sea bed and being in motion at the same time. As a result of such wave and current forcing the bed was eroded by 1 - 2 centimetres over four hours, (Fig. 9). By the time of the next measurement at 9 o'clock on the next day, waves and currents grew considerably (Tab. 1). Multiple wave breaking was observed at the time

of the next measurements. About the area of the experiment, where one of the wave breaking lines was noted, the breaker height was about $H_{br} = 1.2$ m and the maximum current velocity exceeded 1 m/s. Tracer concentration in the vertical profile decreased substantially and the concentration profile became irregular, close to the parabola shifted by a certain value below sea bed line. The maximum concentration of a tracer some 6-10 cm below sea bed line was much smaller than its initial counterpart (about five times). From thorough observations by scuba divers it can be reported that ripples were not present and strong sediment flux, somehow resembling a moveable sheet a few centimetres thick occurred. It should be stressed that the thickness of sediment movement layer estimated by scuba divers was about 2-4 cm (depending on the accuracy of estimation), but not a few millimetres. Further erosion by 9-10 cm was noted from 18:00 on 26th May to 9:00 on 27th May; the most intensive changes due to growing waves and currents took place most probably about midnight (Tab. 1).

Figure 9. Variability of vertical concentration profile as a function of hydrodynamic parameters

Subsequent measurements were impossible because of the growing storm. After several hours of that medium storm it was realised that the test box was washed away and no tracer was found in its area.

4. CLOSING REMARKS

From our analysis of the tracer distribution and its coupling with waves and currents one can draw some conclusions concerning the bedload layer. The following points should be made:

- sediment movement under dynamic surf zone conditions is characterized by high intermittence reflected in a stratified structure of bedlayer, whereby each sublayer is governed by different forcing factors. The entire vertical profile of tracer concentration represents then a sum of various sublayers, which are correlated with subsequent wave climate changes,
- vertical profile of tracer concentration displays a pronounced variability in time and space, with predominance of quasi - parabolic profile close to the tracer injection point and a thin quasi - uniform one away from the tracer source; being often the superposition of a few thin 'foils',
- for identical external conditions (wave and currents) the vertical tracer profiles are different at bar crests and troughs, showing clear diversification of sediment mechanics across the surf zone. Fairly thin sheets, below 2 cm in thickness, travel at bar crests and in troughs, due to high sand speeds in one directional (longshore) movement,
- the thickness of each sublayer of the nearbed load is a highly nonlinear function of wave and current velocity, depending on intensity (H) and duration (t) of subsequent wave action, $a = f(H,t) \approx f(H) \cdot \log(b \cdot t/T_s)$.

CHAPTER 302

A SLOPING DUCT FOR THE STUDY OF SEDIMENT TRANSPORT

Jesper S. Damgaard ¹ , Richard J.S. Whitehouse ¹
and Richard L. Soulsby ¹

Abstract.

The details of a large sloping duct at HR Wallingford Ltd. are presented. The duct is capable of sloping to the angle of $\pm 33^\circ$ which exceeds the angle of repose of normal quartz sand. The duct can be tilted laterally as well as longitudinally so that; 1) the effect of combined slopes can be investigated; 2) the aspect ratio can be inverted. At present the duct operates with a steady flow but it can accommodate a wave piston.

1 Introduction.

An important aspect in modelling coastal morphology is the ability to describe the effects of sloping surfaces on sediment transport rates, for example due to longshore bars, dune and ripple formations, dredged channels and trenches and beaches. The research carried out to date is limited, and to remedy this HR Wallingford Ltd has constructed a unique facility to permit the measurement of sediment transport at steep slopes in a controlled environment.

2 Description.

The sloping sediment duct has been purpose-designed for conducting tests on sediment transport on horizontal beds, and shallow and steep slopes up to the angle of repose for the sediment. It has a maximum longitudinal tilt of $\pm 33^\circ$ and can be tilted, or turned, laterally up to this angle for sediment transport studies where a transverse slope is required. In figure 1 the duct is shown at

¹Marine Sediments Group, HR Wallingford Ltd., Wallingford, Oxon OX10 8BA, UK.

Figure 1: Sloping duct at maximum downslope setting.

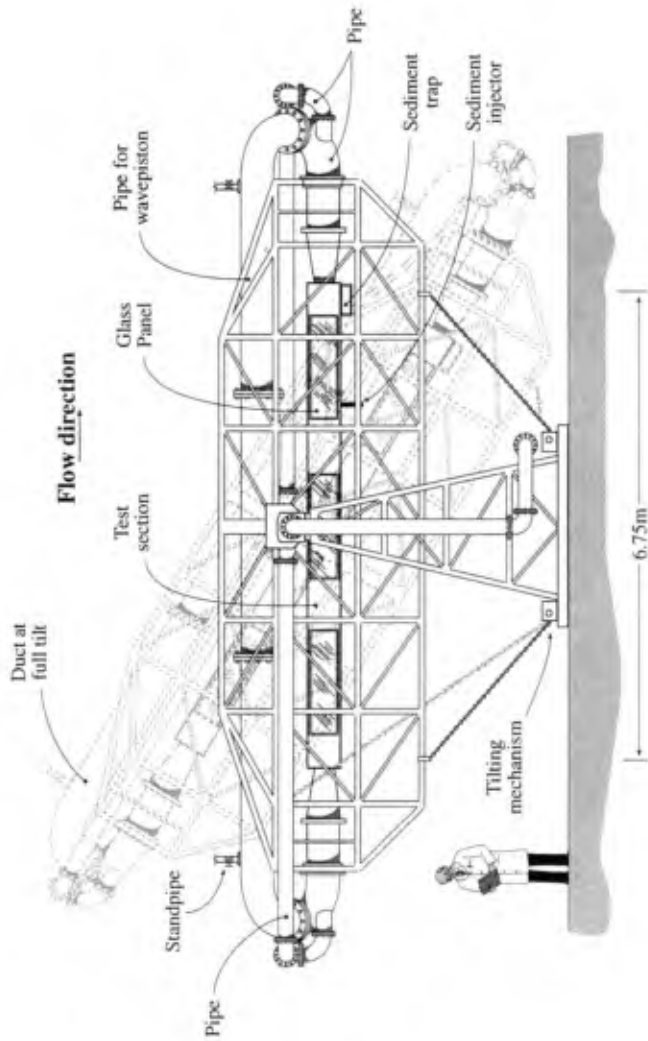

Figure 2: Drawing of sloping duct (not to scale).

full downslope (in the direction of the flow) tilt. The duct consists of a support cage, a test section and a central support on which the support cage pivots. See figure 2.

The dimensions of the test section are 6.75 m long by 0.6 m wide by 0.25 m high with three sections fabricated with glass viewing windows. The ends of the working section have rotating joints, and by tilting the duct laterally through 90° the aspect ratio can be either 1:2.4 or 2.4:1. The downstream end of the duct has a sediment trap which can be emptied by removing a cover plate.

The pump is a P76 centrifugal pump with the following characteristics: maximum head = 13m @ zero flow, design rating = 9m @ $0.17m^3/s$ and head corresponding to the maximum discharge = 5.3m @ $0.21m^3/s$. The maximum discharge corresponds to a mean flow velocity of approximately 1m/s in the duct. The system is a closed conduit with a stand-pipe to avoid water hammer effects.

The flow discharge is measured by an ALTOFLUX K380 electromagnetic flowmeter situated in a straight portion of the 8inch (0.20m) diameter feeder pipework. In each end of the test section there is a small pressure outlet. A Sandhurst Scientific 20mbar differential pressure transducer (GA 64/20E) is used to determine the total head loss in the test section. The distance between the outlets is 5.57m and for a mean velocity of approximately 1m/s, the head loss is of the order 1cm. An absolute pressure transducer (Druck PDCR 930) is installed in the middle of the test section. Provision has been made for mounting a two component Laser Doppler Anemometer (LDA). The laser mounting system rests on rails and can be moved along the test section. An electronically indicating point gauge is installed on the laser mount in order to determine the vertical position of the LDA with an accuracy of $\pm 0.01mm$. Seeding material for boosting the LDA signal can be introduced into the duct while it is operating.

At present the system operates with a steady flow, but it is designed to accommodate a wave piston which will allow oscillatory flows to be generated with periods and amplitudes corresponding to full-scale near-bottom wave motions.

3 Hydrodynamics.

The hydrodynamic properties of the duct have been investigated as a part of the ongoing research. Of particular interest for the sediment transport research is the wall shear stress. For all the experiments that have been conducted so far the floor of the duct has been covered by PVC plates onto which a quartz sand with a median grain diameter of $208\mu m$ has been glued. The sidewall correction method of Vanoni and Brooks (1957) has been used to partition the total pipe friction into wall and bed shear stress. The shear stress has been estimated through head loss measurements obtained by the differential pressure transducer and through LDA measurements in the constant stress layer. It turned out that the variance on the shear stress estimate obtained via head loss measurements was much larger than that of the estimates derived from LDA measurements. Therefore the results

Figure 3: Vertical profiles of mean horizontal velocity measured with the LDA

obtained from the LDA measurements were used to establish the particular pipe friction relation for the duct. The procedure is as follows. First a vertical velocity profile is measured for a range of different discharges. The measuring points in the vertical profile should lie above the viscous sublayer but beneath the core region. See Schlichting (1960) for details. For each discharge the bed friction velocity, u_{*b} , is determined assuming a logarithmic velocity profile

$$\frac{u}{u_{*b}} = \frac{1}{\kappa} \ln \left(\frac{z}{z_0} \right) \quad (1)$$

where u = mean horizontal velocity at distance z above the bed, κ = Von Karman's constant and z_0 = the bed roughness length. A number of velocity profiles are shown in figure 3 for different values of V , mean flow speed, $V = Q/A$, where Q = discharge and A = cross-sectional area.

The bed friction values obtained by equation 1 can be used to estimate the overall pipe friction by applying the sidewall correction method of Vanoni and Brooks (1957). These results have been compared with the Colebrook and White formula (Colebrook, 1939) and a modified version of the C&W formula where the theory of Christoffersen and Jonsson (1985) was used to account for the effect

of uniform grain roughness and where a different value of the constant was used (1.94 rather than 1.74):

$$\frac{1}{\sqrt{\lambda}} = 1.94 - 2 \log \left(\frac{k_s}{R} (1 - e^{-\mathbf{Re}_g/27}) + \frac{18.7}{\mathbf{Re}\sqrt{\lambda}} \right) \quad (2)$$

where λ is the resistance coefficient, $\lambda = 8(u_* / V)^2$, $\mathbf{Re}_g = u_* k_s / \nu$ is the grain Reynolds number, k_s = the Nikuradse equivalent sand roughness, equal to the median grain diameter of bed material, $\mathbf{Re} = 4RV / \nu$ is the pipe Reynolds number and R = hydraulic radius = A/p , p = wetted perimeter. The results are shown in figure 4 using axes based upon Colebrook's original paper.

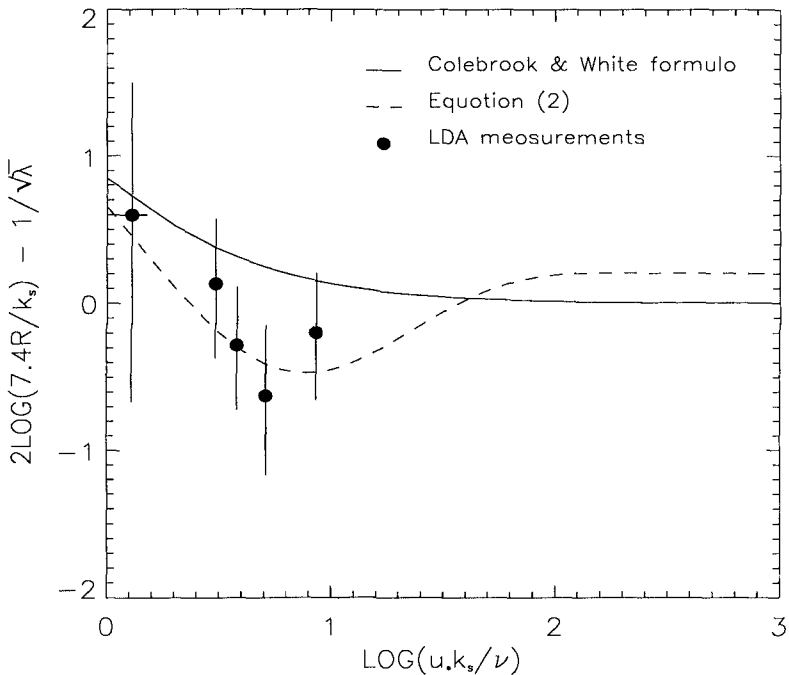

Figure 4: Friction diagram for the sloping duct with a rough floor.

4 Current research.

A study of bed-load transport (erosion rate) on sloping beds in steady flow has been conducted as a part of the MAST G8M Coastal Morphodynamics Project. It is for that purpose that the rough bottom mentioned previously was installed.

Figure 5: Experiments on slope effect on bed-load sediment transport. The values of τ_{cr} are for a horizontal bed.

An electronically driven sediment injector was installed downstream from the centre of the duct with an inner diameter of 20 mm. This device was used to inject sand into the flow to determine the equilibrium pick-up rate for sediment by the flow. The speed of the piston was adjusted until the rate of delivery of sediment matched the rate of removal by the flow. A porthole in the roof of the duct above the injector could be opened to charge the injector with sand and to make observations. At the downstream end of the test section the sediment trap captured the sediment injected into the flow. Figure 5 contains some results obtained in the duct for a range of bedslopes and shear stresses. The bed shear stress, τ , is given as $\tau = \rho u_{*b}^2$, and τ_{cr} is the critical shear stress for initiation of sediment motion on a horizontal bed. The results of this research are discussed further in Damgaard et al. (1996).

5 Conclusions.

The new sloping duct facility at HR Wallingford Ltd has proven to be suitable for large-scale experimental tests with sediments and can also be used for hydrodynamical research. The unique sloping capability of the facility allows the influence of gravity due to a sloping bed (of an arbitrary angle) on the sediment transport to be investigated for all types of sediment. The recent research has concentrated on a fine sand but the duct would be equally suitable for working with gravels as the flow speed achievable is up to $1m/s$.

It is expected that the duct will continue to be used for steady flow tests and, in the future with the addition of a wave piston, for wave or wave-current sediment or hydrodynamic investigations. The duct is currently available to European researchers through the EC Training and Mobility of Researchers - Access to Large-Scale Facilities - programme and it is anticipated that the facility will become available for wider usage by UK and other researchers in the near future.

CHAPTER 303

SEDIMENT DYNAMICS AND PROFILE INTERACTIONS: DUCK94

Donald K. Stauble¹ and Mary A. Cialone²

ABSTRACT

Beach profiles and sediment samples were collected on a daily basis along three cross-shore transect lines during the DUCK94 nearshore experiment lasting for 18 days in October 1994. Conditions ranged from near calm during the first week of the experiment to full storm conditions during the second and third weeks, with a two day initiation of beach recovery at the end of the experiment. The profiles responded with similar elevation change, with little morphologic variability during the calm period. During the storm, the bar migrated seaward 70 to 100 m, but the foreshore exhibited little change. The bar began to migrate shoreward at initiation of recovery. Sediment grain-size distributions vary in the cross-shore direction, with medium size grains on the upper foreshore, coarse gravel deposits on the lower foreshore and progressively finer sands in the offshore direction. After the storm, the foreshore and bar/trough samples were coarser with little change in the nearshore sediment distributions.

INTRODUCTION

To quantify sediment distribution response to forcing functions on the foreshore, bar/trough and nearshore along a three-dimensional beach area, a sediment sampling and analysis experiment was conducted as part of the DUCK94 nearshore field experiment (see Birkemeier et al., 1997 for overview of DUCK94 experiment). This experiment was designed to examine the three-dimensional natural sediment distribution and its relationship to profile change at the U.S. Army Engineer, Waterways Experiment Station, Field Research Facility (FRF) at Duck, N.C. (Figure 1). Sediment distribution changes were measured over the short-term (18-day period) during October, 1994. To increase our understanding of sediment distribution, the experiment focused on our knowledge of the short-term 3-D sediment variations of the entire active profile to document relationships between beach morphology and sediment dynamics from the high water line, seaward to closure depth.

Sediment grain-size distributions for different beach environments change as the beach erodes and accretes in response to changes in wave and tidal forcing. A previous long-term study at the FRF along one profile line characterized a cross-shore variability pattern in

grain-size distributions (Stauble, 1992). During the SUPERDUCK (1986) experiment, a short-term storm erosion and recovery study showed a high degree of three-dimensional grain-size variability but was limited to the foreshore and hinted at nearshore control of the foreshore sedimentation (Stauble et al., 1993). A lack of knowledge exists in relating three-dimensional sediment movement on the entire active beach profile during both fair weather and storm periods to the processes that cause the movement. These processes include a) the swash processes on the foreshore, b) wave breaking, longshore currents, and/or cell circulation (rip currents) in the bar and trough area, and c) wave, tidal and wind driven circulation on the nearshore slope out to closure depth and beyond. The variation in grain sizes in each of these environments is indicative of the different active processes.

EXPERIMENT DESIGN

The experiment design included collection of profile data and sediment samples along three lines, approximately 100 m apart, extending from the dune base to the 6-m depth contour (Figure 2). Surface sediment samples were collected at the dune base, mid-berm, berm crest (area around high water), mid-tide, swash (area around low water), trough, bar crest, and the 3-m, 4-m, 5-m, and 6-m depth contours. Shallow surface sediment samples were collected daily with a hand scoop from the foreshore to wading depth and with a grab sampler on subaqueous portion of each profile using the Coastal Research Amphibious Buggy (CRAB), during the beach profile survey. Samples were collected around the time of low tide on the foreshore. The sampling schedule included daily profile and sediment collection of the foreshore and alternate days for the nearshore area sediment collection for a duration of 18 days in October, 1994. The data sampling time period covered physical conditions ranging from near calm to storm conditions.

Figure 2. Location of profile transects samples (Lines 230, 255, and 270).

DATA ANALYSIS

Physical data: During the experiment several arrays of wave gauges and current meters were deployed within the study area. An offshore wave gauge array was located in 8 m of water, just offshore of the data collection area. Figure 3 shows the mean wave height (H_{m0}) and peak period (T_p) recorded from 2 to 22 October 1994. Profile and sediment data used in this paper were collected from 4 to 21 October. The experiment began just after a period of high wave activity, as the waves diminished to an average H_{m0} of around 0.5 m and a T_p between 3 and 7 sec. This relatively calm period lasted until 9 October. Currents recorded in the trough area landward of the bar between transects 245 and 250 (Figure 2), indicated that the longshore velocity was near zero and the cross-shore velocity ranged from 0 to 0.2 m/s in the offshore direction during this time period (data courtesy of S. Elgar). At the onset of the storm (10-13 October), H_{m0} rapidly increased to around 2 m and T_p increased from a low of 3 sec to around 7 sec. The longshore currents reached their maximum velocity (around 1.3 m/s) to the south, with a steadily increasing offshore component. The wave gauge recorded its maximum H_{m0} of around 4 m on 15 October as T_p increased to around 11 sec. The longshore currents reversed during this time reaching a peak velocity (1 m/s) to the north as the storm progressed up the coast and wave approach angles switched from a northeasterly direction to a more easterly to southeasterly direction. The offshore velocity component in the trough continued to increase to a maximum of around 0.64 m/s on 19 October. The wave height decreased to around 1.5 to 1.0 m as the experiment ended, but the wave period remained around 14 sec.

Profile Data: Beach profile data were collected from a shore-parallel baseline landward of the dune out to a depth of 6 m, some 700 m seaward of the baseline. All profiles are referenced to the 1929 National Geodetic Vertical Datum (NGVD). Profile data were

Figure 3. Plot of nearshore wave parameters and surf zone currents in trough.

analyzed and plotted using the Interactive Survey Reduction Program (ISRP) as described by Birkemeier (1984). Plots of the pre-storm beach profile (5 October) at all three transects showed that the bar crest was about 250 m from the baseline (Figure 4). With the increase in wave height beginning on 10 October, the bar migrated seaward. By 15 October the bar had moved to around 280 m seaward of the baseline. Just one day later, at the height of storm wave activity, the bar had moved to between 310 and 350 m offshore. With steadily decreasing wave heights and long period swell (as the storm moved out of the area), the bar migrated back onshore at profile lines 255 and 270. Profile line 230 was the location of a rip current and the bar remained in its seaward position through 21 October. The foreshore did not change significantly in elevation over the study. During the low wave period at the beginning of the experiment the foreshore was planar, but beach cusps developed on 20 and 21 October as the waves subsided.

Sediment Data: A total of 256 sediment samples were collected and sieved using a sonic sifter at quarter-phi ($\frac{1}{4} \phi$) intervals, ranging from -3ϕ (8.0 mm) to 4.25ϕ (0.53 mm), and weight percentages for each interval were computed. Statistical data were calculated using the method of moments (described in Friedman and Sanders, 1978). High variability was found in the cross-shore grain-size distributions, with the foreshore exhibiting the highest variability. This area between the berm crest and low tide swash contained a bimodal gravel component along with sand size fractions. A localized source of coarse relict sediment has been identified in the area of the FRF by previous investigators (Calliari, 1994). The highest variability in profile elevation and sediment distribution occurred in the lower foreshore and trough/bar area, however the gravel component was restricted to the beach foreshore. The grain-size distribution was much more well-sorted and more uniform in mean size in the nearshore, both temporally and spatially. Figure 5a shows an example of the cross-shore sediment distribution on profile line 270 collected just at the beginning of the storm, representative of the sediment distributions deposited during the period of low wave activity. In contrast, at the end of the high wave period on 20 October, the bar had migrated offshore and the trough had widened. The grain-size distributions (Figure 5b) show a coarser and more poorly-sorted sample from the foreshore to the 3-m depth. Little change in nearshore sand distributions were found between low and storm wave conditions, while an increase in coarse material was measured on the foreshore. The finer-sized sediments were removed from the foreshore, trough and bar crest area, leaving behind a coarse lag deposit.

ANALYSIS AND DISCUSSION

Alongshore and cross-shore sediment distribution variability was related to beach morphology changes as a function of wave and current fluctuation. During the October 1994 experiment, the alongshore beach shape was uniform for the low wave period (first six days) and a "linear" beach was the prevalent form. The cross-shore profile elevation change and sediment grain-size distribution exhibited more variability, with a zone of medium size sands on the upper foreshore and coarse material in the lower foreshore. The size distribution became progressively finer in the offshore direction, through the nearshore trough, over a single bar feature, and the sloping nearshore region.

On 10 October, an extratropical storm system developed over the northern Gulf of Mexico and migrated northeastward into the Atlantic Ocean off of Cape Hatteras on 15 October. During this "northeaster", alongshore currents increased to the south and offshore

flow increased in the trough area. During this phase of the experiment, the bar feature migrated in the offshore direction, while the foreshore maintained a uniform planar shape along the study area. Wave heights continued to grow and reached a maximum of 4 m at the 8-m depth wave gauge on 15 October.

High pressure developed over the eastern United States on 16 October and continued through the end of the experiment. During this phase of the experiment, the longshore drift switched from a southward to northward direction. In the surf zone, offshore currents reached their peak on 19 October. The profile responded with continued seaward migration of the bar feature and widening of the trough. Wave heights decreased on the last two days of the experiment, as long period swell conditions prevailed. Beach cusps formed and a rip current was present at the northern end of the study area. The beach began to take on more three-dimensional profile features with the bar migrating onshore in the southern region as offshore currents rapidly decreased in velocity.

In order to improve our understanding of both spatial and temporal variability in grain-size distribution during high energy events and compare them with calm periods, foreshore samples were collected and analyzed along all three lines, on a daily basis throughout the experiment. Nearshore sediment data collection was planned on a two-day cycle, but large waves precluded collection in the nearshore during the height of the storm event. However, nearshore samples were taken immediately before and after the storm.

Standard statistical techniques were used to analyze the sediment distribution of each beach and nearshore environment. Mean and standard deviation values were calculated for each sample. In general the coarser samples tended to have poorer sorting. The widest range in mean and sorting values was found in the low tide sediments, where the samples contained coarse shell and gravel components, as well as medium to fine quartz sand material. The upper foreshore (high and mid tide) samples had a coarse to medium-sized sand that was better sorted than the low tide (less of a coarse shell and gravel component). The nearshore (trough to the 6-m depth) had a relatively narrow range of mean grain sizes in the fine sand range, with little shell and no gravel size components.

Analysis of a suite of sediment samples using just the mean and standard deviation values is somewhat limiting. The use of Q-mode factor analysis (Klovan, 1966) provides a method to determine the relationship between grain-size distribution and variability in the 3-D sedimentation of the beach and nearshore. Q-mode factor analysis, as applied to sediment investigation, involves the determination of interrelationship between sediment samples. With this method, a group of sediment samples can be arranged into a meaningful order so that the relationship between each sediment distribution is deduced (Davis 1973). One of the main advantages of Q-mode factor analysis is that the entire grain-size distribution is considered in the analysis, yielding a detailed relationship especially when $\frac{1}{4}$ ϕ sample intervals are used. Using an analytical method to determine statistical relationships is more objective because it does not require arbitrary statistical descriptors or a-priori knowledge of the environment and location of samples (Klovan, 1966). A large number of samples can be objectively analyzed without having to manually compare each pair of curves. This reduces the "human interpretation" in relating large numbers of grain size distributions.

Q-mode factor analysis relies on how similarity between samples is defined (Reyment

et al., 1993). In this application, the technique of Imbrie and Purdy (1962) for defining similarity was used. They defined an index of proportionality, or cosine theta function, to determine the degree of similarity in weight percent in each size class between each pair of samples. The cosine theta matrix shows all the information on the relationship between the sample vectors, but it is difficult to interpret (Klovan, 1966). Factor analysis provides a means of analyzing the cosine theta matrix to determine the minimum number of mutually orthogonal "factor axes" needed to account for most of the information in the cosine theta matrix. The first axis accounts for the majority of the information in the cosine theta matrix, the second axis accounts for most of the remaining information in the matrix, and so forth. Thus, the problem is to determine the number of eigenvalues needed to account for most (95-99%) of the information in the cosine theta matrix. Eigenvalues and eigenvectors were determined for the sediment sample data set. Factor loadings, a measure of each sample's weighting or correlation to each factor, can then be determined from the eigenvectors and eigenvalues. This provides the coordinates of the samples in a space of reduced dimensionality (Syvitski, 1991). Lastly, a varimax method of factor rotation is used to rotate the factor axes to maximize the variance of the factor loadings on each factor axes, while retaining their orthogonality.

The sample's weight percent in each phi-class interval is used to represent the sample distribution and can be used to "place" the sample relative to other samples in the Q-mode analysis. For example, if a sample is sieved into twenty-seven phi intervals, the sample can be defined as a vector in 27-dimensional space whose position is uniquely determined by the amount of sediment in each of the 27 classes (Klovan, 1966). With this technique, similarities and differences between samples can be determined and comparisons from day to day can also be made. Factor analysis relates the sediment distribution curves of similar shape, and dominant grain-size distribution peaks. Three factors accounted for 88.7% of the variance in the sample distributions. Factor I accounted for 57.8% of the variance and represented the medium sands between 1 and 2 ϕ (0.5 and 0.25 mm). Factor II accounted for 18.3% of the variance and represented fine sands with a peak frequency of occurrence between 2 and 3 ϕ (0.25 and 0.125 mm), and Factor III accounted for 12.6% of the variance and represented coarser sands, with a peak between -1 and 0 ϕ (2.0 and 1.0 mm). Figure 6 is a triangular diagram, which illustrates the distribution of the sediment samples within the three factors from the Q-mode analysis. Samples that are at the corners of the triangle represent the "end-members" of each factor group and depict a particular sediment distribution (Klovan 1966). The other samples within the triangle can be considered as a mixture of these three sediment distributions. The sediments from the high and mid tide area were strong in Factor I and embody medium grain-size distributions. The samples collected from the nearshore (trough to -6 m) covered a range from strong Factor II through near Factor I and comprise fine to medium grain-size distributions. The low tide samples were strongest in Factor II and include predominantly coarse sands.

To better understand the temporal changes over the duration of the 18 day experiment, factor analysis was run on each individual group (i.e. all high tide or all 3-m depth samples) within the cross-shore distribution of sediment data set to investigate the differences in grain-size distributions at each profile position over time. The factors will change depending on which sediment distributions are more dominant within each data set. Each cross-shore sediment data set was compared to differentiate the change over the low to high wave activity period. Little change was found in the nearshore sediment groups, with each data set grouping around Factor I (representing the fines) over the study period. A somewhat

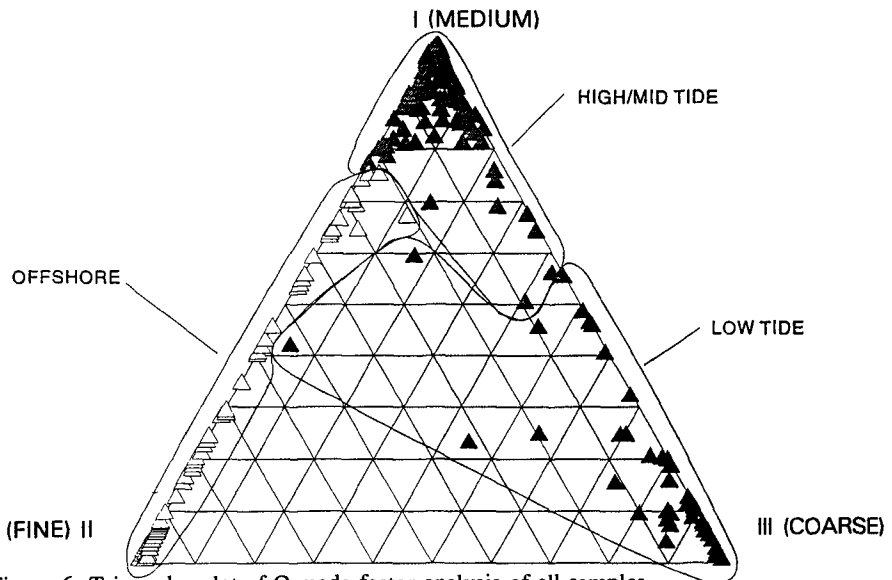

Figure 6. Triangular plot of Q-mode factor analysis of all samples.

more complex grouping was found for the individual foreshore samples over the 18 day study, with the high and mid tide samples grouping more commonly between Factor I (finer) and Factor III (medium), and the low tide samples around Factor II (coarser).

To remove some of the high spatial variability in the foreshore samples, a mathematical composite was made of the high, mid and low tide samples to allow a more clear picture of the temporal change due to storm activity. The 54 composite samples mathematically derived from each of the three profiles per day were analyzed and the grain size variability of the composites was described by three factors representing 94.2% of the variance. Figure 7a shows the triangular plot of the sample distributions within the three factors and representative frequency plots of "end member" samples. Factor I accounted for 79.2% of the variance and represented the finer distributions with peaks around 2ϕ (0.25 mm). Factor II accounted for 12% of the variance and represented coarser grain-size distributions with peaks around -1ϕ (2.0 mm). There was no strong Factor III end member, which accounted for only 3.1% of the variance. Samples that plotted in this area of the diagram had peaks in the medium size range between 1 and 2ϕ (0.5 and 0.25 mm).

To give physical significance of the results of this analysis requires inferring what the end member samples indicate and how the samples group together around these end members. Foreshore composite samples collected from the period of low wave activity (4-10 October) all have a strong grouping toward Factor I. This grain-size distribution is represented by the composite of 9 October on profile line 230 (Figure 7b). All three profile lines exhibited similar composite grain-size distributions. During the period of higher waves (11-19 October) the composites plotted in two groups, one between Factor I and Factor III representing a shift to more medium grain sizes and the second strongly associated with Factor II, the coarse grains. A bi-modal sample from profile line 230 collected on 19 October is representative of this group. Except for the line 230 composite of 20 October

DUCK 94 FORESHORE COMPOSITE

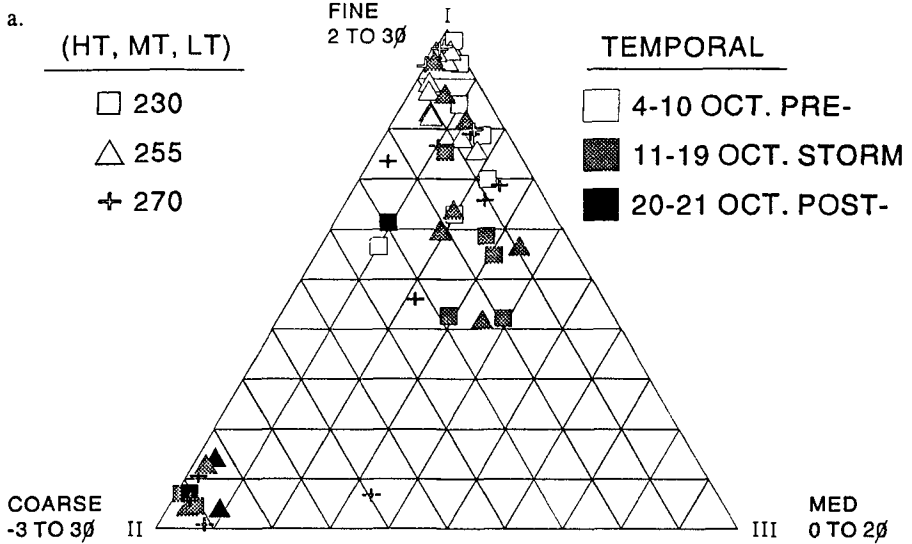

Figure 7. a) Foreshore composite factor analysis and b) examples of grain-size distributions representing Factor I, II and III groups.

all post-high wave samples (20-21 October) plotted strongly as coarse Factor II distributions. The 21 October line 230 sample distribution is an example of this coarse distribution resulting after the storm.

A picture emerges that foreshore and nearshore sediment dynamics are controlled by the wave and current input. During the time of low wave and current activity at the beginning of the experiment, little change was measured on the profile of the foreshore or bar/trough positions and little change in sediment distributions occurred. During the time of high wave and current activity at the latter part of the experiment, the foreshore remained basically unchanged, but the bar migrated seaward and the trough expanded in width. The sediment on the foreshore became coarser and more poorly sorted, particularly in the lower foreshore. Samples from the trough, bar and the 3-m depth also became coarser. Figure 8 illustrates the general trend of the pre- to post-storm sediment distribution change using the mid tide and 3-m depth samples from profile line 270 as an example. A coarse component is present in the grain-size distribution after the storm, possibly a lag deposit of underlying coarse layers exposed as the surficial finer material was removed. Further seaward at the 4-m, 5-m and 6-m depth samples, there was a minimal change in distributions as a result of the storm.

Correlation of sediment data in the trough, bar crest, 3-m, 4-m, and 5-m depth positions, with near real-time physical data such as significant wave height and mean cross-shore and mean longshore currents were possible with an array of sensors positioned 45 m to the north of the center line of sediment sampling. This array of 9 stations extended from the trough seaward over the bar to approximately the 5-m depth contour. The change in longshore current from flow to the south to flow to the north maintained the trough area while strong offshore currents were associated with seaward movement of the bar and the

Figure 8. Post-storm coarsening of sediment at mid tide and -3 m depth at profile line 270.

development of a rip current. On the last two days of the experiment the strong currents dissipated and the bar moved landward. The 3-D component of beach morphology was observed with the formation of beach cusps and the rip current at the northern end of the study area. Sediments became much coarser on the foreshore, and a coarser component was present even in the trough, bar and at the 3-m depth position.

CONCLUSION

The dynamics and evolution of sedimentation patterns on beaches and their link to hydrodynamics are poorly understood and present problems in effectively managing erosion control and storm damage reduction. Present research, using sediment statistical data analysis, is proving beneficial to characterize beach sediment distributions and their spatial and temporal deposition patterns. This study afforded a unique opportunity to couple the beach profile evolution, sediment deposition patterns and their resulting grain size distributions with the physical processes active at that coast.

This research examines the interaction of sediment along a three-dimensional active profile during both erosional and accretional events. Previous sediment studies at the FRF were a long term (17.8 month) study limited to one profile (corresponding to Line 230 in this study) (Stauble, 1992) and a 3-D study of a small 50 m wide area of the foreshore during SANDYDUCK (Stauble et. al, 1993). The DUCK 94 profile response covering one storm event was typical of long-term profile response where the most active part of the profile (bar/trough area) alternately moved seaward during storms and landward during fair weather conditions. From the 3-D perspective, the erosion during high wave and strong offshore surf zone currents moves the bar seaward uniformly with a linear foreshore planform. The recovery phase was more three-dimensional. The bar remaining in a fixed seaward position in the presence of a rip current (north end of the study at Line 230), while the bar migrated landward as the wave and surf zone current energy decreased outside of the rip area (southern area of the study at Lines 255 and 270). The foreshore was also very three-dimensional with the formation of beach cusps during this recovery period.

A better understanding of the dynamic processes of sediment deposition and interaction with profile elevation change on a natural beach was documented. The zonation of sediment characteristics over the entire active beach profile provides a picture of cross-shore grain-size data variability, with highest variability on the foreshore. The low tide samples were the most coarse and poorly sorted, with decreasing grain size and better sorting in the offshore direction. Q-mode factor analysis indicated that the foreshore was finer during the calm period at the beginning of the experiment and became coarser during the storm and recovery period. A coarse lag component contributed to the coarsening of the foreshore. The present study provided more detail to similar findings of Stauble (1992) and Stauble et al. (1993). The nearshore became slightly coarser over the bar and out to the 4-m depth. The seaward most sample distributions (5-m, 6-m depth) remained unchanged throughout the study.

Future research needs should focus on the zonation of coarse material and the interaction of the vertical distribution of layered beds on the foreshore/trough area. Conservation of grain-sizes within the three-dimensional beach (cross-shore and alongshore) is still not well understood. A better understanding of sediment processes can provide input into beach profile numerical models. These studies will ultimately help to understand the fate of beach fill material placed anywhere on the beach profile.

ACKNOWLEDGEMENTS

This research was funded through the Coastal Research Program, Geological Analysis of Shelf/Beach Sediment Interchange work unit. The authors would like to thank J.B. Smith, Andrew Morang and the many volunteers who assisted in the field data collection effort. William Birkemeier provided helpful discussion and review, and along with Michael Leffler and the staff of the FRF provided many hours of assistance in collecting and compiling the profile and sediment data. Dr Steven Elgar provided hydrodynamic data in the trough area, Dr Charles Long provided the 8-m array wave data, Kent Hathaway provided video of the beach and Dr Rob Holman provided detailed topographic maps of the foreshore. Sediment analysis was performed by Robert Jones, Chris Murhead and Amy Hampton. Sediment analysis, data reduction and graphics was performed by Johnnie Davenport, with graphics assistance by Robert Chain. Permission to publish was granted by the office Chief of Engineers

CHAPTER 304

A STUDY ON FLOW STRUCTURE AND SUSPENDED SEDIMENT CONCENTRATION OVER SEAWEED BED

Gozo Tsujimoto

ABSTRACT

Numerical calculation of flow structure and the suspended sediment concentration over seaweed bed under surface wave is conducted using the $k-\varepsilon$ turbulence model. Velocity distribution and suspended sediment concentration over seaweed bed, which is made of a plastic sheet, are measured by use of the electromagnetic current meter and a turbidity meter, respectively.

The characteristic phenomenon such as the vortex formation over seaweed bed is simulated and the calculated vertical profile of suspended sediment concentration is similar to that of experiment. The value of drag force coefficient of seaweed is a few times larger than that of rigid seaweed.

I. INTRODUCTION

Seaweed bed in the sea is an important ground for fishes and shellfishes as nursery ground. So method for artificial seaweed bed creation and technique for selecting appropriate site have been studying. But there are many problems to be resolved. One of them is to understand the mechanism of sediment transport induced by the wave motion and the seaweed motion. The seaweed acts against the water body in motion as the drag force, and the flow mechanism is so complicated by that.

Also a study on wave attenuation and control of sediment transport by using the flexible artificial seaweed a like plastic sheet have been investigated recently. This paper presents an experimental approach and a numerical approach on a study of the flow mechanism and the concentration profile of suspended sediment over seaweed beds.

Dr. Eng., Associate Professor, Dept. of Civil Eng., Kobe City College of Tech., 8-3, Gakuen-Higashimachi, Nishiku, Kobe, 651-21, Japan

II. EXPERIMENTAL METHOD

The experiment was performed in a water tank which was 18m long, 0.6m wide and 1.0m high. Since the seaweed motion in the field is very complicated, an artificial flexible roughness element like a plastic sheet is used as the seaweed in this experiment (from now on, it is called seaweed). The plastic sheet is cut at space of 1mm to 10cm in the length, being placed at the bed. Number of seaweed and its settling space were made to change and eight test runs were performed as summarized in Table 1.

For each of the eight test run, capacitance wave gages were used for the measurement of the free surface elevations, the electromagnetic current meter for that of velocity and the turbidity meter for that of suspended sediment concentration. Sand with diameter of 0.014mm was used as bed materials. The bed material was placed in a uniform thickness of 8cm at the tank bottom, about 2.5m long and 0.4m wide. Also the natural frequency of used seaweed is measured by using the oscillating plate, and its value is between 4.5 and 5.5Hz. The output voltages of their measured values were transmitted to personal computer. In table 1, "u" stands for horizontal velocity, "w" for vertical velocity, "c" for concentration, "H" for wave height and "S" for settling space of seaweed. In the follow figures, the settling position of seaweed is marked as "↑" and the wave phase is set to be zero when the flow direction over the seaweed on the offshore side is changed from offshore to onshore.

Table-1 Experimental Conditions

8	4.3	21	1.22	20	3	u,w

III. EXPERIMENTAL RESULTS

3.1 Velocity vector

Figure 1(a) and 1(b) shows the measured velocity over the seaweed without its motion at the wave phase of $t/T=0.25$ for run No.2 and over the seaweed with its motion at that of $t/T=0.5$. A blank space in fig.1(b) shows no data because of the limitation in measurement system. It is thought that formation of vortex over the vertical plate (like fig.1(a)) under the wave motion is seen at the wave phase of a wave crest. Meanwhile the vortex in fig.1(b) with the seaweed motion is formed over seaweed beds at the wave phase when the

flow direction change from onshore to offshore. There is a phase lag of $\pi/2$ on the formation of vortex between both fig.1(a) and (b) and the location of vortex formation in fig.1(b) is lower than that of fig.1(a), and after the vortex in fig.1(b) is expected, following the motion of the free surface.

Fig.1(a) Velocity profile over seaweed without motion for run 2

Fig.1(b) Velocity profile over seaweed with motion for run 2

Fig.2. Velocity profile over three seaweed with motion for run 8

Figure 2 show the velocity profile for run No.8. The vortex formation is not seen clearly near the top of seaweed. The counter clockwise vortex, however, is formed over the seaweed bed in the onshore side when the flow direction changes from onshore to offshore and its scale is smaller than that of fig.1(b). Also the other clockwise vortex around there is seen. It is thought that the flow filed produced by the seaweed motion before the half period forms a wavy boundary layer along the top of seaweed, producing this clockwise vortex.

3.2 Steady velocity

Figure.3 shows the measured velocity averaged over a wave period for No.8. The flow profile near the top of seaweed is oscillated wavy. The velocity toward upward direction just over seaweed and the velocity toward downward direction between the seaweed are seen,

Fig.3 Steady velocity over seaweed for run 8

respectively, so that these flows form a set of circulation flow, having a large scale which compares with the scale of depth. It, therefore, has a effect on the suspension mechanism of sand particles close to the bed among the seaweed. These phenomena are seen in the case of run No.7, too. No vortex, however, is formed for run 4 and 5 in which the distance between both seaweed is half of run 7 or for run No.1,2 and 5 in which the number of seaweed is only one.

3.3 Suspended sediment concentration

It is known that there are three types of the distribution patterns of sediment concentration in the vertical direction, i.e. concave, convex and linear. Under non-breaking wave field, a region of high concentration is produced close to the bed due to the separated vortex over sand ripples and away from the bed surface the mean value of concentration is decreasing.

Figure 4 shows the vertical distribution of mean concentration for run 3 and in which the numbers show the distance from the settling position of seaweed. The distribution patterns of present study, as shown in fig.4, are concave with the turning point in the middle of depth, away from there all profiles reach a constant value. Those are not seen under non-breaking wave condition. Because no turbulent kinematics energy is supplied from the

upper layer unlike the breaking wave and the flow filed by wind shear stress(e.g., Nielsen 1985; Tsujimoto et al.1995). It is thought that the turbulent kinematic energy generated by separated vortex near the top of seaweed can picks up the sand particles from the bed. Especially the separated vortex on the onshore side is conspicuous, having a large scale in space, so that it exerts the major effects on the suspension mechanism of sand particles. Also sand ripples have been formed at the bottom through eight runs.

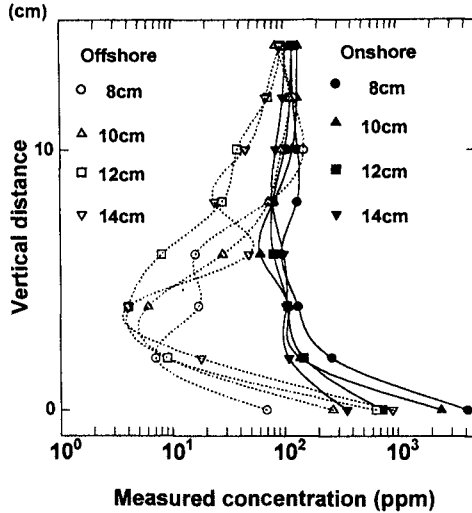

Fig.4 Measured mean concentration of suspended sediment

IV. NUMERICAL APPROACH

4.1 Previous study

Although there are many studies on the flow field with the substance in motion like seaweed, few have considered the mechanism of turbulent flow and sediment transport under wave motion. Asano et al.(1988) investigated the wave damping by using the artificial vegetation. Tsujimoto(1992) studied the mechanism of turbulent flow over an artificial seaweed field using the $k-\epsilon$ turbulent model. The agreement between the calculation and experiment, however, is not satisfactory.

These approaches are characterized by considering the effects of seaweed in the momentum equation as drag force. To calculate the turbulent flow filed over the seaweed bed, the turbulent productions and its dissipation by the seaweed motion should be modeled. There, however, is less knowledge on the production mechanism of turbulence over the seaweed bed under the wave motion and it is not easy for accurate determination on drag coefficient when drag force is adapted in the momentum equation.

4.2 Basic equation

The basic equations describing fluid motion consist of the continuity equation, momentum equations, diffusion equation of suspended sediment and conservation for

turbulent kinematic energy k and its dissipation rate ε . These equations are the same equations as author's used(1991) on calculation of suspended sediment over sand rippled and the effects of seaweed motion includes directly in the calculated grid without estimating that as drag force. These equations are written as follows:

For the continuity

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

For the momentum equation in x-direction

$$\begin{aligned} \frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uw}{\partial z} = & -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial z^2} \right) + \frac{\partial}{\partial x} \left(2\nu_t \frac{\partial u}{\partial x} \right) + \\ & \frac{\partial}{\partial z} \left(\nu_t \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \right) \end{aligned} \quad (2)$$

For the momentum equation in z-direction

$$\begin{aligned} \frac{\partial w}{\partial t} + \frac{\partial uw}{\partial x} + \frac{\partial w^2}{\partial z} = & -\frac{1}{\rho} \frac{\partial p}{\partial z} + \nu \left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial z^2} \right) + \frac{\partial}{\partial z} \left(2\nu_t \frac{\partial w}{\partial z} \right) + \\ & \frac{\partial}{\partial x} \left(\nu_t \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \right) \end{aligned} \quad (3)$$

For the diffusion equation of the suspended sediment

$$\frac{\partial c}{\partial t} + \frac{\partial uc}{\partial x} + \frac{\partial wc}{\partial z} = -\frac{\partial}{\partial x} \left(\left(\nu + \frac{\nu_t}{\sigma_s} \right) \frac{\partial c}{\partial x} \right) + \frac{\partial}{\partial z} \left(\left(\nu + \frac{\nu_t}{\sigma_s} \right) \frac{\partial c}{\partial z} \right) + \frac{\partial w_o c}{\partial z} \quad (4)$$

For k-equation

$$\frac{\partial k}{\partial t} + \frac{\partial uk}{\partial x} + \frac{\partial wk}{\partial z} = -\frac{\partial}{\partial x} \left\{ \left(\nu + \frac{\nu_t}{\sigma_k} \right) \frac{\partial k}{\partial x} \right\} + \frac{\partial}{\partial z} \left\{ \left(\nu + \frac{\nu_t}{\sigma_k} \right) \frac{\partial k}{\partial z} \right\} + P - \varepsilon \quad (5)$$

For ε -equation

$$\frac{\partial \varepsilon}{\partial t} + \frac{\partial u\varepsilon}{\partial x} + \frac{\partial w\varepsilon}{\partial z} = -\frac{\partial}{\partial x} \left\{ \left(\nu + \frac{\nu_t}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial x} \right\} + \frac{\partial}{\partial z} \left\{ \left(\nu + \frac{\nu_t}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial z} \right\} + \quad (6)$$

$$C_{1\varepsilon} \frac{\varepsilon}{k} - C_{2\varepsilon} \frac{\varepsilon^2}{k}$$

$$P = 2\nu_t \left\{ \left(\frac{\partial u}{\partial x} \right)^2 + \left(\frac{\partial w}{\partial z} \right)^2 \right\} + \nu_t \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right)^2 \quad (7)$$

$$\nu_t = c_\mu \frac{k^2}{\varepsilon} \quad (8)$$

where x and z are the horizontal axis and the vertical axis, respectively, u and w are velocity in x and z direction, p is the pressure, ρ is the fluid density, ν and ν_t the

molecular and eddy viscosities, c is the suspended sediment concentration, w_0 is the fall velocity of the sediment particle and the constants in these equations are set at the values proposed by Rodi(1980) as given as follows:

$$C_{\mu} = 0.09, C_{1\epsilon} = 1.44, C_{2\epsilon} = 1.92, C_{3\epsilon} = 1.00, \sigma_k = 1.00, \sigma_\epsilon = 1.3, \sigma_t = 1.00 \quad (9)$$

The natural frequency of seaweed is different from that of the experimental wave, so that the oscillation period of seaweed was set to be the same as wave's. The seaweed motion should be coupled from the wave motion in a strict sense, but the experimental value of velocity of seaweed motion are used herein.

There is no relative velocity in the normal direction to the surface of seaweed, and it is given by the following equation;

$$Vn = V'n \quad (10)$$

where n is a unit vector in the normal direction to the seaweed surface, V is the velocity of water particle and V' is the velocity of seaweed motion. The values of V' are given by the displacement of seaweed per a second in the horizontal direction. The displacement of seaweed in the vertical direction is assumed so small that the vertical velocity can be neglected. The boundary conditions at seaweed surface on the turbulent kinematic energy k and its dissipation rate ϵ are the same as that at the bottom and the concentration is set to be zero there. Other boundary conditions are the same as author's(1991).

4.3 Method of calculation

The conditions of calculation are equivalent to that of the experiment as given in Table 1. Forty elements in the vertical direction are used and the number of element in the horizontal direction is changed from forty to one hundred twenty depended on number of seaweed and a fine mesh scheme is employed near the seaweed. The calculation was conducted to investigate the effect to the flow structure when the phase lag between the wave motion and the seaweed motion and the height of seaweed were changed.

V. CALCULATED RESULTS

5.1 Steady flow

Fig.5 Calculated steady velocity

Figure 5 shows a steady velocity for run 8. The wavy flow near the top of seaweed and the vertical circulation flow between the seaweed are seen as shown in the experimental results (e.g. figure 3). These values are about 20cm/sec and approximately the same value as the experimental one. The calculated values of vertical downward direction, however, are smaller than the experimental values.

5.2 Velocity profile and suspended sediment concentration

Figure 6(a) and (b) show the calculated results on velocity and concentration for run 6. The separated vortex is not seen at the wave phase when a wave crest passes over the seaweed and the wavy flow is only formed near the top of seaweed. So the value of suspended sediment concentration is still low. The suspended sediment cloud is transported from the offshore side to the top of seaweed, but it has little sand particle. A small separated vortex is formed near the top of seaweed for fig 6 (b), but the suspended sediment between the seaweed could not be transported to the upper layer.

Fig.6(a) Calculated velocity and suspended sediment concentration for run 6

Fig.6(b) Calculated velocity and suspended sediment concentration for run 6

Figure 6(c) shows the calculated results at the same wave phase as that of figure 6 (b) for run 8. The settling space of seaweed in this figure is two times longer than that of figure 6(b). Since the separated vortex grows easily in size, much suspended sediment are transported to upward from the bed. The results of this figure gives an evidence that the settling space of seaweed is very important for suspended sediment transport.

Fig.6(c) Calculated velocity and suspended sediment concentration for run 8

5.3 Suspended sediment concentration

Figure 7 shows the calculated vertical distribution of suspended sediment concentration averaged over a wave period, in which the number shows the distance from the position where the seaweed is located. The value of suspended sediment concentration close to the bed is lower than that of experiment, as the effects of sand ripples are not considered in the present calculation. The calculated results around the top of seaweed are close to the experimental values.

Fig.7 Calculated mean suspended sediment concentration for run 2

The suspended sediment concentration decreases lineally with increasing distance from the bed, whereas away from there it attains a constant value and the distribution pattern is concave. Also a certain level where the slope of the vertical distribution of the sediment concentration changes is approximately equal to the height of seaweed.

5.4 Vorticity

The experimental distribution of vorticity is shown in figure 8 for run 2. The vortex with negative sign at the preceding half period and the vorticity with positive sign at the next half period are seen near the top of seaweed.

Fig.8 Contour lines of measured vorticity for run 2

Fig.9 Contour lines of calculated vorticity for run 6

It is thought that the vorticity with positive sign is dominant at this phase; but the seaweed is oscillated at the same frequency of that of water particles toward the same direction, and the vorticity with positive sign are produced late. The similar results are obtained in the present calculation (no figure). The calculated results are shown in figure 9 for run 6. Each vorticity are combined among the seaweed, and they does not grow in size.

5.5 Coefficient of drag force

In the present study the effect of seaweed to the flow mechanism is considered by given the velocity of seaweed motion to calculated mesh. The seaweed field should be considered as the drag force averaged in space in the field, and the estimation on the coefficient of drag force are very important.

Hydrodynamic force $F(t)$ at the each wave phase is calculated by integrated the calculated hydraulic pressure along the seaweed surface, being separated into the drag force and the inertia force as shown eq.(11).

$$F(t) = \frac{1}{2} C_D \rho A u(t) |u(t)| + C_M \rho V \frac{\partial u(t)}{\partial t} \quad (11)$$

in where $u(t)$ is the horizontal velocity just over seaweed close to the free surface, C_D is the coefficient of drag force, C_M is the coefficient of inertia force, A and V are the reference area and volume, respectively. As shown by Ishida(1988), the values of C_D and C_M are assumed to be constant between the adjacent phase and eq.(11) is solved by using the simultaneous equations.

Figure 10 shows the variation of the horizontal velocity and the coefficient of drag force over both the seaweed and the fixed seaweed for run 2. The coefficient of drag force reaches the biggest value at the wave phase when the flow direction changes from onshore to offshore and constant value at other wave phase. Also its value over the seaweed is bigger than that over the fixed seaweed. The drag coefficient C_D is changeable at the each phase, varying from the used value of horizontal velocity. The drag coefficient C_D is generally estimated by the number of the Keulegan-Carpenter number at the wave phase when the wave crest or the wave trough passed over the reference point, when the drag force become maximum.

Fig.10 Time history of drag force and horizontal velocity

It is shown through the experiment that the wave phase lag between the seaweed motion and the wave motion is $\pi/2$. The wave phase lag is varied from the wave condition and kinds of seaweed. Figure 11 shows the relationship between the drag coefficient C_D and K.C. number when the wave phase lag between the seaweed motion and the wave motion is changed from 0 to $3\pi/2$. With increasing the value of KC number, the value of KC number attains to about 5. That is similar to Ishida's results, who measured the wave force acting on a pile structure.

Fig. 11 Drag coefficient and KC number

VI. CONCLUSIONS

The seaweed bed is made of a plastic plate which is oscillated symmetrically with the wave motion and the flow mechanism and suspended sediment concentration over the seaweed bed were investigated by an experimental approach and a numerical simulation. The wavy flow near the top of seaweed and the vertical circulation flow which compared with the scale of water depth are produced by the seaweed motion, respectively. As the separated vortex is formed at the middle of depth, the value of suspended sediment concentration reaches a constant one or increase by the turbulence kinematics energy. That can not be seen under the non-breaking wave.

The turbulent calculation considered the existence of seaweed in the calculated mesh showed as follows:

- 1) The separated vortex over the seaweed is formed later than that over the fixed seaweed.
- 2) The value of suspended sediment concentration attains a constant value away from the bed.
- 3) The settling space between the seaweed and the wave phase lag between wave

motion and seaweed motion have a major effect on the flow mechanism.

- 4) The value of drag coefficient C_D of seaweed estimated as the drag force is several times larger than that of a plate(2.01).

ACKNOWLEDGEMENT

This experiment work was conducted at Kobe City College of Technology. The author wish to express thanks to graduate students; Y.Nagao, H.Arima, Y.Ito and Y.Masuda. A part of this study is supported by the Grant in Aid for Science Research Ministry of Education.

CHAPTER 305

An Energetics Approach for Suspended Sand Transport on Macrotidal Ridge and Runnel Beaches

George Voulgaris¹, Travis Mason² and Michael B. Collins²

Abstract

High frequency observations of hydrodynamics and suspended sediment concentration were acquired from the intertidal zone of a macrotidal ridge and runnel beach. The hydrodynamic data from the electromagnetic current meters were used to calculate sediment transport rates according to Bailard's (1981) energetics model. Additionally, suspended sediment fluxes were calculated for the period of data collection. The contribution of long waves, short waves and mean currents to suspended sediment transport was examined. Application of the energetics model suggested that suspended sediment is the dominant mode of transport. Further, it showed that the waves define net sediment transport rate and direction. However, the measurements revealed that the transport due to mean currents was dominant. The discrepancy between the model and measurements was attributed to vortex ripples which were developed in the intertidal zone. Bailard's model failed to predict the oscillatory mode of transport but it was found to predict accurately the mean mode of suspended sediment transport assuming an efficiency factor value of 0.021 is used in the calculations.

Introduction

Sand resuspension under the action of waves and currents is the primary process controlling seabed erodibility. Successful parameterization of this mechanism is the key element for the development of accurate and predictive morphological models. Presently, Bailard's (1981) sediment transport formula is considered one of the best theoretical models for time-dependent, cross-shore sediment transport (Schoonees and Theron, 1995) and is widely used for the prediction of changes in the coastal zone (*e.g.* Scott *et al.*, 1991). The model is based on the importance of various moments of the fluid velocity in determining transport rates. Previous studies examined the various velocity moments

¹Woods Hole Oceanographic Institution, Woods Hole, MA 02543, U.S.A.

²Department of Oceanography, University of Southampton, Southampton Oceanography Centre, European Way, Southampton, SO14 3ZH, U.K.

under either wave (*i.e.*, Guza and Thornton, 1985; Russell *et al.*, 1995) or steady current dominating conditions (*i.e.*, Thornton *et al.*, 1996). Ridge and runnel beaches, however, are found throughout areas with moderate wave conditions (short-fetched seas) and high tidal ranges (King and Williams, 1949; Orford and Wright, 1978). The combination of high tidal currents and moderate wave activity invalidates the assumptions of the previous investigators regarding the dominant forces (*i.e.* waves or steady currents).

In this contribution, high frequency measurements of instantaneous currents and suspended sediment concentration were obtained on a macrotidal ridge and runnel beach. The data collected are used to: (i) examine determine the relative contributions of long waves, short waves and mean currents to suspended sediment transport; (ii) evaluate the energetics sediment transport model (Bailard, 1981) and velocity moments for macrotidal conditions; and (iii) calibrate the energetics model for suspended sand transport.

Energetics Model

Bagnold's (1966) energetics-based total load sediment transport model for streams has been used as a basis for the development of a model of time-varying transport over a plane sloping bed. The idealised equation for the total (*i.e* bedload and suspended load, $\langle I_t \rangle$) time-averaged immersed weight sediment transport is given by Bailard (1981):

$$\begin{aligned} \langle \vec{I}_t \rangle = & \rho C_f \frac{\epsilon_b}{\tan\phi} [\langle |\vec{U}_t|^2 \vec{U}_t \rangle + \frac{\tan\beta}{\tan\phi} \langle |\vec{U}_t|^3 \rangle \vec{i}] \\ & + \rho C_f \frac{\epsilon_s}{W} [\langle |\vec{U}_t|^3 \vec{U}_t \rangle + \frac{\epsilon_s}{W} \tan\beta \langle |\vec{U}_t|^5 \rangle \vec{i}] \end{aligned} \tag{1}$$

where W is the sediment fall velocity; ϵ_b and ϵ_s are the bed load and suspended load efficiency factors, respectively; β is the local bed slope; ϕ is the angle of internal friction of the sediment; i is the unit vector in the down-slope, offshore (-x) direction; and U_t the total instantaneous velocity.

The above general model has been analysed into the cross-shore ($\langle I_x \rangle$) and longshore ($\langle I_y \rangle$) components for application with random waves (Guza and Thornton, 1985):

$$\begin{aligned} \langle I_x \rangle = & \rho C_f U_m^3 \left\{ \frac{\epsilon_B}{\tan\phi} \cdot [\psi_1 \cos\alpha_1 + \delta_u^3 + \delta_u \left(\frac{1}{2} + \cos^2\alpha_2 + \delta_u^2 \right) + \delta_u \sin\alpha_3 \cos\alpha_3 \right. \\ & \left. + \frac{\tan\beta}{\tan\phi} u^3 \right\} + \frac{U_m}{W} \epsilon_s [\psi_2 \cos\alpha_5 + \delta_u \cdot u^3] + \frac{U_m^2}{W^2} \epsilon_s^2 \tan\beta \cdot u^5 \end{aligned} \tag{2}$$

$$\begin{aligned} \langle I_y \rangle = & \rho \cdot C_f \cdot U_m^3 \cdot \left\{ \frac{\epsilon_B}{\tan\phi} \cdot [\psi_1 \sin\alpha_1 + \delta_v^3 + \delta_v \left(\frac{1}{2} + \sin^2\alpha_2 + \delta_u^2 \right) \right. \\ & \left. + \delta_u \sin\alpha_3 \cos\alpha_3 \right] + \frac{U_m}{W} \epsilon_s [\psi_2 \sin\alpha_5 + \delta_v \cdot u^3] \end{aligned} \tag{3}$$

where U_m is the oscillatory velocity (rms) amplitude. δ_u and δ_v are the steady current strength for the cross-shore and longshore directions defined as \bar{u}/U_m and \bar{v}/U_m , respectively. The most important normalised velocity moments are:

$$\psi_1 = \frac{\langle |\vec{U}_t|^2 (u_{osc}, v_{osc}) \rangle}{U_m^3} \quad (4)$$

$$\psi_2 = \frac{\langle |\vec{U}_t|^3 (u_{osc}, v_{osc}) \rangle}{U_m^4} \quad (5)$$

where the symbols $\langle \rangle$ denote a time-averaged quantity. The velocity components are decomposed into an oscillatory (u_{osc} , v_{osc}) and a mean (\bar{u} , \bar{v}) part, so that:

$$|\vec{U}_t| = \sqrt{u_{osc}^2 + v_{osc}^2 + \bar{u}^2 + \bar{v}^2 + 2(u_{osc} \bar{u} + v_{osc} \bar{v})} \quad (6)$$

The definitions of the remaining parameters can be found in Guza and Thornton (1985, see page 251, eqns 35 and 36). Briefly, α_n ($n=1$ to 5) are the angles associated with the directional characteristics of the various flow moments, while u_3^* and u_5^* are the odd moments of the total instantaneous flow, integrated over the whole wave period. Application of the above model requires information on the moments of the instantaneous velocity field.

In order to obtain a quantitative prediction of immersed weight sediment transport rate, values for the drag coefficient (C_D) and the efficiency factors are required. Bowen (1980) proposed a value of 0.005 for the drag coefficient. Here, the drag coefficient is determined by the flow conditions as function of the ratio z_r/h (Soulsby *et al.*, 1993). The efficiency factors used in this model are known to depend on factors such as flow conditions (laminar or turbulent, steady or unsteady, etc), and the grain size characteristics of the sediments. A list of various suggested values is presented in Table 1.

Author	Bedload	Suspended load
Bagnold (1966), steady flow	0.13	0.010
Bailard (1981,1982) longshore	0.21	0.025
Bailard (1981,1982), cross-shore	0.10	0.020
Bowen (1981), cross-shore	$0.15 \tan \phi$	0.010

Table 1. Efficiency parameter values proposed by various investigators.

Guza and Thornton (1985) applied field data to Bailard's cross-shore sediment transport model to determine the dominant terms in the bedload and suspended load modes. They concluded that suspended load dominates sediment transport processes and

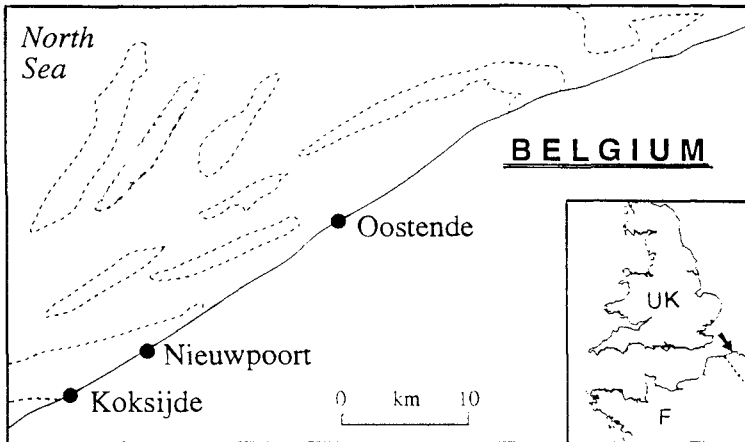

Figure 1. Location of experimental site.

that the normalised velocity moments ψ_2 and $\delta_u u_3^*$ are the most important terms, representing the contribution of the oscillatory and mean flow to suspended sediment transport, respectively.

Bowen (1980), Roelvink and Stive (1989), and Russell et al (1996) have extended Guza and Thornton's (1985) work by examining the relative importance of the long, short period oscillations and mean flow to cross-shore suspended sediment transport. Their analysis was based on the assumption that the longshore currents are much smaller than the orbital velocities ($\bar{v} \ll U_m$). On the other hand, Thornton et al. (1996) presented an expansion of equation (1) which is based on the assumption that mean currents dominate the flow.

Macro-tidal ridge and runnel beaches are found though, throughout areas with moderate wave conditions (short fetched seas); this, combined with the high tidal currents invalidates the assumptions used by the above investigators. In the present analysis the velocity terms of eqns (2) and (3) are examined, assuming that both waves and currents are of equal importance. In addition, almost all of the above studies concentrated on the cross-shore direction only. Due to the importance of the longshore tidally-induced currents found on ridge and runnel beaches it is considered appropriate that both horizontal components (cross-shore and longshore) should be included in the velocity moments analysis.

Experimental Site - Data Collection

The field measurements were obtained at Nieuwpoort-aan-Zee, situated some 13km southwest of Oostende (Fig. 1), from 20th February to 4th March 1994 (Julian days 51-63). The experimental site was outside the influence of any man-made obstructions, such as groynes which are typical elsewhere. The sediment is well sorted, fine/medium sand (mean grain size 0.183mm); at the time of the observations the average beach slope ($\tan\beta$) was 0.012 with an intertidal zone of between 250 and 500m wide. The

Figure 2. Cross-sectional profile of the intertidal zone and locations of instrument stations (A, B, C and D).

experimental site exhibited typical ridge and runnel beach characteristics (Fig. 2) with up to five well defined ridges exposed at low tide.

Tides in this area are semi-diurnal with a large neap to spring variation of 2.7 to 6.5m during the deployment period. Offshore currents are characterised by elongate and asymmetrical tidal current ellipses, with a northeasterly directed residual flood displacement controlling the sub-tidal sediment transport pathways (De Moor, 1991).

The wave climate of the area is typical of short-fetched seas with wave periods 3 to 6s. However, typical wave periods recorded during the deployment period were between 4 and 12 seconds with offshore wave heights of the order of 0.5 to 1m. Dominant offshore wave direction, extracted from wave hindcasting modelling (U.K. Meteorological Office), is primarily from the west-southwest (23% of the time) and secondarily from the north-northeast (10% of the time).

Four instrumented stations were deployed in the intertidal zone (Fig. 2). The instruments deployed consisted of electromagnetic current meters (Stations A, B, C and D), pressure transducers (Stations B, C and D) and optical backscatter sensors (OBS) for measuring instantaneous suspended sediment concentration (SSC, Stations C and D). The OBS data obtained from station C were of too poor quality to be used for analysis. Therefore, the results presented here are based on the data collected at Station D which was located in the upper mid-tidal zone and on the top of a ridge with a relatively flat crest (Figure 2).

Four 2-axis electromagnetic current meters, 3 OBS sensors and a pressure transducer were deployed at station D. All instruments were cantilevered from a stainless steel pipe, set vertically into the beach sand during low water. Three of the electromagnetic current meters were arranged to measure instantaneous horizontal currents at three levels above the sea bed (21.5, 48 and 108.5cm, respectively). The fourth sensor was orientated to measure vertical currents at 70cm above the sea bed. The OBS sensors were installed at elevations 9, 19 and 34.5cm above the sea bed, respectively. Data were collected when

the instruments were fully submerged and for consecutive time intervals of approximately 17min, spanning flood, high water and ebb tide. The sampling frequency within each burst was 8 Hz.

Sediment from the deployment area was used for the calibration of the OBS sensors. A temporally variable background level of "turbidity" was observed during the data collection period. This was due to fine material in suspension, referred to hereafter as "washload", coming from Nieuwpoort Harbour. To maintain uniformity in data analysis, the offset due to this washload was determined as the 10th percentile of the sample values as suggested by Aagaard and Greenwood (1995). This was the magnitude of concentration which corresponded approximately to a significant break in the cumulative frequency of signal values and best represents the separation between the background signal and sediment resuspension events. As Aagaard and Greenwood (*op. cit.*) noted such an approach may introduce some error in computing absolute magnitudes of sediment transport rates. Laboratory experiments showed that this error is less than 10%.

Hydrodynamic and suspended sediment concentration measurements were obtained during 3 tidal cycles on 3rd and 4th March, 1994 (Julian days 62 and 63, respectively). In particular, 6 data sets (runs) were collected during the flood of the morning flood tide of Julian day 62; 9 runs during the evening of Julian day 62; and finally 12 runs were collected during the morning of Julian day 63.

Time-series of cross-shore and longshore velocity (u, v) and sediment concentration (c) were plotted to check data quality. Statistical descriptions of velocity and sediment concentration were computed (i.e mean and standard deviations). Wave characteristics were computed using the moments of the spectra of the pressure transducer signal after correcting for depth attenuation (Voulgaris, 1992). Significant orbital velocities were estimated from the standard deviation of each time-series ($U_m = (2(u_\sigma^2 + v_\sigma^2))^{1/2}$).

The total fluxes have been analysed into mean and oscillatory modes with the latter being decomposed further into fluxes due to incident short (gravity, subscript s) waves and long period (infragravity, subscript L) flow.

$$\overline{u \cdot c} = \overline{u \cdot c} + \overline{u_{osc} \cdot c_{osc}} = \overline{u \cdot c} + \overline{u_S \cdot c_S} + \overline{u_L \cdot c_L} \quad (7)$$

The mean component was calculated (by averaging the entire 17 minute record), and then subtracted from the record, to obtain the oscillatory component. The infragravity (long) component of the signal (u_L, v_L and c_L) was calculated by applying a low-pass filter (cut-off frequency 0.06Hz) to the oscillatory component. The infragravity component was subtracted from the total oscillatory component, thus giving the gravity contribution.

Local fluxes were calculated for each data run according to eqn. (7), for both the cross-shore and longshore directions and for the three elevations above the sea bed where SSC measurements were obtained. Measurements from the current meter installed at 21.5cm above the sea bed were used for the local flux calculations. Oscillatory currents were assumed to be constant through the water column whilst a logarithmic distribution was assumed for estimating the fluxes due to mean currents.

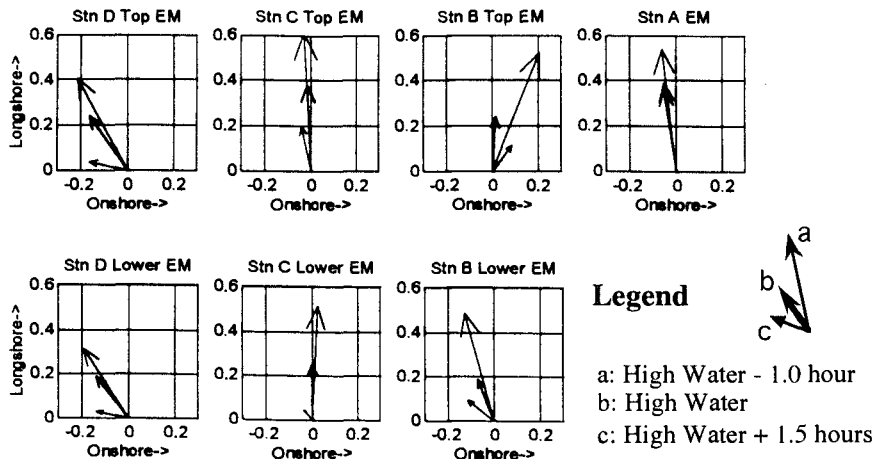

Figure 3. Vector diagrams of mean flow in the intertidal zone (for locations see Fig. 2) at 1 m (top row) and 0.2m (bottom row) above the sea bed (units in m/s).

Results

Overview of Hydrodynamics

In this section an overview of the hydrodynamic conditions in the intertidal zone is presented. This is based on observations from the whole of the experimental period. Typical mean flow patterns in the intertidal zone were found to be tidally-induced. Figure 3 shows the magnitude and direction of the mean current, for a typical tide, before (-1 hour) during and after (+1.5 hours) high water. It is evident that the dominant flow direction is consistently alongshore in the positive (northeast) direction. Maximum longshore flow occurs during the flood stage of the tide and the magnitude of the longshore current reduces as the tide progresses. Preliminary analysis of the hydrodynamic data collected indicates the this behaviour is due to bed friction which causes the longshore currents to lead the tidal elevation inshore. The mean cross-shore flow is generally offshore for all stations. An exception to this is Station B where the currents at 1 m above the bed are generally directed onshore. This station is located at the top of a ridge (see Fig. 2) where the waves exhibit their maximum asymmetry, thus this onshore flow is attributed to onshore mass transport which is balanced by an offshore flow near the seabed.

The wave climate in the intertidal zone exhibits a dependence on tidal stage (ebb, flood, see Figure 4). Local wave height is larger during the flood than during the ebb stage of the tide. This is more enhanced at the offshore stations C and D). This wave height dependence on tidal stage is the result of the interaction of the waves with the tidally-induced longshore currents. During flood, the currents are strongest and are directed toward the northeast. This results in the currents opposing the surface waves which, during the time of observation, were propagating at an angle towards the southwest. This

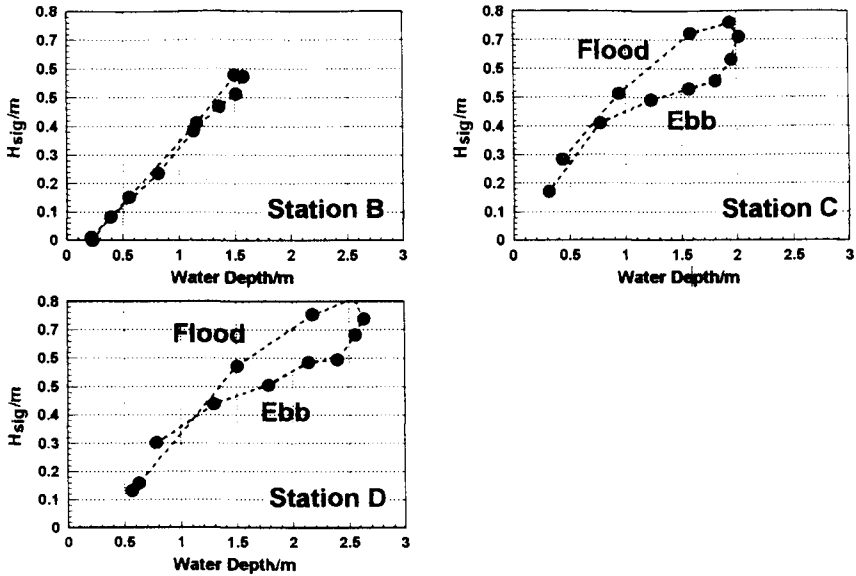

Figure 4. Tidal modulation of the local wave height (H_{sig}) for stations B, C and D (for location see Fig. 2).

opposition of waves and currents resulted in an increased wave steepness. During the ebb stage of the tide, the current strength is significantly reduced (see Figure 3), so that the interaction is much lesser, leading into less steep waves.

Velocity Moments

The relevant flow moments to sediment transport are examined in order to identify the most important terms for macrotidal beaches. Following Guza and Thornton's (1985) approach, the field flow data collected at station D from the lowest current meter are used to estimate the terms of eqns. (2) and (3).

The values of the individual terms such as ψ_1 , ψ_2 , u_3^* , u_5^* , $\delta_{||}$, δ_v and the angles α_1 , α_2 , α_3 , and α_5 have been evaluated for each run during the data collection period and the results are shown in Figure 5. The nonlinear scalar moments ψ_1 and ψ_2 are linked in the transport eqns (2) and (3) to the angles α_1 and α_5 . The moments ψ_1 and ψ_2 , (Fig. 5a) are associated with the wave asymmetry and this is why their variation through the tidal cycles corresponds to the variation in the wave orbital velocity field, as discussed in the previous section (see Fig. 4). However, in the case of a dominant cross-shore oscillatory component, the angles α_1 and α_5 in the case of a dominant cross-shore oscillatory components are expected to be around zero or 180degs (Guza and Thornton, 1985). In the present data set though α_1 varies between -10 and 10 degs with an average value of 5 degs (Figs 5d and e). The angle α_5 is around zero for the first and the last tidal cycles but achieves values of up to 20 degs during the second tidal cycle implying that a significant part of the oscillation occurs in the alongshore direction as well. However these angles are linked to the velocity

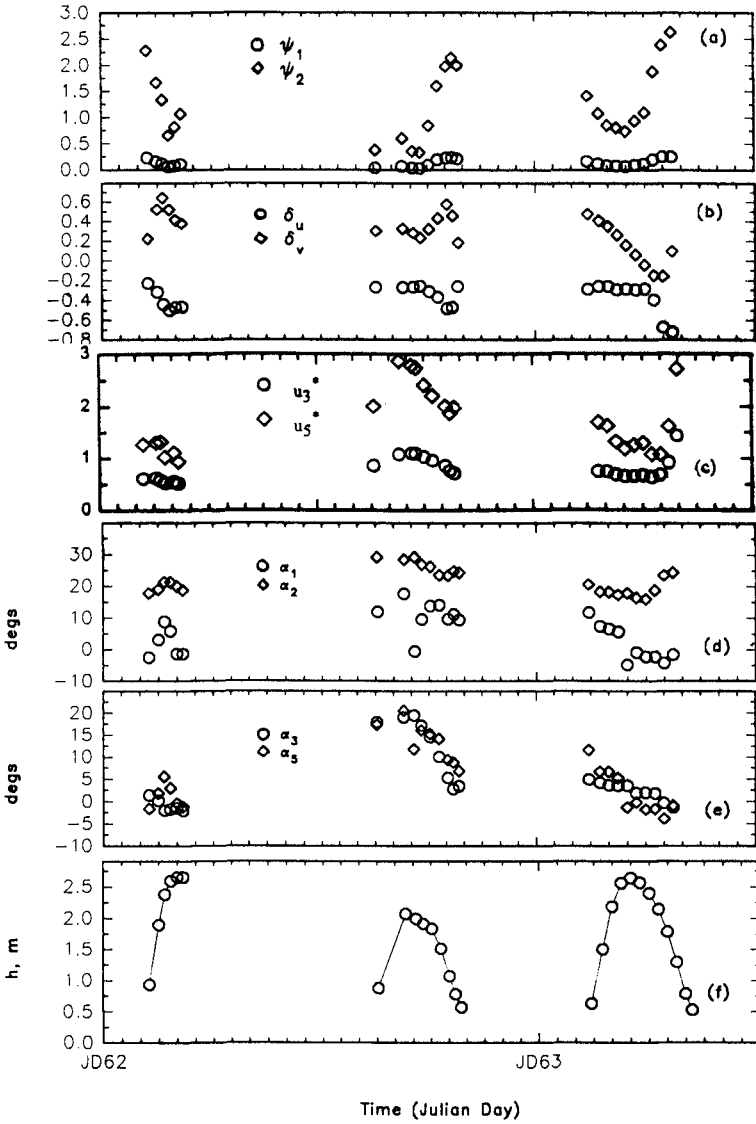

Figure 5. Velocity moment terms used in Bailatd's (1981) energetics sediment transport model (eqs (2) and (3)) as calculated from the measured current velocities from Station D.

moments through their cosine which for the extreme values of 10 and 20degs for the α_1 and α_5 , are 0.98 and 0.94 respectively; this implies that omission of these terms will involve an error of 2 and 6%, respectively in the sediment transport rate attributed to these particular terms.

The relative current strength terms δ_u and δ_v vary in accordance with the mean currents observed at the measuring station. It is characteristic that both terms are very important for ridge and runnel beaches reaching absolute values of up to 0.8 which is significantly higher than the average value of 0.01 observed by Guza and Thornton (1985).

The terms $u3^*$ and $u5^*$ express the contributions of the total currents (mean and oscillatory flow) averaged over the whole wave period. In Guza and Thornton's (1985) studies, these were dominated by contributions from the oscillatory component of the cross-shore currents only. In the present study, both oscillatory and mean currents appear to define these moments. It is characteristic that $u3^*$ is almost constant throughout the data collection period, with an average value of 2.5 (standard deviation 0.34). This value is larger than the theoretical one, derived either assuming a sinusoidal wave ($u3^*=0.42$) or a Gaussian distribution of the wave field ($u3^*=0.56$) with the latter being in good agreement with the field data collected presented by Guza and Thornton (1985). The increased value in the present data set is due to the strong mean flows present which produce an asymmetry of instantaneous flow vector during a wave cycle. The moment $u5^*$ exhibits significant variations throughout the three tidal cycles.

The relative magnitudes of the bedload and suspended load sediment transport and of each individual term of equations (2) and (3) has been examined, assuming that $\epsilon_s=0.025$ and $\epsilon_b=0.20$. Each sediment transport term in eqns (2) and (3) was calculated and then multiplied by the appropriate factor ($\epsilon_b/\tan\phi$, $U_m\epsilon_s/W$). The contribution of each term to the total sediment transport was expressed as a percentage of the total (bedload and suspended load) gross sediment transport rate, with the sign indicating direction of transport. In order to identify any differences in processes under shoaling and breaking waves the analysis was undertaken separately for broken ($H_{ms}/h > 0.20$) and shoaling waves ($H_{ms}/h < 0.20$).

Component	Mode	Term	Contribution
Cross-shore	Suspended	$\psi_2 \cos \alpha_5$	+55%
		$\delta_u u3^*$	-37%
	Bedload	$\delta_u (0.5 + \cos^2 \alpha_2)$	+15%
		$\psi_1 \cos \alpha_1$	+4%
		Others	<4%
Longshore	Suspended	$\delta_v u3^*$	+70%
		$\psi_2 \sin \alpha_5 \cos \alpha_5$	+17%
	Bedload	$\delta_v (0.5 + \sin^2 \alpha_2)$	+16%
		δ_v^3	+7%
		Others	<4

Table 2. Largest terms in energetics sediment transport eqs (2).and (3).

The results suggested that the most important mode of sediment transport is suspended load both in the longshore and cross-shore; this applies to both shoaling and

breaking wave conditions. The most important terms within each mode of transport and for each direction, together with the percentage contribution to the total gross sediment transport rate are shown in Table 2. From these results, it can be seen that suspended load accounts for more than the 80% of the gross sediment transport rate. Thus it can be argued that equations (2) and (3) can be simplified with significant predictive accuracy to:

$$\langle I_x \rangle_s = \frac{\rho \cdot C_f \cdot U_m^4 \cdot \epsilon_s}{W} \cdot (\psi_2 \cos \alpha_s + \delta_u \cdot u_3^*) \tag{8}$$

and

$$\langle I_y \rangle_s = \frac{\rho \cdot C_f \cdot U_m^4 \cdot \epsilon_s}{W} \cdot (\delta_v \cdot u_3^*) \tag{9}$$

for the cross-shore and longshore directions, respectively.

Suspended Sediment Fluxes

Local suspended sediment fluxes from station D and for the lower elevation (9 cm) of SSC measurement are shown in Fig 6 for the cross-shore direction. Mean cross-shore, suspended sediment fluxes dominate; they are directed consistently offshore with maxima occurring at the beginning and the end of the tidal cycle, in shallow water depths where the local resuspension processes are more significant. The absolute values of the mean fluxes are an order of magnitude greater than the oscillatory ones due to gravity and/or infragravity motions. Gravity fluxes are inconsistent; they are directed offshore during the first data cycle, whilst during the second cross-shore suspended sediment flux for the last tidal cycle they are contributing to an onshore flux. Finally, bed contribute to an onshore

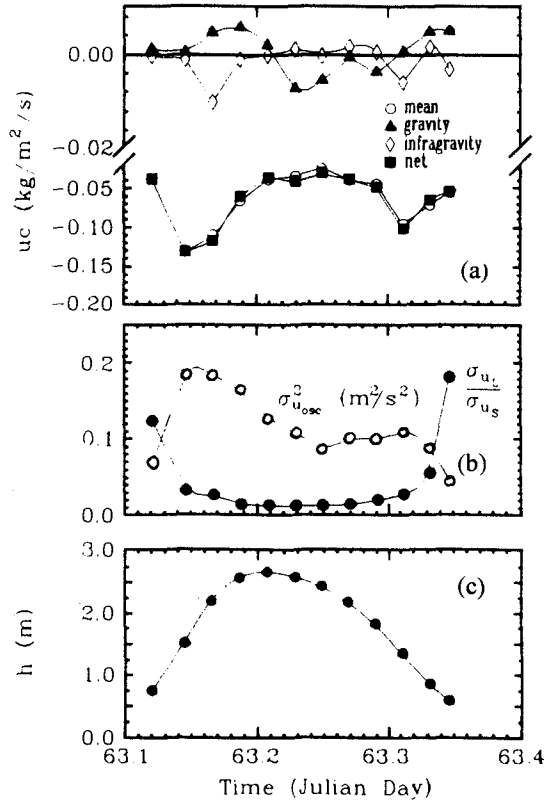

Figure 6. (a) Mean, gravity, infragravity and net local cross-shore suspended sediment flux for the last tidal cycle (Julian day 63) measured at 9 cm above the sea bed. (b) Total variance of oscillatory currents (○) and during the last tidal cycle they ratio of infragravity over gravity kinetic energy (●). (c) Local mean water depth (h).

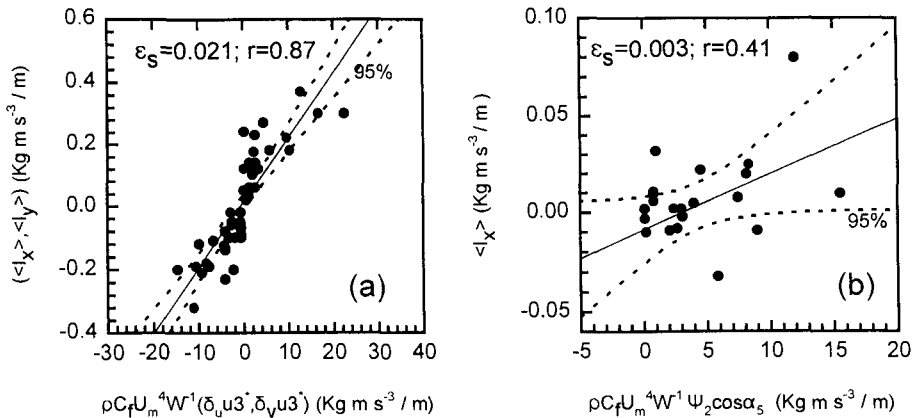

Figure 7. Comparison of measured, depth-integrated immersed weight suspended sediment transport rates with the terms of eqs (2) and (3). (a) Mean mode of suspended sediment transport (cross-shore, $\langle I_x \rangle$ and longshore $\langle I_y \rangle$ data superimposed). (b) Oscillatory mode of transport (cross-shore only).

sediment transport during the flood; during high water the flux is directed offshore and turns again to onshore at the last stage of the ebb tide. The contribution of the infragravity motions is comparable to that of the gravity waves, with the main characteristic being that when the infragravity flux is of any significance it is always directed offshore, in other cases its direction is variable.

Longshore local fluxes (not shown here) are dominated also by the mean fluxes. Both mean and net fluxes are northeasterly (*i.e.* towards the Netherlands). Gravity fluxes although an order of magnitude smaller than the mean, contribute to a northeasterly sediment transport in the direction of wave approach. However, infragravity motions, which result in a southwesterly transport during the first tide, exhibit a variability in direction during the second tidal cycle whilst during the last tidal cycle contribute to a northeasterly transport during the flood and a southwesterly flux during the ebb.

Modelling Suspended Sediment Transport

Depth-integrated values of immersed weight suspended sediment transport rates were obtained by box integrating the measured local suspended sediment fluxes (Voulgaris and Collins, 1996). The lower and upper limits for the integration were the sea bed and 0.5m above the sea bed, respectively. The general patterns observed in the local fluxes analysis were present in the depth-averaged sediment transport rates.

The terms describing sediment transport due to mean currents for both the cross-shore (2nd term in eq. (8)) and longshore directions (eq. (9)) have been combined and

plotted against the predicted mean depth-integrated flux in Figure 6a. A very good agreement was found with a correlation coefficient of 0.87. The efficiency factor (ϵ_s) was determined by regression analysis and was found to be 0.021. The oscillatory component (which is dominated by the gravity mode) of the measured cross-shore suspended sediment transport is plotted against the 2nd term of eq (8) in Figure 7b. There, it can be seen that the correlation is poor; the model always predicts onshore transport due to the waves while the measurements revealed periods of offshore sediment transport. This discrepancy is believed to be due to the presence of vortex ripples which can reverse the sediment transport direction near the bed (Vincent and Green, 1990). Visual observations, during low water, identified ripples with height 0.7cm and wavelength 8.5cm. These were asymmetrical in shape, directed offshore, with curved crests characteristic of ripples occurring under the co-existence of waves and currents. Application of the Wiberg and Harris (1994) model for the period when the intertidal zone was inundated suggested the existence of ripples with height of the order 3 to 5 cm and wavelength 10 to 20cm. The inconsistency between the modelled and visually observed ripple dimensions is attributed to the fact that the latter observations were undertaken during low water when the ripples were washed and flattened out by the swash zone.

Conclusions

In the mid-tidal zone of a macrotidal ridge and runnel beach, under mild conditions, both steady (tidally-induced) and oscillatory currents are equally important for the resuspension of sediment. Their importance is expressed not only in terms of their absolute magnitude but also in terms of wave-current interaction.

Suspended sediment transport is dominated by the mean currents

Bailards (1981) energetics model appears to predict suspended sediment transport due to mean currents quite accurately. However, it fails to predict suspended sediment transport due to wave-induced orbital velocities; this is probably due to the presence of vortex ripples.

The efficiency factor for suspended sediment transport and for the mean mode of transport was found to be 0.021.

Acknowledgments

The authors would like to acknowledge M.P. Wilkin and D.Simmonds for their invaluable assistance. The study was funded by the Commission of the European Community (DG XII) under Contract No. MAS2-CT92-0024-C (C-STAB). This contribution was prepared while G.Voulgaris was at Woods Hole Oceanographic Institution with a Post-Doctoral Award funded by the Mellon Foundation.

CHAPTER 306

Field Tests of Suspended-Load Transport Theories Used in Numerical Models

Thomas E. White ¹

Abstract

Surfzone optical-backscatter measurements were conducted at a long, straight sandy beach near Colorado River, Texas, in order to test velocity-based theories for predicting suspended-load sediment transport. Statistical methods were applied that provided estimates of theory performances, independent of any calibration or tuning of the model coefficients. The models of Ackers and White, Bowen, and Roelvink and Stive showed trends opposite that of the data (increasing transport estimates as measured transport decreased). The Bailard model performed very well in the cross-shore, explaining both the trends in transport and most of the variance, as determined by correlation coefficients. Bailard's model did not explain most of the variance in the longshore data, but comparison of the model's performance with other datasets show good correlation in the longshore. When the original coefficients in the unidirectional-flow-based Ackers and White model are used, very low transport estimates are produced. This suggests that this empirical model that was calibrated for unidirectional flows should not be used in coastal areas without considerable recalibration of the coefficients using high-quality datasets.

Introduction

A series of tests of sediment-transport theories has been performed with different data sets for different transport types:

- Bedload theories were tested with small-scale tracer experiments (White, 1987).

¹Coastal Engineering Research Center, USAE Waterways Experiment Station, Attn: CEWES-CD-P, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA

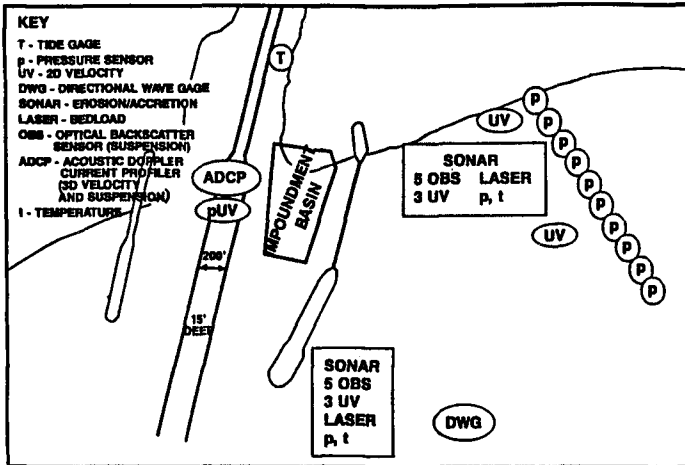

MCCCP COLORADO RIVER, TEXAS

Figure 1: Areas of deployment of each gage type. Gage platforms are not to scale, but for visualization are drawn very large relative to the jetties. The lasers were replaced by micro-OBS gages for bedload.

- The Shore Protection Manual (1984) equation for total longshore transport was tested with large-scale tracer and suspension-trap experiments (White and Inman, 1989).
- Both approximate and exact versions of the SPM longshore-transport formula were tested against each other with surfzone optical-backscatter experiments (White, 1994).
- This paper tests several suspended-load transport equations with optical-backscatter experiments.

Comprehensive arrays of 43 sensors were deployed to measure waves, currents, tides, and sediment transport at a long straight beach with gently-sloping plane-parallel contours near a river outlet, Colorado River, Texas (Figure 1).

This project of monitoring the behavior of the jetty system had several objectives. One was to identify and quantify the sediment budgets for the different parts of the system, in order to evaluate the performance of the sediment-management system of jetties, weir, and dredging (King and Prickett, 1997). Another was to evaluate longshore-transport formulas in the Shore Protection Manual (1984) by comparing the measured longshore sediment transport with the transport estimated from the offshore wave data and the SPM formulas (White, 1994). The topic of this paper is testing suspended-load transport theories at a point, in order to find the best ones to use in numerical models. This paper will describe only the results of this final objective.

Tests of sediment-transport theories can be performed in two very different means on two vastly different scales. Whether to test sediment-transport equations used in numerical models by making measurements at one point ("micro-scale") or by comparing the models' predictions of topographic change with measured topography ("macro-scale") is an ongoing debate. Since the main use of a transport theory is in a numerical model to determine changes in beach topography, one approach is to compare measured topographic change with the changes predicted from each numerical model (Schoonees and Theron, 1995). However, this method incorporates **all** error sources (e.g., grid spacing, coefficients' calibration, "skill" of the modeler, etc.) and cannot **separately** evaluate the transport theory used in the numerical model. It is possible in individual tests that these other factors have more effect than the particular theory that is in the model.

When detailed tests are made of total-load (macro) transport theories, such as the Shore Protection Manual's (1984) well-known longshore-transport formula, the error bars are huge and often larger than the measurements, so that high-confidence objective conclusions can often not be reached (White, 1994; Schoonees and Theron, 1994).

A third problem encountered in testing models with the "macro-scale" method is that individual verification tests invariably test only one model against one set of data. Schoonees and Theron (1995) point out: "Without direct comparative prototype tests the final conclusion as to which are the better models in practice cannot be given."

In this paper, such a direct comparative prototype test is outlined. This approach is to test each theory against transport measured at a single horizontal location. The theory used in the numerical model, not the model itself, is tested.

Experimental Methods

Several state-of-the-art instruments were deployed: an offshore trawler-resistant Directional Wave Gage (DWG), a puv gage of colocated pressure and current sensors, Optical Backscatter Sensors for suspended-sediment concentrations, electromagnetic current meters for velocities, a new cable with internally imbedded pressure sensors for surfzone waves, and Acoustic Doppler Current Profilers for inlet currents and sediment flux.

The surfzone transport was measured by cross-shore integration of the point measurements from three synoptic multi-sensor platform arrays of Optical Backscatter Sensors (OBSs) (Downing, Sternberg, and Lister, 1981) and Electromagnetic Current Meters (ECMs), sonars, and pressure sensors. Figure 1 shows a plan view of the site with various platforms of gages drawn in the general areas where they were deployed. The sediment concentration was measured with OBS2 optical backscatter sensors, which were each calibrated in a flow tank over a wide range of transport values. The sand from the site was sampled prior to each experiment and generally had a median size of 130 microns, with a size distri-

bution that was always single-peaked. The sand from the site was used in the laboratory to calibrate the sensors over a wide range of transport values (from 1 to 300 grams per liter), both prior to and after each of the three experiments.

The currents were measured with standard 1-inch diameter Marsh-McBirney electromagnetic probes, calibrated just prior to use. Pressure sensors were used to determine the range of vertical integration for each platform, and also times when uppermost sensors were out of the water and thus not to be used.

The sediment transport is the direct integration of the product of these two types of calibrated-sensor outputs, as measured in the surfzone:

$$\vec{i} = (\rho_s - \rho)gN_o \int_0^\eta \vec{u}(x, z)c(x, z)dz \quad (1)$$

where \vec{i} is the sediment transport at one horizontal location, ρ_s is the sediment density, ρ the fluid density, g the acceleration of gravity, N_o the solids density (one minus porosity), \vec{u} the fluid velocity, c the sediment concentration, and the integral is taken over the vertical surf depth.

The above integration is first accomplished in the vertical at each platform location by vertically integrating the values of concentration c , longshore velocity v , and vertical range z . See White (1994) for more details. It is important to note that the vertical integration is performed *at each time step of 0.2 seconds*, and is thus unaffected by phenomena with longer time periods, such as bursts of sediment out of the boundary layer. Each sensor measures at one instant, and all the instantaneous products of c , v , and z are vertically summed before moving to the next 0.2s time step.

Theoretical Methods

Theories for computing suspended-sediment transport were obtained via an extensive literature search of several hundred modeling documents (Drake and White, 1995). Five were found to be unique formulas of point transport. Other theories are either variations on these five types, or are not testable with "point" transport measurements. Such other models include (1) diffusion-based theories such as Smith (1977), Grant and Madsen (1979), and Glenn and Grant (1987); (2) the two-layer model of Dally and Dean (1984), and (3) the eddy-viscosity model of Deigaard et al (1986).

The following variables are found in common to many suspended-load theories:
 \vec{i} is the local immersed-weight sediment transport,
 ρ is fluid density, ρ_s is sediment density,
 c_f is a friction coefficient,
 e_s is a suspended-load efficiency, e_b is a bedload efficiency,
 W is sediment fall speed,
 \vec{u} is the fluid velocity,
 ϕ is the sand's angle of internal friction (related to grain size),

h is depth, H is wave height, T is wave period,

g is the acceleration of gravity,

β is the beach slope angle,

\hat{i} is the unit vector in the offshore direction,

x is the cross-shore spatial coordinate, and y is the longshore coordinate.

The value always used for the suspension efficiency was the 0.025 best-fit value found from several experiments, as published by Bailard (1981). A consensus in the literature was reached for a friction coefficient c_f value of 0.007, since to one significant figure, this was the value determined by both Thornton (1970) and Bailard's (1981) experiments.

Three of the models we tested are based on Bagnold's (1966) derivation for both bedload and suspended load in streams. Bagnold's basic concept was that the transport uses a fixed fraction of the available stream power. The derivation of Bagnold's transport relation, along with all of the assumptions may be found in Drake and White (1995).

(1) **Bowen's** (1980) suspended-load model expands Bagnold's basic stream-transport relation using two velocities, an oscillatory and a steady component. Assuming the oscillatory velocity dominates, the formula is expanded in a series and the terms retained yield:

$$\langle \vec{i} \rangle = \rho c_f \frac{e_s}{W} \left[\langle |\vec{u}|^3 \vec{u} \rangle + \frac{\beta}{W} \langle |\vec{u}|^5 \rangle \hat{i} \right] \quad (2)$$

(2) **Bailard** (1981) worked on this problem at the same time as Bowen and independently derived a similar suspended load model. Again expanding in a series and retaining terms yields:

$$\langle \vec{i} \rangle = \rho c_f \frac{e_s}{W} \left[\langle |\vec{u}|^3 \vec{u} \rangle + \frac{e_s \tan \beta}{W} \langle |\vec{u}|^5 \rangle \hat{i} \right] \quad (3)$$

As opposed to Bowen, the reason for the efficiency e_s appearing again in the second term is based on interpretations of Bagnold's claims regarding whether power is contributed through an efficiency factor. For most applications, there is no practical import as to whether β or $\tan \beta$ is used, since the slope is usually small.

(3) **Roelvink and Stive's** (1989) transport model contains transport from two different mechanisms. The stream-power based transport follows the work of Bagnold, Bowen, and Bailard. But they also include transport caused by turbulence from breaking waves:

$$\langle \vec{i} \rangle = \rho c_f \frac{e_s}{W} \left[\langle |\vec{u}|^3 \vec{u} \rangle + K_1 \hat{i} \right] \quad (4)$$

where $K_1 = \beta_d \{ k_t [\exp(h/H_{rms}) - 1]^{-1} \}^{3/2}$

(4) **Larson and Kraus'** (1989) cross-shore transport model extends the energy-dissipation model of Kriebel and Dean (1985) to predict total cross-shore

transport. They add an empirical criterion that determines the **sign** of the transport as either bar growth (offshore transport) or berm growth (onshore transport). Various datasets were used to determine an empirical dividing line between these cases. The resulting model, which forms the basis for CERC's SBEACH cross-shore numerical model is:

$$(i) = \text{sgn} \left\{ M \left[\frac{\langle H_0 \rangle}{WT} \right]^3 - \frac{2\pi \langle H_0 \rangle}{gT^2} \right\} (\rho_s - \rho)gK \left[E - E_{eq} + \frac{\varepsilon_\beta}{K} \frac{dh}{dx} \right] \quad (5)$$

when the rate of energy dissipation is greater than that for an equilibrium beach: $E > E_{eq} - \frac{\varepsilon_\beta}{K} \frac{dh}{dx}$, and zero otherwise.

H_0 is the deep wave height, T the period, W the grain fall velocity, and dh/dx is the beach slope. M , K , and ε_β are empirical constants. The quantity in the first set of brackets is used solely to determine the **direction** of transport, with M the empirical constant dividing their cases of onshore and offshore transport.

The energy dissipation is follows the work of Dean. The dissipation in general and the value for the equilibrium beach are:

$$E = \frac{1}{h} \frac{d}{dx} \left[\frac{1}{8} \rho g H_s^2 \sqrt{gh} \right]; \quad E_{eq} = \frac{5}{24} \rho g^{3/2} \gamma_b^2 A^{3/2}$$

where γ_b is the ratio between wave height and depth, and A is the profile shape parameter.

Note that the Larson and Kraus model requires substantially different measured quantities than the other models. Not only are wave heights and periods used, but their variation across the surf zone must be known.

(5) **Ackers and White's** (1973) river-transport model was not originally developed for or intended for use in an oscillatory flow. However, it has been adapted for use by the Coastal Engineering Research Center for use in modelling the fate of offshore dredge dumps. The fate of these dumps is thought to initially be governed primarily by currents rather than waves. Hence this model was used, and is now being applied to other situations where there is a strong unidirectional (current) component, such as at inlets. Since this model is seeing so many uses in the coastal region, it was included in this testing program.

The unidirectional transport in the original paper is modelled as:

$$(i) = 10^{-6} \frac{\rho_s - \rho}{\rho_s} C_g \left(\frac{F_*}{A_g} - 1 \right)^m \left(\frac{\rho_s D \bar{u}}{\rho h u_*} \right) (\rho \bar{u} h) \quad (6)$$

Some of the final parameters, such as depth h and density ρ cancel. What remains are sediment parameters (density ρ_s and size D) and fluid parameters (ρ , a velocity in the direction of transport \bar{u} , and a friction velocity $u_* = \sqrt{c_f u_T}$). The velocity u_T is the total velocity, and the velocity \bar{u} is the velocity in the direction of transport. So in the cross-shore case, the appropriate instantaneous velocities are the one that appears twice in the numerator, $\bar{u} = u$ (u being the instantaneous cross-shore velocity) and $u_* = \sqrt{c_f (u^2 + v^2)}^{0.5}$ in the denominator.

The remaining parameters are four 'numbers' used in the model. C_g is a function of grain size determined by fitting to Ackers and White's original data set:

$$\log C_g = 2.86 \log D_* - (\log D_*)^2 - 3.53; D_* = D \left[\frac{g(\rho_s - \rho)}{\rho \nu^2} \right]^{1/3}$$

where D_* is a dimensionless grain diameter. The exponent m is another empirically fit number $m = 9.66 D_*^{-1} + 1.34$, as is $A_g = 0.23 D_*^{-1/2} + 0.14$. For fine to medium sediments (suspension) the mobility number F_* is the square root of Shields' number:

$$F_* = \sqrt{\theta} = \frac{\sqrt{\rho} u_*}{[gD(\rho_s - \rho)]^{1/2}}; G_* = C_g \left[\frac{F_*}{A_g} - 1 \right]^m$$

G_* is the so-called transport parameter into which are lumped all the empirical numbers.

Statistical methods

Methods were developed to objectively judge theory performance (White, 1987). The degree of success of the developed theories can be judged by computing correlations between predicted and measured variables by objective statistical techniques. A simple linear regression is performed between measured transport (y) and transport predicted from the models (x):

$$y = mx + b; r = m \frac{\sigma_x}{\sigma_y} \quad (7)$$

where r is the correlation coefficient and σ is the standard deviation using N weighting. Negative values represent anti-correlation. The r^2 values are the fraction of the total variance in the data explained by the method.

For a selected level of confidence, say 90%, confidence limits can be computed. Since the correlation r is not a Gaussian function, it must first be translated into a variable that is Gaussian in order to compute confidence limits. The upper confidence limit is: $w^+ = w + Z/\sqrt{N(N-3)}$ where Z comes from the cumulative normal (Gaussian) distribution tables. The lower limit is computed likewise, except there is a $+$ instead of $-$ before the fraction. The quantity w is from a theorem that determined w is a Gaussian function of the correlation r : $w = \tanh^{-1} r$. The confidence limits allow us to state how confident we are that one theory performs better than another theory. Once translated back into r -space via the inverse of the above equation, we obtain a range of correlations for each theory. If the ranges in correlations r for one theory's performance do not overlap the range computed for another theory's performance, then we may conclude at the specified level of confidence that the theory with the higher r values performs better than the one with lower values. The reason for this

exercise is to show that random variation in small amounts of experimental data have not, by chance, provided an incorrect conclusion. The percent confidence specifies the probability that such incorrect conclusions have not occurred.

The statistical methods separate the issues of calibration and testing. Correlation coefficients determine the degree of success of each theory **without calibrating** to the data; confidence intervals determine which theories are better than which other theories; regression slopes determine appropriate coefficients for each of the theories, independently of the quality or goodness-of-fit issue.

Results

Experiments were performed over a two-week period in January 1992 over greatly varying wave conditions. Each experiment consisted of measurements taken each fifth of a second. The vertically integrated transports were then averaged over the recording time for the experiment, typically one to three hours. This dataset consisted of 81 such cross-shore transport and 36 longshore transport experiments.

Unfortunately, we encountered practical problems when using two of the five theories. The **Larson and Kraus** theory requires somewhat different data than the others: considerable information about wave height and period, and also cross-shore variation in these quantities. The original project had the purpose of measuring transport rates and of testing velocity-based theories. Thus such detailed wave information was not computed in the original dataset. Future work is planned to compute these quantities in order to test this theory.

The **Ackers and White** formula was used but produced extremely small values of transport, by several orders of magnitude. Numerous independent checks of the testing program failed to reveal any programming errors. Another possible explanation is that we are incorrectly surmising how to compute the different velocities required by this unidirectional-flow theory. Of course, it is also quite possible that the results are correct and suggest that such a unidirectional-flow theory was not intended for and should not be used in oscillatory flow. Since we encountered such low values in these cross-shore computations, we did not continue testing this theory with longshore data. Thus their theory does not appear in Table 3.

Correlations between theories and measurements were computed over each time period and are listed in Tables 1 and 2 for cross-shore transport and Table 3 for longshore transport. Confidence limits were also computed in order to determine how confident one can be of conclusions that one theory performs better than another.

Modifications to the theoretical transport equations may be extracted from Tables 1, 2, and 3. The slope m could be used to modify the theory's empirical coefficient or the friction coefficient c_f , *provided* a y-intercept were also added to the equation. So one might compute i from the original formula, and then $i_{new} = mi_{old} + b$.

Table 1: Correlation of Theoretical and Measured CROSS-SHORE Transports for the OUTER Surf Zone

Method being correlated with measured transport:	Measured Transport	Bowen (1980)	Bailard (1981)	Roelvink and Stive (1989)	Ackers and White (1973)
	Outer surf, top water column (number of experiments, N = 15)				
μ Mean, dynes/(cm-s)	-3833.	6178.4	-291.9	2062.5	.00003096
σ Standard Deviation, dynes/(cm-s)	8388.	16373.6	776.2	3395.1	.00008103
m, Regression Slope		-.4612	10.2	-2.2	-93015000.
b, Intercept, dynes/(cm-s)		-983.7	-854.1	778.9	-953.7
r, Correlation Coefficient		-0.900	0.945	-0.905	-0.899
r^2		0.810	0.893	0.819	0.808
Lower 90% Confidence Limit for r		-0.921	0.930	-0.925	-0.920
Upper 90% Confidence Limit for r		-0.874	0.957	-0.880	-0.873
Outer surf, mid water column (number of experiments, N = 15)					
μ Mean, dynes/(cm-s)	-3833.	181.5	-83.5	303.9	.000000982
σ Standard Deviation, dynes/(cm-s)	8388.	221.1	162.7	301.2	.000001599
m, Regression Slope		-19.9	50.7	-12.7	4192780000.
b, Intercept, dynes/(cm-s)		-219.3	397.8	13.8	1008.9
r, Correlation Coefficient		-0.525	0.983	-0.455	-0.799
r^2		0.276	0.966	0.207	0.638
Lower 90% Confidence Limit for r		-0.608	0.978	-0.547	-0.352
Upper 90% Confidence Limit for r		-0.430	0.987	-0.352	-0.750
Outer surf, bottom water column (number of experiments, N = 15)					
μ Mean, dynes/(cm-s)	-3833.	40.4	-21.8	151.0	.000000219
σ Standard Deviation, dynes/(cm-s)	8388.	55.2	40.5	157.9	.000000289
m, Regression Slope		-129.7	203.4	-45.3	27350800000.
b, Intercept, dynes/(cm-s)		1411.8	595.5	3005.1	1168.6
r, Correlation Coefficient		-0.854	0.982	-0.852	-0.942
r^2		0.729	0.964	0.726	0.887
Lower 90% Confidence Limit for r		-0.884	0.977	-0.882	-0.954
Upper 90% Confidence Limit for r		-0.817	0.986	-0.814	-0.926

The computed statistics are reported with far more significant digits than the method justifies, in order to retain digits until the rounding of the final result.

Table 2: Correlation of Theoretical and Measured CROSS-SHORE Transports for the MIDDLE and INNER Surf Zone

Method being correlated with measured transport:	Measured Transport	Bowen (1980)	Bailard (1981)	Roelvink and Stive (1989)	Ackers and White (1973)
	Mid surf, top water column (number of experiments, N = 8)

Lower 90% Confidence Limit for r		0.341	0.892	0.482	
Upper 90% Confidence Limit for r		0.488	0.923	0.606	

The computed statistics are reported with far more significant digits than the method justifies, in order to retain digits until the rounding of the final result.

Table 3: Correlation of Theoretical and Measured LONG-SHORE Transports

Method being correlated with measured transport:	Measured Bowen and Bailard Transport (same model in the longshore)	
	Mid surf, top water column (number of experiments, N = 8)	
μ Mean, dynes/(cm-s)	-48350.	-3810.0
σ Standard Deviation, dynes/(cm-s)	18563.3	3714.2
m, Regression Slope		2.205
b, Intercept, dynes/(cm-s)		-39950.3
r, Correlation Coefficient		0.441
r^2		0.194
Lower 90% Confidence Limit for r		0.209
Upper 90% Confidence Limit for r		0.626
	Mid surf, bottom water column (number of experiments, N = 8)	
μ Mean, dynes/(cm-s)	-48350.	-3796.4
σ Standard Deviation, dynes/(cm-s)	18563.	3370.2
m, Regression Slope		2.549
b, Intercept, dynes/(cm-s)		-38674.7
r, Correlation Coefficient		0.463
r^2		0.214
Lower 90% Confidence Limit for r		0.235
Upper 90% Confidence Limit for r		0.642
	Inner surf, mid water column (number of experiments, N = 20)	
μ Mean, dynes/(cm-s)	11,505.	736.9
σ Standard Deviation, dynes/(cm-s)	10,792.	761.7
m, Regression Slope		9.417
b, Intercept, dynes/(cm-s)		4564.8
r, Correlation Coefficient		0.665
r^2		0.442
Lower 90% Confidence Limit for r		0.613
Upper 90% Confidence Limit for r		0.712

The computed statistics are reported with far more significant digits than the method justifies, in order to retain digits until the rounding of the final result.

Table 4: Correlations between Model Predictions and Measured Transport

	Bowen (1980)	Bailard (1981)	Roelvink & Stive (1989)	Ackers & White (1973)
January 1992: 81 Experiments for Cross-Shore Transport				
r for outer surf, upper water column	-0.900	0.945	-0.905	-0.899
r for outer surf, mid water column	-0.525	0.983	-0.455	-0.799
r for outer surf, bottom water column	-0.854	0.982	-0.852	-0.942
r for mid surf, upper water column	-0.573	0.544	0.056	
r for mid surf, lower water column	-0.638	0.514	0.284	
r for inner surf	0.417	0.909	0.547	
January 1992: 36 Experiments for Long-Shore Transport				
r for mid surf, upper water column	0.441	0.441		
r for mid surf, lower water column	0.463	0.463		
r for inner surf	0.665	0.665		

All the correlations between models and data are summarized in Table 4. Note that many correlations are negative. This means that the **trend** in the theoretical predictions are opposite the trend in the data. (As measured transport increases, predicted transport decreases.) It does not mean that the direction of the predicted transport is opposite that of measured transport.

Conclusions

Conclusions about model performances can be made from the correlations in Table 4. For the 6 groups of 81 surfzone experiments of 1 to 3 hours length each:

1. The Bailard model performs very well in the cross-shore, predicting most of the variation in cross-shore transport.

Mean $r = 0.81$ and mean $r^2 = 0.70$ (Explains 70% of the variance)

2. The Bowen model and the Roelvink & Stive model do not predict most of the variation in cross-shore transport, and frequently predict the wrong trend (e.g., predicted transport increases as measured transport decreases). The only significant difference between the Bowen and Bailard models is a appearance of the suspended-load efficiency coefficient in the second term, caused by different interpretations of Bagnold's original work on this point by Bowen and Bailard. The results of this study are strong evidence that Bailard's interpretation is correct.

Bowen: mean $r = -0.52$ and mean $r^2 = 0.45$ (45% of the variance)

Roelvink & Stive: mean $r = -0.22$ and $r^2 = 0.36$ (**36% of the variance**)

3. The Ackers and White model performs strangely. Using the coefficients provided in their original publication and making our stated assumptions about how to compute the velocities, results in extremely low values of transport. Results show strong **anti-correlation** with the data. The most likely explanation of the anti-correlation is some local circulation pattern at the outer surf platform, since some of the other models also exhibit this anti-correlation result at that site.

Mean $r = 0.88$ and mean $r^2 = 0.77$ (**Explains 77% of the variance**)

4. The Bowen model and the Bailard model (identical in the longshore) model do not predict most of the variation in longshore transport.

Mean $r = 0.52$ and mean $r^2 = 0.28$ (**Explains 28% of the variance**)

Knowledge of the performance of this model in the longshore is by no means conclusive. Thornton reports in meetings for the Delilah/Duck94 surfzone experiments, that performance levels are similar to what we found here. But we have also tested this model in the longshore against numerous other Shore Protection Manual-type formulas and also other velocity-based formulas in another study using Nearshore Sediment Transport Study sand-tracer data at Santa Barbara, California (White and Grandon, draft). In that study this model performed excellently, with correlations around 0.9.

In another study, the main factor not included in these equations that was found to improve *local* estimates of transport, was inclusion of a sediment threshold-of-motion criterion (White, 1987; White, 1989). In comparing predictions of different local **bedload** transport theories with transport measured by sand tracer, it was found that agreement on direction of transport improved from 70% to 100% of the experiments, once a threshold criterion was added to the theory. We have included threshold subroutines in our testing program and plan to apply such criteria to these suspension models and report the results in a followup paper.

Acknowledgments

The considerable efforts in obtaining the large field data set at Colorado River were performed by the capable staff of the Prototype Measurement and Analysis Branch of CERC, including Mike Carpenter, Bill Grogg, Doug Lee, Rhonda Lofton, Bill Kucharski, Chuck Mayers, Debbie Shafer, and Kerry Taylor. The data-collection systems were designed and built by Ralph Ankeny, Bill Grogg, Gary Howell, and J. Rosati. The analysis of the surfzone time-series data and computation of measured transport were completed by Joon Rhee. Conversion of the author's testing programs to use with OBS data was performed by Rhonda Lofton. Without her considerable programming and data-organization efforts, this paper would not have been possible.

The work presented herein was performed at the Waterways Experiment Station of the US Army Corps of Engineers. Permission was granted by the Chief of Engineers to publish the results.

CHAPTER 307

Shore Protection Studies for Ras-Elbar, Egypt

John B. Herbich¹, Fellow ASCE, Abd-Elfattah Elfiky², Abd-Elmohsen Elmongy³
Ali Elbahrawy⁴, Gamal Elsaed⁵, Member ASCE

Introduction and Background of the Coastal Changes Along the Northern Coast of the Nile Delta

The northern coastline of the Egyptian Nile Delta extends some 280 km from a point 30 km west of the City of Alexandria to 30 km east of the City of Portsaid. The coastline is considered to be in a state of continuous change under the action of sea waves and currents.

Over the years the River Nile and its two main branches, Damietta and Rosetta, supplied large volumes of sediment from the mouth of these branches to the sea. This large volume of sediment exceeded the loss of sediment caused by wave and current action; thereby providing natural beach protection and excess sediment to the Nile Delta.

Construction of the Aswan Nile Dam significantly reduced the volume of sediment deposited along the Nile Delta shoreline causing severe erosion. The erosion started after construction of the first Aswan dam, the development of other dams, and the increasing diversion of the river water for irrigation purposes. After closing the Aswan High Dam in 1966, erosion along the Delta coastline accelerated considerably, resulting in loss of several beaches and blockage of estuaries and navigation channels because of accreting sediment and flooding of coastal villages. The erosion had a severe effect on the nearby agricultural areas because of salt water intrusion affecting these areas.

³Professor, Department of Civil Engineering, Ain Shams University, Cairo, Egypt.

⁴Assistant Professor, Department of Civil Engineering, Ain Shams University, Cairo, Egypt.

⁵Researcher, Department of Civil Engineering, Ain Shams University, Cairo, Egypt.

A successful shore protection management plan must be developed for the next twenty years.

Available Data and Description of the Ras-Elbar Area

Ras-Elbar is located at the Damietta branch mouth of the Nile. This popular resort beach has declined severely over the past twenty years due to extensive erosion. Many hectares of beachfront property have been lost since 1965 and erosion is continuing.

The Ras-Elbar area is only five kilometers away from the new Port at Damietta. The development of the port facilities, related industries and new town development will have a significant economic impact upon the coastal erosion at the Ras-Elbar area, and will affect tourism and industrial development in the area.

The Damietta branch of the River Nile was developed during the tenth century. The Nile sediments, directed toward the west and east sides of this branch, developed this area by wave action. The old maps show that the Ras-Elbar-Damietta promontory advanced about three kilometers in the period between 1800 and 1900. At present, the coast is retreating due to sediment supply cut off since 1966 and the permanent closures of the Faraskour Dam some 20 km south of the mouth. Since 1966 erosion has been quite active in this area. The average retreat of the Ras-Elbar Peninsula had been about 30 m/yr before the construction of the western jetty in 1941. This jetty has stabilized the northern part of the Ras-Elbar shoreline, although the rest of the coast continued to erode with a diminishing rate for a distance of 3 km west of the jetty.

In 1970 a series of three short groins were constructed to protect the eastern part of the resort. In 1982 two Dolosse embankments between groins 1 and 2, and 2 and 3 were constructed. The Ras-Elbar nearshore region showed continuous deepening of the water depth and steepening of its underwater shore slope.

Mathematical Studies and Procedure

Computer hardware. The computer used in this study was an IBM 486 DX2 with a 66 MHz clock speed, a 16 MB RAM memory, a 240 MB hard drive memory and a math co-processor. A Hewlett Packard Laser Jet IV P printer and 1 7475A plotter were used. A Numonics 1.0 x 1.20 m digitizer was used to digitize the Ras-Elbar area drawings. The above equipment was proven to be reliable within the range of this study. The average CPU time was 2 hours.

Phases of this study. This study was conducted for the purpose of establishing and examining protection plans for the Ras-Elbar area coastline and

to determine their long-term impact on the shoreline and the volume of sediment transported.

The study was conducted in four main phases. The first phase established the behavior of the initial shoreline subject to the design wave and served as a base reference.

The second phase studied the effect of a system of detached breakwaters on the behavior of the shoreline under the same wave climate conditions. The system proposed by Delft Hydraulics in 1987 was examined for comparative purposes.

The third phase studied the effect of a system of groins on the behavior of the shoreline having the same wave climate conditions.

Finally, the fourth phase evaluated the effect of a combined system of detached breakwaters and groins on the behavior of the shoreline under the same wave climate conditions. All computer runs were conducted for three wave directions.

Simulation Procedure and System Setup. The procedure was as follows:

1. The shoreline data were digitized using the Autocad release 11.0 with a digitized accuracy of 4.16 m. The digitized data were analyzed and extracted using the Quick surf-Cad based program, and the shoreline digitized data were prepared as DXF file. Ras-Elbar shoreline was digitized using Drawing No. 2 prepared by Tetra Tech Inc.
2. The wave data were prepared using the Coastal Research Institute (CRI) and the Suez Canal Authority (SCA) data recorded over various periods of time.
3. A computational program (GENESIS) (Gravens and Kraus 1992) was used to conduct the required simulation. This program was developed by Hanson and Kraus (1982).

Two major tests were conducted:

1. Conducting sensitivity and error analysis runs:
The changes in the output resulting from the intentional change in the input were examined to determine the limitations of different variables. To produce quality results, a knowledge of the sources of errors is important.
2. Conducting sensitivity analysis runs:
Compromise between the efficiency and accuracy of the numerical code while maintaining its stability. To achieve the stability analysis test, several pre-runs were conducted with various conditions and various shore-protection structure alternatives. As a result of these

runs, two parameters were fixed to maintain the stability (without losing either the efficiency or the accuracy of the numerical scheme). The time step was chosen to be 6 hours; 18,992 time steps were calculated. The number of grid cells within the simulation area reach was 60 with a grid spacing of 50 meters.

The start and setup files were selected for each run of the proposed shore plan. If the proposed plan was not successful due to the formation of tombolos, diffracting structures interaction or ineffective structure position, the file had to be redesigned until a successful run was reached. A simulation time of thirteen years was selected for each run to establish a case of relatively-stable state, undergoing minor or moderate changes. The simulation starting date was November 30, 1986, and the ending date was November 30, 1999. The results were calculated and plotted once a year. Figure 1 shows a general layout of the study area.

The following numerical model arrangement was used for all cases:

- a. the total length of simulated coast was 3 km. This length was divided into sixty equal cells, each 50 m in width.
- b. simulation starting date, November 30, 1986 and ending November 30, 1999,
- c. time step used was 6 hours with a total of 18,992 time steps per run,
- d. shoreline position was calculated and presented once a year,
- e. longshore sediment transport coefficients K_1 and K_2 selected were 0.5 and 0.25 respectively (these values are typically $0.5 K_1 < K_2 < 1.5 K_1$ for sandy beaches from experiments and experience),
- f. the depth of the offshore wave input was 10.0 m,
- g. the number of incoming calculated wave cells was four,
- h. only one wave direction was assumed,
- i. the average effective sand diameter was 0.25 mm,
- j. the average height of land above mean water level was 1.5 m, and the limiting depth of profile movement seaward was -6.0 m,
- k. average beach slope was one on twenty,
- l. it was assumed that the breakwaters and groins were impermeable structures, and
- m. it was assumed that there was no wave reflection from the structures.

Analysis

The series of runs conducted were very illustrative in showing the long-term effect of different structures on the shoreline position. The results of the simulation performed can be divided into four different groups:

1. no protection measures,

Figure 1. Ras-Elbar Study Area

2. effect of a system of detached breakwaters on the shoreline including the systems proposed by Tetra Tech, Inc. and Delft Hydraulics,
3. effect of a system of groins on the shoreline, and
4. effect of a combined system of detached breakwaters and groins on the shoreline.

For all groups, the final shoreline positions were plotted for each year until reaching a semi-equilibrium state. Relations representing the shoreline change and the average net sediment transport rate for all runs were also provided.

The breaking wave heights and angles were computed for each cell point on the grid. A figure representing the net volumetric change of sediment was prepared to indicate whether a region was gaining or losing sediment.

The different shoreline positions, longshore transport rates, and the shoreline changes from measured values were prepared for each run to illustrate the effect of different parameters and protection plans on the shoreline.

Conclusions

The results of this study were found to be reliable and applicable to a wide range of coastal engineering problems. For the Ras-Elbar area the following conclusions can be made:

1. Large fluctuations in littoral drift were noted.
2. The advantage of being able to vary wave conditions and structural protection plans was clearly apparent throughout this study.
3. A system of offshore detached breakwaters has proven to be the most efficient and reliable plan as a long-term shore protection for long reaches of the coastline.
4. Shore protection planning for a whole region was proven to be useful in providing a continuous interaction plan for the whole coastline.
5. This study has shown that increasing the number of breakwaters (from 4 to 7) for the whole region provided better results than employing a two- or four-breakwater system (Figure 2).
6. The ratio of $G = 1.5 B$ proved to provide a good estimate of the length and the gap of a system of detached breakwaters (where G = distance between two breakwaters, B = length of the breakwater). Four locations of detached breakwaters were studied (165, 294, 445 and 545 m) from the shoreline. At a distance of 294 m from shore, the breakwaters provided minimum shoreline changes. For every case there is an optimum design for the detached breakwater system that will provide minimal or moderate shoreline changes, or cause the formation of tombolos.

Figure 2. Protection of Ras-Elbar Area Shoreline - Case Numbers BW1 and BW2

7. A system of inclined and staggered breakwaters behaved in a similar manner to the parallel and continuous systems. The higher cost of constructing staggered or inclined offshore structures would make such a system uneconomical.
8. A combined system of offshore detached breakwaters and non-diffracting groins had a fairly similar result to that of using groins only. However, the higher cost involved in construction of two protection systems make it economically unfavorable. Using diffracting groins (which is more realistic) created more problems due to an overlap of the diffracted wave patterns from the groins and the breakwaters.
9. It is concluded that a complete system of detached breakwaters permits the continuation of shore sediment transport and will not affect the coast downstream of the system after equilibrium is reached. At the same time, this system breaks the energy of the incoming waves causing minimum shoreline change in the shadow zones. Sand nourishment should be considered in conjunction with a system of detached breakwaters to accelerate reaching equilibrium and assuring supply of sediment downstream of the system. Moreover the detached breakwater system tends to change the shoreline in a time-dependent manner. A fairly long time will take place to affect and cause changes in the shoreline.

Recommendations

Recommendations for future work are summarized as follows:

1. A uniform numerical grid of 50 m spacing was used, a finer grid spacing less than 50 m should be considered for refinement of the numerical plan.
2. A one-dimensional program employing constant grid spacing and time-step representations was used in this study and proved to be a flexible, reliable and economical method for shoreline change simulation. Higher order two- and three-dimensional schemes with variable grid spacing and time steps should be considered employing a mainframe computer. It should be noted in representing the physics of the flow and the sediment transport process that a compromise between the overall accuracy and the computation costs must be made.
3. As the shore protection structures employed in this study were assumed to be impermeable, consideration of the use of different coefficients of transmissions and permeability are strongly recommended.
4. Use different wave periods and wave heights to study their effect on the shoreline (only one wave height and one wave period were used in this study).

CHAPTER 308

Stabilizing Beaches Downcoast of Harbor Extensions

John R C Hsu¹ and Richard Silvester, M. ASCE²

Abstract

In geomorphological terms, the sandy shoreline of a bay downcoast of a harbor may be stable or in static equilibrium, or could be in dynamic condition, if sediment is still being supplied from upcoast or from downcoast to form a salient predicted by a static bay shape equation. Should commercial expansion demand a larger port, the general solution is to run a breakwater from the headland or existing structure. This has the potential to create a new static equilibrium beach, often with accretion in the lee which is at the expense of beach erosion downcoast. It is strongly recommended that geomorphic approach be incorporated to stabilize downcoast beaches early in the planning stage of a harbor, or as remedial measures. By creating bay beaches in static equilibrium, the potential beach erosion downcoast of a harbor will be kept to a minimum or may be prevented completely.

Introduction

As Inman (1974) has recalled, man has been interfering with river and coastal environments dated back in 1500 BC when the Minoans constructed wharves in Crete and by 480 BC as the Phoenicians built harbors along the coasts of Lebanon and Israel. Fleming (1992) has also discussed the modern history of harbor developments for fishing ports and major maritime trade. Oliveira et al (1982) has reported disappearances of towns in Portugal, as beaches eroded towards their stable shape.

Despite our current understanding of coastal processes there is a missing link as instanced by the many stories of beach erosion still reported in the technical literatures (for example, Ozaki 1964, Dunham 1965, Inman and Frautschy 1965, Herron and Harris 1966, Jordaan 1970, Sato and Irie 1970, Moni 1972, Lepetit 1976, Tanaka and Sato 1976, Nir 1982, Oliveira et al 1982, Komar 1983, Saxena 1983, Kraus et al 1984, Uda et al 1986, Gonzalez et al 1988, Kuo 1988, Moutzouris 1990).

² Honorary Research Fellow, Department of Civil Engineering, University of Western Australia, Nedlands, WA 6907, Australia

The present status of man's abilities in coastal engineering and shore protection has been well summed up by Inman (1974): "In view of man's present extensive intervention in the coastal zone, mostly based on 'brute force' technology, a careful study of the ancients' ability to work with Nature provides valuable insight for today's problems."

In spite of our great knowledge of wave kinematics and sediment movements in marine situations, engineers have not appreciated the macroscopic view of the coast as imposed by Nature. She has transported millions of tonnes of material to sea and back again in a matter of days and also moved it alongshore. More observations are necessary to ascertain the long-term stability of waterlines produced by persistent swell and the aberrations that occur during storm sequences. It is the former which is the concern of this paper.

Many researchers have recognized the effect of harbor construction on sediment transport downcoast, but without adequate quantitative prediction. Herron and Harris (1966) believed that "harbor works are the principal offenders" that have interrupted the balance of natural littoral drift existing over hundreds or thousands of years. Even so, the question of how to predict a stable shoreline in the lee of such structures remains unanswered. It is hoped this situation is overcome with the current submission and other works by Hsu et al (1993) and Silvester and Hsu (1993). In terms of the beach erosion downcoast of harbor extensions, these authors believe it is not so much a need to look back on our achievements but a need to observe natural processes in geomorphological terms and apply them.

Beaches Downcoast of Harbors

In geomorphological terms the stability of a sandy shoreline can assume a bay shape that is *stable* or in *static equilibrium* if the littoral drift is negligible or non-existent, or it can be in *dynamic equilibrium* if drift is still being supplied with sand from upcoast or from within the bay. Whilst this supply is constant the bayed beach can remain in place for decades, but should it decrease the shoreline will recede towards the static equilibrium shape, the final limit to which it will go.

If on a straight sandy length of coast a breakwater or other structure is run out to sea, the immediate result will be interception of littoral drift and the formation of a bay downcoast of the impediment. This will become further indented until sediment bypasses the new structure and dynamic equilibrium is restored. This sudden loss of land instigates the insertion of protective measures such as seawalls or groins, that are usually ineffective since man is fighting with Nature. The walls reflect waves obliquely and so generate short-crested waves (Silvester 1972; Hsu 1990) which expedite the longshore transport. On the other hand, straight groins accelerate drift by forming rip currents during storms that carry vast volumes of material offshore, there to be transmitted downcoast by subsequent swell.

Similar to the eroding beaches on straight coasts, discontinuity or interruption of sediment supply from upcoast has been considered as the main cause of beach erosion downcoast of harbors (Herron and Harris 1966, Komar 1983, Uda et al 1986). This may be attributed to the construction and extension of long breakwaters and dredging of deep access channels.

An additional factor is the potential of salient/bay formation in the lee of the breakwaters, caused by an improper alignment of a new breakwater and the

positioning of its tip. This implies that a large volume of sand is needed, often from the beach downcoast, to build up a salient in the form of a bay. In addition to the evolution of shoreline, it also causes change to the bottom topography in the vicinity of the structures (Sato and Irie 1970). The slopes of beach faces downcoast were found to become steeper with armouring units subsided in front of seawalls. (Uda et al 1986; Hsu et al 1994)

Universal Bay Shape Equation

Crenulate-shaped bays are ubiquitous, occurring as they do on oceanic margins, coasts of enclosed seas, lakes, and even river shorelines. They are indicative of Nature's way of balancing the wave energy with the sediment load to be carried. Bays have thus been maintained in the same position for thousands of years in spite of the fierce storms that hit them infrequently. But for the rocky headlands spaced along the coast, vast indentations would have been formed with the downcoast extremity almost normal to the orthogonals of the most persistent swell (Silvester 1976).

Geographers and geologists have published on bay shapes (Halligans 1906) with the first recognition of this as a stable feature by Jennings (1955), unfortunately without full knowledge of the wave action involved. Davies (1958) observed the importance of wave refraction but not diffraction. Langford-Smith and Thom (1969) noted the zeta-shaped beaches of the New South Wales coasts of Australia, without scientific analysis of their profiles. Although the crenulate shaped bays have received the attention of many scientists (Bird 1984, Carter 1988, Davis 1985, Phillips 1985, Shepard 1973, Zenkovich 1967), their stability has only been examined by engineers (Silvester 1960; Le Blond 1979; Silvester et al 1980). This geomorphic feature has existed for some thousands of years (at least since the last still stand of sealevel), but have become more indented during the past century due to the dearth of sediment for many reasons (Silvester and Hsu 1993). In this relatively short period in geologic time rivers have been harnessed, which results in less supply of sediment to the coast for spreading by wave action. This has resulted in bays approaching their static equilibrium condition, causing greatest erosion at the most indented position of the bay with practically no change at either end.

Yasso (1965) suggested the logarithmic spiral for predicting the shape of the crenulate-shaped bays, which Silvester (1974) adopted for many years. But this was found to be inaccurate for the downcoast region where the beach straightens (Hsu and Evans 1989). A polynomial form resulted from data of a multitude of bays examined as follows:

$$R/R_0 = C_0 + C_1 (\beta/\theta) + C_2 (\beta/\theta)^2 \quad (1)$$

with the variables R , R_0 , β and θ as given in the definition sketch of Figure 1. The values of constants C_0 , C_1 and C_2 are available in Hsu and Evans (1989) and Silvester and Hsu (1993), in tabular and graphical form. It is noted that the wave obliquity (β) is measured between the control line (R_0) and the downcoast beach tangent. For a stable or near stable beach this is normal to the orthogonal of the persistent swell which sculpts the shape. The straight crests of these incoming waves at the point of diffraction, at the other end of the control line, are also angled β to it, from which arcs (R) are drawn at angle θ to it. Thus, by knowing R_0 and β the value of R is determined for a specific θ , so that the complete periphery of the static equilibrium bay can be drawn. It has been shown that the logarithmic spiral

fits only the curved portion of the actual bay, whereas the parabolic formula fits the complete periphery exceedingly well (Hsu and Evans 1989).

Figure 1. Definition sketch of a new empirical equation for static bay shape.

Besides the shaping of bays in the lee of headlands, equation (1) can be applied to salients behind offshore breakwaters (Hsu and Silvester 1990), as seen in Figure 2. These accretions are not triangular but assume the parabolic curve either side of the apex, as dictated by the diffracting and refracting waves and the associated longshore current circulation. This added land is at the expense of beaches beyond the extremities of the breakwater, if beach nourishment is not carried out.

Figure 2. Definition sketch of a salient formed in lee of an offshore breakwater, with normal wave approach, based on the static bay shape equation (1).

Influence of Upcoast Headland Conditions

A natural headland is depicted in Figure 3 a & b as A and the downcoast limit as B in which control line $AB (= R_{01})$ angled to the downcoast tangent by wave obliquity β_1 . When breakwater AC is built the new diffraction point C gives a new control line CB and new angle β_2 , which results in a changed static equilibrium or

stable shape. This natural reshaping will take place inspite of any modest attempts with groins or seawalls to prevent its fruition.

Looking first at Figure 3a, the existing bay may be in dynamic equilibrium, with littoral drift still passing through, as seen by the full line in the figure. The dotted curve denotes the stable shape for control line AB , to which the beach would erode if all sand supply around point A should cease. Now, when the breakwater AC is inserted its length and orientation could be so chosen that diffraction at point C and control line CB , with the static bay for CB being the same as the dynamic for AB . This can be achieved close enough for erosion at all points around the periphery to be negligible. If, however, sand were finally to bypass point C the resulting beach may become dynamic once more with a beachline seawards of this stable shape. But it should be designed for the static condition in case this additional drift ceases in the future.

Figure 3. Effect of positioning a breakwater tip (a) in a dynamic bay, and (b) in a static bay, for harbor planning and beach erosion control.

Now turning to Figure 3b, the dotted curve represents the static equilibrium shape for control line AB which is the existing beach. When breakwater AC is added the new control line CB creates a new static beach which involves massive accretion in the lee of headland A . The material for this has to be supplied from the region of B because the beach was originally stable. This causes a new downcoast tangent to operate that determines a new β_2 for equation (1). The situation would detract from the calm water area serving as an anchorage but could be attractive for tourism purposes.

It must be remembered that the stable waterline being predicted applies to swell conditions or calm weather. When storm waves arrive, the beach berms will be removed offshore to form a bar, which take some days to be returned. In the case of static equilibrium the same waterline will result, but all infrastructure should be kept landward of the receded storm limit.

Case Studies of Stabilization

Conventional defense solutions, such as seawalls, groins and offshore breakwaters, have been used to stabilize eroding beaches downcoast of harbors without much success. Sand bypassing and nourishment schemes have also been tried, with some degree of success in the short term. However, the geomorphological approach, involving the construction of stable bay beaches, will be attempted in this paper. This may be regarded as a permanent solution.

Like the medical profession, which prefers to make sick people better by the administration of drugs or surgery, coastal engineers have concentrated on rectifying problems rather than preventing them. Some of these are due to their own mismanagement. Many medicos are now working holistically in looking at the whole person (body, mind and emotions) to find causes rather than remedies as such. In approaching a coastal situation from a geomorphological viewpoint the final trends can be examined which point to a permanent rather than a temporary solution.

As will be seen in many of the cases to be presented, the macroscopic view of the whole coastline gives a better picture of a problem, than looking at a limited section of it. Erosion can be predicted long before it is likely to take place and hence means can be devised to prevent it. In some of the Japanese harbors the breakwater extensions are mammoth, with lengths in terms of kilometers. The incentive may be large current expenditure to generate a larger budget next year. These structures certainly produce many subsidiary problems such as siltation and erosion which demand more money.

1. Durban harbor, South Africa

The erosion of beaches north of Durban harbor on the Indian Ocean of South Africa has been presented by Jordaan (1970). This involved siltation at the port entrance, which is continually dredged and dumped out to sea or along the eroding beaches. The suggested solutions entailed Y or L shaped groins plus two offshore sand breakwaters, each 300 m in length and spaced apart the same amount, and 600 m from the beach. Whether any of these have been implemented does not affect the this exercise to apply the principle of static bay shape.

Using the tip of the outer breakwater as the diffraction point (*A*) the resulting stable bay *A* is shown in Figure 4. This indicates substantial erosion even if minor attempts are made to prevent it. The need is for a new diffraction point to the north in order that a beachline seaward of the present can be established. Such a point (*B*) can be provided by an island breakwater *BD* from which bay *B* is formed. The space between structure *BD* and the existing inner breakwater will permit some wave action to round-off this waterline to the existing (old) breakwater as shown. The beach between it and the main port structure will be reoriented as indicated by the dotted line.

The accretion anticipated for bay beach *B* could be supplied from dredging of the entrance channel that appears to be continuous. Otherwise the siltation would come from beaches to the north. It is expected that the groins will be removed and their stone etc used in the new breakwater *BD*. The offshore sand mounds (if built) could also be removed and perhaps utilized as fill for the beach *B*.

To help overcome the necessity for dredging at the port entrance the outer breakwater could be extended as shown (*AC*) which would reflect waves obliquely. The short-crested system so established would transmit material across the slightly diverted navigation channel and create a shoal near the tip *B*. It would finally find its way to the beaches. This new structure would prevent swell entering the gap between breakwater *B* and the existing structure so that beach *B* would extend to the tip of the old breakwater.

Figure 4. Durban harbor, South Africa

2. Esperance port, Western Australia

Esperance Bay is part of a continuous chain of embayments facing the Southern Ocean in the south of Western Australia. The curved shoreline, in geomorphological terms, was in dynamic equilibrium, implying its stability was maintained by the uninterrupted supply of littoral drift. However, the construction of a breakwater and dredging of an entrance channel for the Port of Esperance between 1962-65, with breakwater extension in 1973-75, has cut off the littoral drift. This has forced the shoreline to recede back to a potential static equilibrium, which is destined by Nature. This limit is landwards of the existing shoreline (see Figure 5). A total of 573,000 m³ of dredged material was placed onto the beach.

The engineering solutions taken to combat with the eroding beach at Esperance has been a low-cost rock groin field with beach renourishment, which has been an ongoing task ever since 1969. Between 1977 and 1995, sand renourishment at an average rate of 23,100 m³/year has been placed on sections of beaches suffering the worst erosion. Two headlands in the shape of a walking sticks with fronting beaches are proposed to achieve the overall stability with one-off beach nourishment to form a bay, rather than a field of short groins or offshore breakwaters with continual renourishment.

Figure 5. Esperance Bay, Western Australia

3. Hua-Lien harbor, Taiwan

Hua-Lien harbor is located on the Pacific Ocean coast of Taiwan at latitude 24°N. Two breakwaters (*AB* and *CD*) were constructed in 1987, as noted in Figure 6 (Hsu et al 1994). Prior to this extension, erosion of the coast south of the harbor entrance had been experienced, resulting in lengthy seawalls protected by concrete armour units which have steepened the offshore area. The stable beach for breakwater *CD* is shown dotted (bay for *D* in the figure) which is landward of the majority of the protected area, except at the northern tip where accretion would inhibit the discharge of the stream in the lee of breakwater *AB*.

One solution to these two problems is to extend the breakwater from *CD* to *DE*. The new diffraction point at *E* will produce the waterline shown as salient for *DE*, which is seaward of the current shoreline protected by the seawall. The remainder of the beaches will be stabilized, so not requiring other protection such as groins or seawalls. An offshore breakwater *FG* may be constructed which will intercept material in the lee of the main breakwater *DE* to form the secondary curve in the form of a salient to ensure that the stream outlet will not silt up.

Figure 6. Hua-Lien harbor, Taiwan

4. Ohtsu harbor, Japan

The fishing harbor at Ohtsu on the east coast of Honshu, Japan (see Figure 7 for location), as seen in Figure 8, had a small breakwater complex initially in 1977. It was added to point *A* in 1984, as noted in the figure. The island structure created a new diffraction point *A* that caused accretion west of the groin at Edokomi river and between that and the Satone river outlet. The static equilibrium bay shape for point *A* is seen to match this erosion some distance from the port. To overcome this a revetment was built which suffered undermining and collapsed in places during 1983.

Figure 7. Map of Japan, showing locations of harbors discussed.

Offshore, in the region of the island breakwater, accretion was measured between 1977 and 1984. This was probably due to the oblique reflection of waves from this 600 m long structure that transmitted scoured material to this area. Uda et al (1986) believed these measurements were erroneous soundings. They were aware that the island breakwater had caused the beach accretion but stated: "the current induced the sand movement toward the lee of the breakwater". These authors believe it is the wave direction of approach due to diffraction that generates the new waterline orientation.

Two alternatives are shown in Figure 8 to rectify this problem, namely, either to extend from *A* to *B* or to provide a separate structure *CD*. The new diffraction points *B* and *D* result in stable beaches as shown, which indicate substantial accretion adjacent to the Edokomi river groin but less erosion further west. The additional material required for beach stability could be provided from dredging the outlets of these two rivers, to give the stable beach shown between the two groins. To deal with the slight erosion to the west an offshore breakwater could be constructed from the revetment that should be removed.

5. Oarai harbor, Japan

Oarai harbor on the Honshu coast of Japan (see Figure 7) has had many researchers analyze it (Sato and Irie 1970, Mizumura 1982, Kraus et al 1984 and Uda et al 1986). It was a small port comprising two breakwaters at 45° to the coast which was silted up quickly between 1911 and 1916. By 1976 a new breakwater was built to point *A*, in Figure 9, for which the predictable bay shape (not shown) matched the existing beach at the time (Hsu et al 1993; Silvester and Hsu 1993). In

1981 it was extended to point *B*, and to point *D* by 1985, of which the stable bays for *B* and *D* are shown. This involves massive accretion, which had partially been achieved by 1988. The sediment needed was at the expense of erosion downcoast.

In order to achieve a stable shape more in keeping with the 1988 shoreline, or even the current profile, two extensions to *E* or *F* are suggested, together with their resulting beachlines. It is seen that *F* matches the 1988 shoreline at the groin-type structure, even though it is landward of it towards the south. It is envisaged that the two small groins would be removed, which would permit the sand to find its way back to renourish beaches to the south that have been eroded. The extension of *AB* to *F* infers that breakwater *CD* would be removed as it is no longer needed for wave attenuation.

Figure 8. Ohtsu harbor, Japan

Figure 9. Oarai harbor, Japan

6. Hazaki harbor, Japan

Hazaki fishing harbor is located at the outlet of the Tone river in Honshu, Japan (see Figure 7 for location). As seen in Figure 10, a breakwater was commenced in 1974 and extended in 1976 with another started nearer the mouth. Additions were made to both in 1978 and to the SE one in 1981. By this time erosion had commenced some 600 m from the NE breakwater with accretion adjacent to it. In 1983 a shore parallel section 350 m in length was inserted to calm waters in the harbor, which became silted very quickly. Uda et al (1986) believed this was due to sediment discharge from the Tone river but the actual mechanism was not discussed. These authors believe it was due to waves being reflected obliquely from this shore parallel arm. These transported sand along it, depositing it at the entrance, which subsequently was moved into the harbor. The leg added in 1984 (see Figure 10) did little to prevent this as the mass-transport current of the short-crested wave system would have still formed a shoal at the entrance.

An extension of this leg to point A in the figure would achieve two important objectives. Firstly, continued oblique reflection will transmit sediment from the Tone river in a NW direction to form a shoal beyond the scoured area in proximity to its tip where an access channel can be maintained. This shoal will continually be fed to the downcoast beach. Secondly, the new diffraction point A will create a stable bay shape, as indicated in the figure, which will require no further structures to keep it in place. The accretion already there will thus remain for all time.

Figure 10. Hazaki harbor, Japan

7. Iwafune harbor, Japan

The shoreline evolution at Iwafune harbor (see Figure 7 for location) has been discussed by Hsu et al (1993) and Silvester and Hsu (1993). As seen in Figure 11 a large triangular land mass had been accreted up to 1988, from having attained to a stable bay shape for A in 1965. The static bay for diffraction point A matched extremely well the waterline at that time. The extensions of the main breakwater from A to B and then to C (by means of a detached structure) relocated the diffraction points for the incoming swell waves. The resulting bay shapes are shown which predict much more siltation if sand is available from the southern beaches. To overcome the present erosion many groins and an offshore breakwater system have been installed with little effect. The reason for this is that littoral drift still

occurs offshore, just after each storm, as the storm bar is being moved back to the beach.

To prevent the transposition of further material from southern beaches it is recommended that two offshore breakwaters be installed (see Figure 11), with concomitant groin removal. The outer structure would have stable bay C pass through its southern tip, with the tombolo curved bay stretching to the tip of the inner breakwater. its curved tombolo would be tangential to the 1988 or present shoreline. The fill required in the lee of and south of each new breakwater could be transported by truck or pipeline from the large triangular landmass, in order to reduce siltation at the harbor mouth.

Figure 11. Iwafune harbor, Japan.

Conclusion

1. Bay beaches form downcoast of headlands or man-made structures that can be in dynamic equilibrium (continued littoral drift) or static equilibrium (zero littoral drift).
2. Should the diffraction point for persistent swell waves be altered, the bay as in (1) above will change, which may involve siltation in the lee of the structure and/or erosion downcoast.
3. A bay initially in dynamic equilibrium can be stabilized by a judicious selection of breakwater location, which then does not require any other defense measures.
4. Many major ports have suffered siltation as noted in (2) above after extension of breakwaters, together with erosion of downcoast beaches.
5. There is a dire need for coastal engineers to emulate Nature, who has maintained crenulate-shaped bays for aeons, by taking a geomorphic approach to their problems, both at the planning stage and in remedial measures later.

CHAPTER 309

OBSERVATION OF NEARSHORE CURRENTS AND BEACH CHANGES AROUND HEADLANDS BUILT ON THE KASHIMANADA COAST, JAPAN.

Saito, K.* , T.Uda**, K.Yokota*, S.Ohara*, Y.Kawanakajima* and K.Uchida***

ABSTRACT

Nearshore currents and beach changes around headlands built on the Kashimanada coast facing the Pacific Ocean were investigated through the field observation. In order to confirm the effectiveness of headland system to stabilize sandy beach, nearshore current field and shoreline change around headlands were measured as well as the comparison of measured value with the results of numerical simulation of nearshore currents. Comparison of development of a rip current around a completed, anchor-type headland and a groin-type headland under construction was also made and superiority of anchor-type headland to suppress the development of a rip current in the vicinity of the structure was clarified.

I. INTRODUCTION

In recent years, a method to stabilize sandy beach by using headlands has been applying on several coasts in Japan in place of the detached breakwaters and the effectiveness has been confirmed. One of the examples is given on the Kashimanada coast as shown in Photo 1, where headland system was introduced to stabilize coastline(Uda et al., 1988). Now, construction of 40 headlands is underway with 1km intervals. The headland system to stabilize sandy shoreline was originally proposed by Silvester(1976). In his study headland system in which a headland of asymmetric shape is built on the sandy beach, was considered under the obliquely incident wave conditions. On many coasts, however, wave direction varies from season to season. In this condition, symmetric type of headland is more effective to stabilize the sandy beach. On the Kashimanada coast, therefore, headlands of a symmetric shape were built.

In the planning of headland system, due considerations must be paid to the shape and its effect to surrounding nearshore current field. For example, under

the obliquely incident wave conditions, a rip current will be developed along the groin-type headland, whereas in case of the T-shape headland, development of a rip current is suppressed because of the sheltering effect of head-part of the headland. These differences deeply relate to the stabilization of sandy beaches between headlands. However, poor experience of constructing headland system on the real coasts prevents these understandings.

Photo 1 Aerial view of headlands on the Kashimanada coast (Dec.1993).

This study aims at the investigation of nearshore currents, beach changes around these headlands, and the confirmation of their effectiveness. To this purpose, the comprehensive field observations and the numerical simulation of nearshore currents were conducted. The study is composed of three contents as shown in Fig.1. First, the results of the field observation on nearshore currents around headlands are described. Field observations were carried out at three times from 1991 to 1993, in which aerial pictures were taken at a constant time interval from a helicopter to investigate diffusion of dyed water. In 1991, pre-observation was done in the vicinity of headlands, aiming at studying the difference between a groin-type and an anchor-type headland. In 1992, observations were done not only near the headland but also in the extensive area between two completed headlands in order to investigate nearshore currents and rip currents. In these observations, however, photographs were taken from a relatively low altitude. Therefore, in 1993, in order to simultaneously investigate current field in extensive area, high altitude photographs were taken from 1,000 m, as well as the bottom sounding.

In addition to these observations, beach stabilizing effect was investigated around a group of headland on the basis of several photographs and soundings,

which have been carried out recurrently. Moreover, numerical simulation of nearshore currents was carried out and results of numerical simulation were compared with the observed nearshore current pattern. Current pattern was well agreed with the observed one.

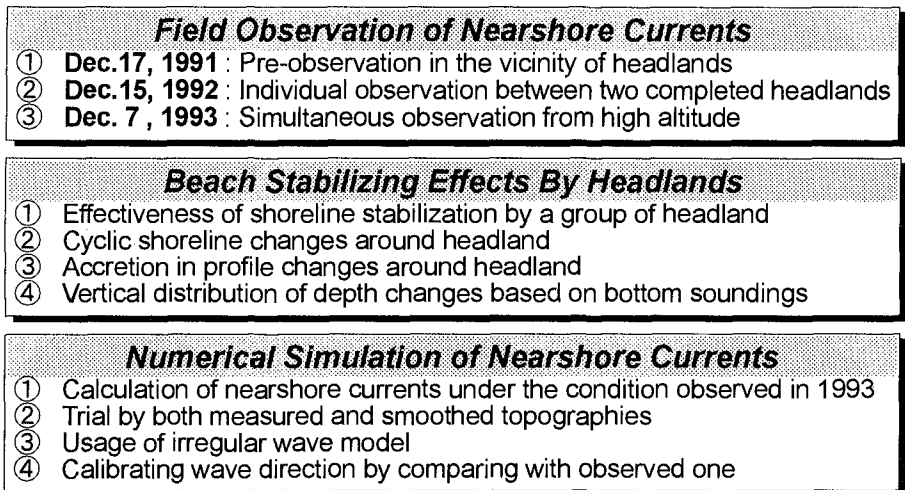

Fig.1 Outline of this study.

II. FIELD OBSERVATION OF NEARSHORE CURRENTS

2.1 GENERAL

Figure 2 shows the location of study site. The Kashimanada coast is located in the southern part of Ibaraki Prefecture facing the Pacific Ocean, where construction of 40 headlands with 1 km intervals is now underway. Construction works were begun in 1984, and by 1995, six sets of headlands were completed. Figure 3 shows the plane shape of the headland. Headland has an anchor-shape, of which offshore length is about 150 m and the head-part length is about 100 m. The head-part has a semi-circular shape and its offshore slope is as mild as 1/3 to reduce wave impact against the structure. The offshore surface of the headland is covered by armor units of 4 tons and the main part is built by natural stones of 1 ton. Field observations were carried out mainly between No.10 and No.11 headlands on the Ono-kashima coast located in the middle of the Kashimanada coast. The Ono-kashima coast is a sandy beach next to Kashima Port and beach slope is about 1/80, and the coastline length is about 12.5 km.

2.2 NEARSHORE CURRENT PATTERN AROUND THE COMPLETED HEADLAND

Photo 2 shows the nearshore current pattern around the completed headland measured on Dec. 17th, 1991, ① : right after the injection of dyestuffs to the foot part of a completed anchor-type headland No.10, ② : 6 minutes after the injection, and ③ : oblique aerial photo after ten minutes. In case of an anchor-type headland, it is realized from the comparison of successive aerial photographs that a nearshore circulation cell was formed on the south side of headland because of the wave dissipating effects of head-part. This is considered to be effective to contain the nearshore currents between headlands.

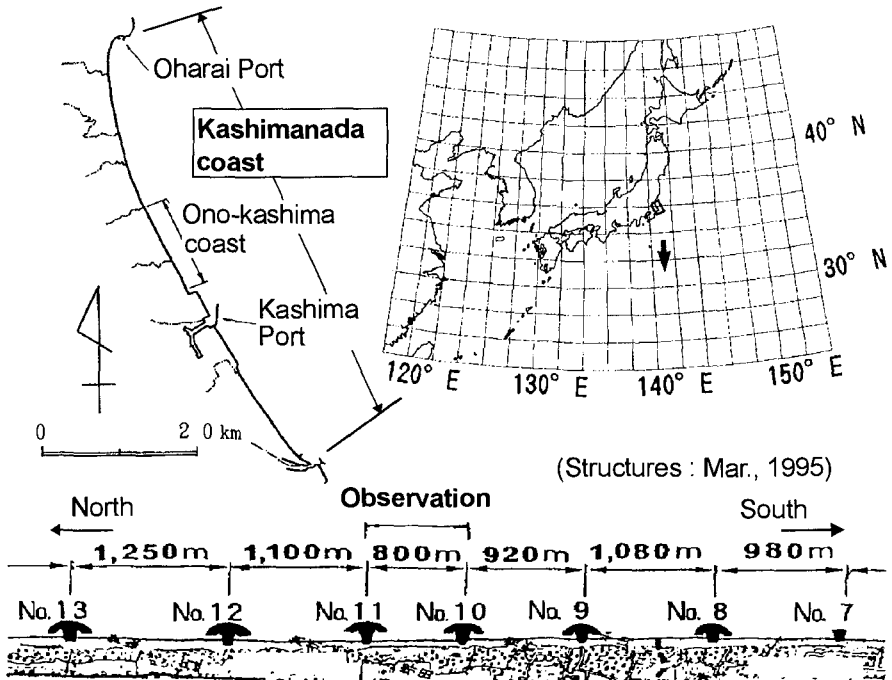

Fig.2 Location of study site.

Fig.3 Plane shape of anchor-type headland.

2.3 NEARSHORE CURRENT PATTERN AROUND THE GROIN-TYPE HEADLAND

Photo 3 shows the rip currents developed along the groin-type headland (No.9) under construction observed on Dec. 17th, 1991. In this case, dyed water injected to the foot of the groin-type headland was carried fast along the groin by the rip current. Then, dyed water spread out offshoreward and was diffused, implying that sand will be carried away to downcoast to accelerate the beach erosion on upcoast of the headland.

2.4 RESULT OF NEARSHORE CURRENT OBSERVATIONS IN 1992

Figure 4 shows the nearshore current field observed on Dec. 15th in 1992 in the extensive region covering between No.10 and No.11 headlands. The figure shows changes in dyestuff clouds, their moving velocity and wave direction, which were measured from aerial photographs. Diffusion of injected dyed water was traced by the aerial photographing from the helicopter at 15 seconds interval, and the diffusion pattern of dyed water is traced at 1 minute interval.

① RIGHT AFTER THE INJECTION OF DYESTUFFS TO THE FOOT PART.

② 6 MINUTES AFTER THE INJECTION.

③ OBLIQUE AERIAL PHOTO AFTER 10 MINUTES.

Photo 2 Advection of dyed water around the completed headland of anchor-type (Dec. 17th, 1991).

During the observation, significant wave height was 1.3 m, and the period was 9.1 s due to the wave record measured off Kashima Port by an ultrasonic wave gauge. And also incident wave angle was read to be about 15 degree counterclockwise to the normal to the shoreline from the aerial photograph.

Because of the oblique wave direction, southward longshore currents are predominant and the circulation cell is formed on the north side of No.10 headland. On the other hand, on the north side of No.11 headland, a rip current occurs, which passes over head-part and flows out in the offshore direction. Furthermore, a rip current is occurred at a central part of the beach between No.10 and 11. The position of the rip current is located approximately 500m south of No.11 headland and is a little south from the center of headlands.

When mass flux by waves is considered, it is considered that the flux is mainly heading shoreward from between No.11 headland and the position of the rip current. And it returns to offshore by this strong rip current at central part of the beach. On the contrary, the longshore distance between the rip current in the central part and No.10 headland is short, so that the shoreward mass flux in this area is considered to be small and therefore the strength of the rip current just north of No.10 headland is weak.

- ① RIGHT AFTER THE INJECTION OF DYESTUFFS TO THE FOOT PART ② 2 MINUTES AFTER THE INJECTION

- ③ 6 MINUTES AFTER THE INJECTION ④ 12 MINUTES AFTER THE INJECTION

Photo 3 Advection of dyed water around the groin-type headland (Dec. 17th, 1991).

Fig.4 Diffusion of injected dyed water between No.10 and No.11 headlands (Dec. 15th, 1992).

2.5 RESULT OF THE HIGH ALTITUDE PHOTOGRAPHING IN 1993

Figures 5 and 6 show the diffusion process measured on Dec. 7th in 1993. The significant wave height and period were 1.6 m and 7.6 s, and waves were incident from clockwise direction in this observation period as shown in the figure. The condition of this incident wave angle contrasts to the wave characteristics in 1992.

Fig.5 Diffusion of injected dyed water between No.10 and No.11 headlands(Dec. 7th, 1993).

Fig.6 Velocity field of nearshore current determined from advection rate of dyed water front (Dec. 7th, 1993).

As a whole, northward longshore currents were induced, and counterclockwise circulation cell was observed in the vicinity of the north side of No.10. Furthermore, northward longshore currents developed next to this circulation cell. This longshore current is reduced to a rip current at a location of 300m distant from No.11 headland. On the south side of No.11 located on the downcoast, another clockwise circulation cell was formed in the lee side of the headland. A part of this circulation reduces to the rip current and it superimposes the main rip current induced in the central part of the beach. In addition, about 400m off the shoreline, weak southward longshore currents were measured.

These results mean the formation of a large-scale clockwise circulation cell between headlands. Development of this circulation cell is considered to be effective to confine sediment between headlands, and to stabilize the sandy beach.

III. TOPOGRAPHIC CHANGES

3.1 SHORELINE CHANGE

Sea bottom surveys and aerial photographing for monitoring shoreline changes have been recurrently carried out on this coast. Figures 7 and 8 show the shoreline changes around headlands determined from the aerial photographs. As shown in Fig.7, the shoreline retreats in the southern part between headlands and a stepwise shoreline was formed due to the southerly wave incidence, which is the predominant wave direction on this coast. Near the headlands as shown in Fig.8, wide foreshore (tombolo) was formed behind the headland. All these show the effectiveness of headland system to contain sand between headlands, and to form dynamically stable beach between headlands. In this headland system, the interval between them is about 1 km, which is wide enough to keep the coastal scenic beauty on the natural sandy beach. Detached breakwaters are effective against beach erosion. But they have killed scenic beauty of the beach by the dense installation. Usually in Japan, the length is 100m and the opening width is 50m. In the headland system, however, the number of the headlands per unit distance is much less than that of detached breakwaters, thus this system is much more economical.

Fig.7 Changes in foreshore width between 1986 and 1993.

Fig.8 Shoreline changes around completed headlands between 1986 and 1993.

Figure 9 shows the temporal shoreline changes from 1986 to 1993 in the vicinity of No.11 headland. Surveys have been carried out in the same month of December in each year. In this figure, completion time of groin-part and head-part of the headlands are also shown. As shown in this figure, shorelines on the south side (S1~S3) of the headland No.11 change with the same phase, whereas on the north side (N2~N3) of the headland, the opposite mode of shoreline changes occur except the change at N1 located very close to headland and at the concave location. After the construction of the head-part in 1989, shoreline changes turn to the accretion tendency. It is understood that cyclic shoreline change occurs because of the seasonal change in wave direction in the zone next to the structure obstructing longshore sand movement. In short, the north side of headland is eroded and accretion occurs on the south side by southerly waves in summer, and then in winter, opposite phenomenon appears. Furthermore, it is realized that the accretion effect of headland overlaps on the above seasonal changes.

Fig.9 Temporal shoreline changes around headland No.11 between 1986 and 1993.

3.2 PROFILE CHANGES

Regarding the accretive effect of headland, it is also investigated by the bottom soundings along the survey lines arranged with 25m interval. Figure 10 shows the typical cross-shore profile changes around No.10 headland between July, 1987 and August, 1993. On the line of CN100, development of bar-trough topography was seen before the construction, but since 1992 when the head-part had been completed, bar-trough development becomes weak. On CN50 approaching 50m to headland further, because of the wave sheltering effect of the headland, accretion is seen at nearby the shoreline. Then, on CNO nearest to the headland, a large amount of sand is accumulated to form a tombolo. The thickness of accreted sand at a distance of 100m offshore reaches to approximately 3m. On the other hand, a local scouring is not seen off the head, and a gentle slope of approximately 1/100 is formed. Thus, it is confirmed that accretive effect of headland is remarkable around No.10. because of the wave sheltering effect by its head.

Fig.10 Typical profile changes in a period between July, 1987 and August, 1993.

3.3 VERTICAL DISTRIBUTION OF DEPTH CHANGES

On the basis of the sounding data, a vertical distribution of the standard deviation of the water depth change was examined. Fig. 11 shows the result. The vertical axis indicates the mean depth in meter. They were examined between No.10 and 11 headlands from 1987 to 1993. The significant topographic changes is occurred between -6m to +3m with two peaks at the shoreline and -3m. The peak of -3m is considered to be caused by the changes of bar-trough topography. This distribution shows a range of the remarkable topographic change. And the tip depth of the headland is approximately 3m depth. Therefore, the headland is located at a place which almost contains the range of the remarkable topographic change. This fact means the headlands on this coast is located at a offshore limit for demonstrating its effect.

Fig.11 Vertical distribution of depth change between No.10 and No.11.

IV. NUMERICAL SIMULATION OF NEARSHORE CURRENTS

4.1 NUMERICAL MODEL AND COMPUTATIONAL CONDITION

Numerical simulation for the nearshore currents was carried out to compare field data observed in 1993. Table 1 shows the computational condition. In the nearshore current simulation, wave field was first calculated by the irregular wave model. Then, nearshore current field was calculated on the basis of the above wave field and with given some coefficients. On the other hand, regarding the sea bottom topography, two cases of the calculations as described in Table 1 and shown in Figs.12 (Chart 1) and 13 (Chart 2) were carried out. Chart 1 is the original topography data sounded on Dec. 16th, 1993, and Chart 2 is the

smoothed one. The reason using also Chart 2 is why the bottom topography would be changed by the storm continued during 9 days since the above-mentioned nearshore current observation.

Table 1 Computational conditions.

Term	Condition
Computation area	Longshore 2,000 m × Offshore 1,000 m
Mesh size	$\Delta x = \Delta y = 10$ m
Initial topography	Chart 1 : Original bathymetric chart (Dec. 1993) Chart 2 : Smoothed bathymetric chart
Structures	Present (headland No.10 and No.11)
Sea wave conditions	Height and Period : decided from observation at Kashima Port on Dec. 7th, 1993. Direction : Trial in the range of observed direction
Tidal level	T.P.+0.806m
Computation time	1 day
Irregular wave computation	Dividing number of frequency : 5 Dividing number of direction : 11 Directional concentration coefficient : $S_{\max} = 25$
Nearshore current computation	Friction factor : $C_f = 0.01$, Lateral eddy viscosity : $25\text{m}^2/\text{s}$ Time step : $\Delta t = 0.5$ s, Boundary condition : Open

Fig.12 Original bathymetric chart (Chart 1) and selected point for verification of wave direction.

Fig.13 Smoothed contour chart (Chart 2).

4.2 VERIFICATION OF WAVE DIRECTION

First, the wave direction was verified. Table 2 shows the trial cases and results. Besides, as a representative point for verification, St.2 in Fig.12 was selected because it is located in the center, and therefore the influence due to the structures is small enough. As shown in Table 2, in total 8 cases of trials were conducted, and the best fit of the offshore wave direction to reproduce the measured wave direction resulted in -25 degree as case 7 or 8.

Table 2 Measured and calculated wave directions at selected points.

No.	Topography	Wave conditions				Wave directions		
		Height (m)	Period (s)	Direction	Tide level (T.P. m)	St.1	St.2	St.3
1	Chart 1	1.57	7.6	-14.5°	0.806	-1.4°	2.0°	-7.4°
2	"	"	"	-20.0	"	-5.1	-2.1	-9.5

Mean angle measured						-13.7	-13.3	-5.1

4.3 RESULTS OF COMPUTATION

Figure 14 compares calculated current pattern with the observed one. Nearshore circulation cell on the downcoast of No.10, a rip current at the head of No.11, and a rip current at a location of longshore distance 900 m agreed considerably well. On the other hand, in case of using Chart1, a very strong onshore current occurred and discrepancy was large on the shoal located in the middle of the sandy beach.

Fig.14 Comparison of observed and calculated nearshore current field.

V. CONCLUSIONS

Main conclusions in this study are summarized as follows :

- ① Nearshore current field with a longshore stretch of about 800m was measured. Development of nearshore circulation cell in the vicinity of headlands was confirmed. And, a rip current induced from the shoreward mass flux were also confirmed.
- ② Due to the shoreline changes around headlands observed by aerial photographs, the shoreline was stabilized to form a step-wise configuration responding to the oblique wave incidence. Furthermore, it was found that seasonal shoreline variation was superimposed to this shoreline to form dynamically stable shoreline.
- ③ Numerical simulation of wave field and nearshore currents were carried out. Results of numerical simulation agreed well with the observed one to show the effectiveness of the wave and current model.
- ④ This study summarizes field experiences regarding headland system in Japan. And this information is thought to be important for further application on the other coast in place of the detached breakwater.

CHAPTER 310

NOURISHED BEACH CONTROL BETWEEN BALIS AND ARENYS HARBOURS (SPAIN)

F. Javier Escartín⁽¹⁾, Alfonso Vidaor⁽²⁾, A.M. Castañeda⁽³⁾ and Nuria Lupón⁽⁴⁾

ABSTRACT

A description of the monitoring works carried out in the Maresme beaches between Arenys de Mar and Balis Harbour after the completion of the regeneration works consisting on the demolition of the existing groins and the execution of an artificial nourishment is presented.

INTRODUCTION

Maresme beaches are located close to the city of Barcelona (40 km in the northwest) and because of this they are frequently visited all year round.

The zone was suffering an important regression that couldn't be restrained by any attempts of stabilization. So in February of 1992, a regeneration project of this coastal zone was carried out as a part of the works that the Spanish Public Works Ministry has been doing on the Catalan Coast.

The nourishment works began in August 1993 and the first phase of the regeneration was finished in October of the same year, in March of 1994 the second phase ended.

Because of the high investment dedicated to this work, an accurate monitoring of the beaches was planned in order to obtain a better understanding of the beach behaviour with respect to the littoral processes and thus to implement appropriate coastal management strategies.

The monitoring has been divided in two different parts:

- A field systematic monitoring of the beaches
- A shoreline evolution analysis using a numerical model of simulation

Following the predicted evolution, the possible actions will be analyzed in order to guarantee the adequate maintenance of the desired stability conditions and quality.

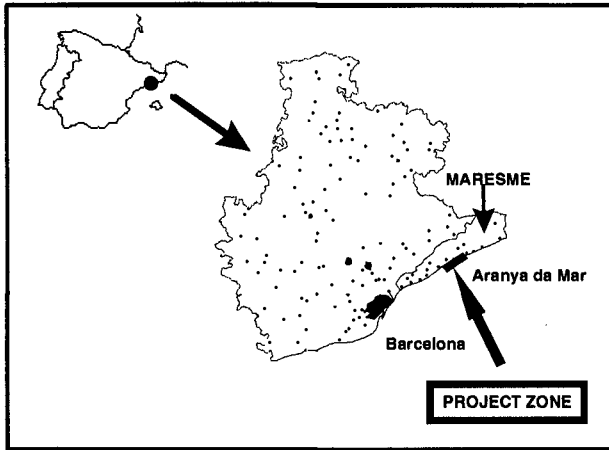

Figure 1: Project location

HISTORY

Maresme littoral is a fisiographic unit which is spread out between Tordera River mouth and Barcelona Harbour.

From the littoral dynamics point of view the working scheme of the stretch, is simple: This area has a NE-SW orientation with a net littoral transport from east to west, and net rates around 40.000 and 100.000 m³/year.

After Arenys Harbour was built in the late forties, littoral dynamics of the beaches in the southwest of the Harbour were strongly modified suffering a regression that could not be restrained by any of the attempts of stabilization carried out. Mainly seawalls and transversal groins.

In the closest zone to Arenys Harbour, a seawall about 2 km long was built to protect the railway line, and far away to the south, for 2.5 km, a set of eleven transversal groins were constructed.

The nourishment project was designed with the double objective of:

- obtaining a great stable beach area
- establishing an important nourishment source for the Maresme beaches in the southwest of Arenys Harbour as far as Barcelona.

The total length of the regeneration was 4.5 km, with a beach width of 70 to 110 m and an elevation of 2.5 m. The mean slope was 1/10.

The total volume of sand was 3.8 million cubic meter. Ten of the eleven transversal groins were demolished.

MONITORING WORKS

Monitoring program consists in bathymetric and topographic works which are performed every six months with the purpose of identifying areas where accretion and erosion occur.

Bathymetric surveys of the whole area were carried out just after the works were completed.

The field data available for this study were those carried out in:

- July 1993 (before regeneration works)
- October 1993 (at the end of the first phase)
- November 1993 (specific survey for the mouth of Arenys Harbour)
- January 1994 (also in the mouth)
- March 1994 (at the end of the second phase)

- February 1995 (first survey)
- July 1995 (second survey)

With these data and employing a digital terrain model, comparative shoreline and isopaches planes, and comparative diagrams of control profiles are obtained.

Some of the results of these works are shown in figure 2 where shorelines corresponding to every bathymetric survey are drawn.

Since the nourishment ends until the february of 1995's monitoring survey, shoreline stepped back around 30 meters along all the study zone except the both ends, westward Balis Harbour and eastward Arenys Harbour. It has been a sediment accumulation which means a shoreline advance, in some points a very significant advance (70 meters close to Arenys Harbour counterdike).

It has also been a shoreline advance in the central part of the stretch, downstream of the Hotel Colon groin.

From February to July 1995, shoreline position has hardly modified what indicates a relative tendency to stabilization. A light tilting takes place at westward beach of Arenys Harbour with an important accretion in the counterdike due to wave diffraction effect.

The control profile analysis also indicates (fig. 3) the local advance and receed of the shoreline. Different studied profiles show how the shoreline has receed 30 meter in profile 82 or has advanced in the other points. It can be seen in any profile that July 95's shoreline tilt around February 95 position with 3 meters variation.

Figure 2: Shoreline evolution

Figure 3: Control profiles evolution

NET SEDIMENT TRANSPORT

A sedimentary budget was done with the purpose of estimating sand volume mobilized by wave action since the completion of the works until July 1995.

Analysing the volumes in the considered cells, the sand quantity lost in this area through the SW extreme during this period was 46,923 m³.

Finally, from these volumes, estimate longshore transport calculations were made.(Figure 4). At this figure two zones can be clearly distinguished:

- In the first zone, from Balis Harbour, and for a length of 3,000 meters, the net sand transport has the NE-SW direction with a maximum value of 89,307 m³/year.
- In the second zone, from this point to Arenys Harbour, the net sand transport has the SW-NE direction with a maximum value of 81,190 m³/year.

In the first zone a relative minimum exists as a consequence of the sand accumulation due to the Hotel Colon groin that acts as a partial barrier.

SHORELINE EVOLUTION NUMERICAL MODELIZATION

Parallel to the monitoring work performed taking account of the field data, a shoreline numerical modelization was executed.

This study was structured in two different parts:

- calibration of numerical model employing the first survey data
In order to obtain good transport coefficients necessary for long term coastal evolution prediction, a calibration was carried out. Then a verification of the obtained coefficients was done.
- simulation of the shoreline behaviour in a 10 year term

The numerical model used for the simulation was GENESIS by CERC.

The main variables involved in one-line shoreline evolution model are wave climate, sediment characteristics, closure depth, coastal structures and boundary conditions.

In this work, different sets of wave data were used. Height and period of wave data proceeded from Tordera escalar buoy, and directions were obtained from visual data of routing ships registered in this sector. With both set of data a continuous register for a year was built up.

The selected boundary conditions were:

- null longitudinal transport in the Arenys Harbour breakwater which means that it acts as a total barrier
- permeable transversal groin in the Balis Harbour breakwater

Figure 4: Measured net transport

Some simulations for the period end of the works - February of 1995 period were made, by varying transport parameters k_1 and k_2 , in order to obtain a proper adjustment between the numerical values of the longitudinal transport and shoreline evolution in comparison with the measured values. Values found to agree more accurately were $k_1=0,8$ and $k_2=0,5$.

The net longshore transport distribution along shoreline is shown in figure 5, which can be compared with that obtained from measured values: Both distributions present similar global behaviour with identical peaks of transport.

Figure 5: Net transport comparison

The obtained prediction of shoreline evolution is shown in figure 6. A reasonable agreement between measured and predicted shoreline positions can be observed. Both lines present identical accumulation and erosion areas. There is a sediment accumulation close to Balis Harbour and to Arenys Harbour, and sediment erosion in the rest of the stretch, specially downstream of Arenys Harbour.

Figure 6: Shoreline prediction

10 YEAR SHORELINE MODELIZATION

Afterwards, with parameters obtained previously, a long term simulation was made in order to find out the beach evolutive trend for the next ten years. In this case a mean climate obtained from visual data is used. Shoreline from July of 1995 is employed as initial position.

Boundary conditions are the same. The existence of a seawall which represents the edge of urbanized area, that can not be overpassed by the shoreline regression, is considered as well.

Figure 7 shows the result. It can be observed that since the 7th year, shoreline has receded, in some points, reaching the edge of the urbanized area. The other points remain rather stable.

Points where regression is maximum are situated downstream of Arenys River Mouth. This zone has been traditionally protected by seawalls.

The most important observations are:

- Westward of Arenys Harbour, shoreline tends to stability but downstream a strong erosion takes place, so after the 6th year less than 10 m of the beach width remains. Points where regression is maximum are situated downstream of Arenys stream outlet. This zone has been traditionally protected by seawalls.

- Hotel Colon Groin doesn't represent, a total barrier to longshore transport and its presence has no influence in the beach behaviour.
- But in the long term, erosive trend of the coast situated downstream of the Arenys stream outlet could move downstream, causing the beach to lie in the Hotel Colon groin.

Figure 7: 10 year shoreline evolution

ACTIONS

To restrain the erosive trend of the stretch, two possible actions have been suggested and studied:

- A periodical beach fill, upstream of the stretch (westward of Arenys Harbour)
- Construction of a detached breakwater

Figure 8 shows the first action modelization. As it can be seen in the diagram, an annual beach fill of 40,000 m³ of sand, after the third year, produces stability of the entire beach.

Secondly, with a detached breakwater a salient is generated (figure 9), what means an important increment in the beach surface in this area.

Since there is a possibility of an erosion later on in this point, beach fills are also studied (figure 10). Subsequently the beach would be totally stabilized.

Both solutions satisfy the stabilization objective of the regenerated beach.

Figure 8: Periodical beach fill modelization

Figure 9: Detached breakwater modelization

Figure 10: Detached breakwater with periodical beach fill modelization

CONCLUSIONS

- To guarantee extensive coastal zone regeneration, it is very important to carry out monitoring of the shoreline evolution.
- The monitoring and control processes should be completed with simulation models in order to:
 - improve the understanding of littoral processes
 - predict the evolutive trends
 - the necessary actions, their evolution and quantification could therefore be analyzed
- Monitoring continuity will allow the feed back of the calibration of the model and a better adjustment of both, the regenerated beach evolution simulation and the effect of the suggested actions.

CHAPTER 311

NUMERICAL SIMULATION OF SHORELINE CHANGE WITH LONGSHORE SAND WAVES AT GROINS

Hans Hanson¹, M. ASCE, Michelle M. Thevenot², Nicholas C. Kraus³, M. ASCE

ABSTRACT: Longshore sand waves (LSWs) are macro-morphologic features that maintain form while migrating along the shore with speeds on the order of kilometers per year. LSWs can dominate shoreline evolution by causing both apparent long-term erosion and accretion seemingly unrelated to the calculated or estimated net and gross longshore sand transport rates. This paper explores three possible mechanisms, wave asymmetry, form advection, and surf-zone contraction, hypothesized to maintain and translate LSWs. The mechanisms are implemented within the framework of a shoreline change numerical model. Simulations implementing the LSW evolution mechanisms are tested with observations made of LSWs at Southampton, Long Island, New York. Consideration is also given to movement of LSWs at and through groins. It is concluded that fundamental questions remain on processes governing the behavior of LSWs.

INTRODUCTION

Shoreline change can be calculated by one-line numerical simulation models for a wide range of coastal structures, beach fills, waves, and boundary conditions. Such models are based on the continuity equation and a transport rate formula for the particulate movement of sand, such as the CERC formula (SPM 1984). It is well known that the one-line model, with a particulate transport rate formula dependent upon the incident wave angle, reduces to the diffusion equation. The result is that perturbations in

shoreline position will tend to be smoothed, unless controlled or sustained by a boundary condition or another constraint. Particulate transport rate formulas pertain to micro-scale or meso-scale motion (minutes to hours or days) and are stepped through time, typically at 3- to 6-hr intervals, for calculation cell widths typically on the order of 50 to 500 m.

Engineers are becoming aware of morphologic features in the nearshore having much longer time and space scales that may impact project performance. Such features maintain their identities for months to years and move while preserving form. One such collective movement (Sonu 1968) of consequence is that of longshore sand waves (LSWs) (see Thevenot and Kraus (1995) for a literature review of LSWs), large wave-like features that migrate alongshore with a characteristic speed of kilometers per year. Verhagen (1989) examined a 100-year record of LSWs present along 20 km of Dutch coast and concluded that periodic accretion observed in a groin field coincided with the passage of LSWs and not to trapping of littoral (particulate) drift by the groins. LSWs have been associated with intermittency in sand supply, such as the discharge of river sediments, sediments discharged from inlets, artificial injection of a large quantity of sand, and welding of shoals on to the shore.

Recently, Thevenot and Kraus (1995) presented a one-line model that includes both particulate transport and representation of LSWs as a collective motion, and they successfully simulated LSW migration observed at Southampton Beach, Long Island, New York. The purpose of the present paper is to investigate possible mechanisms that maintain and translate LSWs and to extend the one-line model to examine LSW movement in groin fields. The model is tested with data from Southampton Beach.

THEORETICAL CONSIDERATIONS

Here, we discuss three mechanisms we hypothesize might act singly or jointly in the nearshore to preserve LSWs and translate them alongshore. First, basic concepts underlying longshore sand transport and shoreline change calculation are introduced.

General Relations

Shoreline change models have become a standard technique for calculating the long-term evolution of sandy beaches under impressed waves, boundary conditions, and coastal engineering activities (Hanson and Kraus 1989). In these models, the longshore sand transport rate is usually represented by an expression of the form

$$Q = Q_o \sin 2\theta_b = Q_o \sin \left[2 \left(\theta_o - \arctan \left(\frac{\partial y}{\partial x} \right) \right) \right] \quad (1)$$

where Q_o = amplitude of longshore sand transport rate, θ_b = angle of breaking wave crests relative to the shoreline, θ_o = angle of breaking wave crests relative to an axis set parallel to the trend of the shoreline, y = shoreline position, x = distance alongshore, and $\partial y/\partial x$ = local shoreline orientation. For beaches with gentle offshore slopes, it can be

assumed that the breaking wave angle, θ_b , relative to the shoreline and the shoreline orientation, $\partial y/\partial x$, are small. For such a situation, if the amplitude of the longshore sand transport rate and the incident breaking wave angle are constant (independent of x and time t), the equation for the change of shoreline position y reduces to the one-dimensional (1D) diffusion equation (Larson *et al.* (1997)

$$\frac{\partial y}{\partial t} = \epsilon \frac{\partial^2 y}{\partial x^2} \quad (2)$$

in which

$$\epsilon = \frac{2Q_o}{D} \quad (3)$$

where D = sum of depth of profile closure and elevation of the berm. Eq. (2) describes diffusion or spreading of perturbations that might be located along the shoreline, the diffusion acting to obliterate the distinct and persistent shoreline sand forms which are the subject of this study.

In this study, three possible mechanisms are postulated and investigated, by means of a one-line model, which may be responsible for the preservation of the form and translation of the center of mass of LSWs. These mechanisms are (1) wave asymmetry, (2) form advection, and (3) surf-zone contraction.

Wave Asymmetry Mechanism

There are a wide range of expressions for calculating the amplitude of longshore sand transport rate Q_o . For example, the SPM (1984) gives the relation

$$Q_o = \frac{\rho g}{16} H_b^2 C_{gs} \frac{K}{(\rho_s - \rho)\lambda} \quad (4)$$

where H_b = significant breaking wave height, C_{gb} = wave group velocity at breaking, ρ (ρ_s) = density of water (sediment), g = acceleration due to gravity, K = non-dimensional empirical coefficient (approx. 0.5 - 0.8), and λ = porosity of sand (approx. 0.4). Eqs. (1) and (4) show that breaking wave height and direction are the dominant parameters determining the magnitude and direction of the longshore sand transport rate.

Thevenot and Kraus (1995) postulated that a LSW would refract waves toward it, similar to wave convergence at a headland, and this wave asymmetry would tend to "pack" the sand in place on the LSW. Their calculations with a simple 1D wave model showed this phenomenon to be potentially valid. To further evaluate the possible influence of wave asymmetry on LSW migration, breaking wave input for the shoreline change model was calculated with a full 2-dimensional (2D) wave transformation model (Larson and Hanson 1996) that was executed every time step.

The mild-slope equation (Berkhoff 1972) is often employed to describe the transformation of linear water waves. A simplified form of this equation was used in the present study, where diffraction was neglected, but energy dissipation due to depth-limited breaking was included. The dissipation was incorporated as a sink term in the equation for conservation of wave energy flux, and the magnitude of the dissipation was estimated according to the procedure of Dally et al. (1985). The mean water elevation was computed from the cross-shore momentum equation. The wave calculations involved in these simulations were, therefore, much more rigorous than what is normally done for shoreline-change model simulations. A practical limitation in accuracy is the finite grid size, as the breaking wave height and angle are calculated at discrete points across-shore.

Advective Form Mechanism

As shown by Inman (1987) and by Larson and Kraus (1991), the longshore migration of LSWs may be incorporated into Eq. (3) by including a morphologic form-advective term $V(\partial y/\partial x)$ to yield the advection-diffusion equation for a conservative substance

$$\frac{\partial y}{\partial t} + V \frac{\partial y}{\partial x} = \epsilon \frac{\partial^2 y}{\partial x^2} \quad (5)$$

where V = the migration speed of the LSW. Thevenot and Kraus (1995) related V to a longshore water discharge parameter R defined as (Kraus & Dean 1987)

$$R = \frac{1}{2} d_b v_b v_{ls} \quad (6)$$

in which d_b = depth at wave breaking, y_b = the distance from the shoreline to the break point, and v_{ls} = mean velocity of the longshore current. The discharge parameter was considered as an appropriate means to express the form speed because R is a macro-scale quantity, as is V .

The longshore current velocity may, in turn, be calculated using an accepted empirical relation (Komar & Inman 1970)

$$v_{ls} = \frac{1.35}{2} \gamma \sqrt{g d_b} \sin(2\theta_b) \quad (7)$$

in which γ = ratio of wave height to water depth at breaking. Based on these parameters, the volume rate of transport Q_{LSW} may be calculated as (Thevenot and Kraus 1995)

$$(Q_{LSW})_{calc} = \alpha (R - R_{crit}) \quad (8)$$

where α = empirical proportionality coefficient, and R_{crit} = threshold value of R . Both of these values must be determined from field measurements or from inferences made through modeling of shoreline change. On the other hand, based on geometric properties, the volume rate of transport may be estimated as

$$(Q_{LSW})_{est} = \eta DV \quad (9)$$

where η = amplitude of the LSW measured from the ambient shoreline. Elimination of Q_{LSW} between Eqs. (8) and (9) gives an expression for the migration speed of the LSW to be substituted in Eq. (5) as:

$$V = \frac{\alpha(R - R_{crit})}{\eta D} \quad (10)$$

Contracted Surf Zone Mechanism

This analysis is based on the assumption that the presence of a LSW does not alter the alongshore location of depth contours beyond the depth of closure. Under this assumption, because the LSW protrudes seaward from the ambient shoreline, the slope of the profile on the LSW must be steeper than that of the adjacent beach.

The beach profile is assumed to follow a Bruun - Dean equilibrium ($y^{2/3}$) shape. Along the ambient shoreline (unaffected by the LSW), the horizontal distance from the shoreline to D_c is the active width of the surf zone y_c . The equilibrium shape relation for y_c may be expressed as

$$y_c = (D_c/A)^{3/2} \quad (11)$$

where A = empirical scale parameter. Along sections of shore occupied by a LSW, the active width of the surf zone will decrease. If an equilibrium profile is assumed to exist along these sections as well, the steeper profile will be characterized by a modified scale parameter A^* given by

$$A^* = D_c/(y_c^*)^{2/3} \quad (12)$$

where y_c^* is the modified active width, $y_c - \eta$ (Fig. 1). Similarly, the surf-zone width, defined as the distance y_b from the shoreline to the breaker line at depth D_b , may be written as

$$y_b = (D_b/A)^{3/2} \quad (13)$$

Fig 1. Definition sketch for the contracted surf zone approach.

along ambient beach sections, whereas along the beach at the LSW, the corresponding relation reads:

$$y_b^* = (D_b/A^*)^{3/2} \tag{14}$$

By expressing the longshore sand transport rate Q as an Inman-Bagnold-type relation and applying the continuity equation for the longshore transport of water yields

$$\begin{aligned} Q &\sim v_{ls} H_b^2 & Q^* &\sim v_{ls}^* H_b^{*2} \\ v_{ls} Area_b &= v_{ls}^* Area_b^* \end{aligned} \tag{15}$$

where $Area_b$ = cross-sectional water area between the shoreline and breaker depth, and the superscript * denotes values in the region of the LSW. Based on the unmodified longshore sand transport rate distant from the LSW, the corresponding rate along the LSW is given by

$$\frac{Q^*}{Q} = \frac{A}{A^*} \left(\frac{y_c}{y_c^*} \right)^{5/3} \tag{16}$$

CALCULATION RESULTS

In the following, predictions of the three approaches for maintaining and translating LSW are evaluated through numerical simulation.

Wave Asymmetry Calculation Approach

Starting with a representative single LSW with a length of 5.5 km and an amplitude of 34.2 m (Fig. 2), a standard shoreline change model (particulate transport rate only) was run for 2,000 hr with constant offshore (20-m depth) wave climate of $H = 1.0$ m, wave period $T = 6$ sec, and $\theta = 10$ deg. Other parameters in the simulation were time step $\Delta t = 4$ hr, cell spacing $\Delta x = 50$ m, and $K = 0.7$. As has been shown previously

(Hanson and Larson 1987), wave transformation modules run on assumed locally plane and parallel contours that are typically included in shoreline change models produce wave properties alongshore that results in a high degree of symmetrical transport patterns around a protruding symmetric feature such as a LSW. As a result, the LSW experiences little advection, although the diffusion is significant (Fig 2).

In the 2D wave modeling simulations, the number and size of alongshore calculation cells were the same as in the 1D simulation. The calculation area was divided into 50 sections, each of 20-m spacing across shore. Time step and duration of the simulation were the same as in the 1D case. As seen in Fig. 2, the LSW evolution produced by the 2D wave modeling displays a much greater degree of asymmetry, but there was no significant advective LSW motion, although diffusion was significant.

Fig 2. Shoreline change calculated using 1D and 2D wave transformation modeling.

Based on this and other calculations, it is concluded that a 2D wave calculation scheme as run in typical engineering studies will not create enough wave- and associated sand-transport asymmetry around a LSW to cause the LSW to migrate.

Advective Form Calculation Approach

As seen from Eq. (10), the advective speed of any section of a LSW is inversely proportional to its displacement from the baseline. Thus, the center of the initially symmetric LSW in Fig. 3 moves faster than the flanks, resulting in a flatter up-drift plan shape of the LSW and a steeper down-drift flank, in agreement with field observations. From a modeling point of view, the advective speed concept offers significant flexibility. The migration speed is controlled by α and R_{crit} in Eq. (10), whereas the diffusion is controlled by K in Eq. (4).

The initial LSW in Fig. 3 is the same as in the previous figure. In this case, the wave conditions were $H = 1.0$ m, $T = 8$ sec, and $\theta = 20$ deg, and the simulation duration 720 days. The LSW migrates with an average speed of 3 km/yr with a decrease in amplitude of about 50%. Variation of input wave characteristics in several similar simulations (not shown) indicated that the LSW would move in either direction, always migrating in the direction of net sand transport, in agreement with field observations. At the same time,

Fig 3. Calculated LSW migration using the advective form approach.

there was always an increase in length of the calculated LSW with time, while its amplitude decreased due to diffusion. Available field observations seem to indicate that LSWs have a more stable amplitude and do not increase in length.

Contracted Surf Zone Calculation Approach

A simulation was performed with the contracted surf zone approach implemented and with identical conditions as in the previous cases. As seen from Fig. 4, the calculated LSW does indeed move downdrift, but with considerably less speed and diffusion than in the previous case. During the simulated 2 years, the LSW moves with an average speed of 0.6 km/yr while maintaining 82% of its amplitude. At this stage, it is not possible to determine which of the two very different results is correct, because both are reasonable.

Distinguishing Advection and Diffusion

One problem both approaches have in common is, however, that any kind of perturbation in the shoreline will move downdrift, which is not reasonable. For example, the local erosion and accretion associated with the presence of a groin are expected to remain in the vicinity of the groin and not to move alongshore as a coherent form.

Fig 4. Calculated LSW migration using the contracted surf zone approach.

Fig. 5 shows the situation of an initial LSW identical to that in Fig. 3, calculated with the advective-form approach. The simulation was driven with a Corps of Engineers hindcast wave time series for Southampton Beach, Long Island, New York, that covers the period 1956-75. The simulation started on Jan. 1, 1958, and continued for 1,600 days, chosen to represent a period of unusually strong longshore transport wave conditions and a persistent sediment transport to the west (right). With a groin blocking the sediment transport, impoundment or accretion are expected on its updrift side and corresponding erosion on the opposite side of the structure. However, as these features start to develop, they, too, begin to migrate, resulting in the wavy shoreline shape downdrift of the groin. This behavior is unrealistic.

One *ad-hoc* means of eliminating advection of all perturbations is to *a-priori* identify and specify which features are to migrate. These features will subsequently evolve by advection as well as diffusion. Other features that appear spontaneously in response to constraints or placement of beach fills, such as shoreline displacements near groins, will not be subject to the advective mechanisms and not migrate alongshore. Such an *ad-hoc* specification might be implemented in an engineering application if the results are monitored with caution, but it is not satisfactory because it does not address why some

Fig 5. Calculated LSW interaction with a groin using the advective form approach.

shoreline features move and others do not, that is, the physical processes associated with cause and effect of the LSW migration are omitted.

A result of a simulation with such a distinction between advection and diffusion in the advective-form approach is displayed in Fig. 6, representing the same wave conditions as in the previous case, but now only run for 1,200 days. With the LSW distinguishing capability active, accretion as well as erosion adjacent to the groin develop, as expected. With elapsed time, the LSW passes the groin, initially deformed by the presence of the groin, but later resumes its shape as it moves away from the structure.

Application to Southampton Beach

To validate qualitatively the preliminary approach described here to modeling LSW migration, the advective form calculation was applied to the situation at Southampton Beach, Long Island, New York. Here, eleven LSWs present in the early 1990s were identified from aerial photos (Thevenot and Kraus 1995). The LSWs had an average length of 0.75 km, an average amplitude of about 40 m, and an estimated average annual migration speed of 0.35 km/yr. Their speed was found to vary seasonally with the strength of the inferred longshore discharge parameter calculated from the wave hindcast.

Fig 6. Calculated LSW interaction with a groin using decoupled advection and diffusion.

Available aerial photos dated Sep. 4, 1991, Dec. 20, 1991, and Jan. 2, 1993, served as references for the simulations. The simulated shoreline covers 16.9 km, with a spatial resolution of 100 m and a time step of 3 hr. Results of the simulation are shown in Fig. 7. The same wave hindcast time series as in the above was specified, but now starting on Sep. 4, 1956, and ending Jan. 2, 1958, representing the time period Sep. 4, 1991, to Jan. 2, 1993, because the actual time period of the LSW observation is not covered by the hindcast. The hindcast time period was selected to represent typical conditions at the site.

As expected, the LSWs moved to west (to the right in the simulations). However, it was noted that during the last two weeks of the simulation period, i.e., the end of 1957 (representing the end of 1992), the LSWs moved significantly in the opposite direction, ending on the incorrect side of the intermediate LSW positions. This reversal is an artifact of the wave time series in the hindcast for 1957. The calculations were therefore halted 2 weeks before the end of the simulation period.

The locations of the calculated LSW are in reasonable agreement with most of the LSWs in the photographs. However, representation of the amplitudes is poor. The reason for this is, as indicated previously, that the model cannot produce growth in LSW amplitude,

Fig 7. Measured and calculated LSW movement at Southampton Beach, LI, New York.

which appears to be a significant process in the field. It is not known at this point what phenomena are acting to produce a substantial increase in amplitude of the LSWs. It is possible that varying tide level may have contaminated the dimensions of the LSWs measured in the aerial photographs.

CONCLUDING DISCUSSION

Longshore sand waves (LSWs) are a large-scale phenomenon of major significance in coastal engineering and science. The physical processes governing preservation and migration of LSWs have not been firmly identified, no less understood. Predictive models describing LSWs are only at the formative stage, and the present paper has explored three approaches for describing the evolution of LSWs. The interaction between LSWs with groins was also explored.

Comparisons of calculations with measurements of LSWs at Southampton Beach, Long Island, New York, shows that the migration of LSWs may be described by shoreline-change model modified to include a form advection term. However, the temporal and spatial variation in permanence of form and amplitude of the LSWs were not satisfactorily reproduced in the model. Presented results indicate that the advective form calculation approach reproduces the LSW migration better than other methods, whereas the contracted surf zone calculation approach seem. to be superior in preserving LSW amplitude. Further model developments will depend on improved understanding, characterization, and conceptualization of the mechanisms controlling the behavior of LSWs.

ACKNOWLEDGEMENTS

CHAPTER 312

EROSIVE WAVES IN SHORELINE CHANGE DUE TO THE REDUCTION OF A RIVER DELTA

Yoshito Tsuchiya,¹ M. ASCE

ABSTRACT: Using observations of long-term data of shoreline change during the reduction process of a river-mouth delta, space-time shoreline changes and their variations are clarified by the moving-average method. There clearly exist two modes of shoreline changes due to distinct types of erosive wave. The first mode is defined to be an erosive wave propagating down-coast as a diffusion phenomenon. The second was estimated from the variation from the erosive wave and defined to be an erosive wave propagating down-coast as a wave phenomenon. We suggest new terminology for these two kinds of erosive wave. The erosive waves of the first mode are subject to change as positive and negative erosive waves due to the initial and boundary conditions at the river mouth in relation to the sediment input from the river and local change in the submerged river delta. The erosive wave of the second mode propagates down coast faster than the first mode erosive wave. We therefore conclude that shoreline change due to beach erosion can be described as space-time change propagating down-coast as a diffusion phenomenon, upon which shoreline variation propagates as a wave phenomenon faster than the shoreline change. Additionally, a theory for the diffusion-wave phenomenon of shoreline change is attempted using a set of equations of longshore sediment transport rate and continuity of shoreline change to find the dispersion relation of erosive waves.

INTRODUCTION

In the past, it has been considered that shoreline change is a diffusion process, governed by a diffusion-type equation in a one-line theory. It has been observed that, in the reduction process of a river delta, severe shoreline change takes place in the vicinity of the cause of erosion, sometimes with beach collapse, and that shoreline change propagates down-coast like a wave phenomenon. In 1987, Inman defined the propagation velocity of an accretion or erosion wave in terms of the longshore sediment transport rate. By use of this method, Uda and Yamamoto (1994) recently estimated the velocity of a sandy body on the Mihono-matsubara sand spit. In understanding

¹Professor Emeritus, Kyoto University and Professor, Faculty of Urban Science, Meijo University, 4-3-3 Nijigaoka, Kani 509-02, Japan

the shoreline change and establishing methodologies for its control, it is of course very important to recognize whether the shoreline change can be described as a diffusion or a wave phenomenon, or as a diffusion-wave phenomenon.

Recently, Tsuchiya (1995, 1996) studied erosive waves in shoreline change by analyzing long-term shoreline change data from the Shizuoka and Shimoniikawa coasts, using the method of moving average.

In this paper, we analyze data of long-term shoreline change along the Shizuoka Coast facing Suruga Bay by the method of moving average, to find the space-time change of the shoreline and its propagation speed. The narrow, sandy beach was formed on the collision coast due to there being a lot of sediment input from the Abe river. Due to a rapid decrease in sediment input, severe beach erosion and collapse began to take place near the river mouth in 1965. This extends in the direction of longshore sediment transport. The beach erosion can therefore be considered as a reduction process of the river delta. There clearly exist two modes of shoreline change. The first mode is space-time shoreline changes such as positive and negative erosive waves as diffusion phenomena. The second mode is an erosive wave propagating faster than the first mode shoreline change. We demonstrate that shoreline change due to beach erosion must therefore be considered as a diffusion-wave phenomenon.

Additionally, a theory of shoreline change is proposed from a set of equations for longshore sediment transport and continuity of shoreline change. We conclude that the shoreline change can be described by a diffusion-wave phenomenon. The dispersion relation is obtained, and the resulting propagation speed is discussed.

THE DATA

The Shizuoka Coast and Its General Features: Although depth sounding was first performed in 1969, regular surveys of shoreline change and soundings on the

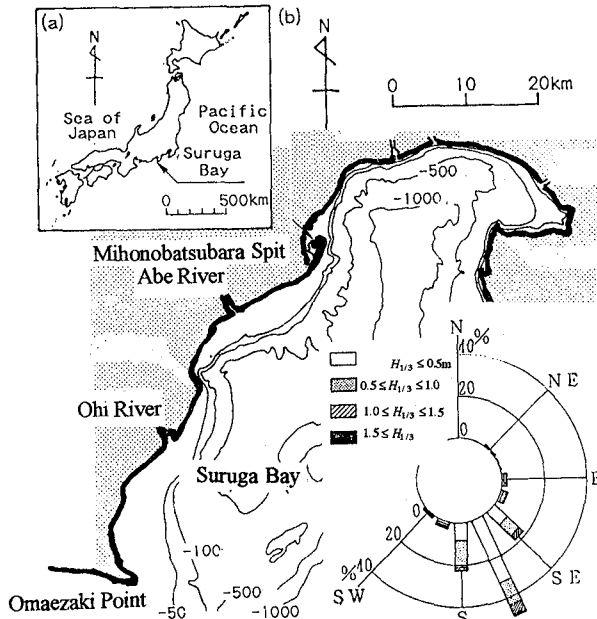

Figure 1. Location of Shizuoka coast and wave rose (Modified from Uda, 1994)

Shizuoka coast have been carried out annually since 1974 by the Shizuoka Prefectural Government.

In this paper, the measured data were used. The Shizuoka coast is one of the Pacific Ocean coasts of the Japanese islands, facing Suruga bay as shown in Figure 1. This coast is a typical collision and mountainous coast according to the coastal classification of Inman and Nordstorm (1971). The width of the coast is very narrow. The beach profiles are very steep and connect with the steep offshore slopes in Suruga bay. Because of the high rate of sediment input from the Abe river, a narrow sandy beach has been formed on the coast by typhoon waves from the south to southeast directions. At the northeast end of the coast, a sand spit called Mihono-batsubara sand spit is beautifully formed by the longshore sediment transport in the northeast direction. Near the sand spit, a sea canyon is located into which part of the longshore sediment is deposited.

Coastal Disasters and the Main Causes of Beach Erosion: Coastal disasters occurred due to the Isewan typhoon in 1959 and Typhoon 6626 in 1966, resulting in

Figure 2. Shoreline changes due to beach erosion and collapse in the initial stages of beach erosion (Toyoshima, Takahashi & Suzuki, 1981).

beach collapse in some locations on the beach north of the river mouth, as shown in Figure 2. Since then sea dikes have been constructed along the coast. Because there was remarkable beach erosion at that time, soundings and shoreline surveys have been carried out along the coast since 1969. The sea dikes were sometimes destroyed and the eroded area extended further along the northeast coast. Therefore offshore breakwaters were begun to be

Figure 3. Annual change of total volume of concrete units used for offshore breakwaters.

constructed, and these are now completed along the whole coast. Figure 3 shows the total volume of concrete units used for the offshore breakwaters. In the Abe River sediment mining had been done widely and severely before 1968 for construction works, resulting in severe beach erosion. We therefore conclude that the main cause for beach erosion is due to the decrease in sediment input from the Abe River, and that the beach erosion can be explained as a reduction process of the river delta.

THE METHOD OF DATA ANALYSIS

Purpose of Data Analysis: Shoreline changes are usually measured at intervals of 100m or 200m. As shown in Figure 2, beach collapse takes place locally over several hundred meters, and extends down-coast as it propagates. The spatial magnitude of shoreline change due to beach erosion is wider and reaches sometimes a few kilometers. Therefore, we have to consider shoreline changes extending from several hundred meters up to several kilometers. The shoreline change data include local shoreline changes and some errors in the measurements. In order to clarify the shoreline changes more naturally than we have understood them, it may be effective to analyze the data using spatial smoothing methods.

Methods of Data Analysis: We have two traditional methods for smoothing fluctuating data; 1) the triangle-weighting or uniform-weighting method, and 2) the Fourier transform method. Shoreline changes take place not only due to beach erosion, but also by beach collapse under the action of wave concentration, and extend widely along the coast. In this paper, the uniform-weighting method was used. The number of points for weighting was determined by considering whether the phenomena in question can be clearly observed in the smoothed data. 11, 13 and 15 points were used for large-scale shoreline change as a diffusion phenomenon, and 3 points were used for variations from the large-scale shoreline change as a wave phenomenon. The applicability of the smoothing method was established by comparing the results from using different numbers of smoothing points. We conclude that, in the data measured at intervals of 100 m, 13 and 15 smoothing points are suitable for large-scale shoreline change, but 3 points for variations from the shoreline change.

THE CLASSIFICATION OF EROSIIVE WAVES

Spatial and Temporal Shoreline Changes: Using the 15-point smoothing method, smoothed shoreline changes and their variations are shown in Figure 4 at intervals of two every years. In the figure there clearly exist two modes of shoreline change. The first mode, indicated by the thick solid curves, is the large-scale shoreline change. The second mode, indicated by the thin curves with marks, is the variation from the first-mode shoreline change. The large-scale shoreline changes show clearly the annual change of shoreline in spatial form from the river mouth of the Abe river. The shoreline change expands widely down-coast in the north-east direction. This shoreline change clearly demonstrates the total shoreline change under the condition of beach erosion, which we understand as a diffusion phenomenon. This shoreline change propagation may correspond to the accretion or erosion wave proposed by Inman (1987). Referring to the cause of beach erosion, which is a decrease in sediment input from the Abe river, this total shoreline change can be understood to be a reduction process of the river delta. However, the boundary condition for the shoreline change at the river

Figure 4. Total shoreline changes with erosive waves (W) down-coast from the river mouth.

mouth will be discussed in relation to the generation of erosive waves, as well as the decrease in sediment input from the river.

Erosive Waves: The thick curves shown in Figure 5 illustrate annual changes in total shoreline change, for which I define an *erosive wave as a diffusion phenomenon*. The erosive wave propagates down-coast, reducing in amplitude gradually. In this case, it has a wave crest defined by a minimum in the spatial shoreline change, and a trough defined by a maximum. Note the fact that the erosive wave is composed of two elementary waves such as positive and negative erosive waves. The positive erosive wave propagates accompanying the negative erosive wave. Further, note that these two waves were generated by different events at the river mouth, probably rapid decrease and increase in sediment input from the river, or their resulting local changes

(a) 1976 to 1982.

(b) 1977 to 1981.

Figure 5. Spatial profiles and propagation of erosive waves (DP) and (DN) with erosive wave (W) before the construction of offshore breakwaters.

in the submerged river delta. Therefore, I define the erosive wave propagating as a diffusion phenomenon as *erosive wave (D)*, and the positive and negative erosive waves as *erosive wave (DP)* and *erosive wave (DN)*, respectively.

When the erosive waves are specified at the river mouth as the initial and boundary conditions for shoreline change, we may predict the total shoreline change using a common shoreline change model. Actually, beach profiles change in relation to shoreline changes around the river delta, so that the application of the model may need further consideration. The thin curves shown in Figure 6 indicate the variations from the erosive wave (D), for which I define an *erosive wave as a wave phenomenon*. This erosive wave propagates down-coast on the erosive wave (D). Thus, I define it as *erosive wave (W)*. The crest and trough of the erosive wave (W) are denoted as *erosive wave (Wc)* and *(Wt)*, respectively.

THE EROSIIVE WAVE(D) AND ITS PROPAGATION AS A DIFFUSION PHENOMENON

Spatial Profiles and Propagation of the Erosive Waves (D): As previously seen in Figure 5, this erosive wave (D) propagates down-coast accompanying erosive waves (DP) and (DN). Note that the spatial profiles of erosive waves (D) have nearly the same form, but reduce their amplitude gradually as a diffusion phenomenon, until the construction of offshore breakwaters. The erosive waves generated during and after the construction are shown in Figure 6, the thick curves with solid marks indicate the erosive wave (D), and the thin curves with open marks the erosive wave (W) propagating on the erosive wave (D). Note that during this period erosive waves (DN) were generated, and then erosive waves (DP) were then generated. Both the erosive waves propagate slowly down-coast in the same form, but their amplitudes clearly tend to decay down-coast. This fact may be due to the offshore breakwater effect of trapping of longshore sediment.

(a) 1987 to 1993.

(b) 1988 to 1994.

Figure 6. Spatial profiles and propagation of erosive waves (DP) and (DN) with erosive wave (W) during and after the construction of offshore breakwaters.

Propagation Speeds of Erosive Waves (DP) and (DN): The amount of data for the erosive waves is limited. Therefore, by use of the successive spatial profiles corresponding to the crests of erosive waves (DP) and (DN), the positions of the crests can be determined. Figure 7 shows the time-change of the crest positions where the straight line with solid diamond and square marks indicate respectively erosive waves (DP) generated before and during/after the construction of offshore breakwaters. The propagation speeds of erosive waves are obtained from the gradient of the straight lines.

Figure 7. Propagation speed of erosive waves (DP) and (DN) before and during/after the construction of offshore breakwaters.

Note that the propagation speed of erosive waves generated during and after is less than that before the construction. Further, note that the propagation speed of erosive waves (DP) and (DN) are the same. This may explain the fact that the spatial profiles shown in Figure 6 are decaying gradually down-coast, but maintain almost the same form. If the straight line of erosive wave (DP) is extended, the time when the erosive wave was generated is found to be around the year 1972. Alternatively, the times when erosive waves (DP) and (DN) were generated during and after the construction are found to be around the years 1983 and 1987, respectively.

Possible reasons for generation of erosive waves (DP) and (DN): As previously discussed the main cause of beach erosion is due to the decrease in sediment input from the Abe river. Uda, Misawa and Matsui (1996) recently qualified this fact considering river bed changes due to mining of sand and gravel in the river. They conclude that the river bed had been lowered within the alluvial reach near the river mouth during mining until 1968, but changed to deposition of sediment during the period between 1970 and 1973. It therefore seems that within the period, there was no sediment input into the beach, resulting in either the direct generation of the erosive wave(DP) shown in Figure 7, or changing the submerged river delta which may have generated erosive waves. They also described that after the generation of the erosive wave no remarkable floods have been experienced, but a huge flood occurred in 1982, of which the maximum discharge was 3,860 m³/sec. It also seems that the flood generated the erosive wave(DN), and that variations in the submerged river-mouth delta in relation to floods might generate erosive waves .

THE EROSIIVE WAVE(W) AND ITS PROPAGATION AS A WAVE PHENOMENON

Erosive Wave (W) and Its Propagation: Figures 8 and 9 show erosive waves (W) generated before and during/after the construction of offshore breakwaters respectively. A careful inspection shows that the erosive waves (W) propagate down-coast, with some exceptions. Note that the wave amplitudes show their maximum values near the river mouth, and reach over 30 m. Further, note that they decay in their propagation down-coast. It seems that this tendency is the same both before and during/after the construction of offshore breakwaters.

(a) 1975 to 1983.

(b) 1976 to 1984.

Figure 8. Erosive waves (W) and their propagation, with wave amplitudes damping down-coast, before the construction of offshore breakwaters.

Wavenumber Spectrum of Erosive Waves (W): The amount of data is not sufficient for calculating wave number spectra of erosive waves (W) accurately. There is also a decay of their wave amplitudes. These may prevent the spectrum from being calculated accurately. However, we tried to estimate them using Mathematica to examine whether a peak wavenumber exists. Figure 10 shows some examples of the spectra. The spectra are not well formed, but there exists a peak wavenumber. The wavelength corresponding to the peak wave number was calculated. Figure 11 shows change in the wave length. It is nearly constant, being about 500 m until 1985, and thereafter varies and increases. This may be due to the trapping effect of longshore

(a) 1987 to 1993.

(b) 1988 to 1994.

Figure 9. Erosive waves (W) and their propagation, with wave amplitudes damping down-coast, during and after the construction of offshore breakwaters.

sediment transport by offshore breakwaters.

Propagation Speed of Erosive Waves (W): From successive crests of erosive waves (W) which were selected from the spatial profiles shown in Figures 8 and 9, the positions of the crests were determined. Figure 12 illustrates time changes of the crest positions of erosive waves (W) where the straight line with solid circles indicates the crest position of erosive wave (DP) and those with open squares and triangles mark the crest and trough positions of erosive waves (Wc) and (Wt), respectively. The propagation speeds of the crest and trough of erosive wave (W) are nearly same, and faster than that of erosive wave (DP). We therefore conclude that the erosive wave (W) propagates faster than the erosive wave (DP). This fact may explain why beach collapse or severe erosion takes place locally at some locations down-coast with the sandy beach being eroded.

Figure 10. Some examples of wave-number spectra of erosive waves (W).

Figure 11. Changes in wavelength corresponding to the peak wavenumber.

Figure 12. Propagation speed of erosive wave (W) compared with those of erosive waves (DP) and (DN).

Possible Reasons for Generation of Erosive Waves (W): Where there exists a wave phenomenon, there must be a generation force to produce the wave. Such generation forces do exist, such as incoming waves with some frequency of occurrence, but what the restoring forces are should be clarified. As will tentatively be explained later, the local change of shoreline may result in changing the total rate of longshore sediment transport. This may generally result in restoring the shoreline change. Therefore, once a local shoreline change has taken place, the shoreline change propagates down-coast, probably decaying in amplitude.

THE EROSIIVE WAVES AS A DIFFUSION-WAVE PHENOMENON AND THEIR PROPAGATION

So far a set of governing equations for shoreline change, composed of the equation of continuity for shoreline change, the total rate of longshore sediment transport and the geometrical relation of shoreline change has been used to derive a diffusion equation for shoreline change. In order to study a natural phenomenon dynamically, a set of both the equations of motion and continuity must be established. The equations of longshore sediment transport rate and continuity of shoreline change are approximately given by (Refaat and Tsuchiya, 1991)

$$\frac{\partial Q}{\partial t} + a \frac{\partial}{\partial x} \left(\frac{Q}{h_b} \right)^2 = b g h_b^2 \left(\sin 2\alpha_{b0} - 2 \frac{\partial y_0}{\partial x} \right) - e \sqrt{\frac{g}{h_b}} Q \quad (1)$$

$$\frac{\partial y_0}{\partial t} + \frac{1}{(1-\lambda)h_k} \frac{\partial Q}{\partial x} = 0 \quad (2)$$

where y_0 is the shoreline position from the datum line, h_b the breaker depth, h_k the threshold depth of sediment movement, g the acceleration of gravity, λ the porosity of the bottom sediment, and a , b and e are practically constants. The second term in the first term on the right side of (1) demonstrates the restoring force of shoreline change in the wave phenomenon. The linearization of (1) and (2) results in

$$\frac{1}{e} \sqrt{\frac{h_b}{g}} \frac{\partial^2 y_0}{\partial x^2} + \frac{\partial y_0}{\partial t} - \frac{\sqrt{2b}}{e(1-\lambda)} \frac{h_b^2 \sqrt{g h_b}}{h_k} \frac{\partial^2 y_0}{\partial x^2} = 0 \quad (3)$$

which is the linearized wave-diffusion equation for shoreline change. Neglecting the first term the second and third terms reduces to the usual diffusion equation of shoreline change. The dispersion relation of (3) is given by

$$\frac{(\sigma/k)^2}{g h_b} = 2b \left\{ \frac{h_b}{(1-\lambda)h_k} \right\} \frac{1}{1 - e \sqrt{g/\sigma^2 h_b}} \quad (4)$$

The term $g/\sigma^2 h_b$ in (4) describes the diffusion term effect on the dispersion. When the term vanishes (4) demonstrates the wave celerity in the wave equation which can be obtained by neglecting the second term. The wave celerity shows that the wave celerity of erosive waves is proportional to the long-wave velocity evaluated from the breaker

depth and the square root of the ratio of breaker depth to threshold depth of sediment movement.

CONCLUSION
