The relationship between $C(x, 0)$ and x is shown in figure 8. Near the sea wall, $C(x, 0)$ decreases exponentially in the leeward direction. It is seen, therefore, that the relationship given by equation (3) is compatible with the data. The decreasing rate becomes small with the increase of the wind velocity. On the other hand, $C(x, 0)$ takes large values with the increase of the wind velocity. The values of $C(x, 0)$ approach to constant values in the region far away from the sea wall. We can estimate the values of $C(0, 0)$ and w_0 / U_m by fitting equation (3) to the data and using the values of \bar{l} . The obtained values are given in table 1. Figure 9 shows the profiles normalized by using $C(0, 0)$ and $w_0 / U_m \bar{l}$. It is seen that $C(x, 0)$ decreases exponentially in the range of $\frac{w_0}{U_m} \frac{x}{\bar{l}} \leq 10$.

Figure 10 shows the relationship between $C(0, 0)$ and U_0 / C_0 . The values of $C(0, 0)$ increase with the increase of U_0 / C_0 . In the case when the relative crown height h_c / H_0 is large, it is seen that $C(0, 0)$ takes small values. Figure 11 shows the dependence of w_0 / U_m on U_m / C_0 . The tendency is seen that w_0 / U_m decreases with the increase of U_m / C_0 and large spray is transported as the wave steepness increases.

4. Conclusions

In this study, the quantity of spray generated from a wave absorbing sea wall under a storm and its landward transport process were investigated experimentally. The obtained main points are as follows.

- 1) Near the sea wall, the spray concentration is determined by the equilibrium between the advection of spray and the sedimentation.

- 2) The spray concentration near the sea wall decreases exponentially both in the vertically upward direction and in the leeward direction.
- 3) The spray concentration on the horizontal bed decreases exponentially in the region of $\frac{w_0}{U_m} \frac{x}{l} \leq 10$.

The authors are grateful to Mr H. Kawakami and Ms Y. Arizumi for their help. A grant from the Ministry of Education, Science and Culture is also acknowledged.

CHAPTER 81

Irregular Wave Kinematics from a Pressure Record

Christopher H. Barker¹ and Rodney J. Sobey²

Abstract:

A local Fourier approximation method is presented for the prediction of the complete kinematics of irregular waves from a submerged pressure trace. The method seeks a potential function and local water surface elevation that fit the pressure record and the full nonlinear free surface boundary conditions very closely in a small window in time. The result is a complete prediction of the kinematics of the waves throughout the water column that satisfies the complete nonlinear equations for irrotational gravity waves. Comparisons with the predictions of steady wave theory are excellent.

Introduction

A knowledge of wave kinematics is necessary for most aspects of coastal engineering. Fluid velocities and accelerations are necessary for the study of the wave loading of structures through the use of the O'Brien-Morison equation. Knowledge of the kinematics near the sea bed are necessary for studies of sediment transport processes. High order steady wave theories are quite successful at the prediction of the kinematics of steady waves, but are not directly applicable to the irregular waves usually found in the field.

Subsurface pressure transducers are a commonly used method for the measurement of waves in the near-shore zone, as they are relatively easy to deploy. They are frequently used in shallow and transitional depth water. Most methods currently in use for the interpretation of these measurements rely on linear wave

¹Doctoral Candidate, Dept. Civil and Environmental Engineering, 412 O'Brien Hall, University of California, Berkeley, CA 94720 USA

²Professor, Dept. Civil and Environmental Engineering, 412 O'Brien Hall, University of California, Berkeley, CA 94720 USA

theory. Linear theory is appealing in that solutions are readily available and can easily be applied to a variety of situations. Unfortunately, linear theory is based on the assumption that wave amplitudes are small. It is also a Stokes theory, with optimum theoretical applicability in deep water. In fact, the cases of most interest in the interpretation of pressure measurements are for large waves in shallow water, exactly the conditions in which linear theory is least adequate.

In this paper, a method is presented for the interpretation of a measured point pressure time history that preserves the full non-linearity of the process, and can be applied to an irregular sea in any depth of water.

Global and Local Approximations

Methods used for the interpretation of irregular wave records fall into two general categories, global and local approximations. Global methods are those that seek a solution that matches an entire measured record, or a single complete measured wave, from trough to following trough, or zero crossing to zero crossing. These methods apply the same frequency and wave number for all z (vertical variation) and t (time).

Local methods seek an approximation to each small local segment of a measured record. In these methods, the frequency and wave number vary, providing a separate solution for each small window in time.

Global Methods

The most commonly used global method for the analysis of irregular waves is spectral analysis, coupled with superposition of linear waves. This method has a number of shortcomings, including the high frequency contamination of the kinematics above the crest (Forristall, 1985; Sobey, 1992). Fundamentally, the difficulties arise from the approximations made by linear wave theory to the free surface boundary conditions. If the full nonlinear free surface boundary conditions are not satisfied, one can expect that the resulting predictions will be inaccurate, particularly near the free surface. Empirical modifications to linear theory have been adopted eg. (Wheeler, 1969), but these no longer conserve mass (Sobey, 1992).

Other global methods rely on zero crossing analysis to identify particular waves that are then analyzed by using steady wave theory for a wave of the same height and period. This approach can provide an order of magnitude estimate for the kinematics, but does not take into account the detail of the record. Dean (Dean, 1965) extended his stream function method to irregular waves, seeking a Fourier expansion for the stream function that fit a water surface record from trough to following trough. While taking into account the detail of the record, the assumption that the wave is globally steady is a major compromise.

Baldock and Swan (Baldock and Swan, 1994) presented a method for the

analysis of a point water surface record that includes unsteady motion. Their method employs a potential function in the form of a double Fourier expansion in time and space. The coefficients of the expansion are found by minimizing the errors in the full non-linear free surface boundary conditions over a grid of nodes in time and space. While comparisons of their results with laboratory data were quite good, the method involves a huge matrix of unknown coefficients and must solve for the water surface far from the actual measurement location. While making no assumptions about the steadiness of the wave field, the method requires an assumed periodicity (usually the length of the record). In order to obtain a good fit to the measured record, a substantial weighting function must be applied to assure that the errors in the boundary conditions are small at the measured location. This need for a weighting function suggests that a local solution may be advantageous.

Local Methods

The Nielsen method (Nielsen, 1986; Nielsen, 1989) uses a local frequency and linear wave theory to find the location of the water surface from a pressure record. Best results were achieved from a stretching method, similar to Wheeler's (Wheeler, 1969), or a semi-empirical transfer function derived from Fourier steady wave theory. In either case, the method does not supply the complete kinematics, and does not satisfy the governing equations.

Fenton (Fenton, 1986) employed a local polynomial approximation to the complex potential function. In this method, the potential function is represented by a separate polynomial in each small window in time. Coefficients of the polynomial are sought that fit the measured pressure record, and the full nonlinear free surface boundary conditions. This approach provides the complete kinematics and satisfies the full governing equations. Based on a polynomial variation with depth, it should work well in shallow water, but may have difficulty in transitional or deep water.

Sobey's Locally Steady Fourier Method (LSFI) (Sobey, 1992) employs a potential function represented by a low order Fourier expansion in a small window in time. It is a method derived for the analysis of a point water surface trace. Local frequency, wave number, and Fourier coefficients are sought that fit the measured record and the full free surface boundary conditions. This method provides the complete kinematics, satisfies the full governing equations, and is successful in all depths of water. The method presented in this paper is an adaptation of Sobey's method to the analysis of a measured pressure trace.

Governing Equations

The formulation of the problem of uni-directional irregular waves is similar to that for classical steady wave theory. The flow is taken to be incompressible

and irrotational. The kinematics can therefore be represented by a potential function, ϕ , where

$$u = \frac{\partial\phi}{\partial x} \qquad w = \frac{\partial\phi}{\partial z} \qquad (1)$$

where u and w are the horizontal and vertical velocities, respectively. Mass conservation then becomes the Laplace equation:

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial z^2} = 0 \qquad (2)$$

The boundary conditions are the bottom boundary condition (BBC),

$$w = \frac{\partial\phi}{\partial z} = 0 \qquad \text{at} \qquad z = -h \qquad (3)$$

the kinematic free surface boundary condition (KFSBC),

$$w - \frac{\partial\eta}{\partial t} - u \frac{\partial\eta}{\partial x} = 0 \qquad \text{at} \qquad z = \eta \qquad (4)$$

and the dynamic free surface boundary condition (DFSBC),

$$\frac{\partial\phi}{\partial t} + \frac{1}{2}u^2 + \frac{1}{2}w^2 + g\eta - \bar{B} = 0 \qquad \text{at} \qquad z = \eta \qquad (5)$$

where η is the location of the free surface and \bar{B} is the Bernoulli constant.

In steady wave theory, periodic lateral boundary conditions are imposed, forcing the solution to be periodic in space and time. With irregular waves, there is no periodicity. Rather, a solution is sought that fits a local segment of the record, the Laplace equation, bottom boundary condition, and both nonlinear free surface boundary conditions.

A form for the potential function in each window is motivated by Fourier steady wave theory. This is the same form as that used by Sobey (Sobey, 1992).

$$\phi(x, z, t) = U_E x + \sum_{j=1}^J A_j \frac{\cosh jk(h+z)}{\cosh jkh} \sin j(kx - \omega t) \qquad (6)$$

U_E and h are the known depth uniform Eulerian current and water depth, J is the truncation order of the Fourier series, A_j are the local Fourier coefficients, and ω and k are the local fundamental frequency and wave number. This form exactly satisfies mass conservation and the BBC. A different set of parameters is found for each segment of the pressure record. While this form for the potential function is periodic, the periodicity is not defined a priori, but found to fit the record, defining a local frequency and wave number.

Fitting to a Pressure Record

While the potential function provides the complete kinematics, the dynamics are found through the unsteady Bernoulli equation:

$$\frac{\partial \phi}{\partial t} + \frac{1}{2}(u^2 + w^2) + \frac{P_d}{\rho} - \bar{B} = 0 \quad (7)$$

where P_d is the dynamic pressure ($P_d = P - \rho g z$). In steady wave theory, the Bernoulli constant is (Longuet-Higgins, 1975):

$$\bar{B} = g\bar{\eta} + \frac{1}{2}u_b^2 \quad (8)$$

where u_b is the velocity at the bed, and the over-bars indicate time averaging. In this case, it will be different in each window. With z defined to be zero at the mean water level, and Eqn. 6 as the potential function, \bar{B} becomes (Sobey, 1992):

$$\bar{B} = \frac{1}{2}U_E^2 + \frac{1}{4} \sum_j \left(\frac{jkA_j}{\cosh jkh} \right)^2 \quad (9)$$

thus all the terms in Eqn. 7 are defined by the potential function except the dynamic pressure, which is given by the measured record.

Eqns. 6 and 7 apply to many periodic flows. There might be any number of these flows that could produce a given pressure record at a single location. It is the free surface boundary conditions (Eqn. 4 and 5) that identify a potential flow as a surface gravity wave. As the solution sought is a gravity wave, these boundary conditions must be included in the formulation. To include the free surface boundary conditions, the location of the water surface, together with the potential function, become the unknowns in each window.

Locating the water surface

The water surface is defined at N surface nodes in each window ($\eta(t_n), n = 1 \dots N$). The elevation of these nodes is unknown, and will be sought as part of the solution. Eqn. 5 is directly applied at each node. In order to apply Eqn. 4 at the surface, the time gradient is estimated by cubic spline interpolation among these nodes. This provides a smooth and consistent estimate at all locations within the window. The spatial gradient can be computed from the time gradient by assuming that the water surface is locally steady. This assumption follows from the steady form of the potential function, and is the same assumption used by Sobey.

$$\frac{\partial \eta}{\partial x} = -\frac{k}{\omega} \frac{\partial \eta}{\partial t} \tag{10}$$

Including the water surface nodes as part of the sought solution introduces N additional unknowns for a total of $3 + J + N$ unknowns in each window $(k, kx, \omega, A_j, \eta_n)$. Eqn. 4 is applied at the locations between the water surface nodes. Eqn. 5 is applied at each of the nodes, yielding $2N - 1$ additional equations. Eqn. 7 is applied at I nodes on the pressure record $(P_d(t_i), i = 1 \dots I)$ within the local window (see Fig. 1).

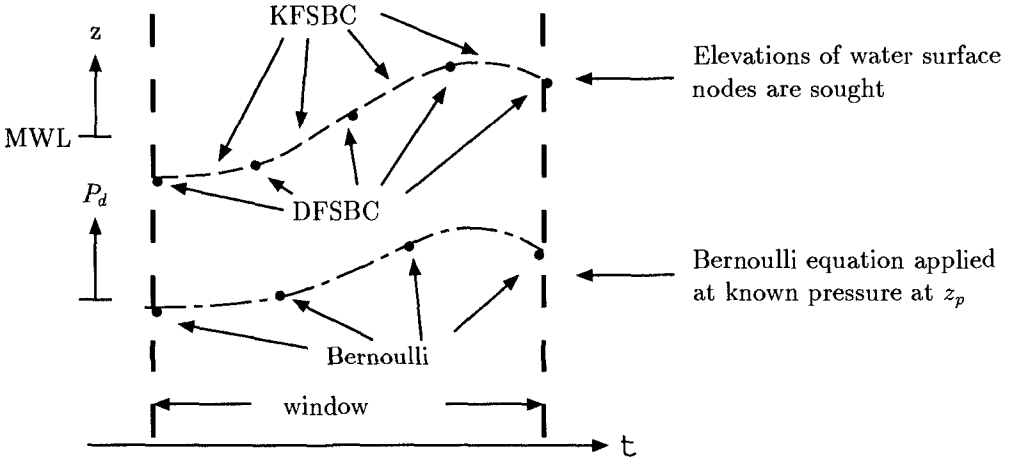

Figure 1: Schematic of system of equations in a window

The problem is uniquely specified for $I + N = 4 + J$ and overspecified for $I + N > 4 + J$. If overspecified, the solution is that which results in the minimum error in all equations, in the least squared sense. Overspecification, with additional nodes on the pressure record, is likely to be advantageous for an actual record to minimize the effect of unavoidable measurement noise.

Computation Methods

Non-dimensionalization

The comparisons of errors of different dimensional quantities would be meaningless. All parameters and variables are scaled by factors computed from physically identifiable parameters. These are the mass density of water, acceleration of gravity, and the mean zero crossing frequency. The characteristic length scale

is g/ω_z^2 , time scale is $1/\omega_z$ and the mass scale is $\rho g^3/\omega_z^6$ where ω_z is the mean zero crossing frequency of the record. The familiar dimensional forms of the equations have been presented in this paper to aid in readability. The unknown parameter, x , appears in the equations only when coupled with the parameter, k . It is simpler to solve for the non-dimensional parameter, kx , essentially a phase parameter in the potential function.

Initial Estimate

The primary process in this LSFI-P method is nonlinear optimization to find the minimum error in a system of nonlinear algebraic equations typically involving 14 equations in 12 unknown parameters. A system as complex as this is likely to have a number of local minima that result in spurious physical solutions. The best way to avoid these solutions, as well as to allow for efficient optimization, is to start with a good estimate for the unknowns in the system, and to have a basic set of criteria for identifying spurious solutions.

The first step in each window is to establish an initial estimate for the optimization procedure. Linear wave theory can be used to produce estimates for the parameters of approximately correct magnitudes.

Nielsen (Nielsen, 1986; Nielsen, 1989) established a method for determining the parameters of a local linear approximation to waves from a pressure record. A similar method is used here. Frequency of a sinusoidal signal of the form $P_d = a \cos(kx - \omega t)$ is available from the second derivative:

$$\omega^2 = -\frac{\partial^2 P_d / \partial t^2}{P_d} \quad \text{or} \quad \omega = \sqrt{-\frac{\partial^2 P_d / \partial t^2}{P_d}} \quad (11)$$

Once the frequency is known, the amplitude and phase of a particular segment of record can be found by rearranging the equation as a linear least squares problem by separating the cosine and sine components:

$$P_d = a \cos(kx - \omega t) = b_1 \cos \omega t + b_2 \sin \omega t \quad (12)$$

The linear terms (a and kx) are a function of ω , reducing the nonlinear problem to one variable (Lawton and Sylvestre, 1971). The estimates for ω , a , and kx are refined by optimizing for the frequency that results in the least error throughout the current window, using Eqn. 11 as a first estimate.

Once the optimum frequency is found, the wave number is estimated from the linear dispersion relation, and the first estimate for the Fourier amplitudes are assigned as follows:

$$A_1 = \frac{a}{\rho \omega \cosh k(h+z) / \cosh kh} \quad A_2 = \alpha A_1 \quad A_j = \alpha A_{j-1} \quad (13)$$

$\alpha = 0.1$ was found to be satisfactory. The location of the water surface is estimated from the linear pressure response function with stretching (Nielsen, 1986).

$$\eta = \frac{P_d \cosh k(h + (P_d/\rho g))}{\rho g \cosh k(h + z)} \quad (14)$$

An estimate for the values of the second time derivative of the record in each window is required. This is accomplished by a least squares fit of a third order polynomial to the record in each window. The derivatives can then be computed from this polynomial. This approach was very successful in the analysis of artificially generated noisy records, resulting in reasonable estimates for the value at the middle of the window, as well as both derivatives at that point.

Optimization

Once there is a reasonable first guess for all the parameters, nonlinear optimization routines can be applied to this system. For the results in this paper, the Levenburg-Marquart algorithm was used as implemented by the Matlab Optimization Toolbox. If the optimization routine successfully finds a minimum, the solution is checked to see if a clearly spurious solution is found. Spurious solutions can be identified by the following criteria: very large or highly variable errors, first order amplitude smaller than higher order amplitudes, unrealistically large or small frequency or wave number. It is unusual for the routine to converge to a spurious solution. It is far more common for the routine not to converge at all.

If no solution or a spurious solution is found, it is necessary to revise the parameters of the solution to make another attempt. For the next attempt, the window width is increased by a factor of 1.5, and the procedure is repeated. If this is not successful, the window width is increased once more to twice the standard width. When increasing the window width is not successful, the order of the potential function is decreased until a solution is found. If none of these adjustments result in a reasonable solution, the window is skipped, and future analysis must be interpolated through that point. These adjustments are most likely to be needed in the long, flat trough of a shallow water wave, where the window needs to be expanded to include some curvature to indicate the frequency. There can also be difficulties near zero crossings, where there is little curvature in the record, and the effects of amplitude and frequency are not independent. Widening the window to include more of the surrounding record is generally successful in this situation as well.

Another complication can be a record that is symmetric about the crest of a wave. In this case, the equations on either side of the crest are not independent. This situation is unlikely to arise in a field record, and can easily be accommodated by using an asymmetric distribution of points in that window.

Results

In order to remove complications from measurement error in the initial testing of the method, pressure records generated by Fourier Steady wave theory (Sobey, 1989) were used. This also has the advantage of providing a solution with the complete kinematics, to compare with results from the LSFI-P method. High order Fourier wave theory is essentially an exact solution for irrotational steady waves that can be applied at any depth (Rienecker and Fenton, 1981; Sobey, 1989). Fig. 2 presents the results after the first guess, before optimization. This is a window near the crest of a steep, shallow water wave generated by 18th order Fourier theory. The predictions for the dynamic pressure are approximately correct, and the water surface estimate is in the vicinity of the actual water surface. Note that the location of the actual surface is given in the plot, but it is not available to help determine the solution. These points were all generated by the method outlined in the previous section, with only the pressure record as a guide. The third plot shows the non-dimensional errors in the Bernoulli equation and the free surface boundary conditions. The errors are of order .03 and show a systematic pattern, particularly in the Bernoulli equation. It is clear from these plots that a better solution can be found.

The results after optimization are given in Fig. 3. At this point the prediction for the dynamic pressure is essentially exact. This is virtually always the case, as the pressure record is available, and the parameters are found to fit that record. The predictions for the water surface are also extremely close. This is an impressive achievement, as location of the water surface was found only by minimizing the errors in the free surface boundary conditions. In this case, the LSFI-P method was able to accurately capture the crest of a steep shallow water wave.

Fig. 4 shows the results of the method for the complete wave. The parameters of the wave are: 5m water depth, 3m wave height, and 10s period, with the pressure record measured on the bottom. The LSFI-P method finds the water surface and the kinematics on the surface essentially exactly. While these results show the complete wave, it is important to keep in mind that each of the indicated points is in the center of a separate window, and was computed completely independently of the other windows. In this case, the standard window width was 2s, with a sixth order potential function and seven water surface nodes. The 2s window width is one fifth of the period of the wave, and is a reasonable length of time to extend the locally steady approximation. It is not expected that the standard window width will exceed about one fifth of the zero crossing period of a record, nor the solution to be of order higher than six.

The dotted lines on the plot are the water surface and horizontal velocity at the surface as predicted by the linear wave theory pressure response function. It is clear that this method completely misses the high, sharp crest, and the large velocities at the crest.

Fig. 5 shows the results of the LSFI-P method for an entire deep water wave.

Figure 2: Results in a window after first estimate

The wave was generated by 12th order Fourier wave Theory, with parameters: 100m water depth, 10m wave height, and 10s period, with the pressure record measured 10m below the mean water level. Standard window width is 1s, with a fourth order potential function and five water surface nodes. Once again the LSF1-P solution matches the actual solution exactly. In the case of deep water, linear wave theory performs fairly well on steady waves, but is not applicable to irregular records, as there is no clearly defined single frequency or wave number.

Conclusions

While the given results are on artificially generated steady wave records, they show the potential for the method for a variety of conditions. In the case of steady waves, the LSF1-P method accurately computed the detail of the wave, using only data from a small window in time. In particular, the method was able to capture the pronounced sharp crest of a steep, shallow water wave. It is expected that it will perform well on segments of an irregular record.

The analysis of regular waves provides guidelines for the parameters to be

Figure 3: Final results in a window

used in the analysis of irregular waves. Higher order solutions and wider windows must be used in shallow water than in deep. Window widths of one fifth of the zero crossing period and a sixth order potential function are adequate for the shallowest waves, and window widths as small as one tenth of the zero crossing period and a third order potential function are adequate for deep water.

The Locally Steady Fourier approximation for irregular waves is an effective method for the computation of the kinematics of irregular waves from a point pressure record. The method results in a complete description of the water surface and kinematics of the waves that fit the given pressure record and the full free surface boundary conditions very closely in a small window in time. Comparisons with the predictions of steady wave theory are excellent.

CHAPTER 82

Nonlinear Refraction-Diffraction of Surface Waves over Arbitrary Depths

Serdar Beji¹ and Kazuo Nadaoka²

Abstract

A nonlinear dispersive wave model recently introduced by the authors is used for sample simulations of directional wave transformations over gently varying depths. Various forms of the generic equation are presented first, and the dispersion and nonlinear characteristics of the model are investigated analytically. Following the numerical descriptions, the experimental data for linear wave propagation over a circular shoal and for nonlinear wave propagation over a topographical lens are compared to the model predictions with satisfactory agreements. Finally, as a demonstration of the unified character of the model, the unidirectional version of the wave equation is implemented for simulating the gradual transformation of an initially second-order Stokes wave train over decreasing depth into a cnoidal wave train.

Introduction

The mean wave-number of a wave field propagating from deep to shallow water changes gradually and, when subject to spatial non-uniformities and non-linearity, causes quite profound modifications in the overall wave pattern. For an accurate description of such phenomena it is essential that a good wave model accommodates the relevant physical mechanisms. One such a model is Berkhoff's (1972) mild-slope equation, which has been used successfully in the last two and half decades. The model however has a few shortcomings, notably its restriction to linear, monochromatic waves. The time-dependent form of this equation (Smith and Sprinks, 1975) performs better in representing a narrow-banded wave field but cannot account for nonlinear effects which are quite appreciable for waves propagating on shallow waters or over sand-bars (Freilich and Guza 1984, Byrne 1969, Young 1989). In the nearshore zone the Boussinesq-type models are probably the best choice; however, their weak

² Professor, Graduate School of Information Science and Engineering, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro-ku, Tokyo 152, Japan

dispersion characteristics imposes limits on the applicable range of these equations. Despite the successful reports of extending their validity range (Witting 1984, Madsen *et al.* 1991, Nwogu 1993, Beji and Nadaoka, 1996), due to the certain assumptions introduced in their derivation, they remain finite-depth equations. The existing wave models then provide only partial representations of the observed effects: the mild-slope type equations are usable only for linear, narrow-banded waves while the Boussinesq equations are restricted by their applicable depth.

In order to overcome the drawbacks of the available wave models; namely, the linearity, narrow-bandedness, and depth-limitation, Nadaoka *et al.* (1994, 1997) advanced a new approach which was termed as the *multiterm-coupling technique*. They expressed the velocity field as a sum, each term comprising a hyperbolic vertical-dependence function and a corresponding velocity vector independent of depth. This expression was then used in nonlinear forms of the depth-integrated continuity and momentum equations in conjunction with the Galerkin procedure which ensured the solvability. The result was a set of wave equations that could describe the evolutions of a broad-banded nonlinear wave field propagating over arbitrary depths. These general equations have been shown to produce the aforementioned well-known wave models as degenerate cases besides generating the second-order Stokes waves on deep water. Here, the single-component (*i.e.*, a single-term expansion of the velocity field) equations in combined form as given by Beji and Nadaoka (1997) is used.

Wave Model and Its Various Forms

Nadaoka *et al.* (1997) give the following continuity and momentum equations as the single-component wave model, correct to the second-order in non-linearity:

$$\eta_t + \nabla \cdot \left[\left(\frac{C_p^2}{g} + \eta \right) \mathbf{u} \right] = 0, \quad (1)$$

$$\begin{aligned} & C_p C_g \mathbf{u}_t + C_p^2 \nabla \left[g\eta + \eta w_t + \frac{1}{2} (\mathbf{u} \cdot \mathbf{u} + w^2) \right] \\ &= \frac{C_p(C_p - C_g)}{k^2} \nabla (\nabla \cdot \mathbf{u}_t) + \nabla \left[\frac{C_p(C_p - C_g)}{k^2} \right] (\nabla \cdot \mathbf{u}_t), \end{aligned} \quad (2)$$

where η is the free surface displacement, $\mathbf{u}(u, v)$ the two-dimensional horizontal velocity vector and w the vertical component of the velocity both at the still water level $z = 0$. C_p , C_g , and k are respectively the phase and group velocities, and wave-number computed according to linear theory for a prescribed incident frequency ω and a local depth h . g is the gravitational acceleration, ∇ stands for the horizontal gradient operator with components $(\partial/\partial x, \partial/\partial y)$, and subscript t indicates partial differentiation with respect to time. Note that (1) and (2) are formulated for varying depth and therefore C_p , C_g , and k are in general spatially varying quantities. The above single-component equations may be considered as evolution equations that can simulate weakly-nonlinear, narrow-banded wave transformations over arbitrary depths. Compared with the Boussinesq-type equations, these equations are superior in the sense that they may be used without any restriction on the depth.

Eliminating \mathbf{u} from (1) and (2) to obtain a wave equation for the surface displacement η results in (Beji and Nadaoka, 1997):

$$C_g \eta_{tt} - C_p^3 \nabla^2 \eta - \frac{(C_p - C_g)}{k^2} \nabla^2 \eta_{tt} - C_p \nabla(C_p C_g) \cdot \nabla \eta - \frac{3}{2} g C_p \left(3 - 2 \frac{C_g}{C_p} - \frac{k^2 C_p^4}{g^2} \right) \nabla^2 (\eta^2) = 0. \quad (3)$$

Equation (3), named as the *time-dependent nonlinear mild-slope equation*, is the wave model adopted in this work. For a prescribed wave frequency and a definite water depth the wave number and the phase and group celerities are determined according to the relations given by linear theory.

Instead of eliminating the velocity field, invoking the existence of a two-dimensional potential function at the still water level $z = 0$ such that $\mathbf{u} = \nabla \phi$ and eliminating the surface elevation from (1) and (2), one obtains

$$C_g \phi_{tt} - C_p^3 \nabla^2 \phi - \frac{(C_p - C_g)}{k^2} \nabla^2 \phi_{tt} - C_p \nabla(C_p C_g) \cdot \nabla \phi + \frac{3}{2} C_p \left(1 - \frac{k^2 C_p^4}{g^2} \right) [(\nabla \phi)^2]_t = 0, \quad (4)$$

where the obvious approximation $(\nabla \phi)^2 \simeq -k^2 \phi^2$ in the nonlinear term is intentionally avoided since ϕ itself is not a directly measurable physical quantity and cannot be specified uniquely in the computations. Note also that for infinitely deep water waves $C_p^2 = g/k$ hence the coefficient of the nonlinear term in (4) vanishes, indicating a linear velocity potential for the second-order waves as in the Stokes second-order theory. The surface displacement on the other hand remains nonlinear regardless of the relative depth.

The linearized form of (3) or (4) is comparable with the time-dependent mild-slope equation of Smith and Sprinks (1975) but equation (3) can simulate a relatively broader wave spectrum as shown by Beji and Nadaoka (1997).

It is possible to extract from (3) a wave equation describing only the one-dimensional, right-going waves (Beji and Nadaoka, 1997):

$$C_g \eta_t + \frac{1}{2} C_p (C_p + C_g) \eta_x - \frac{(C_p - C_g)}{k^2} \eta_{xxt} - \frac{C_p (C_p - C_g)}{2k^2} \eta_{xxx} + \frac{1}{2} [C_p (C_g)_x + (C_p - C_g) (C_p)_x] \eta + \frac{3}{4} g \left(3 - 2 \frac{C_g}{C_p} - \frac{k^2 C_p^4}{g^2} \right) (\eta^2)_x = 0, \quad (5)$$

which may be shown to include the KdV equation as a special case as well as admitting the second-order Stokes waves as solution in deep water.

The counterpart of (5) in terms of the one-dimensional potential is

$$C_g \phi_t + \frac{1}{2} C_p (C_p + C_g) \phi_x - \frac{(C_p - C_g)}{k^2} \phi_{xxt} - \frac{C_p (C_p - C_g)}{2k^2} \phi_{xxx} + \frac{1}{2} [C_p (C_g)_x + (C_p - C_g) (C_p)_x] \phi + \frac{3}{4} C_p \left(1 - \frac{k^2 C_p^4}{g^2} \right) (\phi_x)^2 = 0. \quad (6)$$

It should be remarked that the linear dispersion characteristics of (5) and (6) are better than those of (3) and (4). More specifically, (5) and (6) can simulate waves with broader spectral width than the generic equations (3) and (4). The details on the subject will be reported separately.

Solitary and Stokes Second-Order Waves

It has already been indicated that the wave model provides a unified approach in describing the nonlinear waves at arbitrary water depths. Simple analytical investigations are now presented to clarify the nonlinear characteristics of the model regarding the solitary and Stokes second-order waves. We begin with the solitary waves.

Let us seek a solution of the form $\eta = H \cosh^{-2}[(x \pm C_s t)/l_s]$, where H is the prescribed wave height, l_s and C_s are respectively the length scale and the phase speed of the solitary wave which are yet unknown quantities to be determined from the wave equation (3). The form adopted is the lowest-order solution, the general expression is an infinite sum of hyperbolic cosine functions of higher powers (see Fenton, 1972); for the present purposes however it will suffice. Substituting this expression in (3) and solving for l_s and C_s give

$$l_s = \left[\frac{6(C_p - C_g)(C_p^2 + \frac{2}{3}\beta H)}{\beta k^2 C_g H} \right]^{1/2}, \quad C_s = \left[\frac{C_p}{C_g} \left(C_p^2 + \frac{2}{3}\beta H \right) \right]^{1/2} \quad (7)$$

where $\beta = \frac{3}{2}g \left(3 - 2\frac{C_g}{C_p} - \frac{k^2 C_p^4}{g^2} \right)$ is the coefficient of the nonlinear term in (3) divided by C_p . A matter of historic interest is obvious from the form of l_s . It becomes zero for $C_p = C_g$; that is, nonlinear-nondispersive waves cannot maintain a permanent form simply because there exists no dispersivity to counterbalance the steepening action of nonlinearity. However, allowing the lowest-order dispersion by letting $C_p \simeq (gh)^{1/2}(1 - k^2 h^2/6)$ and $C_g \simeq (gh)^{1/2}(1 - k^2 h^2/2)$, as in the Boussinesq theory, is sufficient to obtain a permanent form. If these approximate forms are used in (7) and the higher-order dispersion contributions are dropped,

$$l_s \simeq \left[\frac{4h^3(1 + H/h)}{3H} \right]^{1/2}, \quad C_s \simeq [g(h + H)]^{1/2}, \quad (8)$$

which are in complete agreement with the classical expressions (Miles, 1980). l_s is the same as Rayleigh's (1876) result and for small H/h it may be replaced with $(4h^3/3H)^{1/2}$, which is the well-known expression.

Assuming that the wave equation (3) admits the second-order Stokes waves as solution we let $\eta = a \cos(k_s x \pm \omega t) + b \cos 2(k_s x \pm \omega t)$ and substitute this expression into (3) to determine the unknown wave number k_s and the second-harmonic amplitude b . The primary wave amplitude a and the frequency ω are taken to be known. Equating the zeroth- and first-order terms to zero gives

$$k_s^2 = k^2, \quad b = \frac{\beta a^2}{6C_p(C_p - C_g)}, \quad (9)$$

where the interaction of the primary wave with the second-harmonic is excluded in the above analysis to be consistent with the perturbation approach of Stokes. Note, for deep water waves $C_p = (g/k)^{1/2}$, $C_g = C_p/2$, and $\beta = \frac{3}{2}g$ hence $b = \frac{1}{2}ka^2$, which is the same as the second-order Stokes theory predicts.

Equation (3) is an evolution equation and therefore, unlike a sharply truncated perturbation solution, produces higher-order nonlinear dispersion effects which are partially correct. If the term produced through the interaction of the primary wave with the second-harmonic is retained, k_s becomes

$$k_s^2 = k^2 \left(1 + \frac{\beta b}{C_p C_g} \right)^{-1}, \quad (10)$$

where b is as given in (9). For infinitely deep water waves equation (10) may be approximately written as $k_s \simeq (1 - \frac{3}{4}k^2 a^2)k$, which is slightly at variance with the Stokes' third-order result $k_s \simeq (1 - k^2 a^2)k$ (approximated for small ka). We may then conclude that the partially correct third-order nonlinear effects produced by essentially second-order wave equation (3) is a good approximation to the Stokes third-order theory. This point has been verified through numerical simulations as well (Beji and Nadaoka, 1997).

Numerical Modeling

Equation (3) is first manipulated into the following form:

$$\begin{aligned} n\eta_{tt} - C_p^2 \nabla^2 \eta - \frac{C_p^2(1-n)}{\omega^2} \nabla^2 \eta_{tt} - \nabla(nC_p^2) \cdot \nabla \eta \\ - \frac{3}{2}g \left(3 - 2n - \frac{\omega^2 C_p^2}{g^2} \right) \nabla^2 (\eta^2) = 0, \end{aligned} \quad (11)$$

where ω is the prescribed dominant wave frequency and $n = C_g/C_p$. Compared with (3) equation (11) is computationally preferable as it requires the storage of only n and C_p (or C_p^2) over the computational domain instead of k , C_p , C_g . Three-time-level centered finite difference approximations were used for the discretization of (11) which resulted in implicit schemes both in x - and y -directions. The three-point-averaging formulation of Zabusky and Kruskal (1965) was used in evaluating the spatial derivatives of the nonlinear terms, as it improved the robustness of the scheme. For computational efficiency an iterative approach was adopted and the domain was swept in the x - and y -directions separately, treating the crosswise new time level variables known by using the last available values. Giving only the time derivatives in discretized form, the x -sweep equation is

$$\begin{aligned} n \frac{(\eta^{k+1} - 2\eta^k + \eta^{k-1}))}{\Delta t^2} - \frac{C_p^2(1-n)}{\omega^2} \frac{(\eta_{xx}^{k+1} - 2\eta_{xx}^k + \eta_{xx}^{k-1}))}{\Delta t^2} \\ = \frac{C_p^2(1-n)}{\omega^2} \frac{(\eta_{yy}^{k+1} - 2\eta_{yy}^k + \eta_{yy}^{k-1}))}{\Delta t^2} + C_p^2 (\eta_{xx}^k + \eta_{yy}^k) \\ + (nC_p^2)_x \eta_x^k + (nC_p^2)_y \eta_y^k + \frac{3}{2}g \left(3 - 2n - \frac{\omega^2 C_p^2}{g^2} \right) [(\bar{\eta}^k \bar{\eta}^k)_{xx} + (\bar{\eta}^k \bar{\eta}^k)_{yy}], \end{aligned} \quad (12)$$

in which the superscript k denotes the time level and $\bar{\eta}^k = (\eta_{i+1,j}^k + \eta_{i,j}^k + \eta_{i-1,j}^k)/3$ with i and j denoting the spatial nodes in the x and y - directions, respectively. The new time level values η_{yy}^{k+1} 's appearing on the right-hand side of (12) are treated as known by using the last computed values so that η^{k+1} and η_{xx}^{k+1} 's appearing on the left-hand side are the only unknowns. The resulting matrix equation is tridiagonal and can be solved quite efficiently.

Similarly, the y -sweep equation is

$$\begin{aligned} & n \frac{(\eta^{k+1} - 2\eta^k + \eta^{k-1})}{\Delta t^2} - \frac{C_p^2(1-n)}{\omega^2} \frac{(\eta_{yy}^{k+1} - 2\eta_{yy}^k + \eta_{yy}^{k-1})}{\Delta t^2} \\ & = \frac{C_p^2(1-n)}{\omega^2} \frac{(\eta_{xx}^{k+1} - 2\eta_{xx}^k + \eta_{xx}^{k-1})}{\Delta t^2} + C_p^2 (\eta_{xx}^k + \eta_{yy}^k) \\ & + (nC_p^2)_x \eta_x^k + (nC_p^2)_y \eta_y^k + \frac{3}{2}g \left(3 - 2n - \frac{\omega^2 C_p^2}{g^2} \right) [(\bar{\eta}^k \bar{\eta}^k)_{xx} + (\bar{\eta}^k \bar{\eta}^k)_{yy}], \end{aligned} \tag{13}$$

in which $\bar{\eta}^k = (\eta_{i,j+1}^k + \eta_{i,j}^k + \eta_{i,j-1}^k)/3$. η^{k+1} and η_{yy}^{k+1} 's appearing on the left-hand side are the only unknowns. The η^{k+1} 's obtained from (12) are only the first estimates, which are used on the right-hand side of (13) for improved computations. Since the x -direction is taken as the main wave propagation direction, equation (12) is solved once more using the updated new time values obtained from (13). In all the computational tests presented later further iterations brought no improvements so it was concluded that three sweeps (x , y , and x again) would be enough for most problems.

Equation (5) may likewise be manipulated into a computationally efficient form

$$\begin{aligned} & n\eta_t + \frac{1}{2}C_p(1+n)\eta_x - \frac{C_p^2}{\omega^2}(1-n)\eta_{xxt} - \frac{C_p^3}{2\omega^2}(1-n)\eta_{xxx} \\ & + \frac{1}{2} [(C_p)_x + C_p n_x] \eta + \frac{3}{4} \frac{g}{C_p} \left(3 - 2n - \frac{\omega^2 C_p^2}{g^2} \right) (\eta^2)_x = 0, \end{aligned} \tag{14}$$

where n and C_p are the only variables to be stored. Equation (14) yields an implicit scheme when three-time-level finite difference approximations are used for replacing the derivatives:

$$\begin{aligned} & n \frac{(\eta^{k+1} - \eta^{k-1})}{2\Delta t} - \frac{C_p^2}{\omega^2}(1-n) \frac{(\eta_{xx}^{k+1} - \eta_{xx}^{k-1})}{2\Delta t} \\ & = \frac{1}{2}C_p(1+n)\eta_x^k - \frac{C_p^3}{2\omega^2}(1-n)\eta_{xxx}^k + \frac{1}{2} [(C_p)_x + C_p n_x] \eta^k \\ & + \frac{3}{4} \frac{g}{C_p} \left(3 - 2n - \frac{\omega^2 C_p^2}{g^2} \right) (\bar{\eta}^k \bar{\eta}^k)_x. \end{aligned} \tag{15}$$

Sample Simulations

The first simulation is linear wave propagation over a circular shoal. This experiment was designed and carried out by Ito and Tanimoto (1972) to test their numerical wave model. The shoal was constructed as concentric circles whose centers were located three wavelengths away from the incoming boundary. The width of the wave flume was $6L_o = 2.4$ m, where $L_o = 0.4$ m is the incident wavelength. Analytically, the water depth h may be expressed as

$$\begin{aligned} h &= h_c + e_o r^2 & \text{for } r < R \\ h &= h_o & \text{for } r \geq R \end{aligned}$$

where

$$\begin{aligned} r^2 &= (x - x_c)^2 + (y - y_c)^2, \\ e_o &= (h_o - h_c)/R^2. \end{aligned} \quad (16)$$

Here, $R = 2L_o$ is the shoal radius, $h_o = 0.15$ m the water depth outside the shoal, $h_c = 0.05$ m the water depth at the center of the shoal located at $(x_c = 3L_o, y_c = 3L_o)$. Thus, the depth to the wavelength ratio at the incoming boundary was $h_o/L_o = 0.375$, which reduced to $h_c/L_o = 0.125$ at the shoal center.

Ito and Tanimoto (1972) performed their experiments for three different incident wave height to wavelength ratios $H_o/L_o = 0.016, 0.026, \text{ and } 0.035$. In the computations however, the selected wave height was immaterial because the linearized form of (11) was used. The computations were done with $\Delta x = L_o/10$, $\Delta y = L_o/6$, and $\Delta t = T/10$. Higher resolutions were found to be unnecessary as the results changed very little. An equally important point is the computational time which for this case was no more than a few minutes on a personal computer. This computational efficiency applied to nonlinear cases as well since the inclusion of nonlinearity amounts to only quasi-linear additions appearing on the right-hand sides of equations (12) and (13). A perspective view of the fully-developed wave field is depicted in figure 1, after 20 wave periods elapsed from the commencement of the computation.

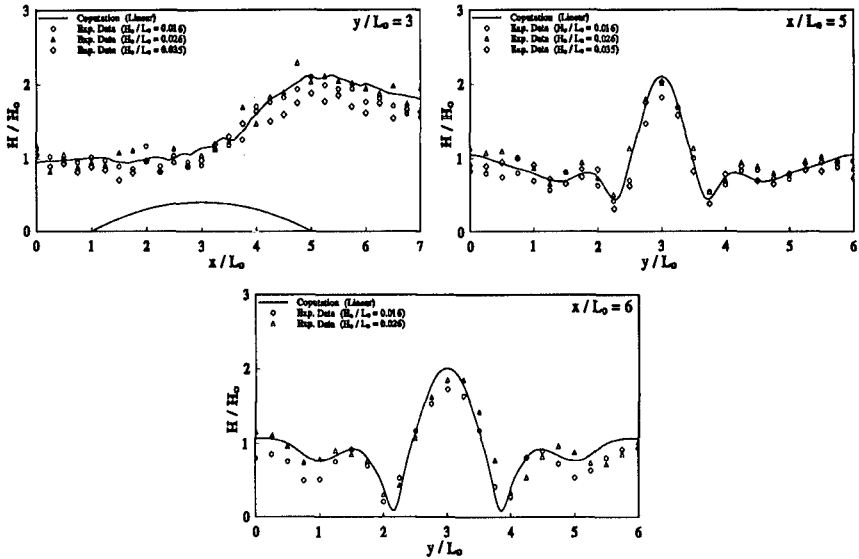

Figure 1: Perspective view of the fully developed wave field over a circular shoal.

In figures 2a, 2b, and 2c, the nondimensional wave height variations along the centerline and across the wave tank are compared with the measurements. As it is seen, the computational results agree remarkably well with the measurements.

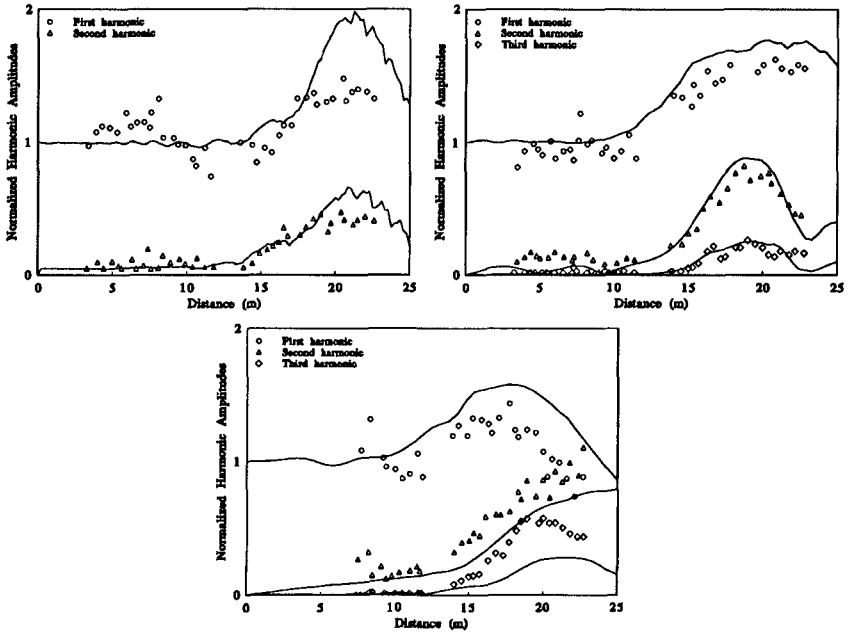

Figures 2a, b, c: Comparisons of the measured and computed wave-height variations along the centerline $y/L_0 = 3$, across the wave tank at $x/L_0 = 7$ and at $x/L_0 = 6$.

The second case is the computation of wave convergence over a bottom topography that acts as a focusing lens (Whalin, 1972). The wave tank used in the experiments was 25.6 m long and 6.096 m wide. In the middle portion of the tank eleven semicircular steps were evenly spaced to form a topographical lens. The equations describing the topography are given in Whalin (1972).

Three sets of experiments were conducted by generating waves with periods $T = 1, 2,$ and 3 seconds and the harmonic amplitudes along the centerline of the wave tank were measured at various stations. For all three cases the computations were performed with a span-wise resolution Δy of $1/10$ of the wave tank width. Since the bathymetry is symmetric with respect to the centerline, only one-half of the tank is discretized. The no-flux boundary conditions are used along the centerline and the side-wall. Figure 3a compares the computed harmonic amplitudes with the measured data for the incident wave period $T = 1$ second and the wave amplitude $a_0 = 1.95$ cm. The time-step and the x -direction resolution were $\Delta t = T/25$ and $\Delta x = L_m/25$ with L_m denoting the mean wavelength computed as the average of the deep-water and shallow-water wavelengths. In figure 3b the case for $T = 2$ seconds and $a_0 = 0.75$ cm is shown, the resolutions were $\Delta t = T/30$ and $\Delta x = L_m/30$. Figure 3c gives the comparisons for $T = 3$ second waves with the deep water wave amplitude $a_0 = 0.68$ cm. Since the harmonic amplitudes were comparable with the primary wave amplitude, it was necessary to adopt somewhat higher resolutions and therefore $\Delta t = T/35$ and $\Delta x = L_m/35$ for this last case.

Figures 3a, b, and c show that the agreements of the computations with the measurements are not as good as the previous case; nonetheless the overall model predictions appear to be acceptable. For nonlinear directional waves, a better numerical approach is expected to yield better results, as the present numerical scheme has been observed to be sensitive (unlike the linear case) to the adopted resolution when the waves were nonlinear.

Figures 3a, b, c: Comparisons of the measured (scatter) and computed (solid line) harmonic amplitude variations along the centerline of the wave tank for $T = 1$ s (top left), $T = 2$ s (top right), and $T = 3$ s (bottom) waves.

To give an idea about the wave patterns, a perspective view of the fully-developed wave field is given in figure 4 for $T = 2$ second waves.

Figure 4: Perspective view of the fully-developed nonlinear wave field over a topographical lens ($T = 2$ s waves).

In order to demonstrate the wide applicable range of the proposed wave model we shall now consider the transformation of an initially second-order Stokes wave train into a cnoidal wave train over uniformly decreasing depth with a constant slope of 1:50. The water depth in the deep section is 20 m and after a distance of 900 m it reduces to 2 m. The incident wave is a second-order Stokes wave with $T = 6$ s and $kH_0 = 0.1$. The initial steepness was chosen small so that an unacceptably large wave steepness in the shallowest region could be prevented.

The computations were done with $\Delta t = T/40$ and $\Delta x = L/40$. Figure 5a shows the spatial variation of the initially second-order Stokes wave as it propagates over the slope. In the deeper region the wave train does not yet feel the bottom so it travels without change of form for more than 500 m. Then, the finite-depth effect begins to steepen the waves. Finally, when the waves reach the shallowest region they are much steeper $H/h = 0.55$ and resemble to the cnoidal waves rather than the Stokes waves, as it can clearly be seen from the closer views given in the figures 5b and 5c. Indeed, the computations with the Stokes theory yields a very unacceptable wave form for this shallow depth as the theory virtually breaks down. Unlike the Stokes theory, the coefficients of the wave model adjusts properly according to the local depth hence enable the model simulate the proper wave form for the depth concerned.

Figures 5a, b, c: Transformation of an initially second-order Stokes wave train into a cnoidal wave train over a uniformly decreasing water depth. The two closer views show respectively the deep and shallow water regions. (Vertical scale is arbitrary.)

Concluding Remarks

Various forms of a recently proposed nonlinear refraction-diffraction model have been presented along with analytical investigations examining its nonlinear and dispersion characteristics. Sample simulations using the time-dependent nonlinear mild-slope equation and its unidirectional form have been performed. The proposed equations do not have any depth restriction and accommodate exact linear shoaling characteristics over mild-slopes so long as the incident wave frequency coincides with the specified dominant frequency of the wave model. The equations also include all the second-order nonlinear contributions and therefore can simulate the cnoidal waves and the Stokes waves with equal accuracy. The proposed equations may thus be regarded models for the combined nonlinear refraction-diffraction of waves over arbitrary depths. It is also worthwhile to emphasize that the applicability of the model equations is not limited to periodic waves; narrow-banded random waves may as well be simulated accurately.

CHAPTER 83

BOUSSINESQ EQUATIONS WITH IMPROVED DOPPLER SHIFT AND DISPERSION FOR WAVE/CURRENT INTERACTION

Qin Chen¹, Per A. Madsen², Ole R. Sørensen² and David R. Basco³

Abstract

Boussinesq-type equations with improved dispersion characteristics for the combined motion of waves and currents are introduced. The ambient current is assumed to be uniform over depth and to have a magnitude as large as the shallow water wave celerity, allowing for the consideration of wave blocking of fairly long waves. The temporal variation of the current is ignored, while the spatial variation is assumed to vary on a larger scale than the wave-length scale. Boussinesq-type equations are derived by explicit use of four scales v , δ , ϵ and μ representing the particle velocity and the surface elevation of the total wave-current motion, as well as the wave-nonlinearity and the wave-dispersion, respectively. Firstly, equations are derived in terms of the depth-averaged velocity to obtain a generalization of the equations of Yoon & Liu (1989) to allow for stronger currents. Secondly, these equations are formulated in terms of the velocity variable at an arbitrary z -location resulting in an improved dispersion relation which corresponds to a Padé [2,2] expansion in the wave number of the squared intrinsic celerity for the fully dispersive linear theory. For vanishing currents, these equations reduce to the equations of Nwogu (1993). Finally, this formulation is enhanced to achieve Padé [4,4] dispersion characteristics. Model results for monochromatic and bichromatic waves being fully or partly blocked by opposing currents are given and the results are shown to be in reasonable agreement with theoretical calculations based on the wave-action principle.

1. Introduction

Various forms of lower-order Boussinesq equations are reported in the literature and they may be classified into three groups as follows: (1) the classical Boussinesq equations for wave motion (e.g. Peregrine, 1967); (2) the Boussinesq-type equations with improved linear dispersion properties (e.g. Madsen et al., 1991; Nwogu, 1993; Schäffer and Madsen, 1995); (3) the Boussinesq equations derived for the combined motion of waves and ambient currents (e.g. Yoon & Liu, 1989 and Prüzer & Zielke, 1990). As shown by Chen et al. (1996), only the equations in the third group incorporate a correct form of Doppler shift in connection with wave-current interaction. Their dispersion relation, however, suffers the same inaccuracy as the classical Boussinesq equations for higher wave numbers. In case of opposing

currents this limitation quickly becomes critical for the applicability of the equations as wave numbers increase with the current speed. It is therefore desirable to improve the equations to achieve Padé-type expansions of the dispersion relation similar to what has been achieved by e.g. Madsen et al. (1991) and Schäffer & Madsen (1995) for the case of pure wave motion. First attempts in this direction were made by Kristensen (1995).

This paper focuses on the derivation and analysis of Boussinesq-type equations with Padé [4,4] dispersion characteristics for coupled wave-current motion. A one-dimensional version of the new equations is solved by the finite-difference method and simulation results of waves blocked by a strong, opposing current are presented.

2. Scaling Assumptions and Governing Equations

As a starting point we consider the combined motion of waves and ambient currents and split the velocity variable into two parts, a wave orbital velocity, u^w and a current velocity, u^c , which is assumed to be uniform over depth. This splitting is only made for scaling purposes and it does not appear in the final equations. A Cartesian coordinate system with the x' -axis and y' -axis located at the still water level (SWL) and the z' -axis pointing vertically upwards is employed. The free surface is defined by $z' = \eta'(x', y', t')$ while the sea bed is defined by $z' = -h'(x', y')$. Non-dimensional variables are used as follows:

$$x = x'/l'_0, \quad y = y'/l'_0, \quad z = z'/h'_0, \quad t = t' \sqrt{(gh'_0)/l'_0} \quad (2.1)$$

where prime denotes dimensional variables and h'_0 and l'_0 denote a characteristic water depth and wave length, respectively. In the following discussion of scales of waves and currents in shallow water we respectively utilize the linear and nonlinear version of the shallow water equations (SWE). The discussion is kept brief and detailed analyses can be found in the work by Chen et al. (1996).

In connection with pure wave motion in shallow water we introduce the classical measures of nonlinearity and frequency dispersion by

$$\epsilon = a'_0/h'_0, \quad \mu = h'_0/l'_0 \quad (2.2)$$

where a'_0 denotes a characteristic wave amplitude. As in conventional Boussinesq theory we shall assume that $\epsilon = O(\mu^2)$ and $\epsilon \ll 1$. Linear long-wave theory can be employed to estimate the order of magnitude of the wave particle velocities (u'^w, w'^w), the free surface elevation (η'^w) and the pressure (p'^w) as well as their temporal and spatial variation.

For pure current motion, the temporal variation of the current is ignored as it is assumed to be several orders of magnitude slower than that of the wind waves. The spatial variation of the current is closely related to the variation of the bottom bathymetry and we generally assume this to vary on a larger spatial scale than the wave-length scale. This can be expressed by $u'^c = u'^c(\sigma x, \sigma y)$, $\eta'^c = \eta'^c(\sigma x, \sigma y)$ and $h' = h'(\sigma x, \sigma y)$, where σ denotes the slow scale, which is yet to be chosen. Coastal currents are typically stronger than the wave particle velocity and weaker than the wave celerity, but in the derivation we use the shallow water wave celerity as the scale of the current speed in order to be able to consider wave-blocking in shallow water. Consequently, we express the order of magnitude of the current velocity by $u'^c = O(v) \sqrt{(gh'_0)}$ in which $\epsilon \leq v \leq 1$. The corresponding surface elevation due to the current is expressed by $\eta'^c = O(\delta) h'_0$ where $\delta = O(v^2)$ as analysed in Chen et al. (1996)'s work. In comparison, Yoon & Liu (1989) used $v = \mu$ and $\delta = \mu^2$ so that wave-

blocking in shallow water was not allowable under their assumptions. By the use of σ , ν , δ and μ we can also determine the order of magnitude of the temporal and spatial variation of the variables.

On the basis of the scaling analyses for pure wave and pure current motion, the scaling of variables in case of coupled wave-current motion becomes

$$u' = O(\epsilon, \nu) \sqrt{(gh'_0)}; \quad w' = O(\epsilon\mu, \sigma\nu\mu) \sqrt{(gh'_0)} \quad (2.3)$$

$$\eta'_t = O(\epsilon, \nu^2) h'_0; \quad p' = O(\epsilon, \nu^2) (\rho gh'_0) \quad (2.4)$$

The order of magnitude of the leading terms in the continuity equation of the SWE becomes

$$\eta'_{t'} = O(\epsilon\mu) \sqrt{(gh'_0)}; \quad h' u'_{x'} = O(\epsilon\mu, \sigma\nu\mu) \sqrt{(gh'_0)}; \quad u' h'_{x'} = O(\epsilon\mu, \sigma\nu\mu) \sqrt{(gh'_0)} \quad (2.5)$$

The order of magnitude of the terms in the momentum equation of the SWE becomes

$$u'_{t'} = O(\epsilon\mu) g; \quad g\eta'_{x'} = O(\epsilon\mu, \sigma\nu^2\mu) g; \quad u' u'_{x'} = O(\epsilon^2\mu, \sigma\nu^2\mu) g \quad (2.6)$$

The spatial variation of the current and the bathymetry was defined by σ which is rather arbitrary. We adopt the assumption in Madsen & Schäffer's (1996) work specifying $h' u'_{x'} = O(h' u'_{x'})$. This assumption in combination with the expression in (2.5) yields

$$\sigma = O(\epsilon/\nu) \quad (2.7)$$

This means that strong currents (with $\nu = O(1)$) can be treated only in connection with weakly varying bathymetries, while weak currents (with e.g. $\nu = O(\epsilon)$) do not imply any restrictions on the bathymetric variations. The condition expressed by (2.7) is basically in agreement with the assumptions by Yoon & Liu (1989) and Dingemans (1994), who used $\epsilon = \mu^2$, $\nu = \mu$ and $\sigma = \mu$.

The governing equations serving as our starting point of derivation are the depth-integrated conservation laws for mass and momentum with the dimensionless variables as defined by

$$\mathbf{u} = \frac{\mathbf{u}'}{\sqrt{gh'_0}}, \quad w = \frac{w'}{\mu\sqrt{gh'_0}}, \quad p = \frac{p'}{\rho gh'_0}, \quad \eta = \frac{\eta'}{h'_0} \quad (2.8)$$

where $\mathbf{u} = (u, v)$ is the horizontal velocity vector; w is the vertical velocity; p is the pressure and η is the free surface elevation of the combined wave and current motion. The actual magnitude of each term appearing in the derivation will be explicitly determined by the use of the scaling assumptions (2.3)-(2.7).

In terms of the dimensionless variables defined by (2.1) and (2.8) we express the depth-integrated mass equation as

$$\eta_t + \nabla \cdot \int_{-h}^{\eta} \mathbf{u} dz = 0 \quad (2.9)$$

where $\nabla = (\partial/\partial x, \partial/\partial y)$ is the horizontal gradient operator, and the depth-integrated horizontal momentum equations as

$$\frac{\partial}{\partial t} \int_{-h}^{\eta} u dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} u^2 dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} uv dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} p dz - p|_{z=-h} h_x = 0 \quad (2.10a)$$

$$\frac{\partial}{\partial t} \int_{-h}^{\eta} v dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} uv dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} v^2 dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} p dz - p|_{z=-h} h_y = 0 \quad (2.10b)$$

while the pressure field reads

$$p(x, y, z, t) = (\eta - z) + \mu^2 \left\{ \frac{\partial}{\partial t} \int_z^\eta w dz + \nabla \cdot \int_z^\eta \mathbf{u} w dz - w^2 \right\} \tag{2.11}$$

The vertical velocity w is evaluated by the vertical integration of the continuity equation from the sea bed to z and the use of the bottom boundary condition, which yields

$$w = - \nabla \cdot \int_{-h}^z \mathbf{u} dz \tag{2.12}$$

The above depth-integrated equations are as exact as their original continuity equation and the Euler equations of motion and the detailed derivation procedure can be found in the literature (e.g. Phillips, 1977). The closure of the equations (2.9)-(2.12) consists of determining the vertical distribution of the horizontal velocity vector \mathbf{u} by the use of the vorticity equations of the fluid. As in Yoon & Liu (1989)'s work, the current field is allowed to be horizontally sheared while the vertical shear is limited. Hence, the vorticity equations read

$$u_z - \mu^2 \nabla w = O(\mu^4) \tag{2.13}$$

$$u_y - v_x = O(1) \tag{2.14}$$

3. Derivation of a Generalized Version of the Equations by Yoon & Liu (1989)

In the previous section the governing equations were listed in non-dimensional form using μ as the only explicit scaling parameter. In the following derivation of the horizontal and vertical particle velocities, the dynamic pressure and the resulting mass and momentum equations we introduce the parameters ϵ , ν , δ and σ as explicit measures of the order of magnitude of each term in the equations. As defined in Section 2 we take $\sigma = \epsilon/\nu$ and $\delta = O(\epsilon, \nu^2)$. Further specifying $\epsilon \leq \nu \leq 1$ ensures that the equations will be also valid in the limit of vanishing currents. Generally, the order of magnitude of the different terms is determined as the maximum of all possible combinations of wave and current components and in this process the difference in horizontal scaling of current and wave components is taken into account. As a key step of the development of Boussinesq-type equations, we must determine the depth-dependence of the horizontal velocity field which can be expanded as a Taylor series with respect to the velocities $\hat{\mathbf{u}} = \mathbf{u}(x, y, 0, t)$ at the still water level.

$$\mathbf{u}(x, y, z, t) = \mathbf{u}(x, y, 0, t) + z \mathbf{u}_z(x, y, 0, t) + \frac{1}{2} z^2 \mathbf{u}_{zz}(x, y, 0, t) + \dots \tag{3.1}$$

We make use of the vorticity equations (2.13) and the local continuity equation to evaluate \mathbf{u}_z and \mathbf{u}_{zz} in (3.1). By the use of the definition of the depth-integrated velocity, \bar{U} and algebraic manipulation (see Chen et al., 1996 for details) we obtain

$$\begin{aligned} \mathbf{u} = & \bar{U} + \frac{\epsilon}{\nu} \mu^2 \left\{ \left(\frac{h^2}{6} - \frac{z^2}{2} \right) \nabla(\nabla \cdot \bar{U}) - \left(z + \frac{h}{2} \right) \nabla[\nabla \cdot (h \bar{U})] \right\} \\ & - \delta \frac{\epsilon}{\nu} \mu^2 \eta \left\{ \frac{1}{6} h \nabla(\nabla \cdot \bar{U}) - \frac{1}{2} h \nabla[\nabla \cdot (h \bar{U})] \right\} + \delta^2 \frac{\epsilon}{\nu} \mu^2 \frac{1}{6} \eta^2 \nabla(\nabla \cdot \bar{U}) + O\left(\frac{\epsilon}{\nu} \mu^4\right) \end{aligned} \tag{3.2}$$

Substitution of (3.2) into (2.12) gives the vertical velocity in terms of \bar{U}

$$w = -\nabla \cdot [(z+h)U] + O(\mu^2) \quad (3.3)$$

By inserting (3.2) and (3.3) into (2.11) and determining the ordering, the pressure field may be expressed as

$$\begin{aligned} p = & \left(\eta - \frac{z}{\delta} \right) + \frac{\epsilon}{\delta} \mu^2 \left[z \nabla \cdot (hU_t) + \frac{z^2}{2} \nabla \cdot U_t \right] \\ & - \epsilon \mu^2 \left\{ \frac{1}{2} \delta \eta^2 \nabla \cdot U_t + \eta \nabla \cdot (hU_t) \right\} \\ & + \frac{\nu \epsilon}{\delta} \mu^2 \left\{ z U \cdot \nabla [(\nabla \cdot (hU))] + \frac{z^2}{2} U \cdot \nabla (\nabla \cdot U) \right\} \\ & - \nu \epsilon \mu^2 \left\{ \frac{1}{2} \delta \eta^2 U \cdot \nabla (\nabla \cdot U) + \eta U \cdot \nabla [\nabla \cdot (hU)] \right\} + O\left(\frac{\epsilon^2}{\delta} \mu^2, \frac{\epsilon}{\delta} \mu^4\right) \end{aligned} \quad (3.4)$$

Use of the definition of depth-averaged velocity in (2.9) and substitution of (3.2) and (3.4) into the depth-integrated equations (2.10) lead to a modified version of the equations by Yoon & Liu (1989) for wave/current interaction in shallow water as follows,

$$\eta_t + \nabla \cdot (hU) + \delta \eta \nabla \cdot U + \nu U \cdot \nabla \eta = 0 \quad (3.5)$$

and

$$\begin{aligned} U_t + \nu(U \cdot \nabla)U + \nabla \eta \\ + \mu^2 [\Lambda_0^I + \nu \Lambda_1^I + \delta(\Lambda_2^I + \nu \Lambda_3^I) + \delta^2(\Lambda_4^I + \nu \Lambda_5^I)] = O(\epsilon \mu^2, \mu^4) \end{aligned} \quad (3.6)$$

where

$$\Lambda_0^I = h\Gamma_t^I; \quad \Lambda_1^I = (U \cdot \nabla)(h\Gamma^I) \quad (3.7a)$$

$$\Lambda_2^I = -\eta \{ \Gamma_t^I + \nabla [\nabla \cdot (hU)] \}; \quad \Lambda_3^I = -\eta (U \cdot \nabla) \{ \Gamma^I + \nabla [\nabla \cdot (hU)] \} \quad (3.7b)$$

$$\Lambda_4^I = -\frac{1}{3} \eta^2 \nabla (\nabla \cdot U_t); \quad \Lambda_5^I = -\frac{1}{3} \eta^2 (U \cdot \nabla) [\nabla (\nabla \cdot U)] \quad (3.7c)$$

where

$$\Gamma^I = \frac{h}{6} \nabla (\nabla \cdot U) - \frac{1}{2} \nabla [\nabla \cdot (hU)] \quad (3.7f)$$

In comparison with the original Yoon & Liu's equations, the new scaling assumptions result in additional terms Λ_2^I , Λ_3^I , Λ_4^I and Λ_5^I . These terms take into account the change in the mean water level due to an ambient current and should be included if we consider $\nu = O(1)$. The Doppler shift properties of both sets of equations however, remain identical and correspond to the Padé [0,2] expansion of the linear dispersion relation of fully dispersive waves. When the speed of an ambient current becomes as weak as the wave particle velocity, all μ^2 -terms in the momentum equation except for Λ_0^I will become negligible in the lower-order Boussinesq-type equations. Then this set of equations reduces to the equations by Peregrine (1967).

4. Equations with Padé [2/2] Characteristics for Wave-Current Interaction

It is desirable to improve the dispersion accuracy of the modified equations we obtained in the last section. For pure wave motion, Nwogu (1993) introduced an alternative to the Madsen & Sørensen (1992)'s equations with improved linear dispersion properties. Nwogu's equations are formulated in terms of the velocity at an arbitrary level instead of depth-integrated or depth-averaged velocities. As shown by Chen et al. (1996), the equations by Nwogu (1993) are not applicable to coupled wave/current motion due to the lack of accuracy in Doppler shift. We shall start our derivation from the generalized version of the equations by Yoon & Liu (1989) (i.e. (3.5) & (3.6)) and consistently replace the depth-averaged velocities by the velocities at an arbitrary elevation by keeping the same scaling assumptions as discussed in Section 2. This also demonstrates an alternative approach to obtaining Nwogu's equations directly from the equations by Peregrine (1967).

As shown in Chen et al. (1996)'s work, the relation between the depth-averaged velocity, \mathbf{U} and the velocity at an arbitrary level, \mathbf{u}_α may be expressed by

$$\begin{aligned} \mathbf{U} = \mathbf{u}_\alpha + \frac{\epsilon}{\nu} \mu^2 \left\{ \left(z_\alpha + \frac{h}{2} \right) \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] + \left(\frac{z_\alpha^2}{2} - \frac{h^2}{6} \right) \nabla (\nabla \cdot \mathbf{u}_\alpha) \right\} \\ - \frac{\delta \epsilon}{\nu} \mu^2 \eta \left\{ \frac{1}{2} \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] - \frac{h}{6} \nabla (\nabla \cdot \mathbf{u}_\alpha) \right\} - \frac{\delta^2 \epsilon}{\nu} \mu^2 \frac{1}{6} \eta^2 \nabla (\nabla \cdot \mathbf{u}_\alpha) + O \left(\frac{\epsilon}{\nu} \mu^4 \right) \end{aligned} \quad (4.1)$$

Substitution of (4.1) into the continuity equations (3.5) and the momentum equations (3.6) leads to a set of equations formulated in terms of the velocities at an arbitrary elevation as follows

$$\begin{aligned} \eta_t + \nabla \cdot (h \mathbf{u}_\alpha) + \delta \eta \nabla \cdot \mathbf{u}_\alpha + \nu \mathbf{u}_\alpha \cdot \nabla \eta \\ + \mu^2 (\Pi'_{\alpha 0} + \delta \Pi'_{\alpha 1} + \delta^2 \Pi'_{\alpha 2} + \delta^3 \Pi'_{\alpha 3}) = O(\epsilon \mu^2, \mu^4) \end{aligned} \quad (4.2)$$

where

$$\Pi'_{\alpha 0} = \nabla \cdot h \Gamma'_\alpha - \nabla \cdot \left\{ \frac{h^3}{6} \nabla (\nabla \cdot \mathbf{u}_\alpha) - \frac{h^2}{2} \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] \right\}; \quad \Pi'_{\alpha 1} = \eta \nabla \cdot \Gamma'_\alpha \quad (4.3a)$$

$$\Pi'_{\alpha 2} = -\frac{\eta^2}{2} \nabla \cdot \{ \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] \}; \quad \Pi'_{\alpha 3} = -\frac{\eta^3}{6} \nabla \cdot [\nabla (\nabla \cdot \mathbf{u}_\alpha)] \quad (4.3b)$$

in which

$$\Gamma'_\alpha = \frac{z_\alpha^2}{2} \nabla (\nabla \cdot \mathbf{u}_\alpha) + z_\alpha \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] \quad (4.3c)$$

and

$$\begin{aligned} \mathbf{u}_{\alpha t} + \nu (\mathbf{u}_\alpha \cdot \nabla) \mathbf{u}_\alpha + \nabla \eta \\ + \mu^2 [\Lambda'_{\alpha 0} + \nu \Lambda'_{\alpha 1} + \delta (\Lambda'_{\alpha 2} + \nu \Lambda'_{\alpha 3}) + \delta^2 (\Lambda'_{\alpha 4} + \nu \Lambda'_{\alpha 5})] = O(\epsilon \mu^2, \mu^4) \end{aligned} \quad (4.4)$$

where

$$\Lambda_{\alpha 0}^I = \Gamma_{\alpha}^I ; \quad \Lambda_{\alpha 1}^I = (\mathbf{u}_{\alpha} \cdot \nabla) \Gamma_{\alpha}^I \quad (4.5a)$$

$$\Lambda_{\alpha 2}^I = -\eta \nabla [\nabla \cdot (h \mathbf{u}_{\alpha})] ; \quad \Lambda_{\alpha 3}^I = -\eta (\mathbf{u}_{\alpha} \cdot \nabla) \nabla [\nabla \cdot (h \mathbf{u}_{\alpha})] \quad (4.5b)$$

$$\Lambda_{\alpha 4}^I = -\frac{1}{2} \eta^2 \nabla (\nabla \cdot \mathbf{u}_{\alpha}) ; \quad \Lambda_{\alpha 5}^I = -\frac{1}{2} \eta^2 (\mathbf{u}_{\alpha} \cdot \nabla) [\nabla (\nabla \cdot \mathbf{u}_{\alpha})] \quad (4.5c)$$

equations (4.2) to (4.5) form a new set of equations with the improved Doppler shift corresponding to the Padé [2,2] expansion of the linear dispersion relation given by the first order Stokes theory by choosing the appropriate z_{α} as suggested by Nwogu (1993). We shall analyse the dispersion properties in Section 6. When the speed of an ambient current becomes as weak as the wave particle velocity, those terms $\Pi_{\alpha i}^I$ ($i=1, 2, 3$) in (4.3) and $\Lambda_{\alpha i}^I$ ($i=1, 2, 3, 4, 5$) in (4.5) will become negligible in the lower-order Boussinesq-type equations. Then this set of equations reduces to the equations by Nwogu (1993) for pure wave propagation in nearshore regions.

5. Further Enhancement of the Dispersion Accuracy

It is possible to improve the Doppler shift accuracy of the equations we obtained in the last section even further. Starting from (4.2) to (4.5), we shall formulate another set of Boussinesq-type equations by consistent incorporation of the Padé [4,4] expansion of the Doppler shift relation predicted by the first order Stokes theory for waves on uniform ambient currents. Following Schäffer & Madsen (1995), we introduce four free parameters ($\beta_1, \beta_2, \gamma_1, \gamma_2$) which are less than or equal to $O(1)$. Use of each of the operators $-\beta_1 \mu^2 \nabla \cdot (h^2 \nabla)$ and $\beta_2 \mu^2 \nabla \cdot \nabla (h^2)$ on the continuity equation (4.2) leads to

$$-\beta_1 \mu^2 \{ \nabla \cdot (h^2 \nabla \eta_t) + \nabla \cdot [h^2 \nabla [\nabla \cdot (h \mathbf{u}_{\alpha})]] \} \\ + \delta \eta \nabla \cdot [h^2 \nabla (\nabla \cdot \mathbf{u}_{\alpha})] + \nu \mathbf{u}_{\alpha} \cdot \nabla (h^2 \nabla^2 \eta) \} = O(\epsilon \mu^2, \mu^4) \quad (5.1)$$

and

$$\beta_2 \mu^2 \{ \nabla \cdot [\nabla (h^2 \eta_t)] + \nabla \cdot \{ \nabla [h^2 \nabla \cdot (h \mathbf{u}_{\alpha})] \} \} \\ + \delta \eta \nabla \cdot [\nabla (h^2 \nabla \cdot \mathbf{u}_{\alpha})] + \nu \mathbf{u}_{\alpha} \cdot \nabla [\nabla \cdot (h^2 \nabla \eta)] \} = O(\epsilon \mu^2, \mu^4) \quad (5.2)$$

Similarly, employing each of the operators $-\gamma_1 \mu^2 h^2 \nabla (\nabla \cdot)$ and $\gamma_2 \mu^2 h \nabla (\nabla \cdot h)$ on the momentum equations (4.4) yields

$$-\gamma_1 \mu^2 h^2 [\nabla (\nabla \cdot \mathbf{u}_{\alpha}) + \nabla (\nabla \cdot \nabla \eta)] \\ - \gamma_1 \nu \mu^2 h^2 (\mathbf{u}_{\alpha} \cdot \nabla) [\nabla (\nabla \cdot \mathbf{u}_{\alpha})] = O(\epsilon \mu^2, \mu^4) \quad (5.3)$$

and

$$\gamma_2 \mu^2 h \{ \nabla [\nabla \cdot (h \mathbf{u}_{\alpha})] + \nabla [\nabla \cdot (h \nabla \eta)] \} \\ + \gamma_2 \nu \mu^2 h (\mathbf{u}_{\alpha} \cdot \nabla) [\nabla (\nabla \cdot h \mathbf{u}_{\alpha})] = O(\epsilon \mu^2, \mu^4) \quad (5.4)$$

Adding (5.1) and (5.2) to (4.2), we obtain a new continuity equation

$$\eta_t + \nabla \cdot (h \mathbf{u}_\alpha) + \delta \eta \nabla \cdot \mathbf{u}_\alpha + \nu \mathbf{u}_\alpha \cdot \nabla \eta + \mu^2 (\Pi''_{\alpha 0} + \nu \Pi''_{\alpha 1} + \delta \Pi''_{\alpha 2} + \delta^2 \Pi''_{\alpha 3} + \delta^3 \Pi''_{\alpha 4}) = O(\epsilon \mu^2, \mu^4) \quad (5.5)$$

where

$$\Pi''_{\alpha 0} = \Pi'_{\alpha 0} + \nabla \cdot \left\{ \beta_2 \nabla [h^2 \nabla \cdot (h \mathbf{u}_\alpha)] - \beta_1 h^2 \nabla [\nabla \cdot (h \mathbf{u}_\alpha)] \right\} + \nabla \cdot \left\{ \beta_2 \nabla (h^2 \eta_t) - \beta_1 h^2 \nabla \eta_t \right\} \quad (5.6a)$$

$$\Pi''_{\alpha 1} = \mathbf{u}_\alpha \cdot \nabla [\beta_2 \nabla \cdot (h^2 \nabla \eta) - \beta_1 \nabla (h^2 \nabla^2 \eta)] \quad (5.6b)$$

$$\Pi''_{\alpha 2} = \Pi'_{\alpha 1} + \eta \nabla \cdot [\beta_2 \nabla (h^2 \nabla \cdot \mathbf{u}_\alpha) - \beta_1 h^2 \nabla (\nabla \cdot \mathbf{u}_\alpha)] \quad (5.6c)$$

while $\Pi''_{\alpha 3} = \Pi'_{\alpha 2}$, $\Pi''_{\alpha 4} = \Pi'_{\alpha 3}$, $\Gamma''_\alpha = \Gamma'_\alpha$ as defined by (4.3b-c). Similarly, adding (5.3) and (5.4) to (4.4) leads to new momentum equations

$$\mathbf{u}_{\alpha t} + \nu (\mathbf{u}_\alpha \cdot \nabla) \mathbf{u}_\alpha + \nabla \eta + \mu^2 [\Lambda''_{\alpha 0} + \nu \Lambda''_{\alpha 1} + \delta (\Lambda''_{\alpha 2} + \nu \Lambda''_{\alpha 3}) + \delta^2 (\Lambda''_{\alpha 4} + \nu \Lambda''_{\alpha 5})] = O(\epsilon \mu^2, \mu^4) \quad (5.7)$$

where

$$\Lambda''_{\alpha 0} = \Gamma''_{\alpha t} - \gamma_1 h^2 \nabla (\nabla \cdot \mathbf{u}_{\alpha t}) + \gamma_2 h \nabla [\nabla \cdot (h \mathbf{u}_{\alpha t})] - \gamma_1 h^2 \nabla (\nabla \cdot \nabla \eta) + \gamma_2 h \nabla [\nabla \cdot (h \nabla \eta)] \quad (5.8a)$$

$$\Lambda''_{\alpha 1} = (\mathbf{u}_\alpha \cdot \nabla) \Gamma''_\alpha - \gamma_1 h^2 (\mathbf{u}_\alpha \cdot \nabla) [\nabla (\nabla \cdot \mathbf{u}_\alpha)] + \gamma_2 h (\mathbf{u}_\alpha \cdot \nabla) [\nabla (\nabla \cdot h \mathbf{u}_\alpha)] \quad (5.8b)$$

while $\Lambda''_{\alpha 2} = \Lambda'_{\alpha 2}$, $\Lambda''_{\alpha 3} = \Lambda'_{\alpha 3}$, $\Lambda''_{\alpha 4} = \Lambda'_{\alpha 4}$, $\Lambda''_{\alpha 5} = \Lambda'_{\alpha 5}$, $\Gamma''_\alpha = \Gamma'_\alpha$ as defined by (4.5b-c) and (4.3c). Equations (5.5)-(5.8) form a new set of Boussinesq-type equations for wave/current interaction applicable up to even shorter waves for a suitable choice of the free parameters (β_1 , β_2 , γ_1 , γ_2) and z_α as analysed by Schäffer and Madsen (1995) for pure wave motion. In the following section, we shall analyse the Doppler shift behaviour of this new set of equations in comparison with the Stokes theory.

6. Analysis of Linear Dispersion Characteristics

We shall use dimensional form in this chapter and drop primes for convenience. The one-dimensional version of (5.5) and (5.7) with constant water depth can be expressed as

$$\eta_t + h u_{\alpha x} + (u_\alpha \eta)_x - \beta h^2 (\eta_{xxt} + u_\alpha \eta_{xxx}) + \left[\left(\alpha - \beta + \frac{1}{3} \right) h^3 + (\alpha - \beta) h^2 \eta - \frac{1}{2} h \eta^2 - \frac{1}{6} \eta^3 \right] u_{\alpha xxx} \quad (6.1a)$$

and

$$u_{\alpha\alpha} + g\eta_x + u_\alpha u_{\alpha\alpha} - \gamma gh^2 \eta_{xxx} + \left[(\alpha - \gamma)h^2 - \eta h - \frac{1}{2}\eta^2 \right] (u_{\alpha\alpha x} - u_\alpha u_{\alpha\alpha x}) = 0 \quad (6.1b)$$

where $\alpha \equiv z_\alpha/h + 0.5(z_\alpha/h)^2$, $\beta \equiv \beta_1 - \beta_2$, $\gamma \equiv \gamma_1 - \gamma_2$. By the use of Fourier analysis we obtain the linear dispersion relation of the new equations (5.5) to (5.8) as

$$(\omega - u^c k)^2 = \frac{\left[1 - \left(\alpha - \beta + \frac{1}{3} \right) (kh)^2 \right] [1 + \gamma (kh)^2] k^2 gh}{[1 + \beta (kh)^2] [1 - (\alpha - \gamma) (kh)^2]} \quad (6.2)$$

Different choices of the parameters in (6.2) result in different Doppler shift accuracy. For example, $(\alpha, \beta, \gamma) = (-2/5, 0, 0)$ gives

$$(\omega - u^c k)^2 = \frac{\left(1 + \frac{1}{15} k^2 h^2 \right) k^2 gh}{1 + \frac{2}{5} k^2 h^2} \quad (6.3)$$

This is the Padé [2,2] approximation of the linear dispersion relation given by the first-order Stokes theory. It turns out that (6.3) is also the linear dispersion relation of (4.2) to (4.5). Choosing $(\alpha, \beta, \gamma) = (-1/3, 0, 0)$ yields

$$(\omega - u^c k)^2 = \frac{k^2 gh}{1 + \frac{1}{3} k^2 h^2} \quad (6.4)$$

which corresponds to the linear dispersion relation of the original and generalized versions of the equations by Yoon & Liu (1989) using the depth-averaged velocities as variables.

Schäffer and Madsen (1995) obtained four sets of coefficients. Each of them leads to the highly accurate linear dispersion relation

$$(\omega - u^c k)^2 = \frac{\left(1 + \frac{1}{9} k^2 h^2 + \frac{1}{945} k^4 h^4 \right) k^2 gh}{1 + \frac{4}{9} k^2 h^2 + \frac{1}{63} k^4 h^4} \quad (6.5)$$

which is correct to fourth-order in $(kh)^2$ in comparison with the first-order Stokes' solution. Linear shoaling analyses by Schäffer & Madsen (1995) show that these four sets of parameters all give accurate linear shoaling behaviour. The influence of these four sets of parameters on the nonlinearity of the new equations can be analysed by examination of the transfer functions for sub-harmonics and super-harmonics as discussed in Madsen & Schäffer's (1996) work. The best set of parameters can therefore be chosen based on accuracy in the nonlinear properties. We adopt the one recommended by Madsen & Schäffer (1996) as follows.

$$\left. \begin{aligned} \left(\alpha, \frac{z_\alpha}{h} \right) &= (-0.39476, -0.54122) \\ (\beta, \beta_1, \beta_2) &= (0.03917, -0.12919, -0.16836) \\ (\gamma, \gamma_1, \gamma_2) &= (0.01052, -0.07327, -0.08379) \end{aligned} \right\} \quad (6.6)$$

With this set of parameters, equations (5.5) to (5.8) are applicable to deeper water for waves on ambient currents. For waves on following currents, the currents increase the wave length, thus the application range of the new equations exceeds that of the corresponding equations for pure wave motion. For waves on opposing currents, the currents reduce the wave length so that the applicable area depends on the ambient current speed. We use the linear dispersion properties of the first-order Stokes theory to estimate the applicable range of various forms of the Boussinesq-type equations for wave/current interaction. Solving the linear dispersion relations (6.4) & (6.5) gives two sets of curves corresponding to the dimensionless wave number (kh), relative water depth (h/L_0) and Froude number $F_r = U^c / \sqrt{gh}$. Figs. 7.1a-b illustrate the applicable areas of the new equations (5.5) & (5.7) and the equations by Yoon & Liu (1989) in case of opposing currents, respectively. The 5% error contour for kh as compared with the first-order Stokes' solution is also shown. Obviously, the new form of the equations gives a much larger applicable range than those of Yoon & Liu's equations.

It deserves to be mentioned that Madsen & Schäffer (1996) recently derived equations with equivalent properties for wave-current interaction by following a different line of derivation: In their work Boussinesq-type equations were derived on the basis of the two wave scales μ and ϵ , while the ambient current was not explicitly considered during the derivation procedure. In contrast to the present work, however, Madsen & Schäffer allowed $\epsilon = O(1)$ rather than $\epsilon = O(\mu^2)$ and retained all nonlinear terms to the particular order of dispersion. In retrospect this is the reason why their equations could account also for the case of ambient currents, as it turns out that the equations derived in this paper appear as a subset of the former equations by Madsen & Schäffer (1996). Since the extra nonlinear dispersive terms included by Madsen & Schäffer (1996) are expected to be minor in the present applications, the code developed for their equations is adapted for the following numerical experiments.

7. Numerical Solutions for Wave-Current Interaction

A one-dimensional version of the equations (5.5) to (5.8) is solved by the finite-difference method. The equations are discretized on a space staggered grid by means of fourth-order central differencing for first derivative terms in space and second-order central differencing for second and third spacial derivatives. The time-integration of the governing equations consists of the third-order Adams-Bashforth predictor and fourth-order Adams-Moulton corrector schemes. This numerical method was utilized in the work by Wei et al. (1995) and Banijamali (1997) and essentially designed to eliminate the truncation errors which mathematically have the same form as the Boussinesq-type terms due to the use of conventional second-order schemes for pure wave motion. It can be adapted for modelling fully coupled wave/current motion. For the case of strong ambient currents with significant nonlinear advection a smaller convergence criterion for the iterating corrector step

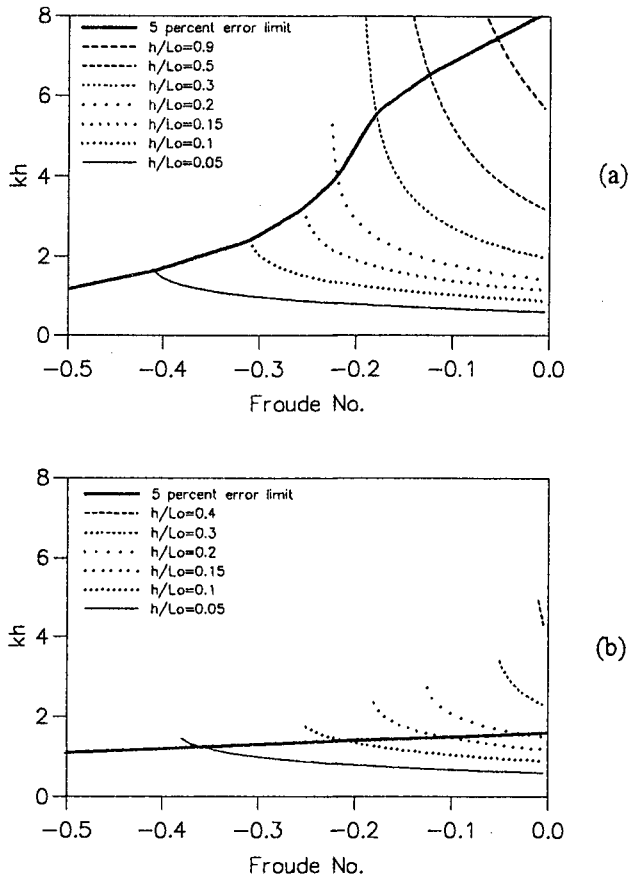

Fig. 7.1 Illustration of the applicable ranges of the equations with (a) the Padè [4,4] expansion (i.e.(5.5) & (5.7)) and (b) the Padè [0,2] expansion (i.e.(3.5) & (3.6)). The area below the 5% kh -error limit predicts the applicable regime.

is required, which leads to more iterations. A prototype of the numerical model for pure wave motion developed by Banijamali (1997) is adopted in the present work. We incorporate the model with non-reflective boundary conditions for fully coupled wave/current motion. The sponge layer technique (Larsen & Dancy, 1983) applicable to absorption of short waves is combined with the Sommerfeld radiation condition for radiating long waves or currents. We shall present some model results in connection with waves blocked by strong opposing currents.

The first test case considers monochromatic waves propagating against a current in a channel with a submerged bar. A sketch of the bathymetry is shown in Fig 7.1a. The channel is 60m long, 0.8m deep on both sides of the bar and 0.2m deep on top of the bar. The western and eastern slopes of the bar are 1/50 and 1/20, respectively. Bed friction is modelled by the use of the Chezy friction law, using a

Chezy coefficient of $300 \text{ m}^{1/2}/\text{s}$ in the sections $0 < x < 37\text{m}$ and $55\text{m} < x < 60\text{m}$, and a coefficient of $30 \text{ m}^{1/2}/\text{s}$ in the section $37\text{m} < x < 55\text{m}$. The relatively strong friction in the latter section serves as a stabilizing factor for the flow simulation. Initially we impose a constant velocity of -0.17 m/s at the eastern boundary and a radiating condition at the western boundary. This leads to an increase in the surface elevation at the western boundary of approximately 0.05m . Fig 8.1b shows the computed spatial variation of the velocity, which is found to be in fairly good agreement with conventional theory neglecting the vertical accelerations of the flow.

Fig. 8.1 Steady open channel flow predicted by the model (dotted line) and the nonlinear shallow water equations (solid line). a) Submerged bar topography; b) Particle velocity.

As the next step we impose a sinusoidal wave train on top of the steady current field. This is done by specifying a velocity condition at the western boundary including the local current obtained in the previous calculation. At the eastern boundary we use a sponge layer which absorbs the short waves while allowing the current to pass through. The incoming wave has a period of 1.2s and an initial height of 0.02m . The grid size and the time step are chosen to be 0.02m and 0.005s , respectively. Fig 8.2 shows the computed surface elevation for the combined wave-current motion. We notice that the oscillatory motion is stopped at the position $x=33.5\text{m}$ where wave blocking occurs because the local current velocity exceeds the local group velocity of the wave. The dotted line in Fig 8.2 indicates the theoretical solution obtained by the principle of wave action and we notice a good agreement with the computations with respect to amplitude amplification as well as the position of the blocking point.

The theory of wave action based on linear progressive wave motion obviously fails close to the blocking point as it predicts the wave height to go to infinity, which does not happen in reality (nor in the model). As suggested by Smith (1975), Stiassnie & Dagan (1979) and Shyu & Phillips (1990) the wave action is

eventually reflected at the blocking point and energy is transferred to much higher wave numbers. Furthermore, the wave numbers of the reflected waves will decrease rapidly with the distance from the blocking point due to the decreasing current.

Fig. 8.2 Monochromatic wave propagation on a spatially-varying, opposing current.

In Fig. 8.3, a bichromatic wave train on a spatially-varying current is simulated. The same bathymetry, steady current field, grid size and time step as in the simulation of the monochromatic wave are employed. The bichromatic waves consist of a 1.2s wave and a 3.0s wave. Both of them have the same wave height of 0.02m. The model predicts that the shorter wave of 1.2s is blocked by the opposing current at the position $x=33.5\text{m}$ (as before) while the longer wave of 3.0s propagates through the blocking point and reaches the eastern boundary where a sponge layer efficiently absorbs the wave energy. The wave profile in Fig. 8.3 with bichromatic and regular wave forms before and after blocking, respectively, illustrates the blocking of the shorter wave in the bichromatic wave train.

Fig. 8.3 A bichromatic wave train propagating on a spatially-varying, opposing current.

9. Conclusions

This paper deals with the derivation and application of Boussinesq-type equations with Padé [4,4] dispersion characteristics for the combined motion of waves and currents in nearshore areas. The waves are assumed to be weakly nonlinear and

the ambient current is assumed to be uniform over depth. In order to allow for the treatment of wave blocking in shallow water we assume the magnitude of the current to be as large as the shallow water celerity. A one-dimensional numerical model has been implemented on the basis of the new equations and as demonstrated it can simulate the complicated phenomenon of monochromatic and bichromatic waves being fully or partly blocked by opposing currents. Further verification of the model against measurements is obviously required, but the results obtained so far are promising and show that the new equations make it possible to simulate a range of complicated phenomena related to the interaction of waves and depth-uniform currents in coastal regions.

CHAPTER 84

The Propagation of Water Waves in Prismatic Channels

Li Li¹, Robert A. Dalrymple² and Jeffrey M. Mlynarski³

Abstract:

Short waves in a channel can present navigational problems and may excite harbor oscillations. Channel sidewalls may reduce much of this wave energy, if they are sufficiently porous or they are sloped. Previously we presented a model for wave propagation in prismatic channels of arbitrary cross-section utilizing a numerical eigenfunction expansion. Here a series of small scale laboratory experiments were conducted to verify the numerical model. Comparisons of the numerical model to the experimental data are made for water surface profile and for eigenfunctions. The possibility of resonance between the edge wave and the second harmonic of the incident wave is also studied.

1 Introduction

Water waves encountering entrance channels present an interesting problem as the waves undergo reflection, refraction, diffraction and shoaling due to shorelines, shoals, jetties, tidal currents, and channels with varying depths. Long waves within channels have served as the impetus for the study of waves. Kelland (1839, as cited in Lamb, 1945) provided a wave equation for waves in triangular channels with the sidewalls inclined at 45°. Scott Russell (1844) provided evidence for the presence of solitary waves in channels. More recently, Peregrine (1968, 1969) examined nonlinear long waves in narrow channel. Golinko (1987) studied the reflection of a long wave from the vertical walls of a channel with a parabolic cross-section. Mathew and Akylas

²Professor, Department of Civil and Environment Engineering, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA

³Student, Department of Civil and Environment Engineering, University of Delaware, Newark, DE 19716, USA

(1990) conducted research on the wide channel case, noting the three-dimensional nature of the waves. Teng and Wu (1994) studied nonlinear long wave in convergent and divergent channels.

However, short waves in a channel also can present navigational problems and may excite harbor oscillations, and less work has been done on short waves. Kelland (1839) and Macdonald (1894) (all cited in Lamb, 1945) obtained analytical solutions for triangular channels with the sidewalls inclined at 45° and 60° to the vertical. Recently, Isaacson (1978) studied wave decay along the center line of a trapezoidal channel with rubble sidewalls in a laboratory experiment. Melo and Guza (1991a, 1991b), through field and numerical means, showed that a tidal inlet comprised of rubblemound jetties absorbed a considerable amount of the wave energy entering the inlet from the ocean into the porous inlet sidewalls. Dalrymple (1992) developed a simple model to explain this behavior using a simple eigenfunction expansion of the waves in the channel (assuming a rectangular channel cross-section) and an impedance boundary condition at the sidewalls. It was assumed that the waves at the mouth of the inlet had a constant amplitude and phase; that is, they were planar and normally incident. One consequence of this assumption and the impedance boundary condition was a fictitious amplification of the waves occurring within one wavelength of the channel mouth. Dalrymple and Martin (1996) have reduced this amplification by including the effect of the scattering of waves into the ocean. Kirby, Dalrymple, Kaku (1994) used parabolic model to study conformal coordinate system. Dalrymple, Kirby, Martin (1994) used spectral model to study conformally-mapped channel, including the diverging channels and circular channels.

Dalrymple, Kirby and Li (1994) using an eigenfunction expansion, studied an arbitrary cross-section channel. The basis of the eigenfunction expansion model is that the wave motion can be viewed as a summation of simple eigenmodes (Y_n) in the cross-channel direction. The amplitudes of the eigenmodes (A_n) are determined at the mouth of the channel. The wave motion (in an assumed ideal fluid) is governed by the following equation:

$$\Phi(x, y, z, t) = \hat{\phi}(x, y) \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t}$$

$$\hat{\phi}(x, y) = \sum_{n=0}^{\infty} A_n e^{i\sqrt{K^2 - \lambda_n^2}x} Y_n(y)$$

$$\frac{d^2 Y}{dy^2} + (\lambda^2 - \overline{K^2} \nu(y)) Y = 0$$

where x is the propagation direction, y is the direction across the channel, z is the direction vertically upwards from the still water level, k is the local wavenumber, g is gravity; C and C_g are the phase and group velocity, corresponding the dispersion relationship, $\omega^2 = gk \tanh kh$.

Channels with symmetric and antisymmetric cross section were studied. With the numerical model, showed that channels with sloping sidewalls give rise to the presence of edge waves, excited by the incident wave field, while the incident wave propagate in the center of channel. The edge wave length is shorter than the incident wave

length. The edge wave amplitude, represented by the zeroth mode eigenfunction, is much higher than the magnitude of the incident wave.

Figure 1: Plane View of Instantaneous Water Surface Elevation in Trapezoidal Channel Case 2; Ocean at the Bottom of Figure, Harbor to the Top. Edgewaves are excited at both the left and the right sides of the channel.

In this paper, a series of small scale laboratory experiments were conducted to verify the theoretical model. We studied the wave motion in triangular and trapezoidal channels with smooth sidewalls. Measurements of the free surface profile at different locations for several cross sections were obtained. The eigenfunctions were obtained from the wave displacement data by using Empirical Orthogonal Eigenfunction (EOF) method and were compared to those obtained from the numerical model.

2 Experiment Set-up

The wave experiments were conducted in a small tank at the Center of Applied Coastal Research at the University of Delaware. This section describes the experimental setup for the wave propagating in the channel and data acquisition procedure.

The tank was 236.0cm long, 122.5cm wide and 20.0cm deep. Waves were generated by a flap wavemaker at one end. Figures 2 and 3 show the experimental setup and tank. Two pieces of glass were used in the tank in order to form a triangular channel. Each piece of glass was 60.0cm wide, 165.0cm long and 0.64cm thick. Each glass panel was supported by two pieces of wood, allowing for the ability to vary the slopes of the sidewalls of the channel and to avoid any major deflection caused by bending. In order to diminish wave reflection, a gravel beach was located at the end of the tank. Four capacitance wave gages were used to measure the variations in the free surface.

Figure 3 shows the setup of the gages. Three gages were mounted on a movable fiberglass boom allowing for measurement at any particular position along the channel. The gages were numbered 1 through 4. Gage 4 in particular was placed parallel to the sloping side of channel and was used to measure the edge waves. Since the channel was symmetric in cross-section, gages were placed on only one side of the channel. In Figure 3, we define y as the horizontal coordinate taken to be positive landward, and $y = 0$ at the location of the midpoint of the channel cross-section.

Figure 2: Experimental Setup (Top View)

Figure 3: Layout of Wave Gages across Triangular Channel (Side View)

2.1 Analysis of Wave Data

Four tests, exploring the effect of varying channel slopes and varying wave frequencies for triangular channels, were conducted, as listed in Table 1.

Table 1: List of Experiments with Triangular Channel

Test	Slope	Wave Period (s)	Water Depth (m)	Measurement Locations			
				Along Channel Distance from Wavemaker d_x (m)		Across Channel Distance from Center point d_y (m)	
S1F1	1:2.9	0.700	0.0705	0.950		0.030 0.070 0.120 0.195	
S1F2	1:2.9	0.800	0.0705	0.985		0.030 0.070 0.120 0.195	
S2F1	1:3.1	0.680	0.0650	0.985		0.015 0.050 0.100 0.190	
S2F2	1:3.1	0.725	0.0650	0.950		0.015 0.050 0.100 0.190	

Two additional tests were also performed for trapezoidal channel, varying the wave frequencies; as listed in Table 2.

Table 2: List of Experiments with Trapezoidal Channel

Test	Slope	Wave Period (s)	Water Depth (m)	Measurement Locations			
				Along Channel Distance from Wavemaker d_x (m)		Across Channel Distance from Center point d_y (m)	
S3P1	1:2.5	0.570	0.0675	0.680		0.120 0.245 0.367 0.450	
S3P2	1:2.5	0.570	0.0675	1.095		0.120 0.245 0.367 0.450	
						0.512 0.565 0.625 0.730	

In order to test the repeatability of the experiments, each test was repeated six times. Test data from the six cases, including the time series and the amplitudes of the free surface waves were used for the data analysis. The eigenfunctions of the wave form across the channel were computed by the EOF method and later compared to the numerical model solution. The contour plots of the instantaneous wave field for the triangular and trapezoidal channels are also shown later.

3 Experimental Results

3.1 Comparison of Numerical Model To Experimental Data for Surface Profile

The amplitude of the propagating wave measured by each gage was used to create a surface profile along channel cross section. The amplitude η^i is defined by the mean maximum magnitude of time series for each gage:

$$\eta^i = \overline{\max(\eta^i(t))}$$

The surface profiles for the numerical solution and the experimental data are shown in Figures 4 through 9 (by symmetry, only half of the channel is shown; solid line indicates results of the numerical solution and the dot marks mean experimental data). The group of dots on the far right, are the experimental data obtained from the measure point close to the shoreline, representing the maximum magnitudes of the edge wave. The group of dots on the far left, are the experimental data obtained from the measuring point near the center line of channel, which represents the maximum magnitudes of the incident wave. The measuring error along y distance is $\pm 0.0018m$. As shown in these figures, there is a good agreement between the experimental data and numerical solution. The edge wave amplitude, represented by the zeroth mode eigenfunction, is much higher than the magnitude of the incident wave.

3.2 Comparison of Eigenfunction from Numerical Model and Experiment

3.2.1 The EOF method

The surface profile is assumed to be a superposition of eigenfunctions. Eigenfunctions can be obtained from the experimental data by using EOF(Empirical Orthogonal Eigenfunction) method.

The EOF method is a widely-used statistical tool which has been used for a number of analyses, including beach profile analysis. For the surface wave profile, the theoretical basis of the EOF method is the same as that for beach profile. The first eigenfunction is selected so that it accounts for the greatest possible amount of the data variance (the variance is defined as the mean square of the free surface displacement). The successive eigenfunctions each in turn are selected such that they represent the greatest possible amount of the remaining variance, Winant, Inman and Nordstrom (1975, as cited in Dean and Dalrymple, 1995).

The free surface displacement time series are recorded at the same time at the I locations across the channel width. Assume that there are K data points in one free surface displacement time series. These measured elevation are denoted as η_{ik} .

$$\eta_{ik} = \sum_{n=1}^N C_{nk} e_{ni}$$

for each I positions. Here, e_{ni} represents the n^{th} empirical eigenfunction evaluated at the i^{th} location across the channel width; and the constant C_{nk} represents a coefficient for the k^{th} recorded data and the n^{th} eigenfunction.

One property of the eigenfunctions is that they are independent of each other and orthogonal; that is,

$$\sum_{i=1}^I e_{ni} e_{mi} = \delta_{nm}$$

where $\delta_{nm} = 1$ if $n = m$, and it is zero otherwise. To obtain the value of the unknown C_{nk} , the error is minimized in the fit of η_{ik} by the eigenfunction. The minimization is carried out in the least squares sense by

$$2 \sum_{i=1}^I (\eta_{ik} - \sum_{n=1}^N C_{nk} e_{ni}) e_{mi} = 0$$

Using the orthogonality relationship,

$$C_{mk} = \sum_{i=1}^I \eta_{ik} e_{mi}$$

Parseval's theorem is then applied: the sum of the squares of the coefficients is equal to the square of the variance. To find each eigenfunction, its contribution to the variance will be maximized. Finally, by using the Lagrange Multiplier approach, the following equation can be obtained

$$a_{im} = \frac{1}{IK} \sum_{k=1}^K \eta_{ik} \eta_{mk}$$

and the symmetric matrix equation

$$\sum_{i=1}^I a_{im} e_{ni} = \lambda e_{nm} \quad (1)$$

Equation 1 is an eigenvalue matrix equation, consisting of a symmetric real coefficient matrix. By solving this matrix equation, eigenfunctions are obtained as many as measured locations I in the cross-section of channel. The eigenfunctions obtained by EOF method from experimental free surface displacement time series are discussed in next section.

3.2.2 Comparison of Eigenfunction from Numerical Model and Experiment

The zeroth mode eigenfunction for the trapezoidal channel obtained from the experiment by the EOF method is compared to that obtained from numerical solution, as shown in Figures 10 through 13. From the numerical model, amplitude of the zeroth mode edge wave is normalized to unity. The next eigenmode has a magnitude of 0.32. The third mode has an amplitude of only 0.18. From the experiment by the EOF method, the maximum amplitude of the zeroth mode eigenfunction is 1.0. The next eigenmode has the maximum magnitude of 0.067. The third mode has an amplitude of only 0.037. From both methods, it is clearly seen that the wave motion can be viewed as a summation of simple eigenfunctions, and the zeroth mode eigenfunction is the dominant one.

Figure 10: Comparison between the Zeroth Mode Eigenfunction for Case S1F2 and Numerical Solution, slope=1:2.9, T=0.800 s, h=0.0705 m, 0.985 m from Wavemaker

Figure 11: Comparison between the First Mode Eigenfunction for Case S1F2 and Numerical Solution

Figure 12: Comparison between the Zeroth Mode Eigenfunction for Case S2F2 and Numerical Solution, slope=1:3.1, T=0.725 s, h=0.0650 m, 0.950 m from Wavemaker

Figure 13: Comparison between the Zeroth Mode Eigenfunction for Trapezoidal Channel and Numerical Solution, slope=1:2.5, $T=0.570$ s, $h=0.0675$ m, 0.680 m from Wave-maker

3.3 Resonance ?

Figure 1 shows the instantaneous wave field obtained by the numerical model for the trapezoidal channel used in the test. It shows that zeroth mode edge wave has a wave length half of the incident wave length. From the nonlinear wave theory, the second harmonic wave over a flat bottom has a wave length equal to half of that of the incident wave. The issue whether there is any relationship between the zero mode edge wave and the second harmonic wave will be discussed here. Typical wave spectra in the experiments for trapezoidal channel are shown in Figures 14 and 15, which indicate the second harmonic wave frequency is twice of the first harmonic wave frequency.

Figure 14: Wave Spectrum from Wave Data at Point: 0.410 m from Wavemaker, 0.425 m from Channel Center Line

Figure 15: Wave Spectrum from Wave Data at Point: 0.820 m from Wavemaker, 0.425 m from Channel Center Line

Figure 16 shows the amplitude of the first three harmonics down the trapezoidal channel along the center line of the half-channel width, and Figure 17 shows the amplitude of the first three harmonics down the trapezoidal channel along the shoreline of the channel. It is seen that the second harmonics does not increase as might be expected by nonlinear interactions with the wave in the channel providing the forcing for edge wave growth (as indicated before). So the edge wave does not exhibit any resonance with the second harmonic of the incident wave.

Figure 16: The Amplitudes of The First Three Harmonics Down the Channel; Channel Mouth to the Left, Channel End to the Right

Figure 17: The Amplitudes of The First Three Harmonics Down the Channel along the Sidewall

4 Conclusion

A series of small scale laboratory experiments for triangular channel and trapezoidal channel were conducted to provide substance to the theoretical argument. It shows the experimental data exhibit good agreement with the numerical solutions. The results from the experiments and the numerical model show that channels with sloping sidewalls give rise to the presence of edge waves, excited by the incident wave field, while the incident wave propagate in the center of channel. The edge wave length is shorter than the incident wave length. The edge wave amplitude, represented by the zeroth mode eigenfunction, is much higher than the magnitude of the incident wave. According to the weight of each eigenfunction, the edge wave modes are the dominant ones in the wave motion. Because the amplitudes of higher harmonics do not increase, the edge wave does not exhibit any resonance with the second harmonic of the incident wave.

CHAPTER 85

A Statistical Approach for Modeling Triad Interactions in Dispersive Waves

Y. Eldeberky^{1,*}, V. Polnikov^{2,+}, and J.A. Battjes³

Abstract

The feasibility of a statistical approach to model the effect of triad interactions on the evolution of wave spectrum is investigated. The approach is based on the Zakharov kinetic integral for resonant triad interactions in capillary gravity waves. For application to dispersive gravity waves, the kinetic integral is modified by inclusion of a spectral filter (smeared delta function), to allow for the cross-spectral energy transfers in dispersive wavefields, with bandwidth to be determined empirically. Numerical investigation of the resulting expression indicates that the energy flux from the spectral peak region toward higher harmonics increases with decreasing water depth.

The interaction integral has been cast into an energy source/sink term and implemented in an energy balance equation that describes the evolution of a unidirectional energy spectrum in shoaling regions. The evolution model is investigated using observations of harmonic generation. Qualitatively the comparisons have shown the ability of the model to generate higher harmonics and a consequent upward shift in the mean frequency. However, quantitatively the model performance needs improvement.

1. Introduction

The evolution of wave spectra in shallow water is significantly affected by the cross-spectral energy transfers between various wave components due to triad

interactions. Boussinesq equations have been used to establish evolution equations for the complex amplitudes of waves propagating over slowly varying topography, simulating harmonic generation (Madsen and Sørensen, 1993).

For computational efficiency in practical applications, phase-averaged energy-based models are preferred. Abreu et al. (1992) have presented a statistical model for the nonlinear evolution of the frequency-directional spectrum, suitable as a source term in a spectral energy balance equation. The model is based on the nondispersive, nonlinear shallow-water equations and an asymptotic closure (Newell and Aucoin, 1971) for directionally spread nondispersive waves. The restriction to nondispersive waves is easily violated in practical application. The consequence of this is an unwanted behavior of the high-frequency part of the spectrum (dispersive waves).

The purpose of this paper is to investigate the feasibility of a statistical approach to model the average effects of triad interactions in dispersive surface gravity waves. The arrangement of this paper is as follows. In section 2, the kinetic integral for triad wave interactions in gravity waves is presented. The kinetic integral is numerically investigated and the results are analyzed in section 3. In section 4, the kinetic integral is used as an energy source/sink term in a spectral evolution model for investigation against observations of harmonic generation. Finally a discussion and conclusions are given in section 5.

2. Kinetic integral for triad interactions in surface gravity waves

The nonlinear triad interactions in surface gravity waves are treated mathematically using the Zakharov kinetic integral (Zakharov, 1968). The evolution equation of the spectral "energy" density n_k due to the triad interaction between (\mathbf{k}, ω) , (\mathbf{k}_1, ω_1) and (\mathbf{k}_2, ω_2) , where \mathbf{k} and ω are the wavenumber vector and the angular frequency respectively, is

$$\frac{dn_k}{dt} = 4 \iint d\mathbf{k}_1 d\mathbf{k}_2 [V_{k12}^2 N_{k12} \mu_{k-1-2} \delta_{k-1-2} - 2V_{1k2}^2 N_{1k2} \mu_{k-1+2} \delta_{k-1+2}] \quad (1)$$

Here V is the interaction coefficient and

$$N_{k12} = n_1 n_2 - n_k (n_1 + n_2) \quad (2)$$

in which the density n_k is related to the surface elevation wavenumber energy spectrum $E(\mathbf{k})$ by

$$n(\mathbf{k}) = \frac{(2\pi)^2 g}{\omega(\mathbf{k})} E(\mathbf{k}) \quad (3)$$

The factor μ_{k-1-2} in (1) is defined as

$$\mu_{k-1-2} = \frac{\Omega}{(\omega_k - \omega_1 - \omega_2)^2 + \Omega^2} \tag{4}$$

Ω is an auxiliary frequency parameter which is small compared to the spectral peak frequency ($\Omega \ll \omega_p$). The factor μ functions as a frequency filter. It is useful to gain insight in its behavior. Using the shorthand notation $\Delta\omega = \omega_k - \omega_1 - \omega_2$ and μ for μ_{k-1-2} , Fig. 1 shows μ (in Hz^{-1}) plotted versus $\Delta\omega$ (in Hz) for various values of Ω . The plot indicates that the filter becomes narrower and more spiky by decreasing the value of Ω , but the integral always equals π independent of Ω .

Fig. 1 μ plotted versus $\Delta\omega$ for various values of Ω . Dashed line: $\Omega=1.0$; Dot-dashed line: $\Omega=0.5$; Solid line: $\Omega=0.1$.

In the limit of $\Omega \rightarrow 0$, the filter becomes a dirac delta function and $\mu_{k-1-2} = \pi\delta(\omega_k - \omega_1 - \omega_2)$. Zakharov et al. (1992) use this limit, which upon substitution in (1) results in the kinetic integral for resonant three-wave interactions. The kinetic integral for resonant interactions gives nonzero contributions only for waves satisfying the resonance conditions

$$\omega(k) - \omega(k_1) - \omega(k_2) = 0 \tag{5}$$

$$k - k_1 - k_2 = 0$$

Exact resonance cannot be satisfied for surface gravity waves in water of arbitrary depth (Phillips, 1960; Hasselmann, 1962) with the following frequency dispersion

$$\omega^2 = gk \tanh(kh) \tag{6}$$

Thus for practical applications in intermediate depth, a formulation which allows for a degree of phase mismatch between the interacting waves is required to model

the cross-spectral energy transfers.

For the problem of off-resonant energetic triad interaction, Holloway (1980) suggested to use (4) for μ_{k12} with a small but finite value of Ω instead of its limit for $\Omega \rightarrow 0$. Thus instead of replacing equation (4) by a dirac delta function we use a smeared delta function (finite value of Ω) to allow for spectral energy transfers in dispersive wavefields. Here we treat Ω as a constant to be determined empirically. The feasibility of this approach will be investigated in the following.

Substituting equation (4) into equation (1) and integrating in k space yield the time evolution of the spectral "energy" density n_k due to triad interaction between components k , k_1 and k_2

$$\frac{dn_k}{dt} = 4 \int dk_1 \left\{ V_{k12}^2 N_{k12} \frac{\Omega}{(\omega_k - \omega_1 - \omega_2)^2 + \Omega^2} - 2 V_{1k2}^2 N_{1k2} \frac{\Omega}{(\omega_k - \omega_1 + \omega_2)^2 + \Omega^2} \right\} \quad (7)$$

This is the final equation describing the slow time evolution of the wave spectrum due to triad interactions. Assuming that the spectral energy is of second-order in nonlinearity: $n(k) \sim \epsilon^2$, one can define the time scale $t_1 = t_p \epsilon^{-2}$ for the slow variation of the wave spectrum. An appropriate value for the filter band-width Ω should be of the order $\Omega \cong t_1^{-1} = \epsilon^2 \omega_p$.

In application to spectral wave models based on the energy (or action) balance equation, source/sink terms are normally expressed in terms of energy (or action) density function $E(\omega, \theta)$ of the sea surface elevation. The relation between the wavenumber spectrum $E(k)$ and the frequency-directional spectrum $E(\omega, \theta)$ is

$$E(k) = \frac{c c_g}{\omega} E(\omega, \theta) \quad (8)$$

The evolution equation of the frequency-directional energy spectrum $E(\omega, \theta)$ can be found by substitution of (8) into (7) and rearranging

$$\frac{dE(\omega_k, \theta_k)}{dt} = 16 \pi^2 g \int_0^{2\pi} \int_0^\infty d\omega_1 d\theta_1 \frac{c_2 c_{g2}}{\omega_1 \omega_2^2} (T_{k12}^+ - 2T_{1k2}^-) \quad (9)$$

Here

$$T_{k12}^+ = V_{k12}^2 \left[\frac{\omega_k^2}{c_k c_{g,k}} E_1 E_2 - \frac{\omega_2^2}{c_2 c_{g2}} E_k E_1 - \frac{\omega_1^2}{c_1 c_{g1}} E_k E_2 \right] \frac{\Omega}{(\omega_k - \omega_1 - \omega_2)^2 + \Omega^2} \quad (10)$$

$$T_{1k2}^- = V_{1k2}^2 \left[\frac{\omega_1^2}{c_1 c_{g1}} E_k E_2 - \frac{\omega_2^2}{c_2 c_{g2}} E_k E_1 - \frac{\omega_k^2}{c_k c_{g,k}} E_1 E_2 \right] \frac{\Omega}{(\omega_k - \omega_1 + \omega_2)^2 + \Omega^2} \quad (11)$$

Note that the units of $E(\omega, \theta)$ is $m^2/\text{Hz}/\text{rad}$. The interaction coefficient V is given by

$$V_{k12} = \frac{g^{1/2}}{8\pi\sqrt{2}} \left\{ [k \cdot k_1 - (\omega_k \omega_1 / g)^2] (\omega_2 / \omega_k \omega_1)^{1/2} \right. \\ + [k \cdot k_2 - (\omega_k \omega_2 / g)^2] (\omega_1 / \omega_k \omega_2)^{1/2} \\ \left. + [k_1 \cdot k_2 + (\omega_1 \omega_2 / g)^2] (\omega_k / \omega_1 \omega_2)^{1/2} \right\} \quad (12)$$

Equations (9-11) describe the time evolution of wave energy spectrum $E(\omega, \theta)$ due to triad interactions. The first term of the integrand T_{k12}^+ represents the sum interaction ($k=k_1+k_2$), the second T_{k12}^- the difference interaction ($k=k_1-k_2$). The present formulation is directionally coupled and thus allows for both colinear and noncolinear interactions. Note that the resonance condition (5) does not necessarily have to be fulfilled in (7).

3. Numerical investigation of energy transfer rate

Aim and method of discretization

The general purpose of the investigations is to study the characteristics of the kinetic integral and the dependence of the nonlinear rate (NLR) of energy transfer on the filter bandwidth Ω and relative depth kh . The Jonswap spectrum is used to describe the frequency distribution of the wave energy and a \cos^2 -distribution is used for the directional spreading. The kinetic integral is calculated by means of simplest trapezium method of integration.

For a sufficiently fine grid (ω, θ) resolution, the values obtained for the kinetic integral do not significantly depend on the choice of grid. This choice is important from the point of view of good resolution of spectral form $E(\omega, \theta)$ and covering a proper interval of frequencies and directions for the output rate dE/dt . After some test calculations, we used a logarithmic frequency distribution with 48 discrete frequencies in the range $0.265 \leq \omega/\omega_p \leq 4$, and a uniform directional grid with 24 discrete components.

Results of calculations and analysis

The calculations of the kinetic integral have been carried out for a range of relative depths $k_p h = 3, 1.2, 0.6$, and 0.3 . Two values for the nondimensional parameter Ω/ω_p are considered, these are 0.01 and 0.1 .

Fig. 2 shows NLR for Jonswap spectrum for $k_p h = 0.3$ and $\Omega/\omega_p = 0.01$. The results are given in one-dimensional form, i.e., integrated over directions. The results show an energy flux from the region near the primary peak toward the higher harmonics. The behavior of the NLR indicates the following two features. First the maximum of the positive lobe occurs at $f/f_p = 1.9$ (less than the location of the first harmonic $2f_p$). This is due to the fact that a triad of waves is considered such that two wave components (ω_1, k_1) and (ω_2, k_2) can force a motion at the vector sum or

difference wavenumber $k=k_1 \pm k_2$ and frequency $\omega(k)$. This consideration implies that the first harmonic appears in the wavenumber spectrum at $2k_p$, which corresponds to a peak in the frequency spectrum at $\omega < 2\omega_p$ (in intermediate water). The second feature is that the area under the positive lobe is smaller than the area under the negative lobe, implying attenuation in the total energy.

Fig. 2 Nondimensional rate of energy transfer in Jonswap spectrum, $\Omega/\omega_p=0.01$, $k_p h=0.3$, directional spreading; \cos^2 -distribution.

For quantitative analysis of the calculations we used the following characteristics:

- maximum value of positive lobe of two-dimensional NLR: MT^+ ;
- maximum absolute value of negative lobe of two-dimensional NLR: MT^- ;
- ratio of total NLR (two-dimensional NLR integrated over frequency and direction) to the absolute value of the total negative part of NLR: D

Table 1 summarizes the results for various relative depths and Ω -values. Note that the parameter D is a measure of energy conservation within the system. Positive values of D indicate energy gain and negative values indicate energy attenuation. Table 1 indicates that NLR is roughly proportional to the value of Ω .

Table 1 *Statistics of nonlinear rate (NLR) of energy transfer for Jonswap spectrum with direction spreading of \cos^2 -distribution*

$k_p h$	3		1.2		0.6		0.3	
Ω/ω_p	0.01	0.1	0.01	0.1	0.01	0.1	0.01	0.1
MT^+	0.1	1.1	1.1	10.7	48	401	2,031	11,071
MT^-	-0.6	-6.1	-1.9	-18.4	-64	-548	-2,566	-17,646
D	-0.48	-0.48	-0.26	-0.32	+0.16	-0.13	+0.12	-0.07

The parameter D measures the percentage of energy gain/loss from the total energy flux across the spectrum. In deep water D reaches large values but there the energy transfers are weak, so that the nonconservation of energy is weak also. As the water depth decreases in shallow water, the NLR increases strongly. In shallow water, although the values of D decrease, the energy attenuation becomes significant because of the strong increase in the NLR values. In fact for $\Omega/\omega_p=0.01$, D indicates an energy gain in shallow water ($k_p h=0.6, 0.3$).

The preceding analysis permits to state the following characteristics of NLR of energy transfers due to off-resonant triad interactions:

1. NLR strongly depends on the relative depth $k_p h$. With decreasing $k_p h$, the intensity of NLR increases.
2. NLR has a non-conservativity feature. Generally it results in an energy attenuation in intermediate and shallow water depths.
3. The intensity of NLR varies in proportion to Ω .

4. Spectral evolution

4.1 Model formulation and implementation

Assessment of the characteristics of the kinetic integral for triad interactions requires verification with observations. For simulation of the spectral evolution, we need to develop a spatial evolution model for the energy spectrum with a source/sink term representing the effect of triad wave interactions. Since the observations used here are measured in flume experiments that are characterized by long-crested waves, the following one-dimensional energy balance equation is used

$$\frac{d}{dx} [c_{g,k} E(\omega_k)] = S_k \quad (13)$$

Here $E(\omega_k)$ is the frequency energy density, $c_{g,k}$ is the one-dimensional group velocity and S_k is the net source/sink term. To implement the effect of triad wave interactions in equation (13), the kinetic integral (9-11) is cast in an energy source/sink term for unidirectional waves as follows:

$$S_{tr}(\omega_k) = 16\pi^2 g \int_0^\infty d\omega_1 \frac{c_2 c_{g2}}{\omega_1 \omega_2^2} (T_{k12}^+ - 2T_{1k2}^-) \quad (14)$$

$$T_{k12}^+ = V^2(\omega_k, \omega_1) \left[\frac{\omega_k^2}{c_k c_{g,k}} E_1 E_2 - \frac{\omega_2^2}{c_2 c_{g2}} E_k E_1 - \frac{\omega_1^2}{c_1 c_{g1}} E_k E_2 \right] \frac{\Omega}{(\omega_k - \omega_1 - \omega_2)^2 + \Omega^2}$$

$$T_{1k2}^- = V^2(\omega_1, \omega_k) \left[\frac{\omega_1^2}{c_1 c_{g1}} E_k E_2 - \frac{\omega_2^2}{c_2 c_{g2}} E_k E_1 - \frac{\omega_k^2}{c_k c_{g,k}} E_1 E_2 \right] \frac{\Omega}{(\omega_k - \omega_1 + \omega_2)^2 + \Omega^2}$$

The energy source/sink term given in (14), for the effect of triad wave interactions, represents a (positive/negative) contribution to the temporal rate of change of spectral density. The energy balance equation (13) comprises a set of first-order ordinary differential equations that describe the evolution of the energy spectrum $E(\omega)$. Giving the initial energy spectrum at the upwave boundary, equation (13) has been numerically integrated using a fourth-order Runge-Kutta method.

4.2 Simulation of spectral evolution

In this section, the evolution model (13) together with the triad source term (14) is investigated using observations for harmonic generation in random waves propagating over a shallow bar (Beji and Battjes, 1993) as well as over a beach profile (Arcilla et al., 1994).

The investigation of the nonlinear rate (NLR) of energy transfers presented in section (3) has shown that the present formulation is not conservative. To ensure energy conservation in the simulation of spectral evolution the following *ad hoc* method is used. First the NLR of energy transfer is estimated as a first guess using the present formulation. Next the integral (of NLR) over the spectrum which represents the total energy gain/loss I is computed. The NLR of energy transfer is then rescaled by adding (or subtracting) the quantity I . If I is negative, implying energy loss, then the area of negative lobe is reduced with I in proportion to the values of the NLR. On the other hand if I is positive, implying energy gain, then the area of positive lobe is reduced with I in proportion to the values of the NLR.

To simulate energy dissipation due to wave breaking over a beach profile, the energy balance equation (13) is supplemented with a source term for depth induced wave breaking after Eldeberky and Battjes (1996), in which the total energy dissipation due to breaking in random waves is calculated according to Battjes and Janssen (1978) and spectrally distributed in proportion to the spectral levels.

Fig. 3 Layout for the experimental setup of Beji and Battjes (1993). All lengths are expressed in meters.

Fig. 4 Bed profile and locations of wave gauges (Arcilla et al., 1994)

To examine the sensitivity of the spectral evolution to the choice of Ω , two values are used in the computations: $\Omega/\omega_p=0.01$ and 0.1 . The computed spectra are compared to the measured ones in nonbreaking waves propagating over a bar (Fig. 3) and breaking waves over a beach profile (Fig. 4). The results are given in Figs. 5 and 6 respectively. The comparisons indicate the following characteristics of the triad source term:

1. The intensity of energy transfers from the primary spectral peak to the higher frequencies is mainly controlled by the choice of Ω -value. Increasing Ω -value results in stronger energy transfers, extended to higher frequencies.
2. The energy transfers to higher harmonics are underestimated when $\Omega/\omega_p=0.01$, and overestimated when $\Omega/\omega_p=0.1$. The latter results in an unwanted behavior for the energy spectrum at the high frequency range (spectral tail).
3. The second spectral peak (in frequency-domain) is shifted to a lower frequency compared with observation. It appears at a frequency less than two times the primary peak. This is ascribed to the fact that triads are considered such that $k=k_1+k_2$, which results in $\omega_k < \omega_1 + \omega_2$ in intermediate water depths.

4.3 Sensitivity to the filter bandwidth

The previous results for the computed spectral evolution have shown dependence of the NLR of energy transfer on the choice of the filter bandwidth Ω . Additional numerical simulations for wave propagation over a shallow bar and beach profile have been carried out with different values of Ω . To evaluate the variation in the spectral evolution for various values of Ω , the variations in the mean frequency of the spectrum are computed. The mean frequency of the energy spectrum is defined as

$$f_m = \frac{\int \omega E(\omega) d\omega}{2\pi \int E(\omega) d\omega} \quad (15)$$

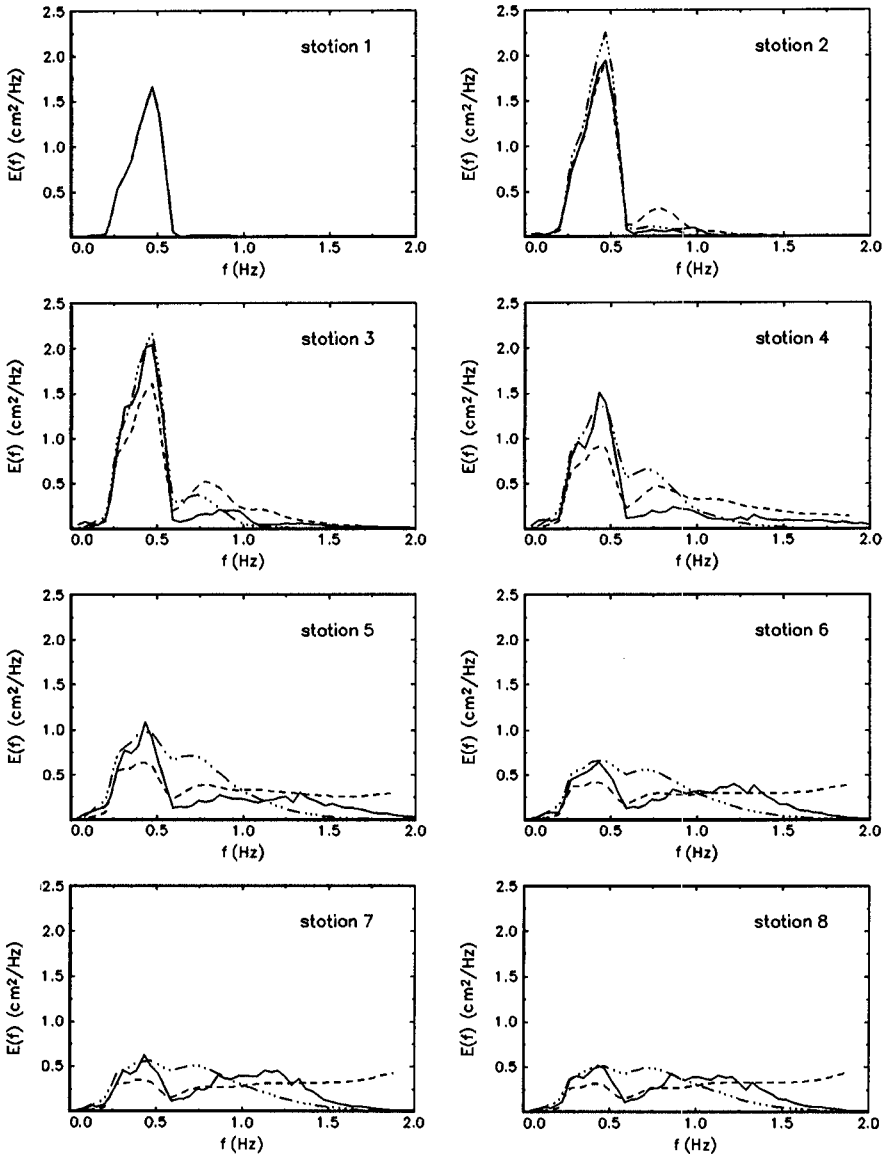

Fig. 5 Energy spectra from experiments (solid lines) and from the evolution model: with $\Omega/\omega_p=0.01$ (dashed lines) and $\Omega/\omega_p=0.1$ (dot-dashed lines) for waves propagating over a shallow bar.

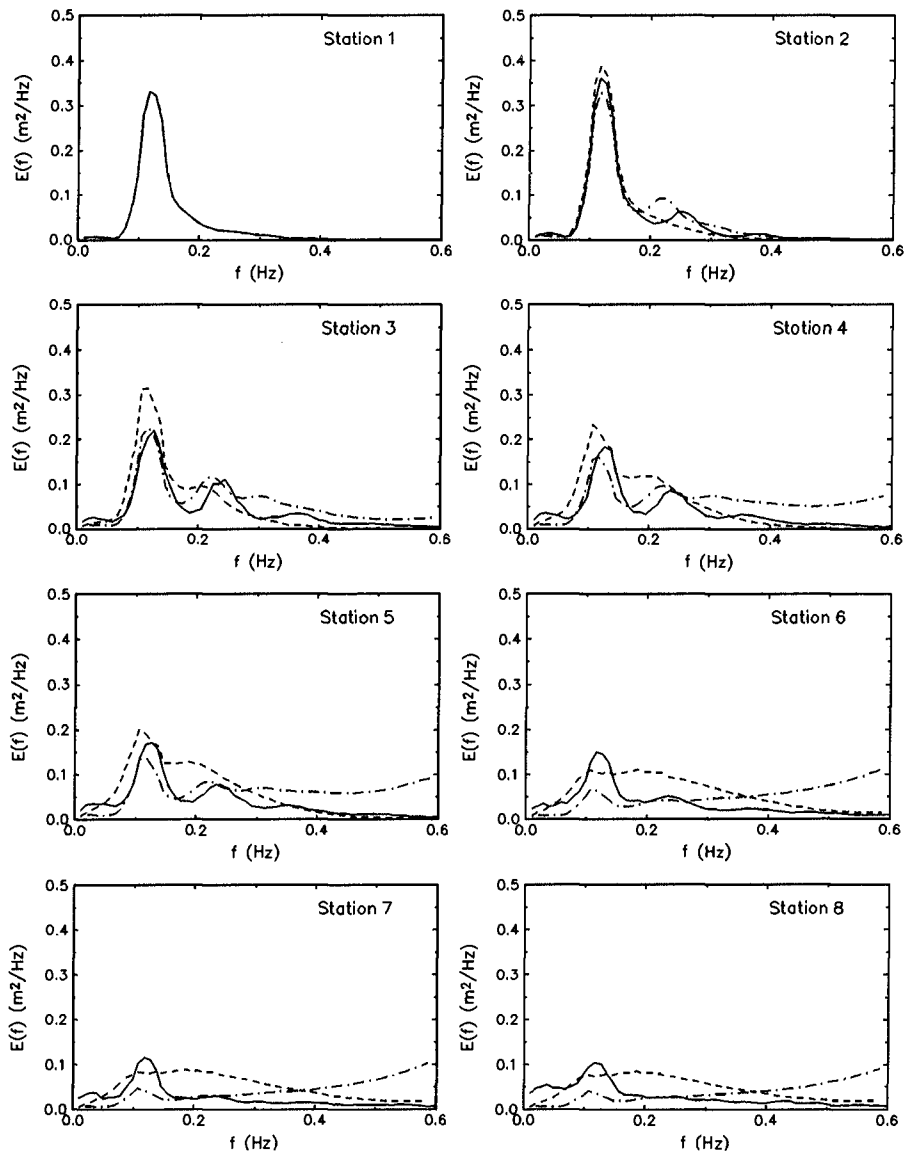

Fig. 6 Energy spectra from experiments (solid lines) and from the evolution model: with $\Omega/\omega_p=0.01$ (dashed lines) and $\Omega/\omega_p=0.1$ (dot-dashed lines) for waves propagating over a beach profile.

Fig. 7 shows the observed variations in the mean frequency in waves passing over a shallow bar and those computed by the evolution model with different values of Ω/ω_p . The observed variation in the mean frequency shows a rapid increase (from 0.43 Hz to 0.85 Hz) over the upslope side and the horizontal part of the bar, which is ascribed to generation of higher harmonics. Beyond the bar crest, the mean frequency remains at a high level without significant change. The computed variations in the mean frequency using the evolution model show a strong dependence on the value of the parameter Ω . The larger the value of Ω/ω_p , the stronger the energy transfers and hence the shift in the mean frequency to higher harmonics. From the results one can see that the best choice for the parameter Ω/ω_p , for best simulation of the observed shift in the mean frequency, in this case is between 0.01 and 0.03.

Fig. 7 Spatial variation of mean frequency f_m in waves propagating over a shallow bar. Solid line: experiment; Dashed lines: evolution model using different values for Ω/ω_p

Fig. 8 shows the observed variations in the mean frequency in waves propagating over a beach profile and those computed by the evolution model with different values of Ω . The observed variation in the mean frequency shows a rapid increase in intermediate water from 0.14 Hz to 0.21 Hz due to harmonic generation. In very shallow water, the mean frequency nearly attains a constant level. The computed variations in the mean frequency using the evolution model show a strong dependence on the value of Ω . In intermediate water depths (between stations 1 and 3) computations with $\Omega/\omega_p=0.04$ and 0.05 seem to best match the observed shift in the mean frequency. In shallow water, all computations with different values of Ω result in a trend which differs strongly from the observed one, significantly overestimating the mean frequency.

Fig. 8 Spatial variation of mean frequency f_m in waves propagating over a beach profile. Solid line: experiment; Dashed lines: evolution model using different values for Ω/ω_p

5. Discussion and conclusions

The feasibility of a statistical approach to model the average effects of triad interactions on the evolution of wave spectrum is investigated. The approach is based on the Zakharov kinetic integral for resonant triad interactions in capillary gravity waves. For application to surface gravity dispersive waves, the kinetic integral is supplemented with a frequency filter to allow for the off-resonant energetic interactions. The filter bandwidth Ω is of small but finite value resulting in a smeared delta function. Ω is treated as a constant to be determined empirically. The interactions integral is used as a source term in an evolution model to simulate observations of harmonic generation in waves propagating over a shallow bar as well as over a beach profile. In general the comparisons have shown the ability of the model to generate higher harmonics and a consequent upward shift in the mean frequency.

The consequences of treating the filter bandwidth Ω as a constant have resulted in an energy attenuation and unguaranteed spectral evolution in some cases. Holloway (1980) proposed to treat Ω as a prognostic variable with magnitude related to the rate of interaction of the three components involved in the interaction and increases with increasing nonlinearity. In Holloway's approach, the magnitude of Ω for the interaction between l , m , and n needs to be determined first by solving three equations representing the interaction rates of the three components. These three equations for each possible triad together with the spectral evolution equations

represent a closed set of equations guiding the evolution of the energy density spectrum.

In principle the approach of Holloway (1980) sketched above may be applied to provide an estimate for the parameter Ω . This may achieve a better prediction of the evolution of the energy spectrum. On the other hand the extensive computational efforts required to resolve the closed set of equations are a concern. For computational efficiency in practical applications, we recommend a parametrized source term for triad wave interactions (Eldeberky, 1996, Chapter 7 and Eldeberky and Battjes, 1997)

CHAPTER 86

A Fully Nonlinear 3D Method for the Computation of Wave Propagation

Andrew B. Kennedy¹ and John D. Fenton¹

Introduction

The computational capabilities for calculating nonbreaking wave evolution have advanced a great deal in recent years. For fully nonlinear models, the adoption of multi-subdomain techniques (Wang et al., 1995, de Haas et al., 1996) has provided much greater efficiency while still allowing the calculation of wave transformation up to overturning. Still, computational times remain great enough that the application of these methods to three dimensional domains remains somewhat limited. The variable depth Boussinesq equations were originally developed with the twin assumptions of mild nonlinearity and frequency dispersion (Peregrine, 1967), but recently, beginning with Witting (1984), there have been concerted efforts to increase their range of applicability. Papers of particular note include Madsen and Sørensen (1992), Nwogu (1993), Wei et al. (1994), Schäffer and Madsen (1995), and Gobbi and Kirby (1996) (GK). Of these, all but GK assume a flow field that varies quadratically in the vertical coordinate y , while GK derive their equations for a quartic vertical variation in the velocity potential. All of these methods have at least one free parameter which is invariably used to calibrate model linear phase speed, linear shoaling, second order transfer functions, or some combination of the three, to known analytic results over a level bed or small slope. For these special conditions, the accuracy of the various Boussinesq equations may be greatly improved and, in fact, the above papers have shown that accuracy is also improved for conditions which differ significantly from the idealised situations used for tuning. However, it is not possible to place confidence in velocities, pressures, and higher order free surface nonlinearities calculated by any of these methods except in reasonably shallow depths. The one exception to this are the GK higher order Boussinesq equations, which are quite complex.

In Kennedy and Fenton (1995) a method was developed to calculate wave evolution over varying topography for one dimension in plan. The flow field was locally represented by a polynomial of arbitrary degree which analytically satisfied Laplace's

¹ Dept. of Mech. Eng., Monash University, Clayton, Vic. Australia 3168

equation. By applying continuity conditions between subdomains, an overall solution to the boundary value problem was obtained and highly accurate time stepping solutions could be obtained. A summary of this, plus another related method appears in Fenton and Kennedy (1996).

In this paper, a method is developed which uses some of the same ideas but is valid for three dimensional fluid motion (two dimensions in plan). Again, the velocity potential is represented in the vertical by a polynomial of arbitrary degree but here, a set of differential equations results for a local polynomial approximation (LPA) to the exact solution. This is shown to provide excellent linear and nonlinear results for a wide range of waves. The degree of polynomial may also be easily changed to give the level of accuracy desired for a particular problem.

Solution of Laplace's Equation

For nonbreaking wave motion, the flow field is usually represented by a velocity potential, $\phi(x, z, y, t)$, and fluid velocities are thus $(u, w, v) = (\partial\phi/\partial x, \partial\phi/\partial z, \partial\phi/\partial y)$, where x and z are the horizontal coordinates and y is the vertical coordinate. The continuity equation for fluid flow to be satisfied at every point in the domain then becomes

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 0, \quad (1)$$

which is simply Laplace's equation in three dimensions. At any time t_0 this velocity potential is subject to the boundary conditions

$$\phi = \phi_s \quad \text{on } y = \eta, \quad (2)$$

and

$$\frac{\partial\phi}{\partial y} - \frac{\partial\phi}{\partial x} \frac{\partial h}{\partial x} - \frac{\partial\phi}{\partial z} \frac{\partial h}{\partial z} = 0 \quad \text{on } y = h, \quad (3)$$

where $h(x, z)$ is the bed elevation, and the free surface elevation $\eta(x, z, t)$ and velocity potential $\phi_s(x, z, t)$ are both known at time t_0 . With the addition of appropriate conditions on the horizontal boundaries, these two conditions (2) and (3), along with the field equation (1) completely specify the problem and may be used to solve for the flow field.

The velocity potential function used here assumes a polynomial variation in the vertical coordinate such that

$$\phi(x, z, y, t) = \sum_{j=0}^r A_j(x, z, t) y^j, \quad (4)$$

where $r \geq 2$, and the A_j coefficients are independent and may vary in time.

From here, there are many directions that could be taken. The Boussinesq approach would be to create a Taylor series expansion about some point in the water column which satisfies the bottom boundary condition (3) to the order of accuracy desired, and proceed from there. However, it is desired here to use an approximation which

distributes error more evenly than is possible with a Taylor series, where error quickly increases away from the expansion point. The obvious approach would now be some sort of finite element method, but this would involve volume integrals, which are slow to compute. Furthermore, unless higher order elements were used, convergence would be slow, and introducing them would increase computational costs significantly.

Therefore, a different approach is used, which is simple in concept, and distributes the error in (1) over the water column. First, constraints are imposed so that the velocity potential satisfies (2) and (3). Next, the average and first $r - 2$ weighted averages of (1) over the water column are set to zero, such that

$$\int_h^\eta y^l \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} \right) dy = 0, \quad l = 0, \dots, r - 2. \quad (5)$$

The appropriate global horizontal boundary conditions finish the specification of the problem and a set of linear equations results, which may be solved as desired.

Once the flow field is known, the free surface elevations and velocity potentials may be updated in time using the evolution equations

$$\frac{\partial \eta}{\partial t} = \frac{\partial \phi}{\partial y} - \frac{\partial \eta}{\partial x} \frac{\partial \phi}{\partial x} - \frac{\partial \eta}{\partial z} \frac{\partial \phi}{\partial z} \quad \text{on } y = \eta, \quad (6)$$

and

$$\frac{\partial \phi_s}{\partial t} = C - g\eta - \frac{1}{2} \left(\frac{\partial \phi^2}{\partial x} + \frac{\partial \phi^2}{\partial z} + \frac{\partial \phi^2}{\partial y} \right) + \frac{\partial \phi}{\partial y} \frac{\partial \eta}{\partial t} \quad \text{on } y = \eta. \quad (7)$$

Alternate Formulations for the Velocity Potential

It is possible to rearrange the form of the velocity potential given in (4) so that it has fewer parameters at each computational point. The velocity potential

$$\begin{aligned} \phi(x, z, y, t) = & \phi_s \left(\frac{y-h}{\eta-h} \right)^2 + A_B \left[(y-\eta) + \frac{f_2 (y-\eta)(y-h)}{f_1 (\eta-h)} \right] \\ & + \frac{\partial A_B}{\partial x} \frac{\partial h}{\partial x} \frac{(y-\eta)(y-h)}{f_1} \\ & + \frac{\partial A_B}{\partial z} \frac{\partial h}{\partial z} \frac{(y-\eta)(y-h)}{f_1} + A_3 (y-h)^2 (y-\eta) \\ & + A_4 (y-h)^2 (y-\eta)^2 + \dots \\ & + A_r (y-h)^2 (y-\eta)^{r-2}, \end{aligned} \quad (8)$$

where

$$f_1 = 1 + \frac{\partial h^2}{\partial x} + \frac{\partial h^2}{\partial z},$$

and

$$f_2 = 1 + \frac{\partial h}{\partial x} \frac{\partial \eta}{\partial x} + \frac{\partial h}{\partial z} \frac{\partial \eta}{\partial z},$$

analytically satisfies both (2) and (3). If made to satisfy (5), the resulting velocity potential will be identical to that described in the previous section. Furthermore, since

two fewer coefficients are defined at each point, computational speed should increase significantly. However, it is obvious that coding will be much more complex and, due to time constraints, and because the main thrust of this paper is to determine the accuracy of this LPA method, the velocity potential formulation of (8) was not used.

Linear Properties

Phase Speed

Using linearised versions of the free surface conditions (6) and (7), analytic LPA solutions for a given level of approximation, r , may be found for a plane progressive wave train. For the level of approximation $r = 2$ (y^2 terms included in ϕ), the phase velocity c is

$$\frac{c^2}{gd} = \frac{1}{1 + \frac{1}{3} (kd)^2}, \tag{9}$$

where g is the gravitational acceleration, d is the fluid depth, and k is the wavenumber. For the level of approximation $r = 3$ (y^3 terms in ϕ), the relationship is

$$\frac{c^2}{gd} = \frac{1 + \frac{1}{10} (kd)^2}{1 + \frac{13}{30} (kd)^2 + \frac{1}{80} (kd)^4}, \tag{10}$$

and using $r = 4$ (y^4 terms in ϕ), the phase velocity is

$$\frac{c^2}{gd} = \frac{1 + \frac{13}{105} (kd)^2 + \frac{1}{420} (kd)^4}{1 + \frac{16}{35} (kd)^2 + \frac{3}{140} (kd)^4 + \frac{1}{6300} (kd)^6}. \tag{11}$$

Figure 1. Small amplitude phase velocity

These expressions are identical to those obtained for Green-Naghdi shallow water Theories I, II, and III respectively (Shields and Webster, 1988). All of these are approximations to the exact small amplitude relationship

$$\frac{c_{exact}^2}{gd} = \frac{\tanh(kd)}{kd}. \tag{12}$$

In both (9) and (10) errors are of $O((kd)^4)$, while (11) contains errors of $O((kd)^8)$. Figure 1 compares LPA and exact phase speeds. Using the LPA level $r = 2$, phase speeds are found to be quite reasonable until a dimensionless wavenumber of $kd = 1.25$ ($L/d = 5$) is reached, while with $r = 3$, phase speeds are adequate up until the nominal deep water limit of $kd = \pi$ ($L/d = 2$). The level of approximation $r = 4$ gives very good results well into deep water and is usable even for a wave with $kd = 2\pi$ ($L/d = 1$) which is a very pleasing result.

Figure 2. Normalised fluid velocities under a small amplitude wave

Fluid Velocities and Pressures

Small amplitude LPA solutions for ϕ may also be used to compare internal fluid velocities and pressures with Stokes first order results. Figure 2 shows the variation of the horizontal and vertical velocities, u and v , over the water column. For a wave with length $kd = \pi/5$ ($L/d = 10$), all levels of LPA approximation give a good result,

although the level $r = 2$ shows slight differences, with the vertical velocity looking least accurate. Decreasing the wavelength to $kd = 2\pi/5$ ($L/d = 5$) increases error for the level $r = 2$, although all other levels predict velocities well. At the nominal deep water limit of $kd = \pi$ ($L/d = 2$), LPA levels $r = 2$ and $r = 3$ have significant errors in velocity, while with $r = 4$, the velocity is still modeled well. For a wave with length $kd = 2\pi$ ($L/d = 1$), all levels of approximation show error, although a convergence toward the exact solution is evident. Results for the dynamic pressure response factor $f(y)$, which gives the ratio of dynamic pressure at any elevation to the dynamic pressure just below the still water level, are identical to the results for relative horizontal velocity.

General Comments

With an overall view of the linear properties, some judgements may now be made. The first is that the level of LPA approximation $r = 2$ is only suitable for waves in shallow and mildly intermediate depths. For all other waves, the assumed structure of the velocity potential is inadequate to describe the vertical variation of the fluid flow. For these reasons, and since other levels are much more accurate, the level $r = 2$ will be discarded. The LPA level $r = 3$ gives significantly better results through to near the nominal deep water limit of $L/d = 2$, both for phase speed and fluid velocities. The level of approximation $r = 4$ has very accurate linear properties into quite deep water, and an increase to an LPA level to greater than this does not appear to be justified at the present time.

It is quite easy to introduce tuning parameters into the solution. By replacing (5) with the more general

$$\int_h^n w_l(y) \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} \right) dy = 0, \quad l = 0, \dots, r - 2 \quad (13)$$

where $w_l(y)$ is some weighting function, sets $\{w_l\}$ were easily found which gave more accurate phase velocities for the LPA levels $r = 3, 4$. However, any increase in accuracy of phase velocity was invariably coupled with a decrease in accuracy of some other quantity of interest. For example, a set $\{w_l\}$ was found where the approximation of (11) for the LPA level $r = 4$ had errors decrease from $O((kd)^8)$ to $O((kd)^{10})$. However, errors in the horizontal velocity at the bed, which could be taken as another measure of accuracy, increased from $O((kd)^8)$ to $O((kd)^6)$. Because of results like this, and because the set of weighting functions $\{1, y, y^2, \dots\}$ is very general, no attempt was made to tune the model for any particular quantity.

Nonlinear Properties

The nonlinear properties implied by the LPA set of governing equations were investigated by comparing their solutions for steady nonlinear waves with numerically exact solutions of the full potential flow equations. Numerically exact waves were generated using the Fourier method of Fenton (1988), while the fully nonlinear LPA solutions were found using the same general idea adapted to LPA.

Figure 3 compares LPA and numerically exact profiles for three highly nonlinear waves. The first wave generated is long, with a length to depth ratio of $L/d = 20$ ($kd = \pi/10$), and a height of $H/d = 0.6$. Both LPA levels $r = 3$ and $r = 4$ predict the profile very well. The second wave has length $L/d = 5$ ($kd = 2\pi/5$) and height $H/d = 0.4$. Once again, both LPA levels tested predict the nonlinear wave profile very accurately. The final wave in Figure 3 is at the nominal deep water limit, with a length to depth ratio of $L/d = 2$ ($kd = \pi$), and a height $H/d = 0.2$. For this wave, the LPA level of approximation $r = 3$ shows small errors, although the overall wave form is predicted well. However, the level $r = 4$ once again provides a solution which is indistinguishable by eye from the numerically exact profile.

Nonlinear phase speeds may also be compared with exact solutions. Figure 4 plots LPA and exact speeds for waves with length $L/d = 20, 5,$ and 2 . Circles, triangles and squares show the highest wave computed for the levels $r = 3, r = 4,$ and numerically exact solutions, respectively. These do *not* represent the limiting waves, but instead describe a failure of the solution method to solve the system of nonlinear equations past these points.

Figure 3. Nonlinear wave profiles

Both LPA levels $r = 3$ and $r = 4$ give a very good estimate of phase speed up to the highest waves tested, with the only significant differences occurring using $r = 3$ with a wave of length $L/d = 2$. However, even here the trend is followed quite well. The results for the level $r = 4$ and the wave with length $L/d = 5$ are especially noteworthy. Here, LPA solutions were found close to the limiting height which predicted the maximum and subsequent decrease in wave speed shown by

Cokelet (1977). This good representation of highly nonlinear waves gives additional confidence in the accuracy of the 3D LPA method.

Time Stepping Solutions

Time stepping solutions of the governing equations may be divided into two main tasks: the LPA solution of Laplace's equation, and the advance of the solution to the next time step. Of the two, the second is the most straightforward, as (6) and (7) were used with either a second order leapfrog or third order Adams-Bashforth technique to update the free surface elevations and velocity potentials. As neither of these methods are self starting, a fourth order Runge-Kutta technique was used for the first few time steps.

Figure 4. Nonlinear wave speeds

To solve Laplace's equation, all coefficients were represented using fifth degree two dimensional B-splines (see de Boor, 1978), which are simply the product of one dimensional B-splines in x and z which have the same centre. Solutions were also computed using third degree B-splines, but convergence was found to be poorer than desired. The sparse system of linear equations which results from the B-spline representation was solved using a line by line successive under-relaxation technique. Using this representation, errors in the LPA solution are theoretically proportional to $(\Delta l)^4$, where Δl is mesh size. This was tested by computing the maximum relative error in vertical velocity at the free surface for a flow field with a flat bed and surface, and free surface velocity potential $\phi_s = \cos(kx)$, where $kd = \pi/10$ ($L/d = 20$). Figure 5 shows the relative error, plotted alongside $(L/\Delta l)^4$ for comparison. Convergence is seen to follow the theoretical behaviour closely. Furthermore, even for a very coarse representation of $\Delta l/L = 1/6$ (6 points/wavelength), relative errors are still only two parts in a thousand, which allows confidence to be placed in computations with relatively coarse resolution.

Figure 5. Convergence of the numerical scheme

Figure 6. Bottom topography for solitary wave reflection

The Runup of a Focused Solitary Wave on a Vertical Wall

For a first test, a solitary wave of height $H/d = 0.2$ was propagated over topography which tended to focus the wave, which was then reflected by a vertical wall. Computations were performed using the LPA level $r = 4$. Figure 6 shows the focusing topography which consisted of a flat bed followed by a double cosine variation in the x and z directions with an amplitude of $0.1d$. However, for all x , the average bed elevation still remained $y = 0$. Different scales L_x and L_z as marked would focus the wave to different degrees, leading to a varying runup on the vertical wall. This numerical experiment could be thought of as representing the effect on solitary wave runup of small variations in topography about a mean. Figure 7 shows a snapshot of the wave's surface profile slightly after maximum runup. The three dimensional effects can clearly be seen.

Figure 8 shows the maximum runup of the wave for varying L_x and L_z . The computed

runup for a level bed and predicted runup for a wave propagated onto an infinite two dimensional shoal of depth $d_s/d_0 = 0.9$ are also shown. The latter result was predicted using the KdV results of Johnson (1973) and the solitary wave runup formula of Su and Mirie (1980). For small spatial scales, the topography has very little effect on runup but, as the scale increases, runup also increases significantly. Although the maximum value for the focused runup is only slightly greater than the predicted result for an infinite shoal, it is by no means clear that the limiting runup has been reached, and a further increase in L_x and L_z might well give significantly higher values.

Figure 7. The reflection of a focused solitary wave by a vertical wall

Figure 8. Maximum runup of a focused solitary wave

Since all of the above computations were performed in an enclosed space with no dissipation, conservation of energy could be used as an independent check on accuracy. For all tests, the maximum fluctuation in total energy at any point in time relative to the initial value was less than 2×10^{-4} .

The propagation of regular waves over Whalin’s topography

For a final test of the LPA method, the propagation of regular waves over Whalin’s

topography was computed. In a series of experiments, Whalin (1971) propagated waves over a semicircular shoal which tended to focus waves on the flat behind the shoal. Many investigators have since performed computations over the same topography.

In these computations, regular waves were generated from one boundary using as input the time series of velocity from the fully nonlinear LPA wave forms. Odd derivatives of surface elevation were also specified at the boundary. On the transmitting boundary, a small amplitude boundary condition was combined with a zone where the evolution equations (6) and (7) gradually changed to become the advection equations

$$\frac{\partial}{\partial t} \left(\frac{\partial \eta}{\partial x} \right) = -c \frac{\partial}{\partial x} \left(\frac{\partial \eta}{\partial x} \right) \quad (14)$$

and

$$\frac{\partial}{\partial t} \left(\frac{\partial \phi_s}{\partial x} \right) = -c \frac{\partial}{\partial x} \left(\frac{\partial \phi_s}{\partial x} \right) \quad (15)$$

where c is some characteristic phase velocity on the shelf. These equations were solved in finite difference form using an upwinding scheme. This type of area around the boundary makes it very difficult for errors due to an imperfect boundary condition to propagate back into the domain, as they are continuously pushed out by the advection equations. All computations shown use the level of approximation $r = 3$.

Figure 9(a). Harmonic Amplitudes along centreline of Whalin's topography, $T = 3$ s, $A_1 = 0.0146$ m. Solid lines indicate present results; dashed lines show results of Rygg (1988); symbols are experimental results of Whalin (1971). Chain-dashed line shows beginning of dissipating beach, which was not reproduced in computations.

Figure 9 shows the experimental and computational harmonic amplitudes along the centreline for the highest waves with experimental periods $T = 1$ s, 2s, 3s. Also included are the results of Madsen and Sørensen (1992) using their extended Boussinesq equations for the $T = 1$ s case and the results of Rygg (1988) using the Boussinesq equations of Peregrine (1967) for $T = 2$ s, 3s.

For the longest wave, with $T = 3\text{s}$, both computational methods severely overpredict the amplitude of the first harmonic and moderately underpredict the amplitude of the second and third harmonics. Although the LPA results for $r = 3$ are shown, increasing the level to $r = 4$ (not shown here) provides no real change. This is somewhat distressing, as both LPA models and the extended Boussinesq equations should operate best in this range. However, the experimental topography used by Whalin was made up of a series of steps and only approximated the smooth topography used in the computations. Consequently, dissipation, neglected in computations, was significant in the experiments, especially for high, long waves. This is speculated to be the major source of discrepancies for this wave.

For the next wave, with $T = 2\text{s}$, computations agree somewhat better with experimental data. Once again, the first harmonic is overpredicted and so, to some degree, is the second harmonic, while the third harmonic is predicted relatively well. Both LPA and Boussinesq computations predict similar features, although there are differences. One strange feature of this wave is that the initial amplitude of the first harmonic used to calculate the incoming waves, which is given as $A_1 = 0.0149\text{m}$, appears to be too high. In actual fact, it appears to be approximately $A_1 = 0.0135\text{m}$. Figure 9(c) shows LPA results for a wave with this initial amplitude, and agreement is much better. The final wave tested had a period of $T = 1\text{s}$, which gave it an initial length to depth ratio of $L/d = 3.27$. Of all waves, this was the best predicted. The computational values of the first harmonic are still slightly high on the final shoal but, aside from some numerical noise near the wave generator, the second harmonic is extremely well predicted. In contrast, the extended Boussinesq equations tend to somewhat underpredict the amplitude of the second harmonic.

Figure 9(b). $T = 2\text{s}$, $A_1 = 0.0149\text{m}$. Dashed lines here are the Boussinesq results of Rygg (1988)

Overall, agreement between experiment and computations is not as good as would be hoped, possibly because of the neglect of dissipation in computations. It is worthwhile to note that for the cases $T = 2\text{s}$, 3s , where computations and experiments differed, both computational models behaved similarly. Therefore, it is believed that the dis-

crepancies result from something other than an inaccurate solution of the potential flow problem.

Figure 9(c). Experimental results from Whalin (1971) $T = 2\text{s}$, $A_1 = 0.0149\text{m}$. Computational results $T = 2\text{s}$, $A_1 = 0.0135\text{m}$.

Figure 9(d). $T = 1\text{s}$, $A_1 = 0.0195\text{m}$. Dashed line shows extended Boussinesq results of Madsen and Sørensen (1992).

Conclusions

The local polynomial approximation method developed here has excellent linear and nonlinear properties for a wide range of waves. The simplicity of its formulation makes it an easy task to change the level of approximation, and thus the accuracy, of the method. Computations over varying topography show good accuracy for highly unsteady, nonlinear cases. For accurate potential flow computations in three dimensions, the LPA method is therefore an excellent choice for the numerical modeler.

Abstract

A fully nonlinear Boussinesq-type model with dispersion accurate to $O((kh)^4)$ is derived. As an extension to the second order extended model proposed by Nwogu (1993), a new dependent variable is defined as a weighted average between the velocity potential at two distinct water depths to force the model to have a (4,4) Padé approximation of the exact dispersion relationship. The present model is similar to the fully nonlinear extension of Nwogu's model proposed by Wei et al (1995), except that the dependent variable is expanded in a fourth (rather than second) order polynomial in the vertical coordinate.

Introduction

Important progress has been made in variable-depth Boussinesq-type models since the development of the more-or-less standard model of Peregrine (1967). Madsen et al (1991) introduced higher order dispersive terms into the governing equations to improve linear dispersion properties. By redefining the dependent variable, Nwogu (1993) achieved the same improvement without the need to add such terms to the equations. Wei et al (1995, referred to as WKGS) used the approach of Nwogu to derive a Boussinesq-type model which retains full nonlinearity. Numerical computations show that the WKGS model agrees well with solutions of the full potential problem over the range of relevant water depths, except for some discrepancies in the vertical profile of horizontal velocity in nearly-breaking waves. These inaccuracies in the prediction of vertical profiles in existing Boussinesq-type models are due to the fact that they assume the velocity profiles to be second order polynomials in the vertical coordinate z . In this paper, we derive a fourth order Boussinesq model in which the velocity potential is approximated by a fourth order polynomial in z . A new dependent variable is defined to be the weighted average of the velocity potential at 2 different elevations in the water column, and the weight and positions are chosen to give a (4,4) Padé approximant of the exact linear dispersion relationship.

Derivation of New Model

The full boundary value problem for potential flow is given in terms of nondimensional variables by

$$\phi_{zz} + \mu^2 \nabla^2 \phi = 0; \quad -h \leq z \leq \delta\eta \quad (1)$$

$$\phi_z + \mu^2 \nabla h \cdot \nabla \phi = 0; \quad z = -h \quad (2)$$

$$\eta + \phi_t + \frac{\delta}{2} \left[(\nabla \phi)^2 + \frac{1}{\mu^2} (\phi_z)^2 \right] = 0; \quad z = \delta\eta \quad (3)$$

$$\eta_t + \delta \nabla \phi \cdot \nabla \eta - \frac{1}{\mu^2} \phi_z = 0; \quad z = \delta\eta \quad (4)$$

Here, x and y are the horizontal coordinates scaled by a representative wave number $k_0 = 2\pi/L_0$, z is the vertical coordinate starting at the still water level and pointing upwards and h is the water depth, both scaled by a typical depth h_0 . η is the water surface displacement and scaled by a representative amplitude a . Two dimensionless parameters are apparent; $\delta = a/h_0$ and $\mu^2 = (k_0 h_0)^2$. Time t is scaled by $(k_0(g h_0)^{1/2})^{-1}$, and ϕ , the velocity potential, is scaled by $\delta h_0 (g h_0)^{1/2}$. We integrate (1) over the water column and use (2) and (4) to obtain a mass conservation equation

$$\eta_t + \nabla \cdot \mathbf{M} = 0; \quad \mathbf{M} = \int_{-h}^{\delta\eta} \nabla \phi dz. \quad (5)$$

For simplicity, we assume a constant depth h_0 ; the variable depth model can be derived in straightforward manner and is presented in Gobbi et al (1996). We assume a fourth order polynomial approximation for ϕ and choose the coefficients to satisfy the bottom boundary condition (2) and Laplace's equation (1), retaining terms up $O(\mu^4)$. The approximate potential is given by (Mei, 1989)

$$\phi = \phi_0 - \frac{\mu^2(1+z)^2}{2} \nabla^2 \phi_0 + \frac{\mu^4(1+z)^4}{24} \nabla^2 \nabla^2 \phi_0 + O(\mu^6) \quad (6)$$

where ϕ_0 is the velocity potential at the bottom. Commensurate with the extension of the velocity potential to $O(\mu^4)$, we seek to derive a set of model equations having a corresponding dispersion relation in the form of a (4,4) Padé approximant, given by

$$\frac{\tanh \mu}{\mu} = \frac{1 + (1/9)\mu^2 + (1/945)\mu^4}{1 + (4/9)\mu^2 + (1/63)\mu^4} + O(\mu^6) \quad (7)$$

For the case of approximations retaining terms to $O(\mu^2)$, the goal of obtaining the corresponding (2,2) Padé approximant is achieved by redefining the velocity potential in terms of the value of the potential at an elevation $z_\alpha = h[(1+2\alpha)^{1/2} - 1]$; $\alpha = -2/5$ and using the resulting reference value ϕ_α as the dependent variable; see Nwogu (1993), Chen and Liu (1995) and Kirby (1996). This procedure is not adequate in the present context. Instead, we define a new dependent variable

$$\tilde{\phi} = \beta \phi_a + (1 - \beta) \phi_b \quad (8)$$

where ϕ_a and ϕ_b are the velocity potentials at elevations $z = z_a$ and $z = z_b$, and β is a weight parameter. $\tilde{\phi}$ may be written in terms of ϕ_0 using (6) to obtain

$$\tilde{\phi} = \phi_0 - \frac{\mu^2}{2} B \nabla^2 \phi_0 + \frac{\mu^4}{2} D \nabla^2 \nabla^2 \phi_0 + O(\mu^6) \quad (9)$$

where

$$\begin{aligned} B &= \beta(1+z_a)^2 + (1-\beta)(1+z_b)^2 \\ D &= \beta(1+z_a)^4 + (1-\beta)(1+z_b)^4 \end{aligned} \quad (10)$$

Inverting (9) gives a formula for ϕ_0 in terms of $\tilde{\phi}$ which is substituted into (6) to get an approximation to the full velocity potential in terms of $\tilde{\phi}$:

$$\begin{aligned} \phi &= \tilde{\phi} + \frac{\mu^2}{2} \left\{ B - (1+z)^2 \right\} \nabla^2 \tilde{\phi} \\ &+ \frac{\mu^4}{4} \left\{ B^2 - B(1+z)^2 - \frac{D}{6} + \frac{(1+z)^4}{6} \right\} \nabla^2 \nabla^2 \tilde{\phi} + O(\mu^6). \end{aligned} \quad (11)$$

Defining the total depth $H = 1 + \delta\eta$, and substituting (11) into (5) gives a mass flux conservation equation for $\tilde{\phi}$ and η :

$$\begin{aligned} \eta_t + \nabla \cdot \left\{ H \left[\nabla \tilde{\phi} + \frac{\mu^2}{2} \left(B - \frac{H^2}{3} \right) \nabla (\nabla^2 \tilde{\phi}) \right. \right. \\ \left. \left. + \frac{\mu^4}{4} \left(B^2 - B \frac{H^2}{3} - \frac{B}{6} + \frac{H^4}{30} \right) \nabla (\nabla^2 \nabla^2 \tilde{\phi}) \right] \right\} = O(\mu^6). \end{aligned} \quad (12)$$

Next we substitute (11) into (3) to obtain an approximate Bernoulli equation, given by

$$\begin{aligned} \eta + \tilde{\phi}_t + \frac{\mu^2}{2} \left\{ B - H^2 \right\} \nabla^2 \tilde{\phi}_t + \frac{\mu^4}{4} \left\{ B^2 - BH^2 - \frac{B}{6} + \frac{H^4}{6} \right\} \nabla^2 \nabla^2 \tilde{\phi}_t \\ + \frac{\delta}{2} \left[(\nabla \tilde{\phi})^2 + \mu^2 \left\{ B - H^2 \right\} \nabla \tilde{\phi} \cdot \nabla (\nabla^2 \tilde{\phi}) + \mu^2 H^2 (\nabla^2 \tilde{\phi})^2 \right. \\ + \frac{\mu^4}{2} \left\{ B^2 - BH^2 - \frac{B}{6} + \frac{H^4}{6} \right\} \nabla \tilde{\phi} \cdot \nabla (\nabla^2 \nabla^2 \tilde{\phi}) \\ + \frac{\mu^4}{4} \left\{ B^2 - 2BH^2 + H^4 \right\} \left\{ \nabla (\nabla^2 \tilde{\phi}) \right\}^2 \\ \left. + \mu^4 \left\{ BH^2 - \frac{H^4}{3} \right\} (\nabla^2 \tilde{\phi})(\nabla^2 \nabla^2 \tilde{\phi}) \right] = O(\mu^6). \end{aligned} \quad (13)$$

If we neglect μ^4 terms from (12) and (13) and set $\beta = 1$, we recover the WKGS model with Nwogu's α being related to B by

$$B = 2\alpha + 1 \quad (14)$$

If, in addition, we neglect products $\delta\mu^2$ or higher, we recover Nwogu's model in the velocity potential form given by Chen and Liu (1995).

Linear Dispersion Properties

Neglecting all terms containing δ in (12) and (13), we obtain the following linear equations for mass flux conservation,

$$\begin{aligned} \eta_t + \nabla^2 \tilde{\phi} + \frac{\mu^2}{2} \left(B - \frac{1}{3} \right) \nabla^2 \nabla^2 \tilde{\phi} \\ + \frac{\mu^4}{4} \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) \nabla^2 \nabla^2 \nabla^2 \tilde{\phi} = 0 \end{aligned} \quad (15)$$

and an approximate Bernoulli equation,

$$\begin{aligned} \eta + \tilde{\phi}_t + \frac{\mu^2}{2} (B - 1) \nabla^2 \tilde{\phi}_t \\ + \frac{\mu^4}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \nabla^2 \nabla^2 \tilde{\phi}_t = 0 \end{aligned} \quad (16)$$

To analyse the dispersion properties of these equations, we assume the following general solution to the equations:

$$\eta = a e^{i(\mathbf{x} - \omega t)} \quad \tilde{\phi} = b e^{i(\mathbf{x} - \omega t)} \quad (17)$$

where ω in the angular frequency nondimensionalized by $k_0 (gh_0)^{1/2}$, a and b are amplitudes, and $i = \sqrt{-1}$. Substituting (17) into (15) and (16) we obtain the linear dispersion relationship for the model:

$$\omega^2 = \frac{1 - \frac{1}{2} \left(B - \frac{1}{3} \right) \mu^2 + \frac{1}{4} \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) \mu^4}{1 - \frac{1}{2} (B - 1) \mu^2 + \frac{1}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \mu^4} \quad (18)$$

The expression (18) is the (4,4) Padé approximant to the exact linear dispersion relationship $\omega^2 = \tanh \mu / \mu$ if we set $B = 1/9$ and $D = 5/189$. The parameters β , z_a , and z_b are chosen in order to obtain these values. Since we have 3 unknowns and 2 equations, there are an infinite number of solutions that give the desired values of B and D . However, an arbitrary choice of β can give imaginary values of z_a or z_b or values lying outside of the fluid domain, making these parameters lack physical significance. It can easily be shown that values of β between 0.018 and 0.467 will give both z_a and z_b to be real values lying inside the water column. In the present paper we arbitrarily choose $\beta = 0.2$, and solve for z_a and z_b to give us the (4,4) Padé approximant to the exact linear dispersion relationship.

Figure (1) shows the ratio of modelled phase speed with Airy's exact linear solution for the standard Boussinesq theory based on depth-averaged velocity, the (2,2) Padé approximant formulation (referred to as Nwogu's formulation for simplicity), and the (4,4) Padé approximant dispersion relationship (referred to as the present formulation). It is clear that the present model has improved linear dispersion properties over Nwogu's already accurate Nwogu's model, and closely reproduces the exact solution through intermediate to deep water. Similarly, the linear group velocity, defined as $C_g = \partial \omega / \partial k$ is shown in figure (2) and the improvement in the present model over Nwogu's model is even more evident.

Figure 1: Ratio of model phase speed and Airy's exact linear solution. Standard Boussinesq (dash-dotted), Nwogu's (2,2) Padé approximant(dotted), Present (4,4) Padé approximant(dashed).

Nwogu (1993) found that the range and accuracy of the (2,2) Padé formulation could be extended by adjusting the model coefficients using an error minimization procedure. In the present case, the authors found that the error surface in the neighborhood of the (4,4) Padé approximant is sufficiently flat so that further adjustment of the model parameters is unwarranted.

Internal Kinematics

The internal kinematics of the present model can be obtained from (11). We define a function $f_1(z)$ as the the velocity potential normalized by its value at position $z = 0$:

$$f_1(z) = \frac{1 - \frac{\mu^2}{2} [B - (1+z)^2] + \frac{\mu^4}{4} [B^2 - B(1+z)^2 - \frac{D}{6} + \frac{(1+z)^4}{6}]}{1 - \frac{\mu^2}{2} [B - 1] + \frac{\mu^4}{4} [B^2 - B - \frac{D}{6} + \frac{1}{6}]} \quad (19)$$

The vertical velocity component w can be obtained by differentiating (11) with respect to z . Similarly to f_1 , a vertical velocity profile function can be obtained by defining $f_2(z) = w(z)/w(0)$:

$$f_2(z) = \frac{\mu^2 [(1+z)] + \frac{\mu^4}{2} [-B(1+z) + \frac{(1+z)^3}{3}]}{\mu^2 + \frac{\mu^4}{2} [-B + \frac{1}{3}]} \quad (20)$$

The corresponding f_2 from the exact linear theory is $\sinh[\mu(1+z)]/\sinh[\mu]$.

Figure (3) shows comparisons of $f_1(z)$ between the exact linear solution $\cosh[\mu(1+z)]/\cosh[\mu]$, Nwogu's model and the present model, for various values of μ . For moderately shallow water, the two models reproduce the exact solution quite well. As μ increases, Nwogu's model starts to deviate strongly, while the present model remains very accurate until quite deep water.

Figure 2: Ratio of model group velocity and Airy's exact linear solution. Nwogu (dotted), Present (dashed)

Figure (4) shows plots similar to figure (3) for f_2 . Notice that Nwogu's model has a linear vertical profile for w , a poor representation in intermediate to deep water. The present model stays close to the exact solution for a wide range of μ . Finally, figure (5) shows the ratio to the exact linear solution $\tanh(\mu)$ of the ratio between vertical and horizontal velocities w/u at $z = 0$, $f_3(\mu)$, for the present model and Nwogu's model. The approximate expression for f_3 is:

$$f_3(\mu) = \frac{w(z=0)}{u(z=0)} = \frac{\mu + \frac{\mu^3}{2} \left[-B + \frac{1}{3} \right]}{1 - \frac{\mu^2}{2} [B - 1] + \frac{\mu^4}{4} \left[B^2 - B - \frac{D}{6} + \frac{1}{6} \right]} \quad (21)$$

The present model agrees better with the exact linear solution than Nwogu's model for a wide depth range.

Second Order Nonlinear Interactions

In the previous sections we have seen that the proposed model has excellent linear dispersion properties as well as a greatly improved representation of the internal flow kinematics. It is useful to analyse some of the nonlinear properties of the model by using analytical tools such as Stokes' type asymptotic expansions and multiple scales expansions. Since these types of analysis have been extensively applied and studied for the full boundary value potential problem, we can obtain an idea of how well the nonlinear version of the present model would perform by comparing some of its nonlinear properties with those of the full problem, and also with WKGS and Nwogu's model, keeping in mind that a numerical implementation of WKGS model has already been tested and compared to data with success. We will now look at the generation of super- and subharmonics by second order Stokes-type interactions. It is well known that in intermediate and deep water the first nonlinear correction of a linear wave solution is a set of bound waves called the superharmonics (resulting from sum-wave

Figure 3: Normalized vertical profile of linear horizontal kinematics for (a) $\mu = 1$, (b) $\mu = 3$, (c) $\mu = 5$, (d) $\mu = 8$. Exact (solid), Nwogu (dotted), Present (dash)

interactions) and corresponding subharmonics (resulting from difference-wave interactions) (Hasselmann, 1962). These bound waves are proportional to products of the amplitudes of solutions to the linear equations. The constants of proportionality (which are functions of the local depth) will be referred to as transfer coefficients. Nwogu (1993) has investigated the generation of these bound waves in his extended Boussinesq model and found qualitatively reasonable agreement with Stokes' theory. Madsen and Sørensen (1993) have found similar results. Kirby and Wei (1994) extended Nwogu's model to full nonlinearity and found that the retention of terms proportional to $\delta\mu^2$ (which are neglected in Nwogu's model and the standard Boussinesq model by assumption) is essential for a prediction of the transfer coefficients to the level of accuracy implied by the order of retained dispersive terms in the original model equations. Here, we derive the transfer coefficients for the present model and compare to results from previous models.

We investigate nonlinear properties of the present model by introducing the perturbation expansion:

$$\begin{aligned}\eta &= \eta_0 + \delta\eta_1 + \delta^2\eta_2 \\ \tilde{\phi} &= \phi_0 + \delta\phi_1 + \delta^2\phi_2\end{aligned}\tag{22}$$

into (12) and (13), and order the equations in powers of δ . At each order $O(\delta^n)$ we obtain:

$$\begin{aligned}\eta_{nt} + L_1\phi_n &= F_n \\ \eta_n + L_2\phi_{nt} &= G_n\end{aligned}\tag{23}$$

where L_1 and L_2 are the linear operators:

$$L_1 = \nabla^2 + \frac{\mu^2}{2} \left(B - \frac{1}{3} \right) \nabla^2 \nabla^2 + \frac{\mu^4}{4} \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) \nabla^2 \nabla^2 \nabla^2 \tag{24}$$

$$L_2 = 1 + \frac{\mu^2}{2} (B - 1) \nabla^2 + \frac{\mu^4}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \nabla^2 \nabla^2 \tag{25}$$

and the forcing terms for the first 2 orders are given by:

$$F_0 \equiv 0$$

$$G_0 \equiv 0$$

$$F_1 \equiv -\nabla \cdot (\eta_0 \nabla \phi_0) - \frac{\mu^2}{2} (B - 1) \nabla \cdot \left\{ \eta_0 \nabla (\nabla^2 \phi_0) \right\} - \frac{\mu^4}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \nabla \cdot \left\{ \eta_0 \nabla (\nabla^2 \nabla^2 \phi_0) \right\} \tag{26}$$

$$G_1 \equiv -\frac{1}{2} (\nabla \phi_0)^2 + \frac{\mu^2}{2} \left\{ 2\eta_0 \nabla^2 \phi_{0t} - (B - 1) \nabla \phi_0 \cdot \nabla (\nabla^2 \phi_0) + (\nabla^2 \phi_0)^2 \right\} - \frac{\mu^4}{4} \left\{ \left(\frac{2}{3} - 2B \right) \eta_0 \nabla^2 \nabla^2 \eta_{0t} + \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \nabla \phi_0 \cdot \nabla (\nabla^2 \nabla^2 \eta_0) + \frac{1}{2} (B - 1)^2 \nabla (\nabla^2 \phi_0) \cdot \nabla (\nabla^2 \phi_0) + 2 \left(B - \frac{1}{3} \right) (\nabla^2 \phi_0) (\nabla^2 \nabla^2 \phi_0) \right\} \tag{27}$$

We assume the following random linear sea as the solution to the $O(1)$ problem:

$$\eta_0 = \sum_n a_n \cos \psi_n; \quad \phi_0 = \sum_n b_n \sin \psi_n; \tag{28}$$

where a_n and b_n are nondimensional amplitudes of the functions η_0 and ϕ_0 , $\psi_n = \mathbf{k}_n \cdot \mathbf{x} - \omega_n t - \theta_n$, \mathbf{k}_n is the n -component wavenumber vector nondimensionalized by k_0 , \mathbf{x} is the horizontal coordinates vector nondimensionalized by $1/k_0$, ω_n is the n -component angular frequency nondimensionalized by $k_0(g h_0)^{1/2}$. Substitution of (28) into the $O(1)$ set of equations (23) with $n = 0$ gives a set of n relationships between ω_n and $k_n = |\mathbf{k}_n|$; each of them is the same as (18). We also find a relationship between a_n and b_n given by:

$$b_n = \frac{\omega_n}{k_n K_n} a_n; \quad K_n = k_n \left\{ 1 - \frac{\mu^2}{2} k_n^2 \left(B - \frac{1}{3} \right) + \frac{\mu^4}{4} k_n^4 \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) \right\} \tag{29}$$

Following the standard perturbation technique, we substitute the $O(1)$ solution (28) into the right-hand-side of the $O(\delta)$ equations (23) to find the forcing of the $O(\delta)$ problem. The forcings F and G in the mass and dynamic equations (23) respectively are:

$$F = \frac{1}{4} \sum_l \sum_m a_m a_l \left\{ \mathcal{F}_{ml}^+ \sin(\psi_l + \psi_m) + \mathcal{F}_{ml}^- \sin(\psi_l - \psi_m) \right\}$$

$$G = \frac{1}{4} \sum_l \sum_m a_m a_l \left\{ \mathcal{G}_{ml}^+ \cos(\psi_l + \psi_m) + \mathcal{G}_{ml}^- \cos(\psi_l - \psi_m) \right\} \tag{30}$$

where

$$\mathcal{F}_{ml}^{\pm} = \frac{\omega_m k_l^2 \pm \omega_l k_m^2 + (\omega_l \pm \omega_m)(\mathbf{k}_l \cdot \mathbf{k}_m)}{\omega_l \omega_m} \quad (31)$$

$$\begin{aligned} \mathcal{G}_{ml}^{\pm} = & \frac{1}{k_l k_m K_l K_m} \left[-\omega_l \omega_m (\mathbf{k}_l \cdot \mathbf{k}_m) + \mu^2 \left\{ \omega_m^2 k_m^2 k_l K_l \right. \right. \\ & + \omega_l^2 k_l^2 k_m K_m + \frac{1}{2} (B-1) \omega_l \omega_m (k_l^2 + k_m^2) (\mathbf{k}_l \cdot \mathbf{k}_m) \pm \omega_l \omega_m k_l^2 k_m^2 \left. \left. \right\} \right. \\ & + \mu^4 \left\{ -\frac{1}{2} \left(B - \frac{1}{3} \right) \left(\omega_l^2 k_l^4 k_m K_m + \omega_m^2 k_m^4 k_l K_l \right) \right. \\ & - \frac{1}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) (\mathbf{k}_l \cdot \mathbf{k}_m) \omega_l \omega_m (k_l^4 + k_m^4) \\ & \left. \left. - \frac{1}{4} (B-1)^2 \omega_l \omega_m k_l^2 k_m^2 (\mathbf{k}_l \cdot \mathbf{k}_m) \mp \frac{1}{2} \left(B - \frac{1}{3} \right) \omega_m \omega_l k_m^2 k_l^2 (k_m^2 + k_l^2) \right\} \right] \quad (32) \end{aligned}$$

Equation (31) is identical to the full Stokes' theory result, except for the approximate dispersion relationship. Equation (32) can be rearranged within the level of approximation of the present model to:

$$\mathcal{G}_{ml}^{\pm} = \frac{-\mathbf{k}_l \cdot \mathbf{k}_m + \mu^2 \{ \omega_l \omega_m (\omega_l^2 + \omega_m^2) \pm \omega_l^2 \omega_m^2 \}}{\omega_l \omega_m} + O(\mu^6) \quad (33)$$

which is, again, formally the same as the full Stokes' theory result but with an approximate dispersion relationship.

The forced solution for η_1 can be obtained by solving (23) and is given by

$$\eta_1 = \sum_l \sum_m a_m a_l \left\{ \mathcal{H}_{ml}^+ \cos(\psi_l + \psi_m) + \mathcal{H}_{ml}^- \cos(\psi_l - \psi_m) \right\} \quad (34)$$

where

$$\mathcal{H}_{ml}^{\pm} = \frac{\omega_m^{\pm} \mathcal{F}_{ml}^{\pm} - k_{ml}^{\pm} \mathcal{G}_{ml}^{\pm} T_{ml}^{\pm}}{4(\omega_{ml}^{\pm})^2 - k_{ml}^{\pm} T_{ml}^{\pm}}, \quad (35)$$

$$T_{ml}^{\pm} \equiv k_{ml}^{\pm} \frac{1 - \frac{\mu^2}{2} \left(B - \frac{1}{3} \right) (k_{ml}^{\pm})^2 + \frac{\mu^4}{4} \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) (k_{ml}^{\pm})^4}{1 - \frac{\mu^2}{2} (B-1) (k_{ml}^{\pm})^2 + \frac{\mu^4}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) (k_{ml}^{\pm})^4},$$

$$k_{ml}^{\pm} = |\mathbf{k}_l \pm \mathbf{k}_m|, \quad \omega_{ml}^{\pm} = \omega_l \pm \omega_m$$

\mathcal{H}_{ml}^+ , \mathcal{H}_{ml}^- are respectively the super- and subharmonic transfer coefficients of the interaction between the (l, m) pair of waves. Figures (6) and (7) show comparisons of the ratio of approximate \mathcal{H}_{ml}^{\pm} to Stokes' solution, for Nwogu's model, WKGS model, and the present model. Note that the poor representation of these coefficients at small μ in Nwogu's model is due to the assumption of weak nonlinearity, as discussed by Kirby and Wei (1994). The present model predicts superharmonic amplitudes very accurately over a wide range of water depths. The asymptotic representation of subharmonic amplitudes is also more accurate than in previous models. However, the new solution deviates more rapidly from the exact solution than do the previous results.

Third Order Nonlinear Interactions

We now extend our analysis to third order interactions. We will focus on obtaining the amplitude dispersion of a simple unidirectional monochromatic wave train. It is well known that at this order, it is necessary to introduce a "slow" time scale into the problem, since resonant interactions take place and the perturbation problem becomes singular. We will concentrate on plane waves traveling in the x direction. The "stretched" time scale is given by:

$$t = t' + \delta t' + \delta^2 t' = t' + T_1 + T_2 \tag{36}$$

We then substitute (36) and (22) into (12) and (13), and order the equations up to $O(\delta^2)$. We assume the solution to each order to be of the form

$$\begin{aligned} \eta_n &= \sum_{m=-(n+1)}^{n+1} \eta_{nm}(T_1, T_2) e^{im(x'-\omega t')} \\ \phi_n &= \sum_{m=-(n+1)}^{n+1} \phi_{nm}(T_1, T_2) e^{im(x'-\omega t')} \end{aligned} \tag{37}$$

We then seek an equation for the $O(1)$ wave amplitude, in T_1 by relating the coefficients (amplitudes) in (37) of each order to the ones of the previous order. After some algebra, the following equation for the wave amplitude $A = \eta_{01}$ is found after we neglect current components (terms involving ϕ_{10}):

$$A_{T_2} + i\sigma_1 |A|^2 A = 0 \tag{38}$$

where, for the present model:

$$\begin{aligned} \sigma_1 &= \frac{-P_{22}}{\omega Q_1 Q_2} \left[4 + 16C_1 \mu^2 - \omega^{-2} (1 + 4C_3 \mu^2 + 16C_4 \mu^4) \right] \\ &- \frac{\omega}{2Q_1} (E_{20} + E_{22}) (\mu + C_1 \mu^3 - \omega^{-2} \mu^{-1} Q_1) \\ &+ \frac{P_{22}}{4\mu^2 \omega^3 Q_1^2 Q_2} \left[1 + (2 + 5C_3) \mu^2 + (10C_1 + 17C_4 + 4C_3^2) \mu^4 \right] \\ &- \frac{3}{16Q_1} \left[1 + C_3 \mu^2 - \omega^{-2} (1 + C_1 \mu^2) \right] \\ &+ \frac{1}{\omega Q_1^2} \left[4 + (8C_3 + 1/6) \mu^2 \right] \end{aligned} \tag{39}$$

and

$$\begin{aligned} C_1 &= -\frac{1}{2} \left(B - \frac{1}{3} \right); & C_2 &= \frac{1}{4} \left(B^2 - \frac{B}{3} - \frac{D}{6} + \frac{1}{30} \right) \\ C_3 &= -\frac{1}{2} (B - 1); & C_4 &= \frac{1}{4} \left(B^2 - B - \frac{D}{6} + \frac{1}{6} \right) \end{aligned} \tag{40}$$

and where $E_{20}, E_{22}, P_{22}, Q_1$ and Q_2 are complicated functions of μ which may be found in Gobbi et al (1996). The corresponding σ_1 for the full boundary value problem is given by:

$$\sigma_{1Full} = \frac{\cosh 4\mu + 8 - 2 \tanh^2 \mu}{16 \sinh^4 \mu} \tag{41}$$

Equation (38) can be integrated to give:

$$A = a_0 e^{-i(\sigma_1 a_0^2 T_2)} \quad (42)$$

where $a_0 = |A|$. The leading order solution of η is, then:

$$\eta_1 = a_0 \cos(kx - \omega_1 t) \quad (43)$$

where

$$\omega_1 = \omega + (\delta\mu)^2 \sigma_1 a_0^2 \quad (44)$$

The coefficient σ_1 characterizes the amplitude dispersion occurring at leading order due to third order wave-wave interactions. Figure (8) shows comparison of the ratio σ_1 from the present model and from WKGS model to the Stokes' solution to the full problem. The present model appears to have a better asymptotic approximation to the full problem, with excellent agreement in shallower water and acceptable agreement in intermediate to deep water.

Conclusions

A Boussinesq-type model with $O(1)$ nonlinearity and $O(\mu^4)$ dispersion has been proposed. By defining one the dependent variables as the weighted average of the velocity potential at two distinct water depths, it is possible to achieve an extremely accurate (4,4) Padé approximant for the linear dispersion relationship. A major improvement over the existing second order models has been found in the prediction of the internal flow kinematics. A perturbation approach was carried out to analyse random wave second order nonlinear interactions and it has been shown that the present model predicts the transfer coefficients of super and subharmonics generation very well over a wide range of water depths. Finally, the present model predicts well the amplitude dispersion due to third order nonlinear wave-wave interactions. The authors are now preparing a more thorough paper, and are working on the direct solution of the proposed equations by numerical techniques.

CHAPTER 88

Fast methods for computing the shoaling of nonlinear waves

J. D. Fenton¹ and A. B. Kennedy¹

Abstract

Accurate nonlinear numerical methods for wave propagation have existed for some years. Most of these are very demanding of computer resources as they use global means of approximation which usually requires the costly solution of a full matrix equation at each time step. It is the aim of the present paper to describe and to compare the features of two new methods for the two-dimensional propagation of nonlinear waves over varying topography. A method based on local polynomial approximation is presented, which was found to be efficient, cheap and accurate. A novel boundary integral method is also presented, which was capable of good accuracy even for waves which overturned. For practical purposes, the local polynomial approximation method is to be preferred and may have some useful contributions to make.

Introduction

In computing nonlinear wave evolution over topography, there has always been a trade-off between accuracy and efficiency. On one hand, boundary integral equation methods (BIEM) have been able to perform accurate potential flow calculations past the point of overturning, but their computational expense has traditionally been very high. On the other hand, Boussinesq-type methods have had a much smaller computational cost, especially for large domains, but are limited to mildly nonlinear, mildly dispersive waves. Recently, there have been many attempts both to increase the efficiency of BIEM (Wang *et al.*, 1995, de Haas *et al.*, 1996) and to increase the accuracy of Boussinesq-type approximations (Madsen and Sørensen, 1992, Nwogu, 1993, Wei *et al.*, 1994) However, much room still remains for fast methods which can accurately predict wave evolution.

This paper presents details of and results from two new potential flow methods which have not yet been widely published, but combine excellent accuracy with a reasonable

¹ Dept of Mechanical Engng, Monash University, Clayton, Vic., Australia 3168

computational cost. The first is a finite depth technique which assumes that the flow field is represented locally by polynomial variation. Two variants are presented: one has excellent accuracy for highly nonlinear waves, while the other has greater efficiency at the cost of some accuracy for nonlinear waves. Both variants have a computational cost which is linearly proportional to the number of computational points, which makes them suitable for computations over large domains. The second method presented here is a BIEM which is formulated differently from those currently in use. This new form is simpler, potentially more accurate, and allows for the use of faster solution techniques than are currently standard. It is not as robust as the local polynomial approximation (LPA) method presented and does take longer to run, but unlike that method it can describe wave overturning. As with all boundary integral techniques, accuracy remains good up to overturning.

Governing Equations

For irrotational flow a velocity potential $\phi(x, y, t)$ exists such that the fluid velocity vector $(u, v) = (\partial\phi/\partial x, \partial\phi/\partial y)$, restricting consideration here to two dimensions. If the fluid is incompressible, the potential satisfies Laplace's equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0. \quad (1)$$

At any time t , this elliptic equation is governed by the conditions on the domain boundary. At all points along the free surface specified by $y = \eta(x, t)$:

$$\phi = \phi_s(x, t), \quad (2)$$

where ϕ_s is known. The kinematic boundary condition on the bed is

$$\frac{\partial \phi}{\partial y} - \frac{\partial h}{\partial x} \frac{\partial \phi}{\partial x} = 0 \quad \text{on} \quad y = h, \quad (3)$$

where $h(x)$ is the bed elevation. Along the left and right boundaries, the horizontal velocity is set to

$$\frac{\partial \phi}{\partial x} = f(y). \quad (4)$$

These equations completely specify the velocity potential, and (1) may then be used to solve for the flow field. To advance the solution in time, the free surface kinematic boundary condition is used to advance the free surface elevation:

$$\frac{\partial \eta}{\partial t} = \frac{\partial \phi}{\partial y} - \frac{\partial \eta}{\partial x} \frac{\partial \phi}{\partial x} \quad \text{on} \quad y = \eta, \quad (5)$$

and the unsteady form of Bernoulli's equation, modified here to compute the rate of change of ϕ_s at a surface point, is used to advance the free surface velocity potential ϕ_s :

$$\frac{\partial \phi_s}{\partial t} = C - g\eta - \frac{1}{2} \left(\left(\frac{\partial \phi}{\partial x} \right)^2 + \left(\frac{\partial \phi}{\partial y} \right)^2 \right) + \frac{\partial \phi}{\partial y} \frac{\partial \eta}{\partial t} \quad \text{on} \quad y = \eta, \quad (6)$$

where $C(t)$ is constant throughout space.

Slightly different versions of these equations are generally used for BIEM which do not assume a single valued free surface, and use Lagrangian methods to track moving surface particles.

Local Polynomial Approximation Methods

In finite depths, the representation of a velocity potential locally by a polynomial can provide an excellent approximation to the flow field. Local polynomial approximation (LPA) methods for one dimension in plan use this principle to model wave evolution over varying topography, with very good results. A preliminary version has been given by Kennedy and Fenton (1995). Two main variants are summarised here: a fully nonlinear model which can provide highly accurate results, and an model which uses Taylor expansions about the undisturbed surface to increase speed, but which sacrifices some accuracy for high waves. For both methods, the expense of solution at each time step is directly proportional to the number of computational subdomains, which allows wave evolution to be computed over relatively large regions with a reasonable computational cost.

Solution of Laplace's Equation

For both the fully nonlinear and expansion LPA methods for one dimension in plan, the basic method of solution for Laplace's equation is very similar. As shown in Figure 1, the computational domain is divided into subdomains extending vertically from the free surface to the bed. In any typical subdomain, m , the velocity potential ϕ_m at any point (x_m, y) is represented by the polynomial

$$\phi_m(x_m, y, t) = \left[A_{0R} + \text{Re} \left(\left(\sum_{j=1}^{n-1} (A_{jR} + iA_{jI}) (x_m + iy)^j \right) + (x_m + iy)^n \begin{cases} A_{nR}, & n \text{ odd} \\ iA_{nI}, & n \text{ even} \end{cases} \right) \right]_m \quad (7)$$

where n is an integer ≥ 3 which controls the level of approximation, $i = \sqrt{-1}$, $\text{Re}(\dots)$ means taking the real part. The A coefficients are functions of time. For any given n , it is these A coefficients which must be chosen to best satisfy the boundary value problem. Because of the complex formulation used, Equation (1) is identically satisfied. With the introduction of subdomains, two additional constraints are introduced: the velocity potential, ϕ , and its normal derivative, $\partial\phi/\partial x$, must be continuous across subdomain boundaries.

The velocity potential ϕ may be made analytically continuous across subdomain boundaries through a transformation of basis functions which, in addition, almost halves the number of independent coefficients. However, $\partial\phi/\partial x$ will still be discontinuous across boundaries. (Details of the transformation may be found in Kennedy and Fenton, 1995.) In a domain with M subdomains, the revised basis functions may now be thought of as having n independent coefficients defined at each internal boundary between subdomains, plus n coefficients at each of the left and right global

Figure 1: Definition sketch for local polynomial approximation boundaries, for a total of $(M - 1)n + 2n = (M + 1)n$ independent coefficients. The constraints on these are as follows. At each internal boundary between subdomains, the free surface velocity potential is set to the specified value, satisfying (2). Next, the bottom boundary condition (3) is imposed, using the average value of $\partial\phi/\partial x$ across the boundary. The remaining $n - 2$ constraints at each internal boundary match the horizontal velocity, $\partial\phi/\partial x$, across the boundary at $n - 2$ discrete points. For overall continuity, these collocation points are here set to the Gauss-Legendre points for level $N = n - 2$, using the free surface (or still water level for the expansion method) and bed as limits. At each of the left and right global boundaries, (2) is also specified at the surface and (3) at the bed. However, instead of a velocity match as with the internal boundaries, the horizontal velocity at the boundary, $\partial\phi/\partial x$, is instead set to the known value at $n - 2$ collocation points, satisfying (4).

All of these constraints result in a set of block banded linear equations. These may be solved using any banded or block banded matrix solver, both of which have a computational cost which is directly proportional to the number of subdomains, M . This allows for the computation of wave evolution over reasonably large areas without great expense. Traditional methods which use global approximation usually have a computational cost proportional to the second or third power of the number of computational points.

Linear Dispersion Characteristics

Here, as a test of the ability of polynomials to describe the flow field, we consider what results they give for the linear phase speed, compared with traditional approximation by periodic functions in x and hyperbolic functions in y . As subdomain lengths go to zero, a set of differential equations for the velocity potential results, which may be easily solved for the case of small amplitude waves over a level bed. Figure 2 shows the LPA small amplitude phase speed relative to the exact relationship for the levels $n = 3, 4, 5, 7$, with collocation points set to the Gauss-Legendre points for $N = n - 2$. Accuracy for the level of approximation $n = 3$ is poor in anything other than shallow water but increasing to $n = 4$ gives usable small amplitude results past the nominal deep water limit of $kd = \pi$ ($L/d = 2$). The level of approximation $n = 5$ (usually used with the LPA expansion method) has good dispersion characteristics even for

very short waves with $kd = 2\pi$ ($L/d = 1$), while with $n = 7$, phase speeds remain excellent past a dimensionless wavenumber of $kd = 3\pi$ ($L/d = 2/3$).

Figure 2: LPA linear phase speed

Fully Nonlinear LPA

The fully nonlinear version of LPA can provide excellent accuracy for finite depth potential flow calculations. There are two main steps: Laplace's equation is solved exactly as described earlier, and a time stepping method (here usually third or fourth order Adams-Bashforth) is then used to solve the evolution equations (5) and (6) to advance the solution to the next time step. If the Gauss-Legendre points of level $N = n - 2$ are used as collocation points, then the first $n - 3$ weighted moments of flow will be conserved between subdomains, as well as having velocity matches at the collocation points. For an accurate potential flow method, computations are also quite efficient. For a very large computational run with 900 subdomains and 4000 time steps, total run time for the level $n = 7$ would be about 3.5 hours on a Pentium 150 personal computer. Figure 3 shows the shoaling of a solitary wave of initial height $H/d = 0.15$ as it propagates onto a shelf of depth $0.5d$. The classical fissioning into multiple solitons is clearly evident, with the leading wave reaching a final dimensionless height on the shelf of 0.507. As an independent estimate of computational accuracy, relative energy fluctuations were less than 2×10^{-4} .

LPA Free Surface Expansion Method

The free surface expansion method is somewhat more complex, with two major differences from the fully nonlinear version. The first difference is that, instead of solving Laplace's equation using the free surface and the bed as limits, it is instead solved between the still water level and the bed. The mode coupling free surface expansion of Dommermuth and Yue (1987) is then used to relate the value of ϕ at the free surface to the value of ϕ at the still water level. The order of expansion may be easily changed to accommodate the level of nonlinearity of the problem considered.

Figure 3: Results from the LPA method for the propagation of a wave over a shelf of depth 50%

Accuracy is still, of course, less than the fully nonlinear version for higher waves, but there is one major advantage: since the upper limit of the computational domain remains constant through time, a matrix equation must only be filled and decomposed once, rather than at each time step as with fully nonlinear LPA. This decomposed matrix is then solved with different right hand sides at each time step, which is much faster.

It is worthwhile to implement the second major change only if the computational domain is invariant with time, as is the case here. This involves another change of basis functions, so that there is only one independent variable per computational point. Details of this transformation may be found in Kennedy (1997). With the new basis functions, all conditions but (2) are automatically satisfied, so this constraint is used at every computational point to generate a new set of linear matrix equations for the LPA solution to Laplace's equation. The new matrix is purely banded and has both fewer variables and a smaller bandwidth than with the previous basis functions. Computational speeds are therefore further increased. A reasonable analogy may be made between the new basis functions and B-splines, as both are piecewise continuous polynomials which use a set of interpolation conditions to reduce the number of independent computational variables to one per computational point. These new basis functions could also be computed for the fully nonlinear version, but to retain full accuracy, they would have to be recomputed at each time step as the free surface moves. This would slow down computations, which is why they were not used.

The two parameters which control the accuracy of the LPA expansion method are the degree of the polynomials, n , and the order of free surface expansion, Q . While the fully nonlinear LPA was developed to calculate potential flow problems with very high accuracy, the LPA expansion method is viewed as a tool for more practical problems. To give reasonable nonlinear accuracy, which is mostly controlled by the order of free surface expansion, Q , and good frequency dispersion, which is only affected by the LPA level, n , the parameters $Q = 3$ and $n = 5$ were generally used.

For an example of the capabilities of the method, computations here will be compared with the experimental results of Beji and Battjes (1993) as reported by Ohyama *et al.* (1994). In this experiment regular waves were propagated over a two dimensional bar-trough setup and time series of surface elevations were taken at various points. Two wave trains were considered – both were initially of reasonably small amplitude in intermediate depths, but became significantly nonlinear over the bar.

The first wave train had an initial height of $H_0/d = 0.05$ and a period of $T\sqrt{g/d} = 9.903$. Figure 4 shows a comparison between computed and experimental values at Stations 1, 3, 5 and 7, which are, respectively, just before the bar, on the bar crest, on the downslope and in the trough. Agreement is quite good, with the LPA expansion model accurately predicting the steepening of the wave as it progresses up and sheds secondary waves on the bar, and its decomposition into higher harmonics on the downslope. As the wave progresses, computations begin to overestimate wave heights slightly due to the lack of dissipation in the model, and a small phase difference appears. However, similar differences were also noted in the fully nonlinear boundary element computations of Ohyama *et al.* (1994).

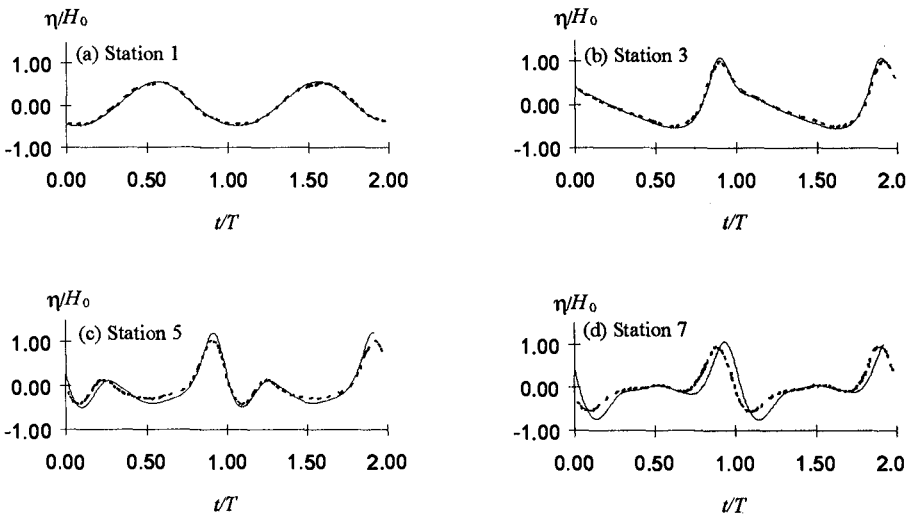

Figure 4: Measured and computed time series, $H_0/d = 0.05$, $T\sqrt{g/d} = 9.903$.

Figure 5 shows results for the second wave train which was shorter, with a period of $T\sqrt{g/d} = 6.189$ and an initial height of $H_0/d = 0.0625$. Due to its shorter length, this wave did not evolve as much passing over the bar, but the model still predicts the features of its evolution well. A small phase lag is visible at the last station. The fully nonlinear results of Ohyama *et al.* (1994) were similar to those here, although the phase lag at Station 7 was somewhat smaller. Overall, the expansion model predicts wave evolution quite well, and may be relied on to provide a good estimate of nonlinear wave evolution for a wide range of waves.

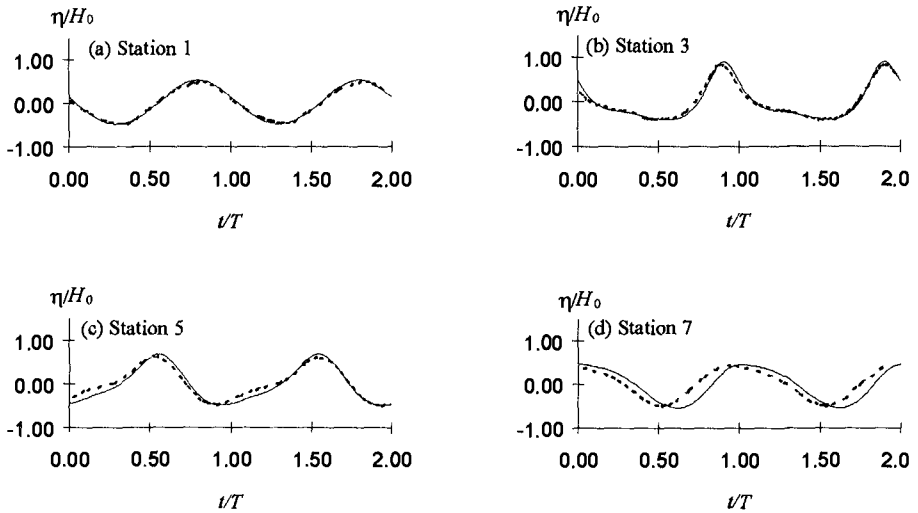

Figure 5: Measured and computed time series, $H/d = 0.0625$, $T\sqrt{g/d} = 6.189$. Solid lines – computations, dashed lines – experiment

Computations with the expansion method are quite fast. For example a computation with 900 subdomains and 4000 time steps would have a total run time on a Pentium 150 personal computer of about 10 minutes for the LPA level $n = 5$ and expansion level $Q = 3$, compared with 3.5 hours for the fully nonlinear version using $n = 7$.

A new boundary integral equation method

Introduction

The approach of using boundary integral equations for the study of waves in deep water was initiated by Longuet-Higgins and Cokelet (1976), who set up and solved a boundary integral equation with a logarithmic kernel. A different approach was introduced by Vinje and Brevig (1981), who used the Cauchy integral theorem in terms of a complex potential function. A number of powerful results have been

obtained in recent years for waves over topography, including Dold & Peregrine (1985), Grilli *et al.* (1989, 1994), and Subramanya & Grilli (1994). A brief history of various attempts using BIEM is described by Liu *et al.* (1992).

A quicker but less accurate approach was introduced by Leitão and Fernandes (1992), who took as the upper surface of the computational domain the undisturbed water surface, and used a second-order Taylor expansion there. As with the LPA expansion method described above, their computational domain was constant, and they only had to solve a matrix equation once rather than at each time step.

Fenton (1992 & 1996) has developed a method for the solution of Laplace's equation in two dimensions which has some advantages over traditional methods: it is simpler in theory and implementation, yet is more accurate. Of particular importance to the problem of shoaling waves, is that it allows the use of iterative methods for solution which are rapidly convergent because of the nature of the equations and because information from previous time steps can be incorporated. A preliminary study applying that method to shoaling waves has been published (Fenton, 1993), but in that work it was concluded that the method advocated, despite its high accuracy for fixed domains, was somewhat fragile for shoaling. Here, the method will be briefly described and the results of rather more robust computations will be described.

Theory

Consider a two-dimensional region such as that shown in Figure 1 containing an incompressible fluid which flows irrotationally, in which case a scalar potential function ϕ exists and satisfies Laplace's equation: $\nabla^2\phi = 0$. As ϕ is an harmonic function, another function ψ exists, related to ϕ by the Cauchy-Riemann equations: $\partial\phi/\partial x = \partial\psi/\partial y$ and $\partial\phi/\partial y = -\partial\psi/\partial x$. It can be shown that if these relations are satisfied, then the complex function $w = \phi + i\psi$, where $i = \sqrt{-1}$, has a unique derivative with respect to the complex variable $z = x + iy$, satisfies the integral equation

$$\oint \frac{w(z) - w(z_m)}{z - z_m} dz = 0, \quad (8)$$

for a reference point m . In this equation, unlike other formulations, the integrand is everywhere continuous, even at $z = z_m$, and its numerical approximation should be simpler and potentially more accurate. It will be shown below that using this form leads to a system of algebraic equations which are all nearly diagonally dominant, giving desirable numerical properties.

Boundary conditions: On the sea bed, assumed impermeable here, the condition that flow does not cross the boundary is $\psi = 0$. On the free surface, denoted by $y = \eta(x, t)$, the governing equations are nonlinear, partly because the location of the free surface also appears in them. There are two equations: one is the kinematic condition that the velocity of a particle on the surface is equal to the fluid velocity at that point. These have been described above. A slight difference here is that a Lagrangian description is used, like other BIEM, such that surface particles are followed and it is necessary to update the ϕ on the surface. This necessitates the

computation of the material derivative which can be shown to become

$$\frac{D\phi_m}{Dt} = -g\eta_m + \frac{1}{2} \left| \frac{dw}{dz} \right|_m^2, \quad (9)$$

a differential equation for ϕ_m at the free surface particle. This gives us a way of calculating ϕ as time evolves so that at any instant it is known at all points on the free surface, while we know that $\psi = 0$ on the sea bed. Hence we have enough boundary information to obtain a solution of equation (8) at each time step, namely to obtain the values of ϕ on the bottom and ψ on the free surface, so that $\omega = \phi + i\psi$ is known at all points, dw/dz can be calculated, the solution advanced, and so on.

Numerical scheme using periodicity around the contour

Around the boundary all variation is periodic, for in a second circumnavigation of the boundary the integrand is the same as in the first, and so on. This suggests the use of methods that exploit periodicity to gain handsomely in accuracy. A continuous co-ordinate j is introduced here, which is 0 at some reference point on the boundary, and after a complete circumnavigation of the boundary has a value N , which will be taken to be an integer. The integral in equation (8) can be written

$$\int_0^N \frac{w(z(j)) - w(z_m) dz}{z(j) - z_m} \frac{dz}{dj} dj = 0. \quad (10)$$

Now a numerical approximation is introduced to transform the integral equation into an algebraic one in terms of point values. The integral in equation (10) is replaced by the trapezoidal rule approximation:

$$\sum_{j=0}^{N-1} \frac{w(z_j) - w(z_m)}{z_j - z_m} z'_j = 0, \quad (11)$$

where $z_j = z(j)$ and $z'_j = dz(j)/dj$, but in which after the differentiation, j takes on only integer values. In this case the trapezoidal rule has reduced to the simple sum as the end contributions are from the same point, $z_0 = z_N$ because of the periodicity. This is a particularly simple scheme when compared with some such as Gaussian formulae which have been used to approximate boundary integrals. Where the integrand is periodic, as it is here, the trapezoidal rule is capable of very high accuracy indeed, a fact which is relatively little-known.

In the form of equation (11), the expression is not yet useful, as the point $j = m$ has to be considered. It is easily shown that in this limit, the integrand (and hence the summand) becomes $dw(m)/dm$, and extracting this term from the sum gives the expression with a "punctured sum" $j \neq m$:

$$\frac{dw}{dm}(m) + \sum_{j=0, j \neq m}^{N-1} \frac{w_j - w_m}{z_j - z_m} z'_j = 0, \quad (12)$$

for $m = 0, 1, 2, \dots, N - 1$, and where the obvious notation $w_j = w(j)$ etc. has been introduced. The notation $dw(m)/dm$ means differentiation with respect to the continuous variable m , evaluated at integer value m . It is convenient here to introduce the symbol Ω_{mj} for the geometric coefficients:

$$\Omega_{mj} = \alpha_{mj} + i\beta_{mj} = \frac{z'_j}{z_j - z_m}, \quad (13)$$

whose real and imaginary parts are the coefficients α_{mj} and β_{mj} . One is free to use either the real or imaginary part of the integral equation and of the sum which approximates it, equation (12). The two parts can be extracted to give

$$\frac{d\phi}{dm}(m) + \sum_{j=0, j \neq m}^{N-1} [\alpha_{mj}(\phi_j - \phi_m) - \beta_{mj}(\psi_j - \psi_m)] = 0 \quad (14)$$

and

$$\frac{d\psi}{dm}(m) + \sum_{j=0, j \neq m}^{N-1} [\alpha_{mj}(\psi_j - \psi_m) + \beta_{mj}(\phi_j - \phi_m)] = 0. \quad (15)$$

One of these equations can be used at each of the N computational points, provided either $d\phi/dm$ or $d\psi/dm$ is known that point, which can be done from the boundary conditions as described above. Each equation is written in terms of the $2N$ values of ϕ_j and ψ_j . If N of these are known, specified as boundary conditions, then there are enough linear algebraic equations and it should be possible to solve for all the remaining unknowns.

As equation (14) can be used on the free surface where $d\phi/dm$ can be evaluated and where ψ_m is the unknown and (15) on the sea bed where $d\psi/dm = 0$, and where ϕ_m is unknown, examination of the coefficients shows that the system of equations is nearly diagonally dominant, which suggests a certain computational robustness, and the possibility of iterative solution.

Distribution of computational points: The linear algebraic equations approximating the integral equations have been expressed relatively simply in terms of the coordinates of the computational points z_j and the derivative around the boundary, z'_j . The accuracy of the method depends on how continuous the latter are, and in Fenton (1992, 1996) some effort was spent in ensuring continuity across corners of the boundary. In fact it was found that even if no special spacing was used, the accuracy was still surprisingly high.

Numerical computation of coefficients: In problems of wave shoaling, the boundary of the computational region, including the sea bed and the free surface, is quite irregular. The periodicity around the boundary may be exploited to give a simple scheme for computing the necessary derivatives around the boundary. The main problem is to compute values of the z'_j . Also, it is convenient to be able to use a means of interpolation between the computational points for plotting purposes which

has the same accuracy as the underlying numerical method. Both can be accomplished simply and economically using Fourier approximation, once again exploiting periodicity as the boundary is traversed. If fast Fourier transform programs are available, the z'_j may be computed easily and accurately in $O(N \log N)$ operations, where there are N boundary points.

Set-up and solution of system of equations: When the z'_j have been obtained, the coefficients $\Omega_{mj} = \alpha_{mj} + i\beta_{mj}$ can be calculated and used in expressions (14) and (15), one for each point at which an unknown exists. As the equations are nearly diagonally dominant, however, it should be possible to exploit the simple Gauss-Seidel iterative procedure, particularly for timestepping problems such as those for wave propagation, and in practice this was found to work very well indeed. The computational effort is $O(N^2)$ per iteration, and the happy result was found in the present work, that as all boundary points are interpreted as Lagrangian particles, and carry the geometry of the problem with them, then the coefficients are very slowly varying, and a forward extrapolation of previous results gave such an accurate initial estimate that typically only five iterations were necessary each time step. Much programming detail can be avoided if the step of assembling into a matrix is bypassed. In this case, equations (14) and (15) may simply be rewritten: for points on the free surface to give an equation for ψ_m , and for points on the sea bed an equation for ϕ_m .

In practice, a procedure of over-relaxation can be adopted to give faster convergence. It was found convenient in the present work where the coefficients changed slowly, not to store all the coefficients α_{mj} etc., as this requires storage of $O(N^2)$, but to generate the coefficients necessary for each equation every time it had to be evaluated such that the storage was $O(N)$, and large numbers of points could be used. Overall, the implementation of the scheme in the form described here was particularly simple.

Results

The only results reported here are for a wave height $H/d = 0.25$ and a length 25 times that of the depth, rather higher than that used in Figure 3 above. The initial conditions were computed using an accurate Fourier method. The wave was allowed to propagate across a shelf with a cosine profile, which shoaled to $1/4$ the depth in a distance of roughly half the horizontal length scale of the wave, a rather more abrupt case than Figure 3, and corresponding to the shoaling of a wave on a coral reef. Results are shown in Figure 6, and they show some of the interesting phenomena associated with this nonlinear problem. After the wave travelled almost right across the shelf, quite quickly it started to grow in height, travelling over water of constant shallower depth, and the large feature of a shelf developed behind the wave, which seemed to be in the process of separating from the main wave and possibly becoming part of an oscillatory tail. At the final stage a sharp crest began to form, which turned over as shown, the surface particles in this latter stage experiencing very large accelerations.

Figure 6: High wave on a steeply-shelving beach showing overturning

Conclusions

The local polynomial methods were found to be robust, accurate, and efficient, and may provide a useful practical means of computing nonlinear wave propagation over extended regions and times. The boundary integral method can be used to simulate shoaling considerably faster than other similar methods, and it has the potential to be more accurate than them. It can describe wave overturning with relatively few points, but for some problems it was found to be not as robust as had been hoped. Its most appropriate application might be to methods such as those of Leitão and Fernandes (1992) which use such a fixed domain with approximate boundary conditions.

CHAPTER 89

STRUCTURE OF FREQUENCY DOMAIN MODELS FOR RANDOM WAVE BREAKING

James T. Kirby¹ and James M. Kaihatu²

Abstract

We consider the form of a breaking wave dissipation term for use in spectral or stochastic wave evolution models. A time-domain Boussinesq model is tested for accuracy in modelling evolution of second and third moment statistics in shoaling and breaking waves. The structure of the dissipation term in the time domain is then used to infer the corresponding structure of the term in the frequency domain. In general, we find that the dissipation coefficient is distributed like $1/S_\eta(f)$, where $S_\eta(f)$ is the spectral density of the surface displacement η . This implies an f^2 dependence for the coefficient in the inner surfzone, as opposed to a constant distribution over frequency as suggested by Eldeberky and Battjes (1996).

Introduction

Recently, there have been several suggestions on how to structure the breaking wave dissipation term in spectral or stochastic wave evolution models, with the principle question being how to structure the dissipation coefficient as a function of frequency. As an example, Mase and Kirby (1992) developed evolution equations for the shoreward (x direction) evolution of component amplitudes $A_n(x)$, where the A_n are related to surface displacement η according to

$$\eta = \sum_{n=1}^{\infty} \frac{A_n(x)}{2} e^{i \int k_n(x) dx - \omega_n t} + c.c. \quad (1)$$

where k_n is related to ω_n through a suitable wave dispersion relation. Index n is the analog in the discrete spectral representation to a continuous dependence on frequency f in the continuous spectrum representation, and the two representations will be used interchangeably below. Restricting our attention here to wave breaking effects, the evolution equations may be written as

$$A_{n,x} = -\alpha_n A_n + \dots \quad (2)$$

¹Professor, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA. kirby@coastal.udel.edu

²Oceanographer, Oceanography Division (Code 7322), Naval Research Laboratory, Stennis Space Center, MS 39529-5004

where the omitted terms are related to shoaling and nonlinear interaction effects. Mase and Kirby (1992) proposed a form for α_n given by

$$\alpha_n = \alpha_0 + (f_n/\bar{f})^2 \alpha_1 \tag{3}$$

with

$$\alpha_0 = F\beta \tag{4}$$

$$\alpha_1 = (1 - F)\beta \frac{\bar{f}^2 \sum_n |A_n|^2}{\sum_n f_n^2 |A_n|^2} \tag{5}$$

and where β is determined from a bulk dissipation model such as the one of Thornton and Guza (1983). Based on analysis of laboratory data and numerical results, Mase and Kirby chose to set $F = 0.5$, indicating a dissipation term with a partial dependence on the square of the frequency. They also found that choosing $F = 0.0$, corresponding to an f^2 dependence for the entire dissipation term, destroyed the tail of the computed power spectrum in very shallow water but had little impact on the evolution of spectral shape away from the shallowest measuring gages.

Eldeberky and Battjes (1996) have suggested that a similar formulation corresponding to the choice $F = 1.0$, spreading the dissipation term uniformly over all frequencies, should be utilized, and showed that an adequate description of power spectrum evolution was obtained in several simulations of field data. Eldeberky and Battjes did not consider the effect of this choice on the evolution of higher statistical moments. More recently, Chen et al (1996; referred to as CGE) have examined a number of laboratory and field cases. They have shown that the estimates of power spectrum evolution are relatively insensitive to the choice of F , with error-minimizing F values occupying the entire range $0 \leq F \leq 1$ for various field and laboratory cases. Aside from the Mase and Kirby case, error measures changed by as little as 20% over the entire range of values. In contrast, all data sets support the choice of $F = 0.0$ when error measures based on third-moment statistics are introduced, with the exception of the Mase-Kirby data set. (This last discrepancy is fairly weak, however). There is a clear trend towards increasing error with increasing F in most data sets.

In this talk, the problem of determining the form of the spectral dissipation term is approached from a different direction. Instead of considering a bulk energy decay and an arbitrary distribution of dissipation over f , we instead consider the structure of the dissipation term in a time-dependent Boussinesq model setting, and consider the contribution of the term to energy loss and the structure of that loss in the frequency domain. This loss is then related to the spectral evolution equations, and the form of the dissipation term is deduced. We find that, in general, the dissipation coefficient is distributed more or less as $S_\eta(f)^{-1}$, where $S_\eta(f)$ is the power spectrum of the surface displacement η . For the case of a smooth spectrum, this result indicates an f^2 dependence in the dissipation coefficient in the surfzone, consistent with CGE's results with $F = 0.0$. The conclusions here are based on an examination of the Mase and Kirby (1992) data set, which is well modelled by the chosen time-domain breaking wave model.

Time-Domain Model for Wave Breaking

The literature includes examples of a number of formulations for computing wave breaking in the context of Boussinesq wave models. Three examples include an eddy viscosity model (Zelt, 1991), a surface roller model with an assumed two-layer velocity profile (Schäffer et al, 1993), and a surface roller model with a computed horizontal profile (Svendsen et al, 1996). Schematically, the eddy viscosity model may be written as

$$u_t + uu_x + g\eta_x + \text{dispersive terms} - (\nu_b u_x)_x = 0 \quad (6)$$

The simple roller model of Schäffer et al (1993) is written in the context of a model for total volume flux, and may be written schematically as

$$P_t + \left(P^2/H\right)_x + gH\eta_x + \text{dispersive terms} + R_x = 0 \quad (7)$$

where

$$R = \int_{-h}^{\eta} \left(u_{\text{rot}}^2 - u_{\text{irrot}}^2\right) dz \quad (8)$$

and

$$H = h + \eta \quad (9)$$

The more complex roller model of Svendsen et al (1996) is essentially of the same form. While these models differ in both form and theoretical intent, it may be shown that the numerical representations of each dissipative term are similar. In particular, the contribution of each dissipation term is highly localized in space and time, since it is concentrated on the front face of the breaking wave. Further, the contribution of each dissipation term is about the same size, since each successfully calibrated model must extract the same amount of energy. An illustration of this fact is given by Figure 9 of Svendsen et al (1996).

Since our primary goal below is to examine the spectral signature of the wave energy decay, we can conclude that, due to the structural similarity of the various breaking models in the time domain, it should not matter which of the existing models is used to perform the analysis. The analysis will be based on the eddy viscosity model of Zelt (1991) for two reasons: it is already incorporated in an existing time-domain Boussinesq model (Wei and Kirby, 1996), and it is simple to interpret the terms in the eddy viscosity model in terms of measured sea surface elevations, as described below.

Leading-Order Energy Balance

Let $r = R/H$ or $-\nu_b u_x$ represent the breaking-induced momentum deficit per unit depth. Then, each of the models above may be written in the form

$$u_t + uu_x + g\eta_x + \text{dispersive terms} + r_x = 0 \quad (10)$$

Neglecting nonlinear and dispersive effects, we have

$$u_t + g\eta_x + r_x = 0 \quad (11)$$

$$\eta_t + (hu)_x = 0 \quad (12)$$

Multiplying (11) by ρhu , (12) by $\rho g\eta$ and adding then gives

$$E_t + F_x = -\epsilon_b \tag{13}$$

where

$$E = \frac{1}{2}\rho g\eta^2 + \frac{1}{2}\rho hu^2 \tag{14}$$

is the local energy density/unit surface area,

$$F = \rho gh u\eta \tag{15}$$

is the flux of energy in the x direction, and

$$\epsilon_b = \rho h u r_x \tag{16}$$

is the local rate of energy decay. Each of these quantities may be averaged in time, yielding (for a stationary wave process)

$$\langle F \rangle_x = -\langle \epsilon_b \rangle \tag{17}$$

The average or bulk energy decay (ϵ_b) can be specified according to models such as the one of Thornton and Guza (1983), which models the data set considered below quite well. Each of the quantities in (17) may be thought of as the sum of contributions from each frequency to the total value; i.e.,

$$\langle F \rangle = \sum_n F_n; \quad \langle \epsilon_b \rangle = \sum_n \epsilon_{bn} \tag{18}$$

We will attach a meaning to each of these component terms in the analysis below.

In order to proceed further, we need to choose a model to evaluate ϵ_b . This will be done using the Zelt (1991) eddy viscosity model.

Eddy Viscosity Model

The eddy viscosity appearing in (6) is written by Zelt (1991) as

$$\nu_b = -\ell^2 u_x; \quad \ell = B\gamma (h + \eta) \tag{19}$$

where $\gamma = 2$ is a mixing length parameter determined by Heitner & Housner (1970) and chosen so that the resulting model correctly predicts the width of a hydraulic jump. The factor B is given by

$$B = \begin{cases} 1 & ; \quad u_x \leq 2u_x^* \\ u_x/u_x^* - 1 & ; \quad 2u_x^* < u_x \leq u_x^* \\ 0 & ; \quad u_x > u_x^* \end{cases} \tag{20}$$

and provides a somewhat smoothed onset of breaking dissipation when the local breaking criterion is exceeded. The breaking criterion is given in terms of a critical velocity divergence, chosen to be

$$u_x^* = -0.3\sqrt{g/h} \tag{21}$$

The accuracy of this formulation in modelling breaking random waves will be illustrated below. The model is particularly useful to us in the present context because the terms in the model may be evaluated (to leading order) using time derivatives of the surface elevation. Using $u_x \approx -\eta_t/h$, we get

$$\nu_b = B\gamma^2 h^2 u_x \approx B\gamma^2 h \eta_t \quad (22)$$

$$B = \begin{cases} 1 & ; \eta_t \geq 2\eta_t^* \\ \eta_t/\eta_t^* - 1 & ; \eta_t^* \leq \eta_t < 2\eta_t^* \\ 0 & ; \eta_t < \eta_t^* \end{cases} \quad (23)$$

$$\eta_t^* = 0.3\sqrt{gh} \quad (24)$$

Finally, the instantaneous energy dissipation may be written as

$$\epsilon_b = -\rho h u (\nu_b u_x)_x \approx -\rho \left(\frac{\eta}{h} \right) (\nu_b \eta_t)_t \quad (25)$$

The advantage of this formulation is clear in the context of evaluating experimental results, since the energy loss term that would be predicted by the numerical model may be deduced directly from the measured data. Thus, in order to evaluate dissipation effects, we may proceed without actually running the model in the majority of cases, provided that the model as formulated is known to be an accurate predictor of the wave field in sample representative cases.

Laboratory Data

The experimental data considered here is taken from Run 2 of Mase and Kirby (1992). The present results have been reproduced for a number of other data sets, and a more comprehensive view of the study will be published elsewhere. The single case shown here suffices as an indication of the results for a wide range of conditions studied to date.

Figure 1 shows a schematic of the experimental facility. The experimental wave conditions correspond to a Pierson-Moskowitz spectrum generated in 47cm of water, with a peak frequency $\bar{f} = 1Hz$ and a significant wave height of 6cm. Waves were measured using capacitance wave gages at twelve stations across the 1:20 beach profile. Data for the analysis below is taken from the measurement at the $h = 10cm$ depth. This depth corresponds to a point where the probability of breaking is increasing rapidly but the saturated inner surfzone has not yet been established.

A sample of 20 seconds of measured and computed time series of surface elevations at $h = 10cm$ is shown in Figure 2, which indicates an accurate reproduction of wave heights and phases in the numerical model. Computations were performed using the extended fully-nonlinear Boussinesq model code of Wei et al (1995), which is capable of propagating waves in the large water depths used in this experiment. Second and third moment statistics were computed based on the entire experimental run, covering about 800 wave periods. Figure 3 shows the evolution of significant wave height up the beach slope and through the surfzone, while Figure 4 shows the evolution of skewness and asymmetry. Reproduction of measured values by the numerical model is good in both cases.

Figure 2: Sample of measured (solid) and predicted (dashed) time series of elevation η for Run 2 of Mase and Kirby (1992). Measurements at $h = 10\text{cm}$, corresponding to analysis of dissipation rates below.

Figure 3: Measured (solid) and predicted (dash) significant wave heights for Run 2 of Mase and Kirby (1992).

Figure 4: Measured (solid) and predicted (dash) skewness (circles) and asymmetry (stars) for Run 2 of Mase and Kirby (1992).

Analysis of Data

Having verified that the numerical model is capable of correct reproduction of second and third moment statistics in the evolution of a shoaling and breaking random wave train, we may now examine the results for energy dissipation in the model based on a direct analysis of the laboratory data. Figure 5 shows a short segment of the record of surface displacement $\eta(t)$ and dissipation $\epsilon_b(t)$ at $h = 10\text{cm}$. Dissipation $\epsilon_b(t)$ is computed directly from the measured data using (25). We compute the smoothed power spectrum of each of these quantities for the entire data run, according to the definitions

$$S_\eta(n) = \frac{\langle |A_n|^2 \rangle}{2\Delta f} \tag{26}$$

$$S_{\epsilon_b}(n) = \frac{\langle |\hat{\epsilon}_{bn}|^2 \rangle}{2\Delta f} \tag{27}$$

where $\hat{\epsilon}_{bn}$ is the Fourier transform of the dissipation term and where brackets here indicate ensemble averaging. Results for the Run 2 data at $h = 10\text{cm}$ are shown in Figure 6.

Figure 5: Time history of surface elevation and computed loss $\epsilon_b(t)$ for 9 seconds of Run 2, showing two strong breaking events at a 10cm depth.

Returning to the schematic frequency domain model, we may rearrange the original model equation

$$A_{n,x} + \dots = -\alpha_n A_n \tag{28}$$

into the form of an energy equation

$$\left\{ \frac{1}{2} \rho g |A_n|^2 \sqrt{gh} \right\}_x = -2\sqrt{gh} \alpha_n \left(\frac{1}{2} \rho g |A_n|^2 \right) \tag{29}$$

Figure 6: Power spectrum $S_\eta(f)$ of surface displacement (lower trace) and $S_\epsilon(f)$ of energy loss (upper trace) for Mase and Kirby (1992) Run 2 data.

The quantity in brackets on the left hand side of (29) represents the contribution to the wave energy flux from the n 'th frequency component, or F_n . The quantity on the right is the contribution to the loss of wave energy at that frequency, or ϵ_{bn} . Using the definitions of power spectral densities (26) and (27), we may write the dissipation coefficient in the form

$$\alpha_n = \frac{1}{\rho g \sqrt{gh}} \frac{1}{\sqrt{2\Delta f}} \frac{[S_{\epsilon_b}(n)]^{1/2}}{S_\eta(n)} \quad (30)$$

Results similar to those presented in Figure 6 may now be utilized to determine the form of α_n . Analysis of a number of data sets has indicated that the spectral tail of $S_\eta(f)$ tends to have an f^{-2} dependence on frequency after breaking is established. This is consistent with the notion that the wave form tends towards a sawtooth shape, with a vertical front face and a linear back slope. We note that this is somewhat simplistic representation of the waves, as it implies that the wavefield would have significant asymmetry and zero skewness, whereas the measured data exhibits a balance between skewness and asymmetry in the inner surfzone. Nevertheless, the f^{-2} dependence seems to characterize several of the data sets which have been examined extremely well.

In contrast, Figure 6 shows that the dependence of $S_{\epsilon_b}(f)$ on f is relatively weak, so that this quantity can be taken to be constant. This is consistent with the notion that the dissipation term has the character of a sequence of isolated, spike-like processes. Taken together, these results indicate that the dominant frequency dependence of α_n is given by

$$\alpha_n \propto S_\eta(n)^{-1} \quad (31)$$

and we may further infer that this dependence translates into a dependence on f^2 in the inner surfzone. Figure 7 shows a sample distribution of $\alpha(f)$ as calculated from (30), together with a best quadratic fit to the calculated distribution. The fit is centered fairly close to the frequency of the spectral peak at $1Hz$, and the dependence of α on f is clearly quadratic towards higher frequencies.

Figure 7: Sample $\alpha(f)$ deduced from data (according to (30)) together with a best quadratic fit.

Effect of Choice $F = 1$ on Modelled Waves

The results of the previous section strongly imply that a value of $F = 0$ should be chosen in the model (3)-(5). CGE have shown that the choice of F does not introduce a strong bias in the prediction of evolving power spectra. It appears that there is a preferred spectral shape that is obtained in shallow water, for which the reasons are still unclear. The effect of redistributing the loss differently across the spectrum serves mainly to enhance or suppress the nonlinear transfer of energy needed to maintain the target spectral shape.

In particular, the choice $F = 1$ implies that the rate of energy loss is the same in all spectral components, which accounts for the entire pattern of overall energy loss in evolving waves (Mase and Kirby, 1992; Eldeberky and Battjes, 1996). However, if the dissipation term is chosen to account for all changes in spectral energy density, there is necessarily a parallel suppression of all nonlinear energy transfer across the spectrum during the breaking process. This loss of an active transfer should suppress the imaginary part of the bispectrum, and would be evidenced by a loss of front-to-back asymmetry in the wave form, or a loss of statistical asymmetry. CGE have shown the consequence of choosing $F = 1$ on the prediction of third moment statistics, which

are severely damaged. A more graphic example is provided by Liu (1990, see pages 55-57), who modelled the breaking decay of a periodic wave using a dissipation coefficient which was uniform across the modelled spectrum. The resulting wave crests in the surfzone clearly lose their asymmetry, which provides direct evidence that nonlinear energy transfer across the spectrum has been suppressed.

In contrast, the choice $F = 0$ strongly concentrates dissipation at higher frequencies. As a result, there is necessarily a high rate of nonlinear transfer of energy across the spectrum from low to high frequencies, in order to maintain the tail of the spectrum. This accounts for the presence of a strong, negative asymmetry. This choice is much more sensible in light of our understanding of the nonlinear processes going on in this region, and agrees with a direct analysis of the behavior of a well-tested time domain model of the breaking process.

Conclusions

The results of this study indicate that dissipation due to wave breaking should be biased strongly towards higher frequencies in spectral calculations, and that an f^2 dependence in the dissipation coefficient comes closest to matching the desired structure of the breaking terms using a simple functional dependence. This result supports the conclusions of Chen et al (1996) and is obtained by an entirely different route, being based on an analysis of the frequency structure of the dissipation term in a time-domain wave evolution model.

A much more comprehensive description of the results of this study is currently being prepared, and will consider the form of the dissipation coefficient in the outer surfzone as well as in the established inner surfzone. In particular, there is some indication that, in regions where the breaking events are infrequent, that there is a tendency for α_n to be slightly negative at frequencies below the wind wave peak. This result could be thought of as the effect of distributing a set of localized momentum sources in the domain. Each breaking wave event would impart a kick to the water column in the manner described by Rapp and Melville (1990). The irregular, widely-spaced-in-time nature of these kicks translates into a wave generating mechanism at low frequency, and could contribute to the growth of the low-frequency wave climate in the surfzone.

CHAPTER 90

A HAMILTONIAN MODEL FOR NONLINEAR WATER WAVES AND ITS APPLICATIONS

A.K. Otta¹, M.W. Dingemans², A.C. Radder³

Abstract

Evolution equations for nonlinear long waves are considered from an approximation to the exact Hamiltonian (total energy) for the water waves. The approximation which is used here has two distinct advantages over many other formulations which are commonly used for the same purpose. Further, a variation of these evolution equations is considered in order to incorporate higher-order nonlinearity. Numerical solutions of the evolution equations have been carried out for both the systems. Application of these models is illustrated in some practical cases. Comparisons between experimental measurements and computed results show that the model can be used for satisfactory prediction of nonlinear transformation of non-breaking waves over varying depth. Two features for further investigation are: (i) inclusion of both short-wave and long-wave nonlinearity so that the model can be used with uniform validity from deep to shallow water and (ii) modifications of the evolution equations so that they can be applied to propagation of breaking waves in a robust way.

Introduction

Commonly used nonlinear equations for propagation of water waves can be categorised into two main groups: Stokes-type valid in deep water and Boussinesq-type valid for fairly long waves. Several modifications to classical Boussinesq equations have been presented in an attempt to increase the validity of the model equations with respect to frequency dispersion and varying depth (e.g., Madsen *et al.*, 1991; Dingemans & Merckelbach, 1996). In this article, we discuss an alternative approach based on an explicit Hamiltonian formulation (Radder, 1992) for modelling of nonlinear waves over varying depth. The explicit expression for

¹[Formerly at Delft Hydraulics], ICCH, Agern Alle 5, DK-2970 Hørsholm, Denmark

²Senior Researcher and corresponding author, Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

³Senior Researcher, Rijkswaterstaat-RIKZ, P.O. Box 20907, 2500 EX The Hague, The Netherlands

the kinetic energy in the form of a surface integral involving the free surface potential φ and the surface elevation ζ is derived by using a conformal mapping in the complex plane. Therefore, the formulations are limited in a strict sense to unidirectional problems in the horizontal space.

Formulations

We use the symbols $\zeta(x, t)$ and $\varphi(x, t) = \Phi \{x, \zeta(x, t), t\}$ to denote respectively the free surface elevation and potential where Φ is the usual velocity potential. The evolution equations for ζ and φ follow the Hamiltonian structure (see, for example, Benjamin and Olver, 1982):

$$\frac{\partial \zeta}{\partial t} = \frac{\delta \mathcal{H}}{\delta \varphi} \quad , \quad \frac{\partial \varphi}{\partial t} = -\frac{\delta \mathcal{H}}{\delta \zeta} \tag{1}$$

where \mathcal{H} is the total energy (sum of potential and kinetic energy) of the water mass which reads as

$$\begin{aligned} \mathcal{H} &= \frac{1}{2} \rho g \int_{-\infty}^{\infty} \zeta^2 dx + \frac{1}{2} \rho \int_{-\infty}^{\infty} dx \int_{-h}^{\zeta} (\nabla \Phi \cdot \nabla \Phi) dz \\ &= \int_{-\infty}^{\infty} \frac{1}{2} \rho g \zeta^2 dx + \frac{1}{2} \rho \int_{-\infty}^{\infty} dx \sqrt{1 + (\zeta_x)^2} \varphi \Phi_n . \end{aligned} \tag{2}$$

The essential difficulty in deriving explicit evolution equations from (1) and (2) lies in the vertical integral or the Neumann operator of the potential Φ in the expression for kinetic energy density. This is where different procedures differ in the way that the simplifications are made. Several of the more commonly known weakly nonlinear formulations (either of the Stokes or Boussinesq-like approximations) correspond to some of these variations. Recently, Craig and Groves (1994) have presented a comprehensive discussion of these variations.

The basis for our approach is an explicit formulation of the Hamiltonian for two-dimensional water wave problems (unidirectional propagation) presented by Radder (1992). All details of the derivations are not included here. These may be found in Radder (1992), Otta and Dingemans (1994a) and Dingemans and Otta (1996). Radder has shown that an exact expression for the kinetic energy \mathcal{T} as a function of the free-surface variables ζ and φ can be obtained in an explicit form using a conformal mapping, namely the Woods' transformation from the physical space (horizontal and vertical coordinates x and z) to $(-\infty < \chi < \infty, 0 \leq \xi \leq 1)$. This expression for the kinetic energy in the χ space along the free surface ($\xi = 1$) is given by

$$\mathcal{T} = -\frac{\rho}{2\pi} \int_{-\infty}^{\infty} d\chi \frac{\partial \varphi}{\partial \chi} \int_{-\infty}^{\infty} d\chi' \frac{\partial \varphi}{\partial \chi'} \log \tanh \frac{\pi}{4} |\chi - \chi'| \tag{3}$$

where \log is the natural logarithm and the variable χ is related to x along the free surface through

$$\frac{dx}{d\chi} = \left(\frac{d/d\chi}{\tan d/d\chi} \right) \zeta(\chi) + \left(\frac{d/d\chi}{\sin d/d\chi} \right) h(\chi) . \tag{4}$$

The mapping (4) is valid exactly for arbitrary variation of depth h and surface elevation ζ .

We need to inverse the Jacobian, given by (4), in order to express \mathcal{T} in the physical space. It is, however, difficult to obtain an exact inversion. Consequently, we shall use an approximation to the exact Jacobian leading to an approximation of the Hamiltonian (\mathcal{H}^a) in the physical space. A notable distinction of the method is that the positive definiteness of the kinetic energy density can be ensured for each approximation if one selects the inversion such that $\frac{dx}{d\chi} > 0$.

The simplest approximation which accounts for long-wave nonlinearity (it is assumed that $kh \cdot ka$ is small) for moderately high waves is arrived at by $dx/d\chi \approx \eta$ where η is the total water depth ($h + \zeta$). The resulting Hamiltonian \mathcal{H}^a is

$$\frac{\mathcal{H}^a}{\rho} = \frac{1}{2} \int_{-\infty}^{\infty} dx g \zeta^2 - \frac{1}{2\pi} \int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dx' \phi_x \phi_{x'} \log \tanh \frac{\pi}{4} \left| \int_x^{x'} \frac{dx''}{\eta} \right|. \quad (5)$$

With regards to the approximate inversion we introduce the variable p such that

$$\frac{dx}{dp} = h + \zeta \quad (6)$$

and the resulting evolution equations are

$$\frac{\partial \zeta}{\partial t} = \frac{1}{\pi} \frac{\partial}{\partial x} \int_{-\infty}^{\infty} dx' \varphi_{x'} \log \tanh \frac{\pi}{4} \left| \int_x^{x'} \frac{dr}{\eta} \right| \quad (7)$$

$$\frac{\partial \varphi}{\partial t} = -g\zeta - \frac{1}{2\eta^2} \int_{-\infty}^x dx' \int_x^{\infty} dx'' \frac{\varphi_{x'} \varphi_{x''}}{\sinh \left(\frac{\pi}{2} \int_{x'}^{x''} \frac{dr}{\eta} \right)}. \quad (8)$$

We note that for this approximation, positive definiteness is maintained as long as the total water depth ($h + \zeta$) remains greater than zero. This feature of positive definiteness is not guaranteed in the entire wave spectrum in many other approximate Hamiltonian system. Another significant advantage is that in the limiting case of infinitesimal waves the dispersion relationship of the evolution equations derived from (5) is identical to that from the classical linear wave theory over uniform depth. This has the positive consequence that linear propagation and shoaling are properly predicted for all free components over the entire wave spectrum in transferring from deep to shallow water although nonlinear interactions of the short-wave type may suffer from the same limitation as when Boussinesq formulations are used.

Higher-order Description

The approximation (5) and the evolution equations derived therefrom do very well in reproducing long-wave nonlinearity as will be shown later. However, for better description of the form near the crests during wave steepening and propagation of higher waves, higher-order nonlinearity needs to be incorporated in the evolution

equations. Both short-wave and long-wave nonlinearity can be accounted for in the approximate Hamiltonian in a hierarchical way by seeking higher-order inversion to (4) than used in (6). This is, however, not very straightforward. Instead, we choose an intermediate approach where the evolution equation for the surface elevation is obtained by replacing χ by p in the exact expression for the kinetic energy; *i.e.*,

$$\frac{\partial m}{\partial t} = \frac{1}{\pi} \int_{-\infty}^{\infty} dp \varphi_{p'} \log \tanh \frac{\pi}{4} |p - p'| \tag{9}$$

with $\zeta(x, t) = \partial m / \partial x$ in combination with the dynamic free surface boundary condition used directly for the free surface potential, *i.e.*

$$\frac{\partial \varphi}{\partial t} = -g\zeta - \frac{1}{2} \varphi_x^2 + \frac{1}{2} \frac{(\zeta_t + \varphi_x \zeta_x)^2}{1 + (\zeta_x)^2}. \tag{10}$$

Numerical Solution

The evolution equations (7) and (8) are not convenient for direct numerical treatment due to the singular kernels and the double integral in the latter. The integrands are first regularised to make them more amenable for numerical solution. The modified equations (Otta & Dingemans, 1994a) are presented in the following:

$$\zeta_t = \frac{1}{\pi} \frac{d}{dx} \left[-\pi v \eta + \int_{-\infty}^{\infty} dx' \lambda(x', x) \log \tanh \frac{\pi}{4} \left| \int_x^{x'} \frac{dx''}{\eta} \right| \right] \tag{11}$$

$$v_t = -g\zeta_x + \frac{d}{dx} \left[\frac{1}{\eta^2} \int_{-\infty}^x dx' v \eta \zeta_t \right] \tag{12}$$

where

$$v = \varphi_x, \quad \lambda(x', x) = v(x') - \frac{\eta(x)}{\eta(x')} v(x). \tag{13}$$

The equations, given by (11) and (12), are numerically solved using an predictor-corrector scheme, namely the Adams-Bashforth-Moulton method. The spatial discretization of the right hand sides of the equations is carried out using the **sinc**-series approximation (Lund & Bowers, 1992). More about the characteristics and advantages of using the **sinc**-series and the high order of accuracy of the numerical scheme used is described in a separate article under preparation.

Certain advantages are gained by carrying out the numerical evaluation of the evolution equations, given by (9) and (10), in a uniformly spaced p -space. Using the sinc approximation to express $\mathcal{V}(p')$ ($\mathcal{V} = \varphi_p$), *i.e.*,

$$\mathcal{V}(p') = \sum_{l=-\infty}^{\infty} \mathcal{V}_l \operatorname{sinc} \frac{p' - pl}{\Delta p} \tag{14}$$

with l denoting the grid index and Δp the uniform interval between two consecutive grids in the p -space we obtain the discretised form of the evolution equation (9):

$$\left. \frac{\partial m}{\partial t} \right|_j = \sum_l \nu_l I(|l-j|; \Delta p) \quad (15)$$

where

$$I(|l-j|; \Delta p) = -\frac{1}{\pi} \int_{-\infty}^{\infty} dp' \operatorname{sinc} \frac{p' - p_l}{\Delta p} \log \tanh \frac{\pi}{4} |p_j - p'|. \quad (16)$$

For a time-invariant value of Δp , the terms $I(|l-j|; \Delta p)$'s remain constant and need to be evaluated only once. We note, however, that the x -coordinates corresponding to the fixed values of p grids are time-variant. The local evolution rates $[\zeta_t(x, t), \varphi_t(x, t)]$ then need to be transferred to the constant p -grids through the relation

$$\begin{aligned} \frac{d\psi}{dt}(x^p, t) &= \frac{\partial \psi}{\partial t} + \frac{dx^p}{dt} \frac{\partial \psi}{\partial x} \\ &= \frac{\partial \psi}{\partial t} + \frac{dx^p}{dt} \frac{\partial p}{\partial x} \frac{\partial \psi}{\partial p} \end{aligned} \quad (17)$$

where ψ is used to denote either ζ or φ and x^p denotes the x -coordinate of a constant p -value. The value of x^p itself is updated with time.

Boundary Conditions

The evolution equations (with the exception of (10)) described so far include an integral over the infinite span. This has its origin to our deliberate choice of excluding the lateral boundary from the formulations in order that the Hamiltonian can be expressed as a function of ζ and φ . With no further modifications, these evolution equations can be used to study an initial value problem. This means that the span in the x -interval for the numerical solution has to be much longer than the physical interval of interest with the consequence that the required computational time increases tremendously. This is, however, not necessary.

Consider for example the evolution equation (9). We rewrite this equation as

$$\begin{aligned} \frac{\partial m}{\partial t} &= \frac{1}{\pi} \int_{-\infty}^{p_0} dp \varphi_{p'} \log \tanh \frac{\pi}{4} |p - p'| + \frac{1}{\pi} \int_{p_0}^{p_n} dp \varphi_{p'} \log \tanh \frac{\pi}{4} |p - p'| \\ &\quad + \frac{1}{\pi} \int_{p_n}^{\infty} dp \varphi_{p'} \log \tanh \frac{\pi}{4} |p - p'| \end{aligned} \quad (18)$$

where p_0 and p_n denote respectively the begin and end point of the computation interval. Though the intervals of the first and third integrals in (18) outside the computational interval are semi-infinite, the rapid decay of the function $\log \tanh()$ appearing in the kernel of the integral allows reduction of the interval to usually a few (local) water depths without any loss of accuracy. We assume for simplicity

that the bottom stretches uniformly to the left of p_0 and the right of p_n . For generating incoming waves in the computational interval, we use an appropriate theory to translate the time record of surface elevation $\zeta(t)$ at a given location (say p_0) to a space and time record for both ζ and φ outside of the computational interval. In the simplest way this is done by using linear theory to specify the incident field in the offshore side. On the shallower part a sponge layer can be introduced to absorb the radiating waves. For this purpose the evolution equations are modified; *i.e.*,

$$\zeta_t = R_\zeta(\zeta, \varphi) - \mu(x)\zeta \quad (19)$$

where $R_\zeta(\zeta, \varphi)$ represents the unmodified part of the equation and $\mu(x)$ a damping coefficient. In many cases, the introduction of a sponge layer over a reasonable length of the computational domain allows absorption of the radiating waves such that the third integral in (18) becomes non-significant. In a more general approach, a combination of the sponge layer and a Sommerfeld type of radiation condition can be implemented to specify the space and time record of ζ and φ outside of p_n to compute the third integral in (18). Details of the types of boundary conditions and the procedures are described in Otta & Dingemans (1994b) and Dingemans & Otta (1996).

Examples of Applications

In this section we discuss the application of the models to some critical cases. An illustrative example is the study of the propagation of a solitary wave over a bottom of constant depth. The initial surface profile $\zeta(x, t = 0)$ and the potential $\varphi(x, t = 0)$ are specified from Tanaka's (1986) solution which may be considered exact. Fig. 1 shows that this profile changes considerably with a decrease in the crest height and the formation of a dispersive tail during the propagation according to (7) and (8). The change in crest height and the dispersive tail is much less prominent when the set of evolution equations with the higher order of nonlinearity is used.

An example of practical interest is the propagation of waves over varying depth. To test the validity of our two models for such cases we consider an experimental setup (Fig. 2) as described in Luth *et al.* (1994) and used in Dingemans (1994). Transformation of an incident train of periodic waves is shown at different locations along the bar in Fig. 3. The incident waves are of mild amplitude such that they do not break over the bar. The computed profiles shown here are obtained by using (9) and (10). The nonlinear interactions on top of the bar (at location $x = 13.5$ m) and the propagation of the free waves behind the bar (location $x = 19$ m) are reproduced in a satisfactory manner. Though not shown here, results obtained from (7) and (8) for this case have been found to be nearly as good with only slightly differences near the crest. In a previous study (Dingemans, 1994), the model based on (7) and (8) has been found to yield better agreement with experimental measurements than many Boussinesq-like models.

Figure 1: Computed profiles of a solitary wave (initial height/depth= 0.4) during propagation over a bottom of constant depth. Solid line: based on (9) and (10); dashed line: based on (7) and (8).

Wave Breaking

The evolution equations, given by (7) and (8) or by (9) and (10), are valid for waves which do not break. Wave-breaking is, however, of great practical significance in coastal areas. In field conditions, wave breaking in shallow water is identified by overturning of the water surface and plunging on to itself (plunging breaker) or the formation of a thin jet near the crest that spills over (spilling breaker). There are several difficulties, both physical and numerical, in modelling this process of breaking reasonably. Although a proper description of the water motion in the neighbourhood of breaking is essential for some purposes, it is sufficient to incorporate the main effects of breaking in the post-breaking behaviour of wave propagations for many a problem. To incorporate this effect in weakly nonlinear equations two steps are essential. Since either overturning of the surface and the spilling jet may not be manifested in the model behaviour or the numerical limitations of an adopted scheme may not permit computations advancing to the desired point, a criterion has to be used to indicate the incipience of breaking. Secondly, the evolution equations (derived originally for non-breaking waves) have to be modified so that the effects of wave-breaking (*e.g.*, energy dissipation) are incorporated within the framework.

Several criteria have been used in different models for the definition of the onset of breaking. For example, Schäffer *et al.* (1993) found it necessary to use a

Figure 2: Geometry of the experimental setup.

criterion of the maximum of the local surface slope reaching a value of 20° in their time-domain Boussinesq model to a mark the onset of breaking. We consider here a criterion which is based on the idea of the Jacobian of the conformal mapping $d\chi/dx$ becoming zero. This condition has been mentioned for horizontal bottom by Dingemans and Radder (1991) using a first-order expression for the Jacobian including both short-wave and long-wave nonlinearity. For varying depth, the criterion reads as

$$\eta(p) + \int_0^\infty \frac{d[\zeta(p+q) + \zeta(p-q)]}{\exp(\pi q) - 1} - \int_0^\infty \frac{d[h(p+q) + h(p-q)]}{\exp(\pi q) + 1} = 0. \quad (20)$$

The criterion (20) has been found to be a good indicator of the onset of breaking for waves of symmetric permanent form and some cases of asymmetric forms before plunging (Radder, 1995; personal communication) although a comprehensive analysis of the criterion for the onset of breaking in dynamical situations is still very much needed.

During numerical experimentations with the model equations (7) and (8) we have observed that the condition (20) was never reached in the computed surface form while breaking did occur in reality. Though this observation is not completely surprising, it was difficult to predict *a priori*. It is our conjecture that this is caused by the inadequacy in the representation of nonlinearity in the equations (7) and (8). This conjecture is in fact the primary motivation behind the set-up for a higher-order description. On application of the model, based on (9) and (10), the breaking criterion is met in several cases followed by numerical instabilities. An example of such a computation is shown in Fig. 4 where a train of periodic waves is allowed to propagate onshore over a sea-bed profile near Egmond on the Dutch coast. In a preliminary approach to model post-breaking behaviour, we have considered modifying the surface elevation at each evolution step following two criteria: (a) the surface form remains within the limit of the breaker criterion and (b) the modification does not lead to a change in the mass balance. The effect is to reduce the crest height and the surface steepness with an associated dissipation of energy. This approach has shown some qualitative success in a limited number of cases, *e.g.*, during the propagation of a solitary wave

Figure 3: Transformation of a train of periodic sine waves due to propagation over a bar (Fig. 2), Water depth= 40 cm (offshore), 10 cm (over the bar); Incident wave height= 2 cm, period= 2.02 s.

Figure 4: Propagation of a regular wave train towards the shore over the barred bathymetry near Egmond. Incident wave height= 1 m, period= 10 s. The bed profile is not shown to scale. Still-water depth at $x = 0$ is 11.4 m.

on a slope. However, much remains to be done in the formulation of a proper breaking mechanism in the model and making the model practically applicable to breaking waves.

Summary

In the present article, we have discussed two sets of evolution equations. One set of evolution equations, given by (7) and (8), is derived from an approximate Hamiltonian with two important properties: the kinetic-energy density is guaranteed to be positive definite for all wave heights across the entire wave spectrum as long as the local water depth is greater than zero and secondly the dispersion relationship in the limiting case of infinitesimal amplitude is exactly identical to that obtained from the classical linear theory of water waves. These two features are of great practical significance in ensuring stability of the model equations during propagations of an irregular train or of the generated higher harmonics and in representation of proper phase speed of all components. Numerical experiments with some critical test cases show that the model describes the nonlinear transformation during propagation of non-breaking waves over a varying depth satisfactorily. The performance of the model has been found to be superior to that of many Boussinesq-like models during an intercomparison study completed recently. We have experimented with including a higher-order nonlinear representation in the model equations. The experiments indicate that higher-order nonlinearity can improve the result of the Boussinesq-like approximations of fairly long, fairly low waves especially near the breaking point. However, a more systematic approach is necessary than what has been here presented in order to

ensure stability and conservation of energy of the system.

CHAPTER 91

THE ROLE OF WAVE-INDUCED SHEAR STRESSES IN THE MOMENTUM BALANCE EQUATIONS

Francisco J. Rivero and Agustín S.-Arcilla*, M. ASCE

ABSTRACT

The wave-induced shear stresses, which result from the correlation between horizontal and vertical components of the oscillatory velocity after time-averaging the horizontal momentum balance equations, are shown in this paper to play an important role in vertical circulation analysis, having the same order of magnitude than other wave-induced (normal) stresses. The model of Rivero and Arcilla (1995) to calculate the wave-induced shear stress for a 2DV situation, based on a mathematical identity that relates this stress to the wave-induced normal stresses and the oscillatory vorticity, is now extended to a general 3D flow. The consequences of neglecting the wave-induced shear stresses are shown to be an overprediction of the waves effect on the description of the vertical profiles of the mean (current) velocity. Theoretical examples of such effects are presented and discussed for some simplified situations (the undertow and longshore current vertical profiles).

1. INTRODUCTION

The correlations between horizontal (\tilde{u}_i) and vertical (\tilde{w}) components of the oscillatory (wave) motion, which appear explicitly in the time-averaged momentum balance equations as wave-induced (effective) shear stresses, have been shown to play an important role in the analysis of the vertical distribution

* Associate professor and professor, Maritime Engineering Laboratory (LIM), Catalonia University of Technology (UPC), Campus Nord (módul D-1), Gran Capitá s/n, 08034 Barcelona, Spain

of wave-induced currents (see e.g. Deigaard and Fredsøe (1989), De Vriend and Kitou (1990), Stive and De Vriend (1994), and Rivero and Arcilla (1995), to mention some recent references). However, most circulation models have, until very recently, neglected the $\langle \tilde{u}_i \tilde{w} \rangle$ -contribution ($\langle \rangle$ denotes the time-averaging operator over a wave period) by simply arguing that the two wave velocity components, \tilde{u}_i and \tilde{w} , are 90° out of phase. This result, which corresponds to periodic waves of permanent form, is not valid for real waves propagating over a sloping bottom and/or with energy dissipation (be it in the bottom boundary layer or in the free surface area for the roller of breaking waves).

The purpose of this paper is to present new formulations to calculate the wave-induced shear stresses $\langle \tilde{u}_i \tilde{w} \rangle$, based on mathematical identities that relate these stresses to other wave stresses ($\langle \tilde{u}_i \tilde{u}_j \rangle$ and $\langle \tilde{w}^2 \rangle$), easier to calculate by any given wave theory (e.g. linear theory), and the vorticity of the oscillatory velocity, and to investigate the relevance of these stresses in vertical circulation analysis.

The outline of the paper is as follows. Section 2 gives an overview of the model of Rivero and Arcilla (1995) to calculate the wave-induced shear stress $\langle \tilde{u} \tilde{w} \rangle$ in a 2DV situation. This model is extended in section 3 to a general 3D flow, and its implication in the horizontal momentum balance equations are discussed in section 4. Theoretical examples on the role of wave-induced shear stresses in the description of the vertical circulation for some simplified situations are given in sections 5 (undertow profiles) and 6 (longshore current profiles). Finally, section 7 presents the summary and conclusions.

2. WAVE-INDUCED SHEAR STRESS IN A 2DV FLOW

For a 2DV situation (as that encountered in a wave flume), in which waves propagate along the x-direction and the z-axis is directed vertically upwards (Fig. 1), Rivero and Arcilla (1995) derived a mathematical identity which relates the wave-induced shear stress $\langle \tilde{u} \tilde{w} \rangle$ to other wave-induced stresses ($\langle \tilde{u}^2 \rangle$ and $\langle \tilde{w}^2 \rangle$) and to the (scalar) vorticity of the oscillatory flow $\tilde{\omega} = \frac{\partial \tilde{u}}{\partial z} - \frac{\partial \tilde{w}}{\partial x}$:

$$\frac{\partial}{\partial z} \langle \tilde{u} \tilde{w} \rangle = \langle \tilde{w} \tilde{\omega} \rangle - \frac{1}{2} \left[\frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] \quad (1)$$

where the oscillatory components of the velocity (\tilde{u} and \tilde{w}) are defined such that $\langle \tilde{u} \rangle = \langle \tilde{w} \rangle = 0$, and hence, $\langle \tilde{\omega} \rangle = 0$.

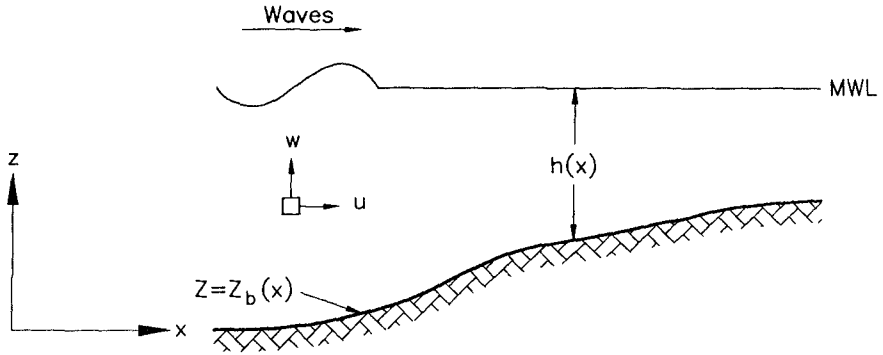

Figure 1. Domain definition sketch -2DV situation- (after Rivero and Arcilla, 1995).

Assuming irrotational flow ($\tilde{\omega} = 0$) and invoking linear wave theory to evaluate $\langle \tilde{u}^2 \rangle$, $\langle \tilde{w}^2 \rangle$ and the near-bed value of $\langle \tilde{u}\tilde{w} \rangle$, which is given by the kinematic boundary condition at the bottom $z = z_b$ (Putrevu and Svendsen, 1993) —see Fig. 2—, the vertical distribution of $\langle \tilde{u}\tilde{w} \rangle$, after integration of Eq. (1), is found to be linear over depth:

$$\langle \tilde{u}\tilde{w} \rangle = -G \left(\frac{E}{\rho h} \right) \frac{\partial d}{\partial x} - \left[\frac{\partial}{\partial x} \left(\frac{1}{2} G \frac{E}{\rho h} \right) \right] (z - z_b) \quad (2)$$

where d is the still-water depth, h is the mean water depth, E is the wave energy density, ρ is the fluid density, and $G = 2kh / \sinh(2kh)$.

Figure 2. Simplified model for the oscillatory wave motion near the bed. (after Rivero and Arcilla, 1995)

This general expression (2), using linear wave theory, has been applied to simplified situations and has been shown to coincide or degenerate into other existing formulations with comparable simplifying assumptions, viz. irrotational waves over a sloping bottom in the shallow-water approximation (De Vriend and Kitou, 1990), and surf-zone breaking waves over a horizontal bottom (Deigaard and Fredsøe, 1989).

Expression (2) has also been compared (Rivero and Arcilla, 1997) with experimental results for the vertical distribution of the wave-induced shear stress $\langle \tilde{u}\tilde{w} \rangle$ in shoaling waves within the framework of a research project (*Dynamics of Beaches*) funded by the EU —see Prinos et al. (1994) for details. Simultaneous time series of horizontal and vertical velocity components, and free surface elevation were measured at several stations along the wave flume and at several points within each station. Various regular and irregular wave conditions were generated with and without a submerged breakwater on a 1:15 sloping beach (Rivero et al, 1996). The experimental results presented here correspond to the test without submerged breakwater under irregular wave action (Test E: Jonswap-type spectrum with $\gamma = 3.3$, peak period $T_p=2.50$ s and significant wave height $H_s=0.25$ m in the deeper part of the wave flume, with water depth $h=3.06$ m). Fig. 3 shows the measured values of $\langle \tilde{u}\tilde{w} \rangle$ at 3 stations located in the shoaling zone, and the predicted $\langle \tilde{u}\tilde{w} \rangle$ -distribution with expression (2). As can be seen from this figure, both the sign (positive) and the trend (decreasing upwards) of the vertical distribution of $\langle \tilde{u}\tilde{w} \rangle$ is correctly predicted by the authors' model, as well as quantitatively.

Figure 3. Comparison between experimental data (squares) and this model (Eq. 2) for the vertical distribution of the wave-induced shear stress $\langle \tilde{u}\tilde{w} \rangle$.

Test E: irregular waves, Jonswap-type, $H_s=0.25$ m, $T_p=2.5$ s.

(after Rivero and Arcilla, 1997)

3. WAVE-INDUCED SHEAR STRESSES IN A 3D FLOW

Explicit expressions for the vertical distribution of the wave-induced shear stresses ($\langle \tilde{u}\tilde{w} \rangle$, $\langle \tilde{v}\tilde{w} \rangle$) in a 3D situation may be found from (2) in a horizontally rotated frame of reference, after assuming that the (irrotational) flow is essentially two-dimensional in the direction of wave propagation x' (see Fig. 4), and neglecting the curvature of wave rays:

$$\begin{aligned} \langle \tilde{u}\tilde{w} \rangle = & -2\mathcal{A} \left(\frac{\partial d}{\partial x} \cos^2 \alpha + \frac{\partial d}{\partial y} \sin \alpha \cos \alpha \right) - \\ & - \left(\frac{\partial \mathcal{A}}{\partial x} \cos^2 \alpha + \frac{\partial \mathcal{A}}{\partial y} \sin \alpha \cos \alpha \right) (z - z_b) \end{aligned} \quad (3a)$$

$$\begin{aligned} \langle \tilde{v}\tilde{w} \rangle = & -2\mathcal{A} \left(\frac{\partial d}{\partial x} \sin \alpha \cos \alpha + \frac{\partial d}{\partial y} \sin^2 \alpha \right) - \\ & - \left(\frac{\partial \mathcal{A}}{\partial x} \sin \alpha \cos \alpha + \frac{\partial \mathcal{A}}{\partial y} \sin^2 \alpha \right) (z - z_b) \end{aligned} \quad (3b)$$

where $\mathcal{A} = \frac{1}{2}G \left(\frac{E}{\rho h} \right)$ is an energy-like magnitude.

Figure 4. Domain definition sketch -3D situation- (after Rivero and Arcilla, 1997).

A more general (differential) expression for $\langle \tilde{u}\tilde{w} \rangle$ and $\langle \tilde{v}\tilde{w} \rangle$, from which their implication in the time-averaged momentum balance equations may be easily assessed, is given by the following straightforward mathematical identities that involve the oscillatory vorticity components,

$$\tilde{\omega}_x = \frac{\partial \tilde{w}}{\partial y} - \frac{\partial \tilde{v}}{\partial z} \qquad \tilde{\omega}_y = \frac{\partial \tilde{u}}{\partial z} - \frac{\partial \tilde{w}}{\partial x}$$

and the continuity equation for the oscillatory velocity components,

$$\frac{\partial \tilde{u}}{\partial x} + \frac{\partial \tilde{v}}{\partial y} + \frac{\partial \tilde{w}}{\partial z} = 0 \quad :$$

$$\frac{\partial}{\partial z} \langle \tilde{u}\tilde{w} \rangle = \langle \tilde{w}\tilde{\omega}_y \rangle - \frac{1}{2} \left[\frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] - \langle \tilde{u} \frac{\partial \tilde{v}}{\partial y} \rangle \quad (4a)$$

$$\frac{\partial}{\partial z} \langle \tilde{v}\tilde{w} \rangle = - \langle \tilde{w}\tilde{\omega}_x \rangle - \frac{1}{2} \left[\frac{\partial}{\partial y} \left(\langle \tilde{v}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] - \langle \tilde{v} \frac{\partial \tilde{u}}{\partial x} \rangle \quad (4b)$$

For an irrotational flow ($\tilde{\omega}_x = \tilde{\omega}_y = 0$), these mathematical identities read:

$$\frac{\partial}{\partial z} \langle \tilde{u}\tilde{w} \rangle = -\frac{1}{2} \left[\frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] - \langle \tilde{u} \frac{\partial \tilde{v}}{\partial y} \rangle \quad (5a)$$

$$\frac{\partial}{\partial z} \langle \tilde{v}\tilde{w} \rangle = -\frac{1}{2} \left[\frac{\partial}{\partial y} \left(\langle \tilde{v}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] - \langle \tilde{v} \frac{\partial \tilde{u}}{\partial x} \rangle \quad (5b)$$

4. WAVE-INDUCED STRESSES IN THE HORIZONTAL MOMENTUM BALANCE EQUATIONS

The "conventional" wave-induced stresses appearing in the time-averaged horizontal momentum balance equations (see e.g. Svendsen and Lorenz, 1989):

$$\text{X-direction} \quad \frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \frac{\partial}{\partial y} \langle \tilde{u}\tilde{v} \rangle + \frac{\partial}{\partial z} \langle \tilde{u}\tilde{w} \rangle \quad (6a)$$

$$\text{Y-direction} \quad \frac{\partial}{\partial y} \left(\langle \tilde{v}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \frac{\partial}{\partial x} \langle \tilde{u}\tilde{v} \rangle + \frac{\partial}{\partial z} \langle \tilde{v}\tilde{w} \rangle \quad (6b)$$

would read, after invoking identities (4a-b):

$$\text{X-direction} \quad \langle \tilde{w}\tilde{\omega}_y \rangle + \frac{1}{2} \frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \langle \tilde{v} \frac{\partial \tilde{u}}{\partial y} \rangle \quad (7a)$$

$$\text{Y-direction} \quad - \langle \tilde{w}\tilde{\omega}_x \rangle + \frac{1}{2} \frac{\partial}{\partial y} \left(\langle \tilde{v}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \langle \tilde{u} \frac{\partial \tilde{v}}{\partial x} \rangle \quad (7b)$$

and assuming irrotational flow ($\tilde{\omega}_x = \tilde{\omega}_y = 0$):

$$\text{X-direction} \quad \frac{1}{2} \frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \langle \tilde{v} \frac{\partial \tilde{u}}{\partial y} \rangle \quad (8a)$$

$$\text{Y-direction} \quad \frac{1}{2} \frac{\partial}{\partial y} \left(\langle \tilde{v}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \langle \tilde{u} \frac{\partial \tilde{v}}{\partial x} \rangle \quad (8b)$$

The implication of taking into account the wave-induced shear stresses, $\langle \tilde{u}\tilde{w} \rangle$ and $\langle \tilde{v}\tilde{w} \rangle$, as given by Eqs.(7a-b), or equivalently, Eqs.(8a-b) for an irrotational flow, with respect to the case in which those stresses are neglected from the conventional form of the time-averaged horizontal momentum balance equations (Eqs. 6a-b), are discussed in the following sections for some idealized situations.

5. UNDERTOW VELOCITY PROFILES

For normally incident waves ($\alpha=0$) on a cylindrical beach ($\partial d/\partial y=0$), the vertical distribution of mean shear stress $\langle \tau_{xz} \rangle$ (associated with viscous and/or turbulent effects) can be found from the time-averaged horizontal momentum balance equation in the cross-shore direction after assuming a given mean pressure distribution (usually, $\langle p \rangle = \langle p_h \rangle - \rho \langle \tilde{w}^2 \rangle$, where $\langle p_h \rangle$ is the mean hydrostatic pressure) —see e.g. (Svendensen, 1984) for the assumptions and motivation of this equation—:

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{xz} \rangle}{\rho} \right) = \frac{\partial U^2}{\partial x} + g \frac{\partial \langle \eta \rangle}{\partial x} + \frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) + \frac{\partial}{\partial z} \langle \tilde{u}\tilde{w} \rangle \quad (9)$$

where $U(x, z)$ is the (undertow) mean velocity and $\langle \eta \rangle (x)$ is the mean water level (set-up/set-down). Eq. (9) shows the vertical variation of the mean shear stress $\langle \tau_{xz} \rangle$ in the $\{x, z\}$ vertical plane.

As already mentioned before, the $\langle \tilde{u}\tilde{w} \rangle$ contribution has been, until very recently, neglected throughout the water column except in the bottom boundary layer, in which it led to the streaming solution (Longuet-Higgins, 1953). The relevance of the $\langle \tilde{u}\tilde{w} \rangle$ contribution in the vertical distribution of $\langle \tau_{xz} \rangle$ can be easily assessed after substitution of identity (1) into Eq. (9):

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{xz} \rangle}{\rho} \right) = \frac{\partial U^2}{\partial x} + g \frac{\partial \langle \eta \rangle}{\partial x} + \frac{1}{2} \left[\frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] + \langle \tilde{w}\tilde{\omega} \rangle \quad (10)$$

Since the $\langle \tilde{w}\tilde{\omega} \rangle$ term will be, in general, unknown—it depends on the vertical distribution of the current velocity—it may be set to zero as a first approximation, in which case Eq. (10) would read:

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{xz} \rangle}{\rho} \right) = \frac{\partial U^2}{\partial x} + g \frac{\partial \langle \eta \rangle}{\partial x} + \frac{1}{2} \left[\frac{\partial}{\partial x} \left(\langle \tilde{u}^2 \rangle - \langle \tilde{w}^2 \rangle \right) \right] \quad (11)$$

It may be, thus, seen that the $\langle \tilde{u}\tilde{w} \rangle$ -term first effect is to halve the normal wave stress contribution to $\langle \tau_{xz} \rangle$. This would mean that unrealistic closure submodels for $\langle \tau_{xz} \rangle$ (i.e. eddy viscosity coefficient ν_t values) must be used to fit measured undertow profiles if the $\langle \tilde{u}\tilde{w} \rangle$ term is neglected in the momentum balance equation (9). It should be noticed that, although wave stress gradients are usually small compared to $g \frac{\partial \langle \eta \rangle}{\partial x}$ inside the surf zone (Svendsen and Lorenz, 1989), that is not necessarily the case outside the breaker region or in the transition zone (Putrevu and Svendsen, 1993). This means that the $\langle \tilde{u}\tilde{w} \rangle$ contribution, and therefore the need to calculate it, is expected to be more significant in areas in which mean water level gradients do not dominate the momentum balance equation.

6. LONGSHORE CURRENT VELOCITY PROFILES

For obliquely incident waves ($\alpha \neq 0$) on a cylindrical beach ($\partial d/\partial y=0$), the vertical distribution of the mean shear stress $\langle \tau_{yz} \rangle$, which may be related to the vertical gradients of the longshore current velocity $V(x, z)$, can be found from the time-averaged horizontal momentum balance equation in the alongshore direction—see e.g. (Svendsen and Putrevu, 1994)—:

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{yz} \rangle}{\rho} \right) = \frac{\partial UV}{\partial x} + \frac{\partial}{\partial x} \langle \tilde{u}\tilde{v} \rangle + \frac{\partial}{\partial z} \langle \tilde{v}\tilde{w} \rangle \quad (12)$$

Upon substitution of identity (4b) with the assumption of alongshore uniformity ($\partial/\partial y=0$), Eq. (12) may be written as

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{yz} \rangle}{\rho} \right) = \frac{\partial UV}{\partial x} - \langle \tilde{w}\tilde{\omega}_x \rangle + \langle \tilde{u} \frac{\partial \tilde{v}}{\partial x} \rangle \quad (13)$$

If, as in the preceding section, the term involving the vorticity is disregarded, the governing equation for the vertical distribution of $\langle \tau_{yz} \rangle$ (13) would read

$$\frac{\partial}{\partial z} \left(\frac{\langle \tau_{yz} \rangle}{\rho} \right) = \frac{\partial UV}{\partial x} + \langle \tilde{u} \frac{\partial \tilde{v}}{\partial x} \rangle \quad (14)$$

In this situation wave stresses are, in the absence of alongshore mean water level gradients, the dominant factors governing the vertical distribution of $\langle \tau_{yz} \rangle$. Again, it may be noticed that the primary effect of the $\langle \tilde{v}\tilde{w} \rangle$ term, as given by Eq. (14), is to reduce (approximately, to halve) the contribution of wave stresses ($\langle \tilde{u} \frac{\partial \tilde{v}}{\partial x} \rangle$ versus $\frac{\partial}{\partial x} \langle \tilde{u}\tilde{v} \rangle$) in the vertical distribution of $\langle \tau_{yz} \rangle$, with respect to the case in which the $\langle \tilde{v}\tilde{w} \rangle$ term is neglected in the original equation (12). This fact indicates that, for a given closure submodel of $\langle \tau_{yz} \rangle$, the predicted curvature of the vertical profiles of longshore currents taking into account the $\langle \tilde{v}\tilde{w} \rangle$ term (Eq. 14) is smaller than the one predicted neglecting the $\langle \tilde{v}\tilde{w} \rangle$ term (in Eq. 12), which may help explaining the good fit of logarithmic functions to field measurements of the longshore current vertical profiles (see e.g. Thornton et al, 1995).

7. CONCLUSIONS

The following general conclusions may be drawn from the theoretical derivations presented in this paper:

- New mathematical identities (4a-b) have been derived which express the wave-induced shear stresses ($\langle \tilde{u}\tilde{w} \rangle$ and $\langle \tilde{v}\tilde{w} \rangle$) in a 3D flow in terms of other wave-induced stresses ($\langle \tilde{u}^2 \rangle$, $\langle \tilde{v}^2 \rangle$, $\langle \tilde{w}^2 \rangle$ and $\langle \tilde{u}\tilde{v} \rangle$), easier to calculate by any given wave theory, and the oscillatory vorticity ($\vec{\omega}$).
- In general, the implication of the wave-induced shear stresses ($\langle \tilde{u}\tilde{w} \rangle$ and $\langle \tilde{v}\tilde{w} \rangle$) in the horizontal momentum balance equations is to approximately halve the contribution of other wave-induced stresses ($\langle \tilde{u}^2 \rangle$, $\langle \tilde{v}^2 \rangle$, $\langle \tilde{w}^2 \rangle$ and $\langle \tilde{u}\tilde{v} \rangle$) with respect to the case where horizontal-vertical correlations are neglected, which has been an otherwise common procedure in vertical circulation analysis.

CHAPTER 92

NONLINEAR WAVE DYNAMICS IN THE SURF ZONE

O. R. Sørensen¹, P. A. Madsen¹ and H. A. Schäffer¹

Abstract

In this paper we shall study and model various nonlinear interaction processes in the surf zone on the basis of a two-dimensional time-domain depth-integrated Boussinesq type model, which features the possibility of wave breaking and a moving boundary at the shoreline. Phenomena to be studied include breaking and runup of bicromatic wave groups on gentle slopes with emphasis on the evolution of surface elevations, the shoreline motion and the low frequency waves generated and released in the surf zone. The model results are compared with laboratory experiments by Mase (1994), and the agreement is generally found to be very good. Special details in the surf beats are investigated, e.g. the motion of the breaker line and of the shoreline, change of wave group modulation through the surf zone, and the sensitivity of surf beats to group frequency, modulation rate and bottom slope.

1. Introduction

Shoaling, breaking and runup of irregular wave trains in shallow water is a nonlinear process involving a number of complicated details. Triad interactions between harmonics in shallow water lead to substantial cross spectral energy transfer in relatively short distances, and during shoaling still more energy will be transferred into bound sub-harmonics and super-harmonics, which will travel phase locked to the primary wave train.

In a number of situations, however, part of the energy may be released as free harmonics, e.g. during the passage over submerged bars or during the process of breaking. When wave breaking occurs, the primary waves and their super-

¹International Research Centre for Computational Hydrodynamics (ICCH). Located at the Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark

harmonics will start dissipating, and this will allow for a gradual release of the bound sub-harmonics and result in free long waves moving towards the shoreline from which they will be almost fully reflected.

To some extent bound long waves will persist in the surf zone depending on the degree of groupiness in this region. The groupiness of the incident waves will generally be partially transmitted into the surf zone, and it may even be reversed if the higher waves in a wave group decay sufficiently during breaking to appear as the lower waves further inshore.

The individual waves in a wave group will break at different depths, which will result in a horizontal oscillation of the breakpoint. The excursion of the breakpoint will depend on the groupiness of the incident waves, and while a linear sinusoidal motion can be expected for a weakly modulated bichromatic group, this is somewhat modified for a fully modulated group where the shoreward extreme of the breakpoint will in principle be at the shoreline. The motion of the breakpoint will result in large time-varying radiation stress gradients in the region of incipient breaking, and this will act as a local forcing of free long waves at the group frequency and its higher harmonics (Symonds et al (1982)). These will propagate in the onshore as well as in the offshore direction. Since the breakpoint forced long waves are basically due to variations of the starting point for the setup, the phenomenon is sometimes referred to as dynamic setup.

The present paper concentrates on the investigations of nonlinear interaction processes in the surf zone using a time-domain Boussinesq type model, which resolves the primary wave motion as well as the long waves. A detailed description of the model can be found in Madsen et al. (1996), while a short description of the model is given in Chapter 2. In Chapter 3 the numerical model is verified with respect to the evolution of surface elevation and shoreline motion due to incident bichromatic wave trains. In Chapter 4 special details of the surf beat mechanism are investigated.

2. Model Description

The numerical model is based on a special type of depth-integrated equations derived by Madsen et al. (1991) and Madsen and Sørensen (1992) and incorporates enhanced linear dispersion characteristics and shoaling properties, which are important for an accurate representation of the nonlinear energy transfer (Madsen and Sørensen, 1993).

The inclusion of wave breaking is based on the surface roller concept for spilling breakers following the formulation by Schäffer et al. (1993). The effect of the roller on the wave motion is taken into account by excess momentum terms originating from a non-uniform velocity profile due to the presence of the roller. The excess momentum terms are a function of the roller thickness and the roller celerity. The instantaneous roller thickness at each point is determined based on a further development of the heuristic, geometrical approach by Deigaard (1989). Breaking is predicted to occur when the local slope of the surface elevation

exceeds an initial critical value, $\tan\phi_B$, using $\phi_B = 20$ deg. During the transition from initial breaking to a bore-like stage in the inner surf zone, the critical angle is assumed to gradually change from ϕ_B to a smaller terminal angle, ϕ_0 which is taken to be 10 deg. The roller thickness is determined as the water above the tangent of slope $\tan\phi$ and the resulting thickness is multiplied by a shape factor which is taken to 1.5. The roller celerity is determined interactively from the instantaneous wave field. The basic approximation is that the waves can locally be assumed to be regular and progressive.

The moving boundary at the shoreline is treated numerically by replacing the solid beach by a permeable beach characterized by an extremely small porosity. This allows for the determination of wave motion in the swash zone and it provides a shoreline condition which like a natural beach tends to be reflective for waves of small steepness viz. the low frequency waves. Radiation of short and long period waves from the offshore boundary is allowed by use of absorbing sponge layers.

Bottom friction is described by the classical quadratic friction law with a friction coefficient f_w of 0.01.

3. Evolution of Surface Elevations and Shoreline Motion

In recent publications Mase (1994,1995) presented experimental results for shoaling, breaking and runup of various types of bichromatic wave trains on a gentle slope. Fig. 1 illustrates the experimental setup. The flume consists of a 10 m horizontal section with a water depth of 0.47 m and a 12 m section with a constant impermeable 1/20 slope. Twelve wave gauges of capacitance type are installed at still water depths of 47, 35, 30, 25, 20, 17.5, 15, 12.5, 10, 7.5, 5 and 2.5 cm, and they are denoted WG1 to WG12. Furthermore, a runup meter is placed at the shoreline. Mase considered a range of wave conditions. Here we shall concentrate on the case with the two primary frequencies $f_1 = 0.95f_m$ and $f_2 = 1.05f_m$, where the mean frequency, f_m was taken as 0.3, 0.4, 0.5, 0.6, 0.8, 1.0 and 1.2 hz, and with the amplitudes $a_1 = a_2 = 0.025$ m.

Fig. 1 Sketch of physical wave flume (Mase, 1994)

The variation in mean frequency from 1.2 hz to 0.3 hz represents a significant change in wave conditions, which are listed in Table 1 in terms of h/L_0 , H_0/L_0 , and ζ , where L_0 is the deep water wave length based on the mean frequency, H_0 is an estimate of the deep water wave height and h is the water depth taken at the toe of the slope. ζ is the surf similarity parameter defined as the beach slope divided by the square root of the deep water wave steepness. Based on Galvin's (1968) classification of wave breaking, Battjes (1974) found that spilling breakers would occur for $\zeta < 0.5$, while plunging would occur for $0.5 < \zeta < 3.3$. Hence, the test cases considered by Mase (1994) cover both regimes, and this will lead to rather different spatial evolutions of wave energy during the shoaling and breaking process. A further analysis of the measurements shows that for decreasing values of the mean frequency, there is a gradual increase in the motion at the group frequency and a pronounced increase in the primary wave motion at the shoreline.

Mean frequency (hz)	h/L_0	H_0/L_0	ζ	Breaker type
1.2	0.43	0.046	0.23	Spilling
1.0	0.30	0.032	0.28	Spilling

Table 1 Wave characteristics of test cases by Mase (1994)

The wavemaker was controlled by a signal generated off-line using linear theory. Thus, advanced features as compensation for generation of spurious sub-harmonics and super-harmonics as well as active absorption of free waves reflected from the slope were not included. Furthermore, the measured frequencies and amplitudes deviated slightly from the target. Altogether, this prevents us from modelling the exact experimental setup and consequently we have chosen to place the numerical model boundary at the position of the first wave gauge (WG1) i.e. at the toe of the sloping beach. The energy of the primary frequencies and their super-harmonics propagates mainly onshore while sub-harmonic energy will propagate offshore as well as onshore. Neglecting the low frequency part of the incident waves, we use the following procedure: The measured signal at WG1 is analysed by FFT, the low frequency motion is removed and the remaining signal is converted into a flux boundary condition using linear theory. At the position of WG1 the waves are generated internally and re-reflection from this boundary is avoided by using a 1 m wide sponge layer offshore from the line of generation. In order to resolve the super-harmonics in shallow water a grid size of 0.02 m and

a time step of 0.01 s is used in the simulations. Numerical simulations have been performed for mean frequencies in the interval between 0.3 and 1.0 Hz. The computed evolution of surface profiles and the resulting shoreline motion agree quite closely with the measurements, indicating that phenomena like dispersion, wave-wave interaction and dissipation due to breaking are well represented by the present model. As an illustration of this Fig. 2 shows for the case of $f_m = 0.3$ Hz the measured and computed time series of water surface elevations at locations WG8, WG10 and WG12 as well as the motion of the shoreline converted into vertical displacement. For clarity the measurements are shifted relative to the computational results by 0.08 m in the figure. All cases were simulated with the same set of standard model parameters, and the quality of the agreement is very good for all values of f_m . This is actually a bit surprising, considering the fact that the roller concept used in the breaker model is primarily suited for spilling type of wave breaking.

The transient shoreline motion is shown in Fig. 3 for the mean frequency $f_m = 0.3, 0.6$ and 1.0 Hz. Again, the agreement between the present model and the measurements is very good. The different wave conditions, ranging from plunging type to spilling type wave breaking, can be seen clearly in the shoreline motion: For the lower mean frequencies the swash of the individual primary waves is quite distinct at the shoreline, while in the case of higher mean frequencies the group induced subharmonic motion dominates the swash oscillations.

It appears that the type of shoreline motion is governed by the type of wave breaking and consequently the surf zone similarity parameter, ζ can be used as an indicator. Hence we can conclude that ζ can be used to characterize the type of shoreline motion, and that plunging/surging breakers result in individual swash, while spilling breakers result in low-frequency dominated shoreline motion.

4. Investigations of Surf Beat

Release of incident bound long waves as well as long-wave generation by a time-varying breakpoint result in a long wave emitted from the surf zone. The amplitude of this wave is a measure of the surf beat activity and it was studied in a series of laboratory experiments by Kostense (1994). The numerical model has been verified against the experimental data by Kostense and the comparison was most satisfactory. For more details see Madsen et al. (1996). Here we shall concentrate on special details of the surf beat mechanism. The following topics are addressed: Trajectories of surface rollers; the motion of the breaker line and of the shoreline; the change of wave group modulation through the surf zone; the sensitivity of surf beats to group frequency, modulation rate and bottom slope.

For this investigation we shall concentrate on incident bichromatic wave groups which are effectively linear at the seaward boundary. This has the advantage that the determination of the amplitude of the outgoing free long waves due to the surf beat can be determined very accurately by simple means. The

bathymetry used for this study consists of a horizontal part of 10 m with a depth of 1.2 m and a part with a constant sloping beach (various slopes are considered).

The grid size, the time step and other model parameters are identical to those used in Chapter 3. Again, bichromatic wave trains are considered. The two primary frequencies are given by $f_1 = f_m + \Delta f/2$ and $f_2 = f_m - \Delta f/2$, where the mean frequency $f_m = 0.60$ hz and the group frequency, Δf is varied in the range 0.02-0.15 hz. The sum of the amplitudes is fixed ($a_1 + a_2 = 0.08$ m) and two different initial modulation rates, $\sigma (= a_2/a_1)$ are considered. In all tests waves are generated inside the model domain and re-reflection from the offshore boundary is avoided by using a sponge layer seawards of the point of generation.

In the first test case the beach slope is $h_x=1/40$, the still water shoreline is at $x=58\text{m}$, while two wave groups with $\sigma=0.2$ and $\sigma=1.0$ are considered. As mentioned above, the sum of a_1 and a_2 at the point of wave generation is constant which implies that the highest waves in each of the two wave groups are of equal size. Hence, we may expect that the outermost breakpoint position, $x_{B,outer}$ will be almost the same for the two wave groups, while the innermost breakpoint, $x_{B,inner}$ will be quite different as it is determined from the smallest waves in the wave group. This is confirmed by Figs 4a-b, which show the computed trajectories of

Fig. 4

Trajectories of surface rollers and shoreline motion.

Group frequency, $\Delta f=0.02$ hz. Bottom slope= $1/40$, $f_m=0.60$ hz, $f_1=f_m+\Delta f/2$, $f_2=f_m-\Delta f/2$; $a_1+a_2=0.080\text{m}$; a) Modulation rate, $a_2/a_1=1.0$ b) Modulation rate, $a_2/a_1=0.2$

the surface rollers and the shoreline motion for a group frequency $\Delta f = 0.02 \text{ Hz}$ in which case the group motion is resolved by 30 mean periods. We notice that $x_{B,outer}$ is practically identical for the two modulation rates, while $x_{B,inner}$ strongly depends on σ . The breakpoint excursion between these two limits is seen to be well resolved by the number of rollers being detected and traced. The almost sinusoidal time-variation of x_B for $\sigma = 0.2$ is significantly distorted as the modulation is increased to $\sigma = 1.0$, the reason being that $x_B(t_2) = x_{B,inner}$ is delayed relative to $x_B(t_1) = x_{B,outer}$ with half a group period *plus* the travelling time

Fig 5 Trajectories of surface rollers and shoreline motion.
 Group frequency, $\Delta f = 0.05 \text{ Hz}$. Otherwise as Fig 4.
 a) Modulation rate, $a_2/a_1 = 1.0$ b) Modulation rate, $a_2/a_1 = 0.2$

necessary for the lowest waves to cover the distance from $x_{B,outer}$ to $x_{B,inner}$. This delay was also discussed by Symonds et al. (1982). In Figs. 5a-b the group frequency is increased to $\Delta f=0.05\text{hz}$. Apparently, this leads to a small shoreward shift of $x_{B,outer}$ and a seaward shift of $x_{B,inner}$ leading to a minor reduction in the breakpoint excursion for both modulation rates. It turns out that this trend is amplified for increasing ratios of the group frequency to the mean frequency ($\Delta f/f_m$) and when this number is larger than say $1/3$ the effective excursion produced by the model almost vanishes.

The shoreline excursion in Figs 4 and 5 is seen to be dominated by low frequency motion while the individual bores almost vanish. The fully modulated case obviously results in the strongest motion, as would be expected from both second order theory for bound waves and from the theory of the generating mechanism due to breakpoint oscillations. The non-sinusoidal variation of the breakpoint position is also found in the breakpoint forcing and thereby in the surf beat motion. Thus, (in Figs 4a and 5a) the shape of the resulting shoreline motion indicates substantial energy on harmonics of the group frequency i.e. $2\Delta f$ etc.

The modulation of the wave groups changes slightly during the processes of shoaling and nonlinear interactions, but much more rapid variations can be expected in the surf zone. In numerical modelling this obviously depends on the type of breaker model applied and as an example the classical assumption of a saturated surf zone (with wave amplitudes proportional to the local water depth) leads to a vanishing modulation. Schäffer (1993), on the other hand, discussed the possibility of a reversion of modulation and such a reversion is indeed possible in the present model, because of the difference between the initial limiting breaker angle for non-breaking waves (20 deg) and the final breaker angle (10 deg) for waves already breaking.

Fig. 6 shows high-pass filtered timeseries of computed surface elevations at three locations for the case of $\sigma=0.2$ and $\Delta f=0.05$ hz. The high-pass filtering ($f > 2\Delta f$) makes it easier to spot the modulation of the primary waves without the influence of the low frequency motion. At $x=49$ m the highest waves have just started breaking and the modulation is similar to the input wave train. At $x=50.8$ m the former highest waves (indicated by I) have been reduced by breaking and are now approximately of the same size as the former lowest waves (indicated by II). Hence the modulation has almost vanished at this location. At $x=52$ m a relatively strong reversion of modulation has occurred and the former highest waves are now the lowest waves in the wave group. A similar trend can actually be observed in Mase's (1994) fully modulated experimental data. We can therefore conclude that the reversion is not just an artifact of the numerical model.

We shall now turn to an investigation of the surf beat sensitivity to group frequency, modulation rate and bottom slope. Emphasis is put on the amplitude of the resulting outgoing free long waves determined on the horizontal section seawards from the surf zone. Figs. 7 and 8 show the computed amplitudes versus the group frequency. In Fig. 7 the amplitude is shown for the bottom slope $h_x = 1/40$ and for the two modulation rates $\sigma = 0.2$ and 1.0 . Fig. 8 shows the amplitude for the case of full modulation ($\sigma=1.0$) and for the three bottom slopes

$h_x = 1/20, 1/30$ and $1/40$. The curves are seen to oscillate with the group frequency, a trend which is in qualitative agreement with the theory of Symonds et al. (1982), who showed the importance of the relative phase between the long waves reflected from the shoreline and the long waves directly generated in the seaward direction by the moving breakpoint mechanism. The computed values of Δf , for which minimum response occurs, are much larger than the values predicted by Symonds et al. This trend is, on the other hand, supported by Kostense's (1984) measurements as well as by Schäffer's (1993) analytical work.

Fig 6 Time series of computed high-pass filtered ($f > 2\Delta f$) surface elevations at three locations. $\Delta f = 0.05$ hz, $a_2/a_1 = 0.2$. Otherwise as Fig 4.

It is therefore likely that the deviation from the prediction of Symonds et al. is due to their omission of the incident bound long waves. Fig. 8 shows that the values of Δf , for which the amplitude of the outgoing long wave is minimum, increases for increasing values of the slope. The effect of the modulation rate is small. Fig. 7 shows that when σ is increased from 0.2 to 1.0 the local minima occur for slightly higher values of Δf .

From Figs 7 and 8 it is seen that the maximum amplitude of the outgoing free long wave increases significantly for increasing modulation rate while there only is a small increase of the amplitude for increasing values of the slope. The main reason for this trend can be related to the incoming bound long waves. Second order theory (valid on a horizontal bottom) predicts that the long waves bound to the incoming wave groups will be proportional to the product of a_1 and a_2 , which indicates a scaling of $\sigma/(1+\sigma)^2$ i.e. they will be almost twice as large with $\sigma=1.0$ as compared to $\sigma=0.2$. Another obvious trend is that the local maxima decrease for increasing group frequencies. This is connected with the overall decrease in thereflection from the shoreline. When $f_m/\Delta f$ is decreased one will expect that the individual rollers connected with the short waves will have a dissipative effect on the long waves. However, the numerical treatment at the shoreline can also be shown to be increasingly dissipative for higher group frequencies. Further investigation is needed in order to quantify the reliability of the numerical model in this regime. A more detailed discussion of these results is given by Madsen et al (1996).

Related and future research

This work is part of an extensive research effort at ICCH within the field of Boussinesq-type modelling. Concurrently with the present applications to strictly cross-shore motion, the investigation of situations in two horizontal dimensions as presented at the 24th ICCE (Sørensen et al. 1994) is continued. Improvements, e.g. with regard to the celerity of the surface roller as well as comparison with laboratory experiments on nearshore circulations are in progress. For applications in one as well as in two horizontal dimensions the main discrepancy between measurements and computation of e.g. the wave height variation appears to be the nonlinear shoaling close to the breakpoint rather than the following decay in the surf zone. This is one of the reasons for pursuing a higher order Boussinesq model as also presented at this conference (Madsen et al. 1996). In the near future the breaking model will be coupled with this higher order model. This will provide a tool for studying waves and current in a region extending from quite deep water and all the way to the shoreline. Related developments accounting explicitly for waves on ambient currents is also documented at this conference (Chen et al. 1996).

Acknowledgement

Many thanks are due to Dr. Hajime Mase from Kyoto University for making his raw experimental data for swash oscillations available to us.

This work has been financed by the Danish National Research Foundation and their support is greatly appreciated.

CHAPTER 93

A Boussinesq breaking wave model with vorticity

I. A. Svendsen, Ke Yu, and J. Veeramony¹

ABSTRACT: The paper describes a breaking wave model based on the classical assumptions for long, moderately nonlinear Boussinesq waves. It is shown that wave breaking can be described by accounting for the effect of vorticity generated by the breaking process. This leads to two additional terms in the momentum equation, both of which represent the enhancement of the momentum flux associated with the extra particle velocities found at and around the turbulent front of the breaking waves. In addition to the wave height decay and profile deformation predicted by earlier breaker models, the present model also provides information about particle velocity profiles including the undertow. Comparisons are made to measurements for these quantities. The similarities and differences between various breaker models are also examined and explained.

1. Introduction

The present paper presents a Boussinesq wave model that includes the effects of wave breaking in the equation of continuity and momentum.

The process of wave breaking has been widely studied during particularly the past two decades. For a long time, almost all detailed information came from experimental investigations but the success of the Boussinesq approach in modelling nearshore wave motion has also lead to Boussinesq models that, by various means, create the decrease in wave height and the transformation of the wave shape observed during breaking in the surf-zone on a gently sloping beach.

Since breaking involves strong energy dissipation, it was natural as a first approach to heuristically add a “dissipation term”, usually taking the form of the double derivative of the unknown variable to the momentum equation. Early examples are Zelt (1991), Karambas et al (1992) and more have followed. If the coefficient for the dissipation term is chosen carefully as in Wei et al (1995), such models can give breaker like wave development. The reason for this will be discussed later.

However, the Boussinesq wave models are developed from the fundamental equations of hydrodynamics. In the case of wave breaking this would mean the

¹Center for Applied Coastal Research, Ocean Engineering Lab, University of Delaware, Newark, DE 19716, USA. Correspondence e-mail: ias@coastal.udel.edu

Reynolds equations, in which the Reynolds stresses represent the only signature of the turbulence generated by breaking. Following the usual procedure, one finds (if the Reynolds stresses, as a reasonable approach, are modelled by means of an eddy viscosity) that the “dissipation term” of the assumed $\partial^2/\partial x^2$ -form originates from the turbulent normal stresses, which are small (see eg. Stive and Wind, 1982) and are very far from modelling the dramatic changes in the momentum flux typical of wave breaking.

An approach closer to meet that goal was used by Brocchini et al (1992) and, in more explicit form, by Schäffer et al (1992, 1993). They observed the importance the roller of a mature breaking wave has in enhancing the momentum flux of the wave. The roller essentially is the volume of recirculating water flow carried forward in the turbulent front at the speed c of the wave. The concept was first used by Svendsen (1984a,b) in the wave averaged equations to calculate wave height decay, set-up and undertow. The two above mentioned models essentially introduced that concept into the Boussinesq equations, and, though there are limitations, the results are remarkably convincing, as they should be because the models give an approximate representation of the actual physics. In addition, such models only represent a moderate extension of the computational work relative to Boussinesq models for non-breaking waves.

Because of the heuristically assumed form of the velocity profiles, these models cannot be expected to provide detailed information about the particle motion in the breaking wave motion, including the undertow. The model presented in the following is aiming at including such information by avoiding apriori assumptions about the velocity profiles. This means it is necessary to include in the model the vorticity generated by the breaking, which is an important feature of breaking waves: the motion is not irrotational as assumed in traditional Boussinesq theory.

The model is therefore formulated in terms of a stream function and the vorticity is an additional unknown which is determined separately by solving the vorticity transport equation. The model equations are outlined in section 2 and section 3 gives additional discussion about particularly the boundary conditions for the vorticity. In section 4 we show a comparison with measurements including particle velocities and undertow. The last section gives a comparison with previous models mentioned above which explains why all these models seem equally successful in predicting the wave height and wave profile development.

2. Outline of model equations

The governing equations are derived from the basic equations for conservation of mass and momentum. Only a brief outline is given here, for more details see Yu & Svendsen, 1995. We consider a breaking wave propagating over a gently sloping bottom topography of depth $h_0(x)$. Fig 1 shows the definitions of all geometrical quantities used. Then the depth integrated equations of continuity and momentum becomes

$$\frac{\partial \zeta}{\partial t} + \frac{\partial Q}{\partial x} = 0 \quad (1)$$

where

$$Q = \int_{-h_0}^{\zeta} u dz \quad (2)$$

Figure 1: Definition sketch showing the geometrical quantities.

and

$$\begin{aligned} \frac{\partial Q}{\partial t} + \frac{\partial}{\partial x} \int_{-h_0}^{\zeta} u^2 dz - (h_0 + \zeta) \frac{\partial \zeta}{\partial x} - \int_{-h_0}^{\zeta} \frac{\partial^3}{\partial x^2 \partial t} \int_z^{\zeta} \int_{-h_0}^z u dz dz dz \\ - \int_{-h_0}^{\zeta} \frac{\partial^2}{\partial x^2} \int_z^{\zeta} u \frac{\partial}{\partial x} \int_{-h_0}^z u dz dz dz + \frac{\tau_b - \tau_s}{\rho} = 0 \end{aligned} \quad (3)$$

where τ_b and τ_s are the bottom and surface stresses, respectively. In (3) the pressure term has been eliminated using the depth integrated vertical component of the momentum equation.

To evaluate the integrals in (3) the velocity u must be determined. In breaking waves the flow cannot be assumed irrotational. However the stream function ψ for the flow satisfies the equation

$$\nabla^2 \psi = \omega \quad (4)$$

where ω is the vorticity which must be determined separately. Equation (4) is solved by introducing the usual assumptions of Boussinesq wave theory that the water depth to wave length ratio μ and wave amplitude to water depth ratio δ are small and δ/μ^2 are $O(1)$. The stream function ψ can then be expanded in a power series

$$\psi = \sum_{n=0}^{\infty} (z + h_0)^n \psi_n(x, t) \quad (5)$$

Substituting this into (4) and solving it turns out to be convenient to distinguish between the rotational and the irrotational part of the solution. Hence for the velocity we define u_r and u_p respectively and find

$$u_p = u_0 - \mu^2 (z + h_0) (2h_x u_{0x} + h_{xx} u_0) - \frac{\mu^2}{2} (z + h_0)^2 u_{0xx} + O(\mu^4) \quad (6)$$

$$u_r = \int_{-h_0}^z \omega dz - \mu^2 \int_{-h_0}^z \int_{-h_0}^z \int_{-h_0}^z \omega_{xx} dz dz dz + O(\mu^4, \mu^2 h_x, u^2 h_{xx}) \quad (7)$$

Though ω is assumed large, the ω_{xx} terms in (7) turn out to contribute little to the solution. The u_r -terms represent the additional terms generated by the presence of vorticity. We further define the discharge Q_r as

$$Q_r = \int_{-h_0}^{\zeta} u_r dz \quad (8)$$

which implies that $Q = Q_p + Q_r$.

When these results are substituted into the integrals of (3) these integrals can be written

$$\int_{-h_0}^{\zeta} u^2 dz = \frac{Q^2}{d} + \Delta M \quad (9)$$

$$\int_{-h_0}^{\zeta} \frac{\partial^3}{\partial x^2 \partial t} \int_z^{\zeta} \int_{-h_0}^z u dz dz dz = \frac{h^3}{6} \left(\frac{Q}{h} \right)_{xxt} - \frac{h^2}{2} Q_{xxt} + \Delta P_{xxt} \quad (10)$$

where $d = h_0 + \zeta$ and again the ΔM and ΔP_{xxt} represent the contributions caused by the breaking. For ΔM and ΔP_{xxt} we get

$$\Delta M = \int_{-h_0}^{\zeta} u_r^2 dz - \frac{Q_r^2}{d} + O(\mu^4) \quad (11)$$

$$\Delta P = - \int_{-h}^{\bar{\zeta}} \int_z^{\bar{\zeta}} \int_{-h}^z u_r dz dz dz + \frac{(h + \bar{\zeta})^2}{3} Q_r + O(\delta, \mu^2, h_x) \quad (12)$$

The Boussinesq equations for the breaking waves therefore become

$$\zeta_t + Q_x = 0 \quad (13)$$

$$Q_t + g(h_0 + \zeta) \zeta_x + \left(\frac{Q^2}{h} \right)_x + \Delta M_x + \frac{h^3}{6} \left(\frac{Q}{h} \right)_{xxt} - \frac{h^2}{2} Q_{xxt} + \Delta P_{xxt} = 0 \quad (14)$$

The two unknowns in these equations are the surface variation ζ and the total instantaneous volume flux Q in the waves. The vorticity ω is determined from the vorticity transport equation, which to the same order of approximation as (14) reads

$$\omega_t = [\nu_t \omega_z]_z + O(\mu^2, \delta) \quad (15)$$

where ν_t is the eddy viscosity. This is solved using the boundary conditions

$$\omega(-h) = 0 \quad (16)$$

$$\omega(\bar{\zeta}) = \omega_s \quad (17)$$

Here ω_s is the maximum value of ω generated near the surface due to the wave breaking.

3. Discussion of boundary conditions for the vorticity

The bottom boundary condition of zero vorticity is consistent with the general neglect of the bottom friction in the model.

At the free surface we can expect that the vorticity will be zero along the part of the surface which is outside the roller area.

In the roller region, the free surface vorticity will also be near zero. However, strong vorticity is generated inside the recirculating roller flow. Measurements in that region of breaking are not yet available for surf-zone conditions, but measurements have been made in weak hydraulic jumps (see Lin & Rockwell, 1994). The flow patterns in all such jumps will of course differ somewhat from breaking waves, in particular far away from the turbulent roller region. Around the roller region, however, the flows in a hydraulic jump and a surf-zone wave are very similar indeed with the same local mechanisms dominating. Hence the measurements around the roller in a hydraulic jump can be expected to model the equivalent conditions in a surf-zone wave well.

There are a number of flow features that play an important role in assessing the vorticity in this region. Considering a vertical section through a point in the roller, one of the dominating features observed in such measurements is the increase in vorticity to a maximum which always occurs at or below the so called dividing streamline, which is the streamline limiting the roller. Above that streamline, the average flow recirculates, below it continues to the downstream. At the toe of the turbulent region, the dividing streamline joins the surface streamline ahead of the jump.

In this region, we can approximate the vorticity ω by

$$\omega \sim \frac{\partial u}{\partial z} \quad (18)$$

and hence we notice that

$$\nu_t \omega \sim \frac{\tau_{zx}}{\rho} \quad (19)$$

Hence the specification of ν_t and ω_s is equivalent to the specification of the shear stress at the lower edge of the dividing streamline used in some breaker models (see eg. Brocchini et al, 1991 or Schäffer et al, 1992). The advantage of the present method, however is that through the solution of the vorticity transport equation, it explicitly models the mechanisms for the effect such a shear stress has on the entire flow, a problem previous models do not address at all.

In spite of the limited knowledge we have about the value of ω and ν_t , there are some very specific bounds on how these parameters vary. One such bound is given by (19). Fig 2 shows an analysis of the maximum shear stress which occurs at or just below the dividing streamline in three different hydraulic jumps with Froude numbers $F = 1.28, 1.44,$ and 1.60 . Here l_r is the length of the roller. We see that in all three cases, $\tau/\rho u_0^2$ (where u_0 is the inflow velocity) varies the same way over the length of the roller.

Another set of bounds for ω near the surface are related to the flow conditions at the toe of the roller. As indicated in Fig 3 in the immediate neighborhood of the toe, the free surface and the dividing streamline can both be approximated by straight lines so that the roller height e in that region increases linearly with distance x_t from the toe ($x_t = x - x_{toe}$). Since the particle velocity in the wave

Figure 2: Variation of the maximum shear stress normalized by the square of the inflow mean velocity for three different hydraulic jumps with Froude numbers of 1.28 ('o'), 1.44 ('•') and 1.60 ('x').

Figure 3: Schematic diagram showing the distribution of vorticity and the approximation at the toe of the roller.

at the surface of the roller is $\sim c$ and at the dividing streamline is $u \ll c$ (where u is close to the velocity in the wave trough) the vorticity ω must vary as

$$\omega \approx \frac{c+u}{e} \quad (20)$$

For dynamic reasons, however, we must also have in that region

$$\tau \propto \rho g e \propto x_t \quad (21)$$

which according to (19) implies that near the toe

$$\nu_t \approx \frac{\tau}{\rho \omega} \propto e^2 \approx x_t^2 \quad (22)$$

Based on the geometry, combined with (19) and measurements of τ and e , we find that ν_t rapidly increases to a maximum value and then decays slowly to near zero before the next breaker arrives.

Based on this information we are able to construct a realistic variation of ν_t and ω_s . We have used

$$\omega_s = A \left(1 - \frac{x_t}{l_r}\right)^2 \quad 0 < x_t < l_r \quad (23)$$

where l_r is the horizontal length of the roller from the toe to the wave crest, which for dynamic reason must be the rear edge of the roller². For ν_t the relationship is

$$\nu_t = Ch \sqrt{ghe}^{-\beta x_t^2} \tanh^2(\alpha x_t) \quad (24)$$

Though the formulation used in the computations shown in the following are slightly more complicated, the expressions above are similar in effect to those used.

When the boundary condition (17) is applied at $z = \bar{\zeta}$ we get the ω variation shown in Fig 4. Between the $z = \bar{\zeta}$ and the instantaneous MWS it is assumed that ω varies linearly from ω_s to zero at the surface. The hydraulic jump measurements indicate that this is a good approximation to the actual variation.

4. Comparison with experiments

Examples of comparisons with experimental results are shown in the following. The experiments used were obtained by Okayasu and analyzed by Cox et al (1995). Waves were generated in the Precision Wave Tank (PWT) at the Center for Applied Coastal Research at a depth of 0.40m and propagated onto a 1 : 35 sloping beach. The measurements were taken at 6 different locations of which some were in the surf-zone. Because a laser-doppler velocimeter was used to measure the velocities, the measurements could only be taken up to a point slightly above the trough level of these waves. Inside the surf-zone, bubble entrainment due to breaking also restricted the measurements.

Figure 5 shows a picture of the model simulations of the waves in the tank at two fixed times. The full line shows the solution of (13) and (14), the dotted line shows the wave transformation without the breaker terms in the equations.

²The rapid fluctuations of the toe position imply that at the turbulent averaged mean position of the toe it has a small but finite thickness (Brocchini and Peregrine, 1996). This justifies the finite value of ω_s at the toe in (23)

Figure 4: The variation of $\omega(x, z)$ for a wave which has started breaking. Above the MWL, ω varies linearly from the value at the MWL to zero at the MWS.

A comparison with the measured and computed wave heights during the experiment is shown in Fig 6. This figure also shows the measuring positions of the experiment. It turns out that the increase in wave height due to shoaling is slightly underpredicted by the model. In the shown calculation, this has been adjusted for by increasing the input wave height at the left boundary so that the breaker height in this comparison is the same as the measurements. This makes the comparison of the model performance in the surf-zone more relevant.

The underprediction of the shoaling process turns out to be a common feature of the $\zeta - Q$ version of the Boussinesq equations used as the basic Boussinesq model. For comparison we find that if a Boussinesq model based on the depth averaged particle velocity is used, the shoaling is overpredicted slightly. The reason for these inaccuracies and for the difference between the two types of Boussinesq models is that they are both lowest order Boussinesq methods in which terms $O(\delta^2, \delta^3, \dots)$ have been omitted. When waves approach breaking, these terms become large enough to influence the solution. The difference between the two model versions appear because the neglected higher-order terms are different in the two versions. Hence, these deficiencies can be eliminated by use of a higher order Boussinesq model (see Wei et al, 1995).

Figure 7 shows a comparison between measured and computed velocity profiles at position L5 which is well into the surf-zone. We see that the agreement is generally acceptable, though it is evident that the lack of measurements near the wave crest makes this comparison less valuable.

Figure 5: Model simulation of the waves at two different times, illustrating the difference between the non-breaking model (-) and the breaking model (—).

Figure 6: Comparison between the measured wave heights ('o') and the computed wave heights (—) for the experiment described in Cox et al (1995).

Figure 7: Vertical variations at L5 of: (B) u/c (Solid - Model, Circle - Data), (C) u_p/c , (D) u_r/c and (E) $\omega/(c/h)$ at different phases marked on (A) the surface elevation (solid - Model results, dashed - Data). $t_0 = 7.773 T$.

Since the effects of turbulence generated by the breaking is included in the model predictions, the average velocity over a wave period should also predict the undertow profiles, which represent a balance in which the shear stresses play a role. Figure 8 shows a comparison between the computed and measured undertow velocities at the 6 measurement positions. Again the agreement is quite good. It is interesting to notice that both measurements and model predictions pick up the principal difference between the undertow under non-breaking waves (parts (A) and (B) in the figure) and breaking waves (parts C-F). Since we have neglected the bottom shear stress, the model predicts a slip velocity at the bottom. It is clear that in the measurements, the effect of the bottom boundary layer is also limited to very close to the bottom.

5. Discussion and comparison with other models

In (13) and (14) the breaker terms are relatively small and it is of interest to see how the strong process of breaking can be properly modelled by adding such seemingly weak modifications.

When solving (13) and (14) the values obtained for Q are actually changed quite substantially. To see this we note that over most of the surf-zone the waves are only changing very slowly. Hence for a given value of ζ we have

$$Q \approx c\zeta \quad (25)$$

which is valid for waves of permanent form with no net mass flux, whether the waves are breaking or not. Therefore, when the wave shape ζ is modified due to

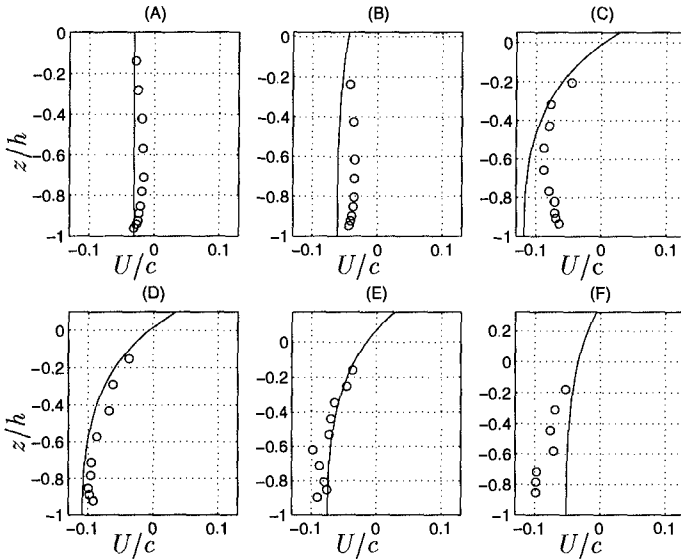

Figure 8: Nondimensional undertow profiles at L1 (A), L2 (B), L3 (C), L4 (D), L5 (E) and L6 (F). (solid) - Model results. (circle) - Data.

the breaking, so is Q .

Even more pronounced is the change in velocity profiles caused by the breaking process. Since Q_r represents a substantial increase in volume flux which is mainly concentrated near the surface it appears that for a given Q the velocity near the bottom must be similarly reduced. This is probably the most significant effect the wave breaking has on the bottom conditions and as the above arguments illustrate, it occurs for simple kinematic reasons³.

It is also illustrative to examine why several, seemingly quite different, Boussinesq models for breaking waves appear to be comparably good at predicting the wave height decay and surface profile development of breaking waves. In particular, three models show the reduction in wave height and change in skewness of the wave profile towards a sawtooth shape that are typical features of mature surf-zone breakers. The three models in question are the model by Wei & Kirby (1995) which is based on a dissipative term with an eddy viscosity, the model by Schäffer et al (1992) in which the breaking effect is generated by including a surface roller in the model and the present model in which breaking is modelled by taking into account the rotational part of the water motion.

To understand why three so different approaches apparently produce similar effects on the wave profiles, we only need to realize that in the Boussinesq

³Another effect of the breaking is the change in the wave profile shape and hence the temporal variation of the pressure gradient and velocities. A third is the added turbulence level even at the bottom.

momentum equation the three models produce almost identical signature of the breaking: the present model and Schäffer et al's model both include two and one terms, respectively, that represent enhancement of the momentum flux. In both models, the (x, t) variation of these terms are approximately the same as shown in Fig 9 (a) and (b). It turns out that, in particular, the position of this momentum enhancement relative to the wave crest is crucial for obtaining the breaking effect. It furthermore appears that in the Wei & Kirby model, the variation of the eddy viscosity has, on a heuristic basis, been chosen so that the "dissipative-term" it creates, in spite of its lack of physical justification, gives an almost identical contribution to the momentum equation. In other words: the Boussinesq equations respond equally to terms that represent the appropriate momentum enhancement, no matter which method are used to determine their variation and magnitude.

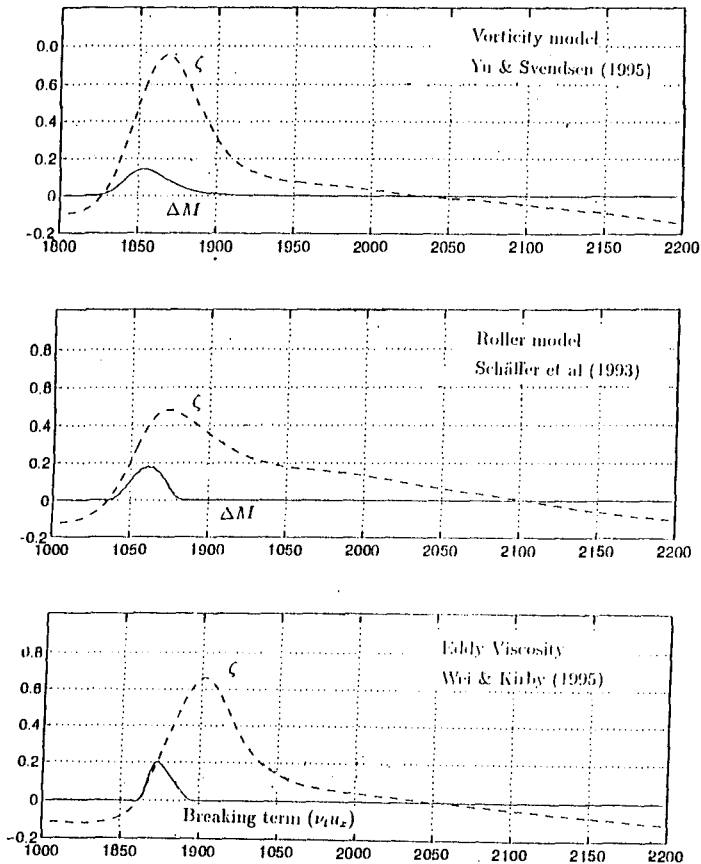

Figure 9: The variation of the terms in the momentum equation which induces breaking, for the three different models discussed in section 5.

6. Conclusions.

The Boussinesq model represents breaking by including the vorticity generated by the breaking. This gives rise to additional terms in the momentum equation which represent the enhanced momentum flux associated with the very large particle velocities at and near the turbulent front of the breaker. The model is based entirely on the Reynold's equations and no artificial dissipation terms are included. It also predicts particle velocities including undertow quite accurately.

CHAPTER 94

ROLLER CONTRIBUTIONS AS INFERRED FROM INVERSE MODELLING TECHNIQUES

¹D.J.R. Walstra, G.P. Mocke, F. Smit

Environmentek, CSIR, PO Box 320, Stellenbosch 7600, South Africa

ABSTRACT

Two independent approaches are discussed whereby inverse modelling is employed as a means of better quantifying roller contributions in the near shore. A so-called integral approach utilizes a coupling between the extended wave energy and momentum balance equations to make inferences regarding roller properties based on wave height and set up measurements. In a somewhat more indirect inverse modelling approach, as first discussed in Mocke et al. (1994), the roller properties are obtained from predicted vertical distributions of internal flow properties such as turbulent kinetic energy, suspended sediment concentrations and undertow velocities which are optimally fitted against measured profiles. An intercomparison between the two approaches is made to get an indication of the validity of the applied theories and inverse modelling techniques. The integral approach further serves to evaluate a new conceptual model for dissipation due to wave breaking

1. INTRODUCTION

Nearshore circulation modelling in wave-dominated environments requires accurate quantification of both wave height and mean water levels across the surf zone. Although attempts at modelling wave height have been relatively successful (Battjes and Janssen, 1978) little progress has been achieved in arriving at a reliable prediction of mean water levels across the surf zone. This is particularly the case for the so-called transition zone immediately following breaking, an area characterized by significant wave height decay whereas the water level remains more or less constant. The observation (Nadaoka and Kondoh, 1982) that the seawards directed return flow or undertow, the primary mechanism for cross-shore sediment transport, attains maximum strength some distance landwards of the breakpoint reinforces the necessity to better quantify this lag effect.

¹ Present address: Delft Hydraulics, P O Box 177, 2600 MH Delft, The Netherlands.

Svendsen(1984) incorporated additional contributions of mass and momentum to account for the presence of the aerated water body or “roller” at the water surface in the surf zone. It was however only with later models such as those of Roelvink and Stive(1989) and Nairn et al(1990) that attempts were made to model the extent of the transition zone and the spatial evolution of the roller. These models incorporated a lag between the production and dissipation of turbulent kinetic energy (TKE) arising from the breaking process. More recently, Dally and Brown(1995) propose an empirical roller model wherein the transition zone arises from the interval in time required for roller creation.

2. INVERSE MODELLING APPROACHES

2.1 System of Equations

Integral Properties

The wave energy balance according to Battjes and Janssen (1978) is used to describe the wave height distribution across the surf zone. Only waves travelling perpendicular towards the coast are considered. The wave energy balance is written as:

$$\frac{\partial F_x}{\partial x} = -D_w \quad (1)$$

Where F_x is the onshore energy flux per unit width and D_w is the time averaged energy dissipation in a breaking wave (LeMehaute, 1962).

With the assumption that breaking waves are modelled as bores travelling towards the coast with the wave celerity (c). Nairn et al. (1990) propose the following equation:

$$\frac{\partial E_w c_g}{\partial x} + \frac{\partial E_R c}{\partial x} + \tau_s c = 0 \quad (2)$$

where E_R denotes the kinetic energy of the roller and τ_s is the shearstress in the nearsurface. The result given in Deigaard and Fredsoe (1989) that the dissipation originates from the work done by the shear stress due to the roller acting on the fluid right below it is included in the third term of Equation 2 (i.e. $D_R = \tau_s c$).

The properties of the roller are described according to Svendsen (1984):

$$E_R = \frac{\frac{1}{2} m_r c^2}{L} = \rho A \frac{c^2}{2L} = \frac{\rho A c}{2T} \quad (3)$$

For the derivation of the dissipation in the roller, D_R , the findings of Deigaard and Fredsoe (1989) are used again to relate the shear stress exerted by the roller onto the underlying wave to this dissipation. The shear stress is derived under the assumption that the position of the roller does not change relative to the underlying wave. This implies that the shear stress induced by the roller should balance the downward force exerted on the roller due to gravity. D_R is then written as:

$$D_R = \tau_s c = \beta \rho g \frac{A}{L} c = \beta \rho g \frac{A}{T} \tag{4}$$

In which A is the cross-sectional area of the roller, T is the wave period, β is the slope of the wave front, and L is the wave length.

Incorporating a contribution due to the wave roller the time averaged momentum equation reads:

$$\left(2 \frac{c_g}{c} - \frac{1}{2} \right) \frac{\partial E_w}{\partial x} + M_r + \rho g h \frac{\partial \eta}{\partial x} = 0 \tag{5}$$

De Vriend and Kitou (1990) presented an analysis in which for the case of spatially varying waves on a sloping bottom the orbital velocity moments were derived. Based on these results Stive and De Vriend (1994) derived an expression for the vertical shear stress distribution in case of a sloping bottom and wave breaking dissipation. At the water surface this expression reads:

$$\tau_t = -\frac{1}{c} \frac{\partial E_w c_g}{\partial x} - M_R \tag{6}$$

The second term on the right-hand side has to be interpreted as the time averaged gradient of momentum in the roller. Using the roller concept (Equations 3 and 4) M_R can be written in terms of the kinetic energy of the roller which yields:

$$M_R = 2 \frac{\partial E_R}{\partial x} \tag{7}$$

By inserting Equation 7 into Equation 6 the energy balance obtained from the momentum balance results:

$$\frac{\partial E_w c_g}{\partial x} + 2 \frac{\partial E_R c}{\partial x} + \tau_s c = 0 \tag{8}$$

The wave celerity c has been included in the gradient of the energy flux of the roller, which is acceptable if it is assumed that the spatial variations in wave celerity are small relative to those in E_R .

Comparing Equations 8 and 2 an apparent inconsistency is visible; there is a factor 2 difference in the term in which E_R appears. This inconsistency was clarified by Deigaard (1993), as discussed in Stive and De Vriend (1994). Deigaard (1993) found that the inconsistency arises from the complicated situation that occurs when the volume of the roller is changing in the wave propagation direction. Besides the shear layer between the roller and the wave there is a net transfer of water from the wave to the roller as the volume of the roller increases, and vice versa if the volume of the roller decreases. This implies that an additional momentum exchange between the roller and the underlying wave is present. The corrections that these considerations give to the shear stress and to the energy balance remove the inconsistency resulting

in an energy balance with the factor 2 included.

Flow Properties

According to 2DV momentum balance considerations, equilibrium between the depth-integrated wave induced momentum flux (i.e. the radiation stress and the set-up gradient) yields a depth-mean zero flow. However, due to the fact that mass and momentum fluxes need not be in balance at any point through the depth a secondary return flow known as the undertow may result.

The undertow equation, which follows from a combination of the local and horizontal momentum balances, has the form (assuming a wave-averaged eddy viscosity for approximation of the Reynolds stresses):

$$\frac{\partial}{\partial z} \left(\nu_t \frac{\partial U}{\partial z} \right) = \frac{\partial}{\partial x} (\overline{u^2} - \overline{w^2}) + \frac{\partial}{\partial x} g\overline{\eta}_x + \frac{\partial}{\partial z} (\overline{uw}) \quad (11)$$

where U is the wave-averaged return flow or undertow, η_x is the mean water level set-up, and u and w are the horizontal and vertical wave-orbital velocities.

For the considered wave-averaged situation the above equation is presumed to be valid from the bottom boundary to the vicinity of the surface.

As discussed by Stive and De Vriend (1994), wave averaged shear stresses are solely due to wave amplitude variations associated with shoaling, and dissipation due to boundary layer shear and/or breaking waves. From a quantification of the wave-related terms, the depth variation of eddy viscosity, the mean mass flux above wave trough level and the shear stress at mean water level may be resolved the undertow variation over depth.

The roller effects of the near surface layer (NSL) are manifested through a shear stress τ_s acting at the mean water level. Hence the upper boundary condition corresponds to:

$$\nu_t \frac{\partial U}{\partial z} = \frac{\tau_s}{\rho} \text{ at } z = z_s \quad (12)$$

A no slip condition applies at the bottom boundary:

$$U = 0 \text{ at } z = 0 \quad (13)$$

According to mass balance considerations the total mass flux (M) in the lower layers balances that in the NSL, from which can be derived the set-up gradient. The assumption is made that the wave terms (orbital velocity movements) can be derived independently from the mean flow. Based on a derivation by Bijker (1974), Stive and De Vriend (1994) proposed approximations for the time-averaged values of the wave terms defined in Equation 11. These are incorporated in the present model. For the determination of the depth dependant eddy viscosity (ν_t) use is made of a two

equation (k - ϵ) turbulence model wherein the dissipation due to wave breaking is the primary forcing term (Mocke and Smith, 1992).

The time-mean vertical distribution of suspended sediment is described by the classical equation describing a balance between an upward flux due to eddy-diffusion and a downward settling component:

$$0 = D_c \frac{\partial C}{\partial z} + w_s C \tag{14}$$

where C is the suspended sediment concentration, w_s the sediment fall velocity and D_c the sediment diffusion or mixing coefficient. The diffusion coefficient is generally assumed proportional to the eddy viscosity.

2.2 Inverse Modelling Procedures

Integral Properties

The inverse modelling procedure using integral properties is illustrated in the flow chart shown in Figure 1. The initial step entails use of the extended momentum equation (Equation 6). Since the wave height and set up are known from measurements the term M_R can be determined directly (inverse model results have a subscript “inv”, and the measured results are extended with the subscript “meas”):

$$M_{R_{inv}} = -\rho g \left(\left(\frac{1}{4} \frac{c_g}{c} - \frac{1}{16} \right) \frac{\partial H_{meas}^2}{\partial x} + h_{meas} \frac{\partial \eta_{meas}}{\partial x} \right) \tag{13}$$

Integrating Equation 8 results in the kinetic energy present in the roller:

$$E_{R_{inv}}(x) = \frac{1}{2} \int_{x=x_b}^x M_{R_{inv}} dx + E_{R_{inv}}(x=x_b) \tag{14}$$

in which the second term on the right hand-side is zero by definition.

The dissipation in the roller, D_R , can be calculated from the energy balance in which the term $M_{R_{inv}}$ obtained from the momentum equation is used to determine the gradient of the energy flux in the roller:

$$D_{R_{inv}} = -\frac{1}{8} \rho g \frac{\partial (H_{meas}^2 c_g)}{\partial x} - c M_{R_{inv}} \tag{15}$$

Note the fact that in the equation above the assumption that the spatial variations of c are small compared to those of $E_{R_{inv}}$ is used.

With the inverse model it is now possible to determine the dissipation in the roller D_R directly from the momentum equation. The only assumption that has to be made is Equation 7 which gives the connection between the momentum and energy balance. The assumption that the spatial variation of the wave celerity can be neglected

compared to the variation of the energy in the roller is not expected to influence the results dramatically.

Having determined E_r using the momentum equation and D_r using the wave energy balance, an inverse modelled β can be found applying the roller approach

according to Svendsen (1984):

$$\beta = \frac{D_r c}{2gE_r} \tag{16}$$

A number of studies have concluded that a constant value of 0.1 gives the best set up results (e.g. Roelvink, 1993).

Following a spline smoothing interpolation of wave height and set up measurements, the procedure outlined above is followed and the cross shore distribution of E_r , D_r , and β are calculated.

Flow Properties

As the most readily available and reliable set of flow measurements, the inverse modelling analysis is carried out principally on undertow data. Limited investigation has however also been carried out using TKE and sediment concentration measurements. The analysis procedure for undertow measurements is illustrated in the flowchart shown in Figure 2. A first estimate of D_r is made using the transition zone model of Nairn et al(1990), however the exercise could also conceivably start with D_w as a first estimate of D_r . With D_r and the wave induced mass flux the independant variables, an optimal combination having least rms error between measured and computed velocities is determined.

The analysis procedures for TKE and concentrations is somewhat simpler in that the sole variable is D_r , the source of TKE production at the surface boundary.

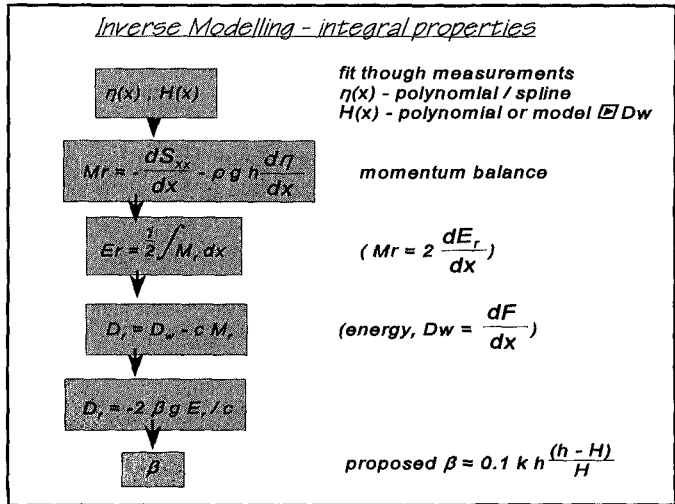

Figure 1 Inverse modelling procedure

3. RESULTS

Integral Properties

Presented in Figure 3 is a step-by-step illustration of an application of the inverse integral modelling approach. Depicted in Figures 3(a) and (b) are measured wave heights(H) and mean water levels(η) for test 1 of Stive(1983). This case corresponds to a monochromatic spilling type wave ($Ho=0.16m, T=1.8s$) with breaking induced on a plane 1:40 beach slope. Using a polynomial fitting procedure a continuous representation of the cross-shore distribution of wave heights and mean water levels is obtained.

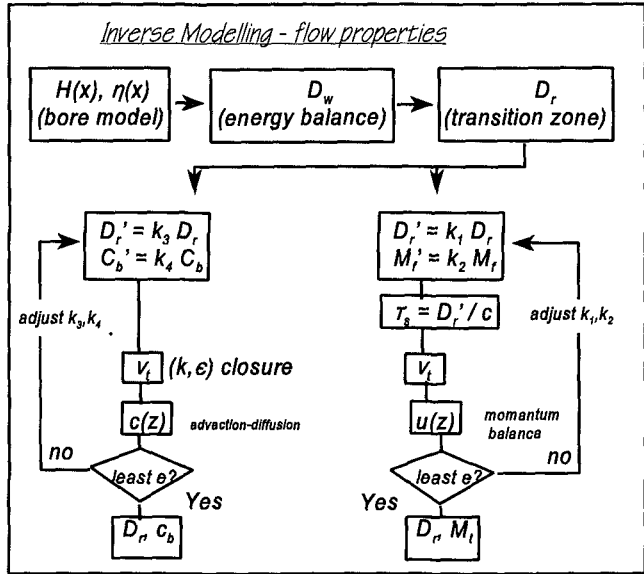

Figure 2 Analysis procedure for undertow measurements

The corresponding cross-shore distribution of wave energy dissipation(D_w), calculated from Equation 1 using linear, 2nd order cnoidal and covocoidal theory, is shown in Figure 3(c).These distributions demonstrate a prominent peak in D_w , immediately following the break point, reflecting the observed rapid attenuation in wave height after breaking.

The fitted wave heights are subsequently used to compute the radiation stress distribution. As illustrated in Figure 3(d) these estimates are highly dependant on the wave theory employed. Also plotted in this figure are measurements of radiation stress made by Stive (1983). The generally accepted tendency for linear theory to significantly overestimate radiation stress in the vicinity of the breaking point is clearly demonstrated. It may further be remarked that although the covocoidal theory provides improved estimates in this region, linear theory is in close correspondence with radiation stress measurements made in the inner surf zone.

Figure 3(e) presents the results of the following step, whereby the cross-shore radiation stress and mean water level distributions are introduced in Equation 16 to solve for M_{riv} . In much the same manner as for D_w , the M_r distribution demonstrates a prominent peak immediately post-breaking. This is consistent with a transfer of momentum to this roller storage term through the initial transition zone. M_r

subsequently attains negative magnitudes in the inner surf zone where excess momentum is transferred from the roller into the underlying flow.

The roller energy E_r distribution is obtained from M_r , using Equation 17. As depicted in Figure 3(f) this parameter has a peak significantly shorewards of the breaking point. This feature is consistent with physical reality, whereby the wave roller is only fully established at the limit of the transition zone.

Using Equation 18 the wave roller dissipation can subsequently be obtained from energy balance. As illustrated in Figure 3(g) this parameter shows a landwards shift in peak value as had been observed for E_r . The D_r distribution can further be seen to be very much different from that previously found for D_w .

From Equation 19 relating D_r to the roller geometry and E_r , the cross-shore distribution of the roller slope may be resolved. For the case under consideration it may be seen from Figure 3(h) that a constant value of the order 0.1 as proposed by Nairn et

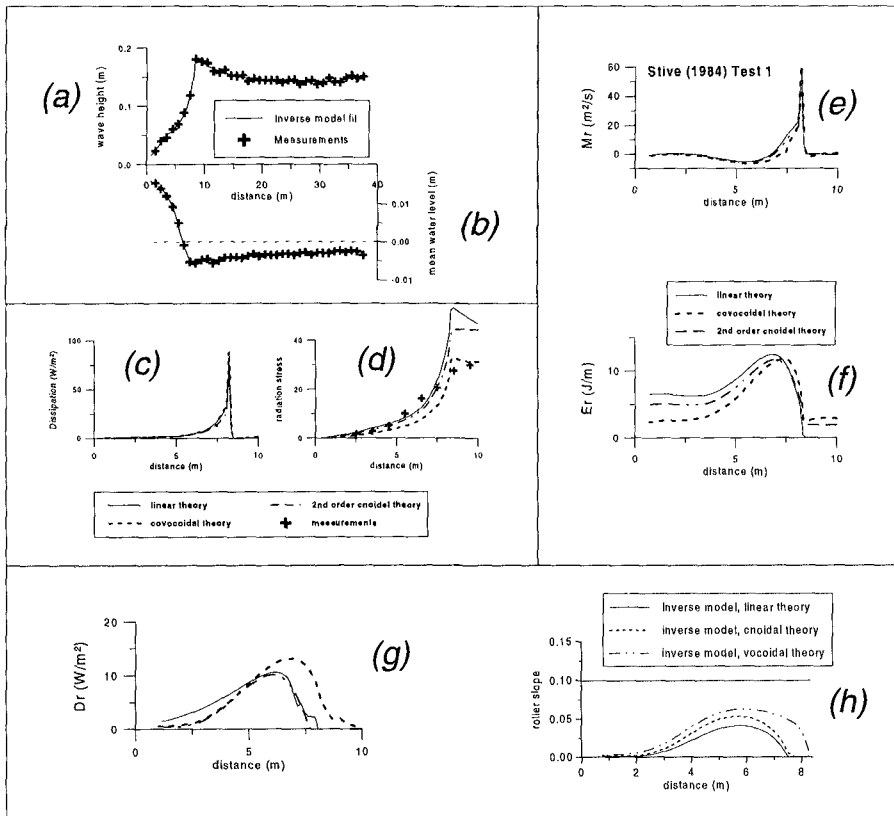

Figure 3 Step-by-step illustration of an application of the inverse integral modelling approach

al(1990) is inappropriate.

For the case of random waves principal reference is made to the LIP11D measurements made in the large scale Delta Flume. For a description of these tests reference should be made to Arcilla et al(1993).

In Figure 4 is shown the fitted H_{rms} and η distributions for measurements made mid-way through test 1A. For the H_{rms} measurements a Battjes and Janssen(1978) type bore model is run until an optimal fit is obtained whilst a spline curve is used for the water level. Using a similar procedure to that described previously for the monochromatic wave case, Figure 5 shows the constituent terms of the momentum balance equation. An initial increase in M_r , coincident with increased wave breaking, is followed by rapid decrease to negative values as both the radiation stress and set-up term increase. Figure 6 depicts cross-shore distributions of D_w and D_r , under linear and cocircular wave theories, for the same case. Although the two wave theories result in very different D_w distributions the inverse modelled D_r distributions are in reasonably good accordance. Although linear theory does not attain the same peak value at around $X=148m$ both theories show a distinct landwards shift from the D_w distribution.

Figure 4 Fitted H_{rms} and eta distributions for measurements of LIP test 1A.

Figure 5 Constituent terms of the momentum balance equation

Model sensitivity

The sensitivity of the inverse modelling procedure to measured mean water levels is illustrated in Figure 7. Depicted in Figure 7(a) are spline fits of the mean water level as recorded on four occasions during Test 1A. Figure 7(b) shows the corresponding D_r distributions for each of the 4 measuring instances. Although water levels do not change by more than about 1cm there are distinct differences between the modelled D_r distributions. This is particularly the case for the situation after 7 hours where a dip in the water level near $X=120m$ results in a D_r peak not evident for other times. On the whole however the principal features of the cross-shore distribution of D_r appear to be consistent.

Slope of wavefront

A principle finding is that β is not constant for all the investigated theories. A new β will be defined which is derived for linear wave theory. The old definition of β being the slope of the wave front is extended with an additional factor that takes the internal dissipation of roller energy into account. Attention is primarily focussed on predicting β in the area where the external roller dissipation is non-zero or relatively large for respectively mono-chromatic and random waves.

Figure 6 Cross-shore distributions of D_w and D_r under linear and covocoidal wave theories for Lip Test 1A

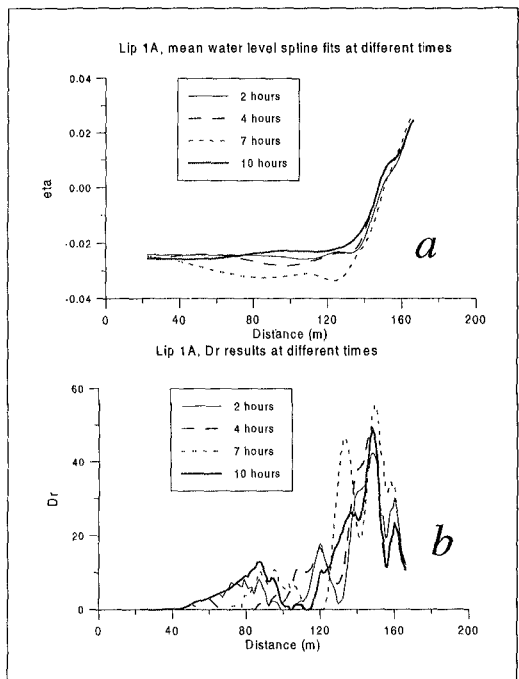

Figure 7 Sensitivity of the inverse modelling procedure to measured mean water levels

An extensive statistical analysis of waveflume experiments (Stive, 1983, Buhr Hansen and Svendsen, 1984, Arcilla et al, 1993) resulted in the following expression for β :

$$\beta = 0.1kh \frac{h - H}{H} \wedge < 0.1 \tag{17}$$

in which k is the wave number, H is the wave height, and h is the water depth.

In Figure 8a the inverse β and the approximation given by Equation 20 are compared for the Stive tests. It is clear from all tests that the proposed simple expression does give a surprising good result. Although β should be zero pre-breaking it also shown for that region so as to indicate the performance of the suggested expression. Even the location at which the dissipation of kinetic energy is initiated is well approximated for most of the tests as the minimum value of the proposed expression for β gives a reasonably accurate indication of this position. Figure 8b the performance of the proposed expression for beta is shown for a number of sets from LIP11D test 2B. Although the variation of the inverse modelled beta are considerable a distinct trend is visible which is represented reasonably by the proposed expression for beta.

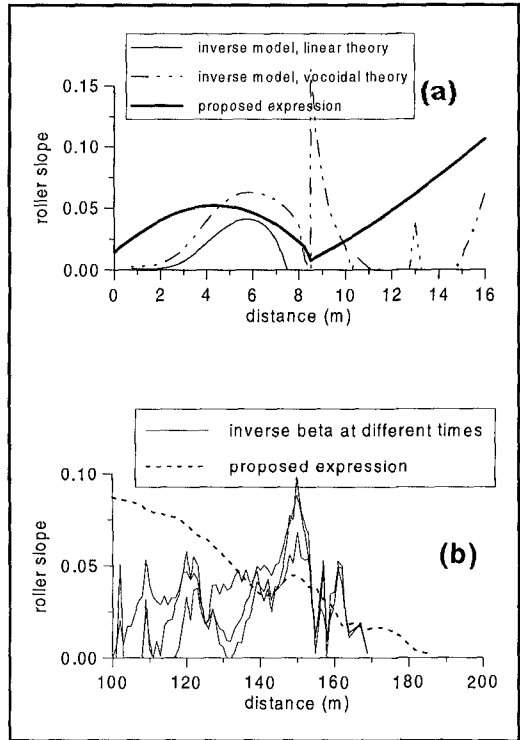

Figure 8 Inverse roller slope and slope expression for (a) Stive test 1 and (b) LIP 1A

Flow Properties

The predicted vertical distributions of TKE shown in Figure 8 are obtained by adjusting Dr so as to minimize the rms error between measurements and predictions. Although the model tends to demonstrate slightly more vertical variability than the measurements of Stive(1983) it is likely that the measurements in the upper part of the water column have been contaminated somewhat due to aeration associated with the breaking process.

Figure 9 depicts the optimal undertow fit for the same test case of Stive(1983). In this inverse modelling procedure both D_r and the wave induced mass flux contribution are adjusted independantly until the rms error is minimized. The precision of this exercise is limited however by the existence of measurements over only part of the depth.

Figure 9 Predicted vertical distributions of TKE for Stive Case 1

As can be seen in Figure 10 the optimal correspondance between measurements and predictions for the LIP11D cases was in most cases very good, with rms errors generally less than 5%.

Intercomparisons

The inverse modelled D_r distributions using the integral approach have been found to differ markedly from those for D_w . Figure 11 compares estimates of D_r as determined by the integral approach and the inverse fits of TKE and undertow measurements for Stive Test 1.

Figure 10 Optimal undertow fit for the Stive case 1

Both inverse approaches show a similar cross-shore distribution and suggest a peak in D_r some 3m landwards of the break point. As previously observed this lag has important implications for localizing the point of maxima for cross-shore and longshore currents and sediment suspension and transport.

Figure 12 compares Dw and inverse modelled Dr distributions for LIP(t=7hrs) case 1A. In general the independent inverse modelling approaches are in good correspondence, with a noticeable landwards shift in the position of Dr peaks relative to Dw. For the cases under consideration such shifts are far from negligible, generally exceeding 10m. Also plotted in Figure 12 are the predicted Dr distributions using both a constant and variable beta value. Although these distributions are in generally close accord to that found by inverse modelling, the lag effect is somewhat underestimated.

Figure 12 Estimates of Dr for Stive Test 1

Figure 11 Comparison between Dw and inverse modelled Dr distributions for LIP(t=7hrs) case 1A

4. CONCLUSIONS

Due to the good agreement between both inverse modelling techniques a strong indication of the validity of both approaches and applied theories is obtained. The two independent inverse modelling techniques clearly indicate a landward shift of the maximum roller energy dissipation compared to the wave dissipation. This suggests that the apparent landwards shift for maxima of TKE, undertow and suspended sediment concentrations and consequently cross-shore and longshore sediment transport rates can only be obtained by accurately predicting the cross-shore distribution of wave heights and especially the mean waterlevel. Although the integral approach is sensitive to the accuracy of wave and water level measurements it can provide continuous cross-shore distributions of roller properties. Recent experiments

provide additional types of data such as the measurement of the roller slope (e.g. Boers, 1996) which can be used to verify the roller expressions proposed by Svendsen (e.g. area of the roller and slope of wave front) and improve the proposed expression for beta.

CHAPTER 95

Wave-Current Interaction in Inlets

Michael J. Briggs¹, Zeki Demirbilek¹, and Debra R. Green²

ABSTRACT

Laboratory experiments were conducted in a flume to study wave-current interaction at the entrance to an inlet. Regular and irregular waves were studied with and without ebb and flood currents. These data are being used to develop a parameterization of the wave breaking criterion in the presence of currents in inlets, provide guidance to the field on the effects of currents on waves, and improve the predictive capability of numerical models for enhancing navigation in inlets.

INTRODUCTION

The coastal zone involves interactions between winds, waves, currents, structures and sediment. To develop a sound coastal management plan for shoreline stabilization and protection near inlets and improve navigation safety, it is essential to have a better understanding of the complicated physics which occur between waves and currents in coastal waters. In the vicinity of tidal inlets and river mouths, currents can significantly modify wave amplitudes, form, and directions. Although wave-current interaction has been studied extensively, little design guidance exists for its effect on wave breaking.

In 1993 the U.S. Army Engineer Waterways Experiment Station's Coastal Engineering Research Center began a large research program entitled the Coastal Inlets Research Program (CIRP). One of the goals of this program is to better understand wave-current interaction in the vicinity of coastal inlets and to develop a wave model that will be an integral part of an Inlet Modeling System (IMS) for numerically modeling waves, currents, and sediment transport over relatively short temporal and spatial scales. Part of this effort involves conducting laboratory studies of wave-current interaction to develop an empirical wave

breaking criterion for waves in the presence of ebb and flood currents.

This paper presents an overview of a CIRP flume experiments and results from an initial analysis of some of the ebb current data. The first section gives a brief summary of some previous flume and basin experiments involving wave-current interaction. The next section gives a comprehensive description of the flume experiments including model setup, wavemaker, current system, instrumentation, and experimental program. The final section presents and discusses some of the preliminary analyses of the flume data for eight representative, wave-ebb current cases.

BACKGROUND

Sakai and Saeki (1984) measured the effect of opposing currents on wave height transformation over a 1:30 sloping beach for a range of wave periods and steepness. They found an increase in wave height and decay rate in the presence of the opposing current. Lai et al. (1989) conducted flume experiments on the kinematics of wave-current interactions for strong interactions with waves propagating with and against a current. They found the influence of the waves on the mean current profiles was small, although opposing waves would give a slightly lower current. They also observed a drastic change in the spectral shape, especially the higher harmonics, following wave breaking in the presence of opposing currents. Their experiments confirmed that blockage of waves by a current (when the wave group velocity equals the opposing current velocity) occurs when the ratio of depth-averaged current velocity to wave celerity without currents approaches 0.25.

Yucheng et al. (1991) and Yucheng and Guohai (1993) noted that breaker indices for finite water depth for regular and irregular waves in the presence of opposing currents can be classified by geometric, kinematic, and dynamic criteria. Typical geometric stability criteria include McCowan's critical crest angle $\beta = 120$ deg, Longuet-Higgin's limiting wave surface slope of about 30.4 deg, McCowan's wave breaking index $\kappa = 0.78$, Miche's limiting wave steepness value $H_b/L_b = 0.142 \tanh kh$, and Goda's limiting relative wave height H_b/h_b as a function of relative water depth h/L_0 and bottom slope m . The kinematic stability parameter is based on the concept that the horizontal water particle velocity u is equal to the wave celerity C at breaking. The dynamic stability criterion relates the vertical acceleration of the water particles in the crest at breaking to a limiting value. They found that the two geometric criteria of limiting wave steepness H_b/L_b and limiting relative wave height H_b/h_b are consistent and stable with values of $H_b/L_b = 0.129$ for irregular spilling breakers with and without currents on a gentle slope.

Briggs and Liu (1993) conducted laboratory experiments of the interaction of ebb currents with regular waves on a 1:30 beach and entrance channel. Good agreement was obtained between these data and numerical model predictions. They found little effect on wave period, but significant increases in wave height and nonlinearity. Raichlen (1993) conducted a laboratory investigation on the propagation of regular waves on an adverse three-dimensional jet. He found increases in incident wave height by a factor of two or more for ebb current to wave celerity (i.e., U/C) values as small as 10 percent.

Suh et al. (1994) developed an equation for the equilibrium-range spectrum of waves propagating on an opposing current in finite depth water. Comparison with experimental data agreed reasonably well with the change in high-frequency energy in the wave spectrum.

Klopman (1994) conducted a series of flume experiments to study flow kinematics of regular and irregular waves in the presence of ebb and flood currents. He found that waves opposing the current increase the horizontal velocity in the upper half of the water column and that this change depends mainly on wave energy and less on the shape of the wave spectrum.

EXPERIMENTAL DESIGN

Model Setup

A 1.5-m-wide, 1.5-m-deep, 64-m-long flume (Figure 1) was used to simulate a three-dimensional flow environment by partitioning the down-wave end of the flume with a temporary vertical wall into an 18-cm-wide, 7.2-m-long channel. Turbulence (due to the ebb currents transitioning from the full width of the flume into the narrower channel) was minimized by a 2.8-m-long, convex-shaped transition zone on the landward side of the channel. Water depth in the flat-bottomed flume was 50 cm. A 14.6-m-long glass window allowed observation in the study area.

The x-axis extended longitudinally down the centerline of the channel from the seaward end of the partition wall or channel entrance at $x=0$. The y-axis origin was at the channel centerline and extended laterally towards the wide part of the flume.

Figure 1. Layout of wave-current flume.

Wavemaker

The hydraulic wavemaker was located 39.6 m from the origin at the channel entrance. It has an 86 cm maximum stroke and is driven in translational motion (i.e., piston mode) by a Digital MicroVax minicomputer. It is submerged 46 cm lower than the floor of the flume, separated by a 20.4-m-long, 1:43 slope. Wave absorption was provided by a 1:5 rock beach on the back wall of the flume and a 1:6 rock beach and several rolls of horsehair on the seaward side of the channel partition.

Current System

Ebb and flood currents were generated with a circulation system consisting of two inflow/outflow boxes, a pump, a pipe manifold, flow meter, and return pipe. The inflow/outflow boxes were separated a distance of 48.1 m and located below floor level at each end of the flume. Each box had a total volume of 0.89 m^3 , measuring 1.07 m long, 1.37 m wide, and 0.61 m deep. A 20-cm-diameter manifold pipe was suspended across the width of the flume in each box to distribute the flow evenly while minimizing wave disturbance and

flow turbulence. Radial cuts extending ± 70 deg from the bottom of the pipe, rather than perforations, were used to increase the cross-sectional area of the manifold to reduce vertical flow velocities to less than 3 cm/s.

The pump and pipe manifold were located midway between the inflow/outflow boxes to minimize flow resistance. A Goulds horizontal split-case centrifugal pump, with a maximum discharge of 126 l/s, was at the center of the manifold. The manifold consisted of 25.4-cm-diameter PVC pipe and ball valves to reverse the flow from ebb to flood. Flow discharge was controlled by an electrically actuated butterfly valve and measured by a Dynasonics clamp-on ultrasonic transit time flowmeter. Typical accuracy of this meter is 1 percent. The return pipe on either side of the manifold was also 25.4-cm-diameter PVC pipe.

Instrumentation

Wave gages. Surface elevations were measured by twenty capacitance wave gages in a 10-m by 0.7-m measurement area, bounded by the channel centerline and the origin at the channel entrance. Eleven of the twenty gages were located along the channel centerline in Row 1. The remaining gages were located on two parallel cross-shore transects: six in Row 2 and three in Row 3. Gage spacing was 91 cm in the x-direction and 37 cm in the y-direction. These spacings corresponded to normalized channel widths of 5 x/w and 2 y/w , respectively, where w is the channel width. Table 1 lists gage locations and normalized distances.

Current meters. Seven acoustic Doppler current meters were used to calibrate ebb and flood currents and quantify the wave-current interaction effect. These current meters are manufactured by Sontek. The system consists of a measurement probe and stem, signal conditioning and processing modules, and a 486 PC.

Incident ebb current flows were measured by two meters positioned inside the channel along the centerline. The meter at the channel entrance was the primary meter, with the interior meter serving in a backup role. Because it was not physically possible to co-locate current meters and wave gages, they were positioned between wave gages along all three

Gage	x, m	y, m	x/w	y/w

transects: two on each of the first two transects and one on the third transect. Table 2 lists meter positions and normalized x/w and y/w distances.

Measurements were made at a depth equal to 0.4 times the depth from the bottom of the flume. This depth corresponds approximately (0.37 factor) to a logarithmic profile for the depth-averaged velocity. This depth was a compromise to ensure that the current meter remained submerged for all wave troughs while providing clearance for the largest wave crests.

Positive u - and v -velocities were oriented in the positive x - and y -axis directions, respectively. Five of the meters measured u -, v -, and w -velocities. However, only those in the horizontal plane were analyzed for this study.

Experimental Program

Wave and current conditions. A total of over 160 cases, representative of wave and current conditions in a typical inlet, were studied. Cases consisted of 12 irregular waves, 6 regular waves, 3 ebb current, 3 flood current, and 96 wave-current combinations. Only the irregular wave and ebb current results are presented in this paper. Table 3 lists corresponding model and prototype values for water depth, and wave and current parameters, based on a model-to-prototype scale of 1 to 20.

Wave calibration. The target frequency spectrum for the model waves was based on the Texel Marsden Arsloe (TMA) spectrum (Bouws et al. 1985). The TMA spectrum is a function of five parameters: peak frequency, Phillip's constant, peak enhancement factor, lower and upper spectral width parameters σ_1 and σ_u , and water depth h . Although identical to the JONSWAP spectrum in deep water, the TMA is modified by a depth-correction factor in shallow water. Peak enhancement factors of 2 and 10 were chosen to simulate sea and swell frequency spreading, respectively. Values of $\sigma_1=0.07$ and $\sigma_u=0.09$ were used for all irregular waves. The Phillip's

constant was calculated based on the target zero-moment wave height H_{m0} .

Control signal durations of 2,000 s were created for each wave case. Data were collected for 1,000 s at a sampling rate of 10 Hz after a waiting time of 60 s to allow the slowest traveling wave to reach the farthest wave gage (W1).

Single channel frequency spectral analysis was used for the data analysis. Data records of 1,000 s were zero-meaned, tapered by a 10% cosine bell window, Fourier transformed, and band averaged, yielding a frequency resolution of 0.05 Hz with 100 degrees of freedom. Values for H_{m0} were computed for all cases.

Two or three iterations were required for each wave case to obtain target values. In general, the agreement between measured and target wave period, wave height, and spectral shape was very good. Table 4 compares measured and target H_{m0} for the 12 irregular wave cases for the average of the 11 gages on the centerline and all 20 gages. The percent deviation between measured and target values is also listed. Overall agreement is excellent for all cases, with a maximum variation of 1.2 percent for the centerline gages and 1.8 percent for all gages.

Current calibration. Software on the PC allowed real-time observation of the current time series and magnitudes. Current data were also collected for 1,000 s, but at a sampling rate of 25 Hz.

Prior to sampling, water was circulated for approximately 30 min to allow the current to reach a steady-state condition. This time is equivalent to 3-5 cycles of the slowest current traveling between inflow/outflow boxes. Seeding was added to the water and mixed to improve the signal-to-noise ratio of the current meters to acceptable levels. Initial calibration of each current condition required an iterative procedure of adjusting the flow control valve and waiting to re-establish steady-state conditions before continuing. After successfully matching the target velocity, the settings of the valve were recorded for future runs.

A current-only case was run first each day. Then, the 12 wave-current combinations for that current were run sequentially with approximately 5 min between each run for the flume to reach steady-state conditions prior to the next run. At the end of each day, the current-only run was repeated as a check on the current stability. The current repeatability was very good during a day's runs.

RESULTS AND ANALYSES

In this section, discussions of the current distribution, current-modified wave parameters, wave amplification, and spectral evolution are presented for eight representative cases. These cases consist of two wave periods ($T=1.57$ and 2.24 s), two wave heights ($H=5$ and 15 cm), and two ebb currents ($U=11.2$ and 44.7 cm/s). They correspond to prototype wave and current conditions of $T=7$ and 10 s, $H=1$ and 3 m, and $U=0.5$ and 2.0 m/s, respectively. Only wave gage and current meter data from the channel centerline are considered in this paper.

Current Distribution

As the ebb current exits the channel it decreases in magnitude and spreads out laterally within the confines of the flume side walls. Figure 2 shows the measured ebb current along the channel centerline for each of the eight wave-current cases. The value for U is plotted versus normalized distance x/w (i.e., equivalent number of channel widths w) seaward of the channel entrance for the $T=1.57$ s cases in the top panel and $T=2.24$ s cases in the bottom panel. All current values are interpolated or extrapolated from the three current measurement locations on the channel centerline.

The stronger ebb currents are felt by the waves at a larger x/w distance from the channel entrance. At this distance, the wave celerity effectively overpowers the current and it

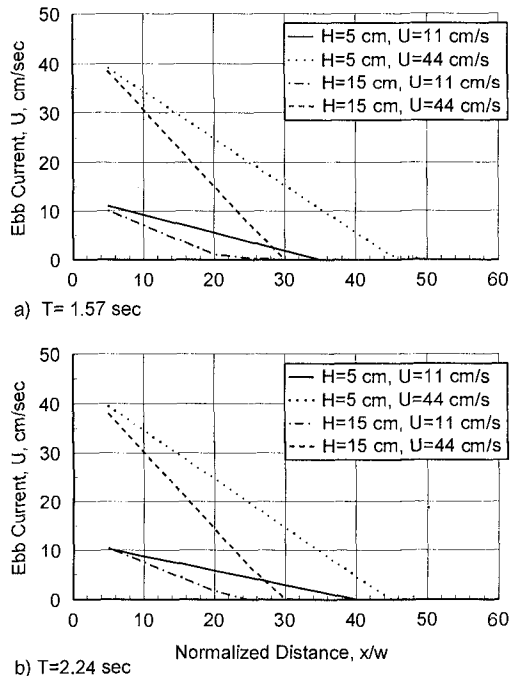

Figure 2. Current distribution.

vanishes. Waves with larger wave heights reduce the current closer to the mouth of the channel, effectively changing the current field.

Wave Parameters

Wave parameters are modified by the presence of a steady, uniform ebb current U . The apparent or absolute wave frequency σ_a and celerity C_a of the wave traveling on the current are reduced relative to their intrinsic or calm water values (i.e. σ_i and C_i) when an ebb current is not present. The wavelength L and wavenumber k remain fixed, however. These relationships are given by

$$\sigma_a = \sigma_i + kU \cos \theta \quad (1)$$

$$C_a = C_i - U \quad (2)$$

where θ = the angle between the direction of wave propagation and that of the ebb current, which is 180 deg in our case. Thus, the absolute wave period $T_a (=2\pi/\sigma_a)$ for waves on an ebb or opposing current is increased or stretched relative to the intrinsic period $T_i (=2\pi/\sigma_i)$. Also, the wave height H and wave steepness H/L are increased. Table 5 lists intrinsic values for the eight cases, based on linear wave theory. The first digit in the "Case" ID corresponds to the wave case from Table 4 and the second digit to the current magnitude.

The numerical wave model REFDIF, a combined refraction-diffraction, parabolic approximation model, was used for computing changes in wave parameters due to ebb and flood currents (Kirby and Dalrymple 1994). Using the flume geometry and measured current data, current-modified wave parameters were calculated with this model. Irregular waves

Case ID	T_i , s	H , cm	U , cm/s	C_i , cm/s	U/C_i	H/L
11	1.57	5	11.2	191	0.06	0.005
13			44.7		0.23	0.005
31	1.57	15	11.2		0.06	0.050
33			44.7		0.23	0.050
41	2.24	5	11.2	207	0.05	0.011
43			44.7		0.22	0.011
61	2.24	15	11.2		0.05	0.032
63			44.7		0.22	0.032

were modeled as equivalent regular waves corresponding to the peak period with $H_{rms} = H_{m0} / \sqrt{2}$.

The change in H/L as a function of U/C_n for each of the eight cases is shown in Figure 3. Values for H/L are calculated by dividing the measured wave height by the predicted wavelength from the REFDIF wave model. The U/C_n values correspond to the different gage locations along the channel centerline. Wave steepness increases by a factor of two for all the cases, and as much as an order of magnitude for case 11 (i.e., $T=1.57$ s, $H=5$ cm, $U=11.2$ cm/s).

Wave Amplification

Figure 4 shows wave amplification H/H_i versus normalized distance x/w for the eight cases. Measured wave height H was divided by incident wave height H_i for the wave-only condition at each location for each case to obtain values of H/H_i .

The largest amplification occurred for the $T=1.57$ s cases (top panel), and for the largest ebb current for both wave periods. Wave height increased by almost a factor of two for case 13 with the larger current. Maximum amplification was somewhat smaller for the $T=2.24$ s cases shown in the bottom panel, on the order of 1.5.

Spectral Transformation

As waves propagate toward the channel entrance, they are affected by the ebb current more strongly. This is manifested in the growth of the higher frequency components. The wave may initially experience gentle or occasional breaking due to blockage of these higher frequency waves, with correspondingly increased wave steepness. The higher frequency components are reduced relative to those previously present. The total energy in the spectrum, however, does not decrease appreciably. According to Lai et al. (1989), the peak frequency may be Doppler shifted to a lower value. Suh et al. (1994), however, did not observe this phenomenon in their experiments.

Figure 3. Current effect on wave steepness

Figure 4. Wave amplification effect.

In a severe breaking environment, however, the spectral shape may change appreciably. The higher frequency components of the spectrum are often completely blocked, resulting in violent breaking and drastic change in the spectral shape. The high-frequency half of the spectrum above the spectral peak may be reduced an order of magnitude relative to its wave-only condition. The peak frequency may be reduced as well.

Figures 5 and 6 are semi-log plots of the measured frequency spectra for wave-only and wave-current conditions for wave periods of $T=1.57$ and $T=2.24$ s, respectively. Gage positions 1 through 6 are shown for x/w equivalent to (a) 5, (b) 10, (c) 15, (d) 20, (e) 25, and (f) 30. The incident wave height is $H=15$ cm in all plots. In each plot, the dotted line corresponds to the wave-only condition at $x/w=55$ (i.e., gage 11), the solid line to the wave-current condition with $U=11.2$ cm/s current, and the dot-dash line to the $U=44.7$ cm/s case.

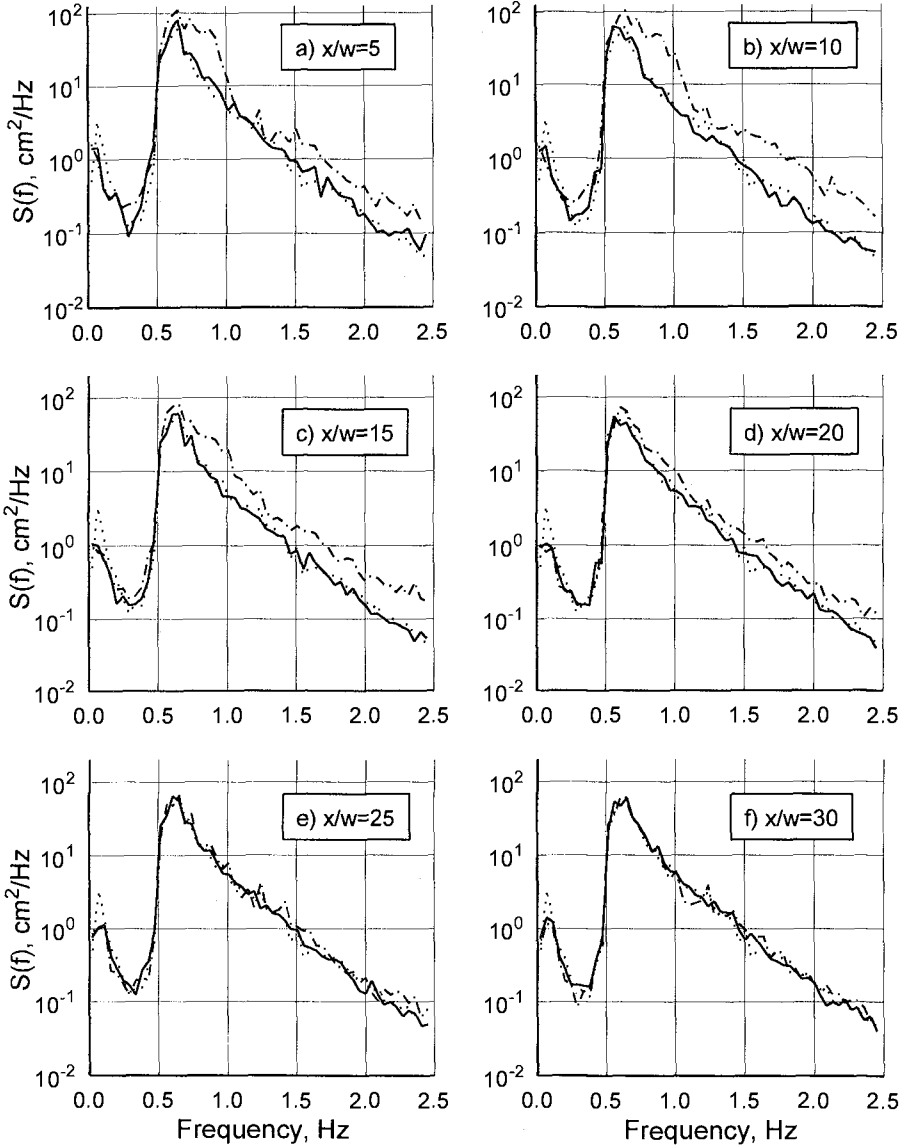

Figure 5. Spectral evolution for $T=1.57$ s, $H=15$ cm cases for $x/w=5$ to 30. Dotted line is wave-only, solid line is $U=11$ cm/s, and dot-dash line is $U=44$ cm/s.

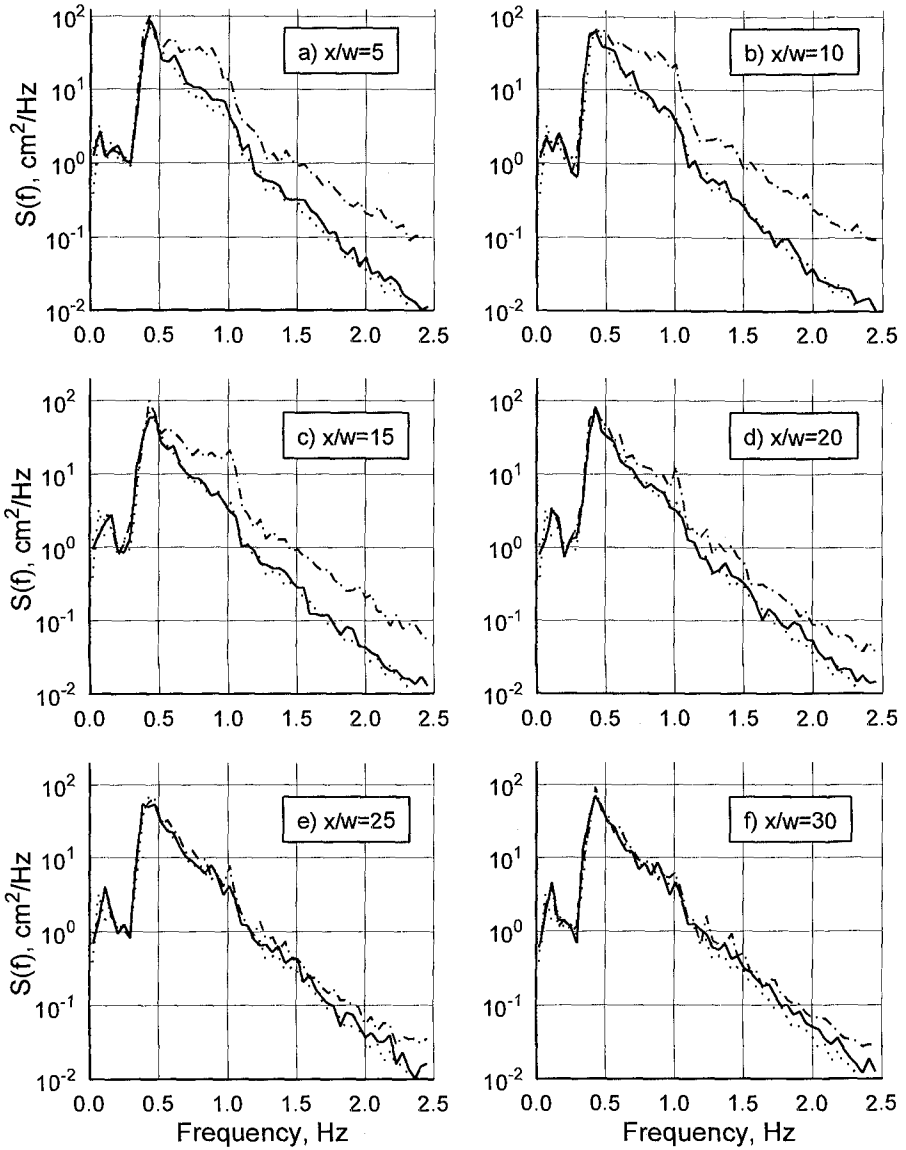

Figure 6. Spectral evolution for $T=2.24$ s, $H=15$ cm cases for $x/w=5$ to 30. Dotted line is wave-only, solid line is $U=11$ cm/s, and dot-dash line is $U=44$ cm/s.

For the $T=1.57$ s cases, the $U=11.2$ cm/s ebb current has little effect on the spectral shape. The wave celerity is much stronger than the current velocity, on the order of $U/C_a=-0.06$ (see Table 5 and Figure 3). The larger current ($U/C_a=-0.23$), however, does have an effect on this wave. Initially, there is little effect, but at $x/w=20$ the higher frequency components increase, reaching a maximum at $x/w=10$. Gentle breaking then occurs between $x/w=5$ and 10, as evidenced by the decrease in the higher frequency components. This is in agreement with the H/L and U/C_a values predicted by the numerical model and the observations of Lai et al. (1989) that the wave blockage limit is approximately $U/C_a \leq -0.25$. There does not appear to be any obvious frequency shifting in the peak frequency, however.

For the $T=2.24$ s cases, again there is no significant effect of the current on the wave spectrum. The U/C_a ratio is on the same order as before. The larger current $U=44.7$ cm/s case causes a growth of higher frequency components, much like the previous case. The decrease in this frequency range is less than before with the most significant decrease occurring between 1.25 and 1.50 Hz. Occasional breaking was observed in this case between $x/w=5$ and $x/w=15$.

These increases in the higher-frequency components of the wave spectra are much like what was observed by Briggs and Smith (1990) and Smith and Vincent (1992) due to shoaling alone. The ebb current appears to enhance this nonlinear growth of the higher harmonics.

CONCLUSIONS

Laboratory experiments were conducted in a flume to study wave-current interaction at the entrance to an inlet. Regular and irregular waves were studied with and without ebb and flood currents. This paper presents an overview of the experiments and results from an initial analysis of some of the ebb current data. Gentle or occasional wave breaking was observed in the larger wave height cases. A numerical wave model was used to predict the effect of the current on the wave parameters. The agreement with these predictions and model measurements with previous experiments was very good. Ebb currents tend to enhance the nonlinear growth of higher-harmonic components, much like shoaling on a beach. Additional research with this data is in progress to develop a current-induced wave breaking criterion, provide guidance to the field on the effects of currents on waves, and improve the predictive capability of numerical models for enhancing navigation in inlets.

CHAPTER 96

Wave Climate of Large Reservoirs and a Revised Wave Hindcast Formula

Pierre Dupuis¹, Jean-Pierre Tournier¹, Octave Caron²

Abstract

Since impounding of the various reservoirs of the La Grande Complex in northern Québec, the riprap of several dams and dykes has suffered some damage during the fifteen-year period that followed. A mandate was given to the Société d'énergie de la Baie James (SEBJ) in January 1992 to review the riprap design and evaluate the necessary repairs. This paper focuses on the revaluation of the design wave with revised wave hindcast formulas based on the large amount of wind and wave data collected.

Introduction

Damage was observed to the riprap of some of the 215 embankment dams and dykes during the fifteen years since impoundment for the various reservoirs of the La Grande Hydroelectric Complex in northern Quebec. In January 1992, La Société d'énergie de la Baie James (SEBJ) was mandated by Hydro-Québec to review the riprap design and performance and to evaluate the necessary repairs. To fulfill its mandate, SEBJ conducted extensive field studies, including wind and wave measurements from four reservoirs and large scale model testing of repair schemes with irregular waves. Model testing is described by Mansard et al. (1996) while riprap repairs and design are presented by Tournier et al. (1996).

Wind and Wave Data Acquisition

Extensive field measurements were made from 1992 to 1995 (SEBJ, 1996a) to establish the wave climate on four large reservoirs of the La Grande Complex that are located within the area delimited by 52 to 55°N of latitude and 67 to 79°W of longitude (figure 1). Wind speed and direction, wind gust and air temperature were monitored continuously and logged every five minutes at three nearby airports and six small islands on the reservoirs by Aanderaa weather stations.

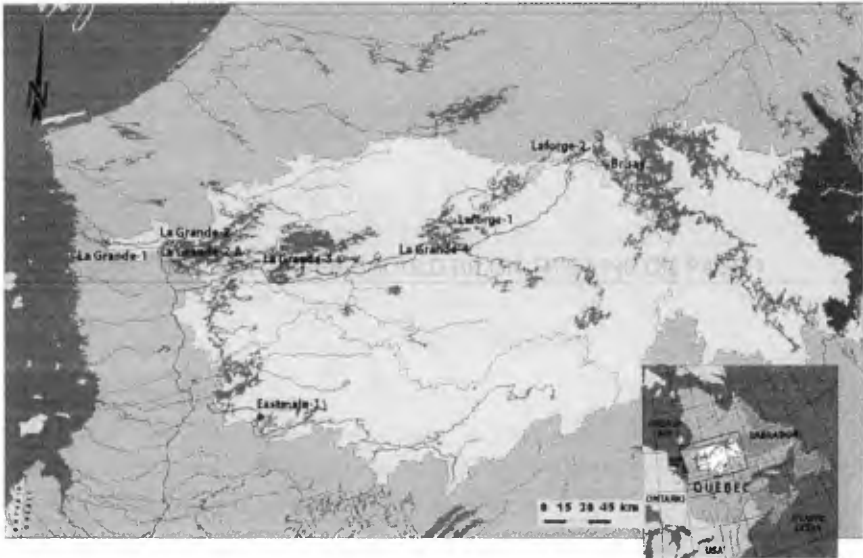

Figure 1. La Grande Hydroelectric Complex

WaveTrack buoys (0,9m diameter sphere) recorded wave trains for 17 minutes at the start of every hour at a sampling frequency of 2 Hz (figure 2). Raw data from the buoy accelerometer and tilt sensors were sent ashore via telemetry to a computer and archived for later processing. Over the four years, 9 different wave sites were monitored. In all, over 38 000 wave records were obtained for the ice free period that lasts from mid-June to the end of October.

This paper focuses on the dyke TA-13 mooring site, in the northern part of the LG-3 reservoir, for which over 9000 records cover all four years and where the most energetic episodes were recorded ($H_{mo} = 2,4$ m in September, 1992). The buoy was moored a few kilometers south of the dyke in order to monitor various fetch length conditions. A weather station was erected nearby on a flat island to record the overwater wind. The wave acceleration record values are processed in the frequency domain to yield the significant wave height (H_{mo}) and the mean period (T_{02}), as defined in IAHR/PIANC (1986). They form the basic set of variables used in further analysis. This is acceptable since evaluation of wave height ratios (figure 3) indicate good agreement with the

Figure 2 WaveTrack buoy

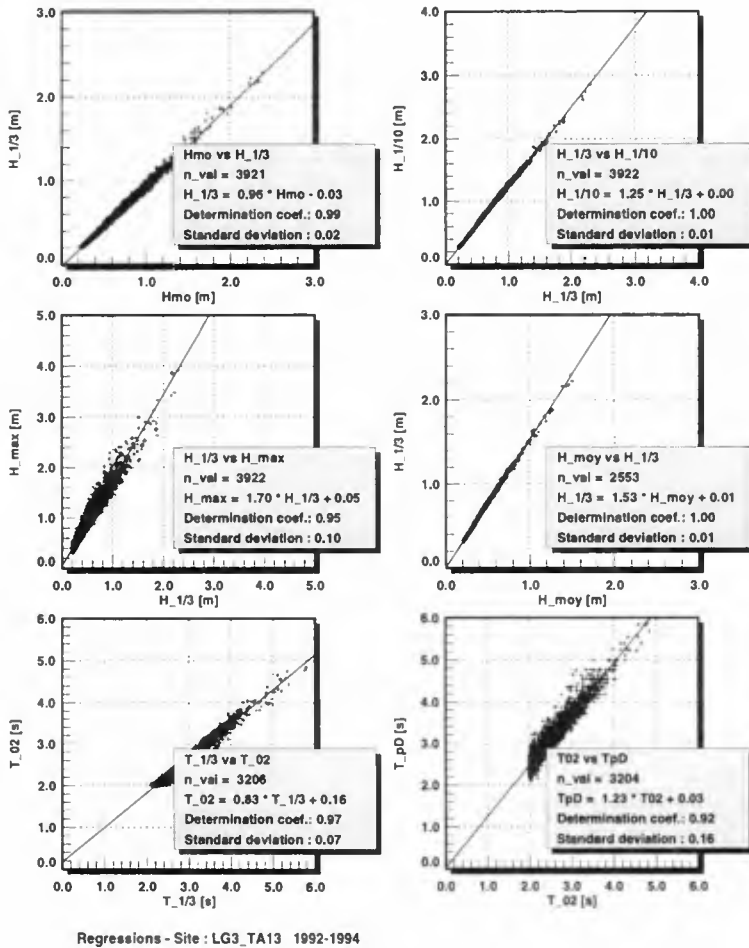

Figure 3. Wave parameter ratios for site TA-13.

Rayleigh distribution. These results are satisfactory for design purposes.

As shown on figure 4, similarity between wind speed and wave height response signals is evident, and similar results are obtained for all sites. This is indicative of the quick response of the body of water to the wind input. It can be noted that the wave steepness attains a limiting value in the vicinity of 0,06 for quite different wave conditions when T_{02} is used. This indicates that the wave energy growth or decay, due to the wind is such that the ratio of wave height to wave length remains the same, when limiting conditions exists. This is very important since it will be used in determining the correct set of values for the various dimensional parameters.

Figure 4. Typical measurements

Dimensional analysis

Based on dimensional considerations, Bretschneider (1965) derives these relations:

$$\frac{gH}{U^2} = \psi_1 \left[\frac{gF}{U^2}, \frac{gt}{U} \right] \quad [1]$$

$$\frac{C}{U} = \psi_2 \left[\frac{gF}{U^2}, \frac{gt}{U} \right] \text{ or equivalently } \frac{gT}{U} = \psi_3 \left[\frac{gF}{U^2}, \frac{gt}{U} \right] \quad [2]$$

With H the wave height, T the period, F the fetch length, U the wind speed and t the duration. ψ_1 and ψ_2 are functional relations that must be determined using wave data. Different editions of the Shore Protection Manual (CERC, 1977, 1984), noted SPM77 and SPM84, suggest the following:

SPM 77	$\frac{gH}{U^2} = 0,00354 \left(\frac{gF}{U^2} \right)^{0,42}$	$\frac{gT}{U} = 0,581 \left(\frac{gF}{U^2} \right)^{0,25}$	[3]
SPM 84	$\frac{gH}{U_a^2} = 0,00160 \left(\frac{gF}{U_a^2} \right)^{0,50}$	$\frac{gT}{U_a} = 0,286 \left(\frac{gF}{U_a^2} \right)^{0,333}$	[4]

where the hyperbolic functions found in the SPM84 are linearized in order to help to compare values from both editions and U_a is the wind stress factor as defined in SPM84. Use of these formulas, however, results in poor hindcast, with over prediction of small wave heights and under prediction of large wave height events, when compared with measured waves in the La Grande Complex reservoirs. An in depth analysis was undertaken to eventually correct the formulas, with the objective being to accurately hindcast the wave hourly time series with locally measured wind data. The general form of the above equations is:

$$\frac{gH}{U_a^2} = \alpha_H \left(\frac{gF}{U_a^2} \right)^{\beta_H} \quad \frac{gT}{U_a} = \alpha_T \left(\frac{gF}{U_a^2} \right)^{\beta_T} \quad [5]$$

with a power law assumed valid and therefore linear regression in the log-log domain of the dimensional variables yields the coefficient and exponent values for these equations. Duration is considered by establishing the celerity of the wave group in deep water, as follows:

$$\frac{C_g}{U_a} = \frac{1}{2} \left[\frac{\alpha_T}{2\pi} \left(\frac{gF}{U_a^2} \right)^{\beta_T} \right] \Rightarrow C_g = \frac{\alpha_T}{4\pi} g^{\beta_T} U_a^{1-2\beta_T} F^{1-\beta_T} \quad [6]$$

$$\int_0^t dt = \int_0^F \frac{dF}{C_g} = \frac{4\pi}{\alpha_T g^{\beta_T} U_a^{1-2\beta_T}} \int_0^F \frac{dF}{F^{\beta_T}} \quad [7]$$

$$\frac{gt}{U_a} = \frac{4\pi}{\alpha_T} \left(\frac{1}{1-\beta_T} \right) \left(\frac{gF}{U_a^2} \right)^{1-\beta_T} \quad [8]$$

Note that equation 8 is defined when α_T and β_T are found.

Regression analysis is performed as an iterative process (figures 5a and 5b) which starts by first specifying starting values for α and β in equation [5]. Equation [8] is then evaluated. Hourly time series are used and time duration is considered to evaluate the dimensional variables. Duration seldom extends beyond 3 hours due to the reservoir size and then only for mild wind states. Only peaks of events are retained when performing the regression. Results give a new set of coefficients and exponent values that affect the relation between duration and fetch length (equation 8). This iterative process converges to specific values of α and β . In parallel with this approach, multivariate analysis is performed to check the validity of the dimensional relations above. By expressing [5] in terms of H , one gets a relation in the form of [9] for which there is an additional constraint on exponent c which must equal: 2-2b.

Multivariate analysis performed on the data set gives exponent values for F and U that do not obey the above constraint (SEBJ, 1996b). In fact exponent "c" of U is found to be 1,21 for the dike TA-13 data set, which is quite close to the wind stress factor exponent (equation 10) given in SPM84. Based on this finding, all subsequent analyses are made with this wind stress factor:

$$H = \alpha_H g^{\beta_H - 1} F^{\beta_H} U^{2-2\beta_H} = aF^b U^c \tag{9}$$

$$U_a = 0,71 U^{1,23} \tag{10}$$

The fact that the wave steepness has a limiting value found to be in the vicinity of 0,06 for different fetch lengths and wind speed, implies that the exponent β_H must be twice the value of the exponent β_T .

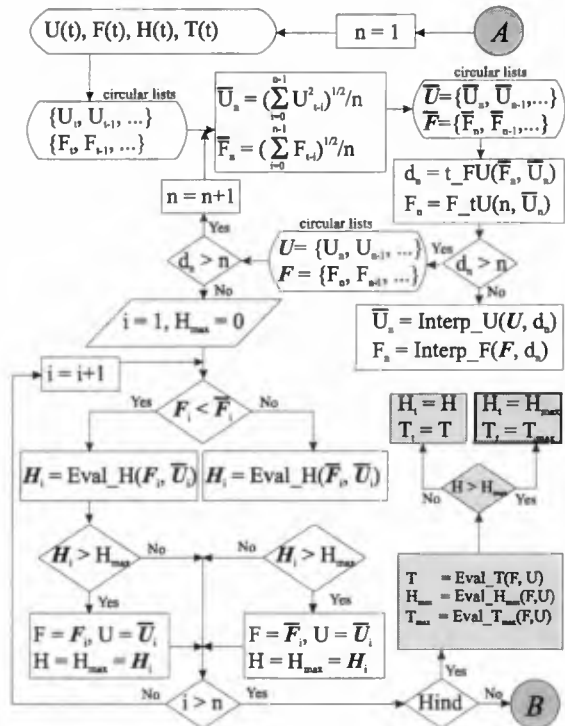

Figure 5a. Flowchart for dimensional analysis

$$S = \frac{H}{L} = \frac{H}{\left(\frac{gT^2}{2\pi}\right)} = \frac{H}{\frac{1}{2\pi} \left[\frac{gT}{U_a}\right]^2} = \frac{2\pi\alpha_H \left(\frac{gF}{U_a^2}\right)^{\beta_H}}{a_T^2 \left(\frac{gF}{U_a^2}\right)^{2\beta_T}} \Rightarrow \frac{2\pi\alpha_H}{\alpha_T^2} \quad \text{if } \beta_H = 2\beta_T \quad [11]$$

This comes, from the definition for wave steepness(see equation 11) , that for S to be constant, F has to vanish, meaning $\beta_H = 2\beta_T$. The maximum wave steepness attainable is found to be theoretically equal to $2\pi\alpha_H / \alpha_T^2$.

Dimensional analysis of site TA-13 data

Analysis is performed with a data set of over 9000 hourly values measured at the TA-13 mooring site. Figure 6 illustrates the body of water (in gray) along with the fetch evaluated following three different approaches (SPM77, SPM84 and the one proposed herein). Testing of different sector apertures were conducted (from 20 to 180 degrees), along with different weighting schemes (\cos^2 , \cos , unity). The use of a 180 degree sector with a \cos^2 weighting scheme, which is a Saville like fetch function, gave the best results for both regular and irregular shoreline cases. The fetch function is defined by the following equation:

$$F(\theta) = \frac{\sum_{\gamma=-90}^{90} R(\theta + \gamma) \cos^2(\gamma)}{\sum_{\gamma=-90}^{90} \cos(\gamma)} \quad [12]$$

- with $R(\theta)$ Length of radial of heading θ [m]
- $F(\theta)$ Length of fetch of heading θ . [m]
- γ Angle formed by the radial and the central radial of the sector. [°]

A wave height of 0,5 m is chosen, as a lower threshold, in order to eliminate the influence of the buoy on the measurement of small waves. Analysis is first

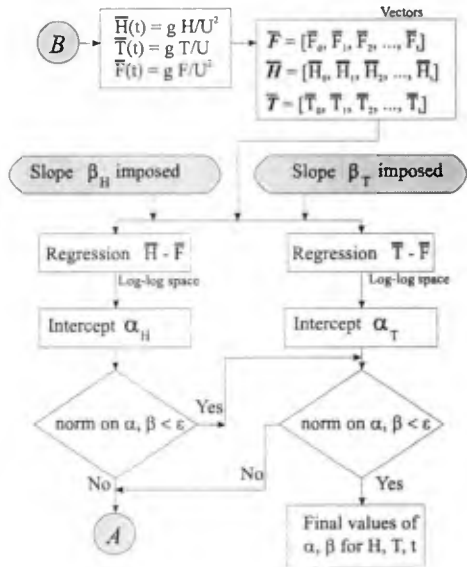

Figure 5b. Flowchart for dimensional analysis

The fetch function is defined by the following equation:

performed according to the procedures given in SPM77 and SPM84 (Table 1). The slope (m_H, m_T) and intercept values (b_H, b_T) of the scatter graph of predicted values against measured values are also listed (figure 7). For the SPM77, the wind speed U is used. When the exponents are forced to the values proposed in the SPM, the difference in α_H are insignificant when compared to equations 3 and 4. This indicates that the wave climate of the reservoir is a short crested wave regime, no different then elsewhere, except for the mean period which is lower.

Exponents of H and T forced and Ua = 0.71 U^{1.23}

Figure 7. Example of dimensional analysis for mooring site TA-13

When exponents are let free to adjust, results are quite different, with lower values for the exponent and higher values for the coefficient. The maximum wave steepness, according to equation 11, are 0,084 and 0,074 respectively, which is high. The slopes from the scatter graphs indicate a tendency to under evaluate large

wave episodes and over evaluate small wave episodes. Results from the analysis of dyke TA-13 yield exponent values of 0,467 and 0,238 respectively for which the ratio of exponent is near 1,96. The resulting wave steepness is found to be 0,065 which is a bit high but acceptable when compared with the values ranging from [0,06-0,065] obtained from measured data (figure 4). Since use of a common variable (U_a) raised to a given power can have adverse effects on the quality of the regression (Kenney, 1993), the right set of parameters is chosen from a subset of results obtained by imposing the regression slope. Table 2 shows the results obtained, when the analysis is performed for different values of β_H imposed with the constraint that β_H is twice the value of β_T . In fact, by forcing the exponent to a given value, better prediction is obtained for H_{mo} when β_H is in the range [0,40-0,45] as it is shown on figure 8.

Table 2. Dimensional analysis results from dyke TA-13 data - β forced

β_H	β_T	α_H	α_T	m_H	b_H	m_T	b_T
0,40	0,200	0,00341	0,598	0,94	0,06	1,05	-0,17
0,43	0,215	0,00281	0,543	0,90	0,10	1,02	-0,04
0,45	0,225	0,00247	0,509	0,87	0,12	0,99	0,04
0,47	0,235	0,00217	0,477	0,84	0,14	0,96	0,12
0,50	0,250	0,00179	0,433	0,80	0,18	0,92	0,17

SEBJ uses exponents of 0,45 and 0,225 which yield good prediction for waves in the range of the large measured wave episodes for both regular and irregular shorelines. The maximum wave steepness value is 0,06 which is the expected value.

Hindcast procedure

Hindcast follows the same process used for dimensional analysis and shown in figure 5a, to evaluate wave height and period for a given hour. Figure 8 illustrates how hindcasted waves from overwater wind compare with measured waves at the buoy site. Both hindcasted and measured signals appear in the upper left. Shown in the upper right is the scatter graph and in the lower right is the ratio between computed and measured values as a function of direction. A perfect fit would mean that all values should lie on the unit circle. During the first year of measurements, influence of trees located in a particular sector of the island, at a greater distance than the recommended 10 times the height of the taller obstacle, was obvious, as the ratio went up. It is thus very important to locate wind stations far away from any obstacles, on flat land. Much of the scatter can be explained by time lag between signals due to the fast response of the water surface to quick change in wind state or to rapidly varying fetch length. This is one of the reason why a fetch defined by a large sector give a better results for a large variety of reservoir shoreline geometry. Notice that some short extreme wave episodes can be missed since the mean hourly wind speed is used and that the significant wave height value can change by more

than 10% within an hour. Any event that lasts is fairly well reproduced. All hourly values are retained for regression in the scatter graph, which was not the case in dimensional analysis, where only peak values were considered. Hindcast at eight other sites gives similar results.

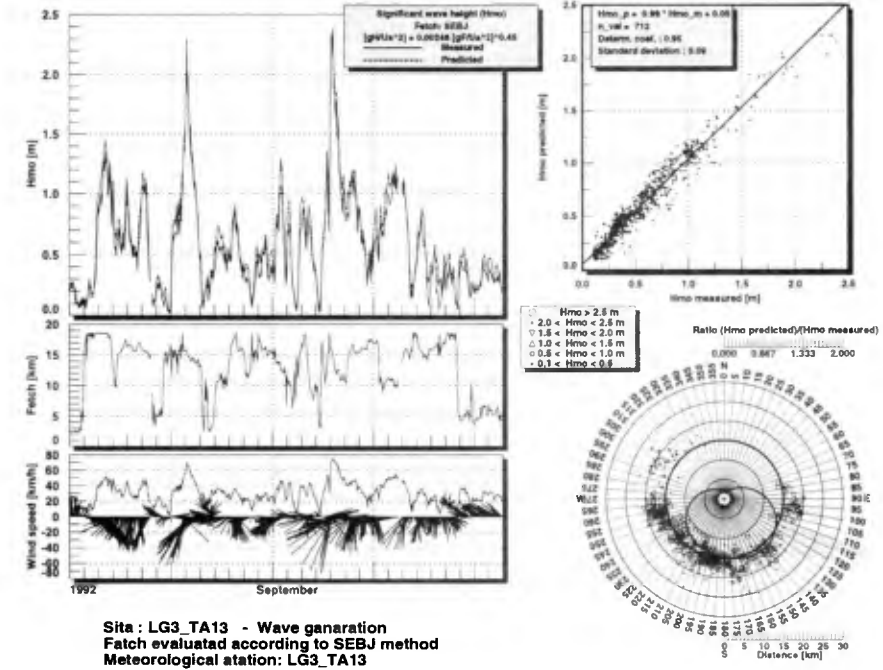

Figure 8. Example of wave hindcast from overwater wind data

Wind overland and wind overwater

Hindcast for lengthy periods of time can be achieved only with airport meteorological stations. The weather stations (figure 9) were used to better define the transfer function between wind measured overland and wind measured overwater, three of which were located at nearby airports.

Figure 9. Retrieval of weather station in November

Comparison between wind overland and wind overwater
Sites: LG2 Airport [V1] - Kanaupscow confluency [V2]
From July to October 1995

Figure 10. Wind overland and wind overwater

Records from both overland and overwater sites are visually inspected and punctual events are associated, to allow for the time lag between the two sites. All selected pairs are then plotted for further analysis. Figure 10 shows the results for one ice-free season. The scatter graph indicates that the wind overwater is larger but rarely exceeds the wind overland by more than 30 km/h. The way these points are distributed on the graph indicates that the ratio should decrease toward unity as the wind speed increases. Since there are only scarce measures for overland wind speed over 50 km/h, the relation can only be assumed for large values of wind speed. For design purposes and until sufficient data covering the upper region is obtained, the following relations are used to hindcast wave conditions from airport wind data:

$$U_w = 1,5 U_l \quad \text{for } U_l \leq 50 \text{ km/h}$$

$$U_w = 0,643 U_l + 42,9 \quad \text{for } 50 < U_l < 120 \text{ km/h}$$

$$U_w = U_l \quad \text{for } U_l \geq 120 \text{ km/h}$$

where U_l and U_w are respectively the wind overland and wind overwater in km/h.

Hindcast with overland wind

Although this empirical relation needs more data for strong wind events, it has the advantage of being easy to implement and should yield a proper annual extreme event since most years will have events with extreme wind overland speed in the vicinity of 50 km/h. In this region, a ratio value of 1,5 yields the envelope curve of measured data. Quality of such procedure is checked using data from the La Grande Airport located 130 km west of site TA-13 for which waves were measured from 1992 to 1995. Results are shown in Table 3. Except for 1994, all differences are within 10%, which is satisfactory.

Table 3. Site TA-13. Measure and hindcast of annual extreme wave event.

Year	Measure [m]	Hindcast [m]
1992	2,39	2,25
1993	1,79	1,80
1994	1,17	1,34
1995	1,69	1,75

Conclusion

Measurement of winds and waves in large reservoirs give good insight into wave generation by wind since the wave field is not contaminated by swell. The fast response of the reservoir is illustrated by the striking similarity between the wind speed and the significant wave height time series signals. Coefficients and exponents cannot be blindly evaluated from regression analysis in the log-log domain since use of a common variable raised to a given power can lead to false

correlation. The fact that wave steepness, using T_{02} , has been measured to be a maximum value around 0,06 enables a relationship between α_H and β_H to be derived and narrows the set of valid values from which to choose the correct pairs. The exponent of the dimensional wave height must be twice the value of the exponent for the mean wave period. For these conditions, it is possible to hindcast wave time series accurately with a model based on dimensional analysis, provided good quality overwater winds are used. Good quality wind hindcast for overland wind is then possible for long periods of time giving an effective tool for dam and dyke riprap design.

CHAPTER 97

SPECTRAL MODELLING OF CURRENT INDUCED WAVE-BLOCKING

R.C. Ris¹ and L.H. Holthuijsen¹

ABSTRACT

Waves travelling against an increasing opposing current tend to dissipate energy and part of the energy reflects back (in blocking conditions). The kinematic behaviour of these waves can be approximated with the linear theory for surface gravity waves. This theory has been implemented for random, short-crested waves in the third-generation wave model SWAN with numerical schemes that are fully implicit. Ad hoc assumptions that are made in other, similar models for blocking conditions are therefore not required and the model is consistent with the underlying theory. To represent the dissipation of the breaking waves in these blocking conditions, the pulse-based model of Hasselmann (1974) as adapted by Komen et al. (1984) has been chosen. Computations have been compared with the flume observations of Lai et al. (1989) in which random waves are blocked with violent breaking by an increasing counter current in relatively deep water. The computations underestimate the dissipation considerably but the addition of the bore-based model of Battjes and Janssen (1978) for steep, breaking waves in deep water improves the agreement with the observations significantly although some discrepancy remains.

INTRODUCTION

Field and laboratory observations of random waves in an opposing current show that the wave spectrum changes considerably, often accompanied with (current-induced) wave breaking. These changes take place rapidly at the moment that waves are blocked by the current. The third-generation spectral SWAN wave model (Holthuijsen et al., 1993; Ris et al., 1994; Holthuijsen et al., 1996) can be used to simulate these wave-blocking conditions in a linear approach as it is fully consistent with the linear wave theory for surface gravity waves. The model includes the third-generation formulation for deep-water wave breaking of Hasselmann (1974) as adapted by Komen et al. (1984). The flume experiments of Lai et al. (1989) offer an excellent opportunity to test this formulation against observations.

WAVE-BLOCKING

The evolution of monochromatic surface gravity waves and surface tension waves in an opposing current in blocking conditions has been described by Shyu and Phillips (1990) and Trulsen and Mei (1993). In the linear approach for a stationary ambient current a wave component that travels against a (spatially) increasing opposing current, increases its intrinsic frequency. It therefore shortens its wave length and decreases its relative propagation speed in geographic space (i.e. group velocity relative to the current). Its absolute frequency obviously remains constant. If, at some location, the relative propagation speed has reduced to be equal (but opposite) to the current velocity, the wave component is blocked. However, its intrinsic frequency continues to decrease and the wave component reflects at this point. After this reflection it continues to travel down-current while it continues to increase its intrinsic frequency. When this frequency enters the capillary range, the relative propagation speed (still directed against the current) increases and a second reflection may occur that sends the wave components up-current again. This capillary effect is ignored here because dissipation will have reduced the energy levels of these components to insignificant values.

This evolution can be readily interpreted for random waves by considering the wave component to travel through geographic and spectral space simultaneously. The evolution of the intrinsic frequency can thus be presented as propagation of energy (or action) over the intrinsic frequencies. If the wave direction is slanting across the current, the resulting refraction can similarly be modelled by propagation over the spectral directions. For a monochromatic wave, the wave height would go to infinity at the blocking point. For random waves this effect is reduced because of the distribution of the wave energy over the continuum of frequencies below the blocking frequency (analogous to reducing the effect of a caustic in geographic space). This does not imply that wave energy (in the gravity range) does not exist in the spectrum above the blocking frequency. Such energy has been generated at some location up-current from the blocking location and travels down-current.

THE WAVE MODEL

In presently operating third-generation wave models, wave-current interactions are commonly computed with explicit numerical schemes (e.g., Komen et al., 1994 and Tolman, 1991) and wave energy beyond the blocking frequency is simply removed in these models. This is an ad-hoc approach that solves a number of operational problems but it is not consistent with the basic equations underlying the models. For instance, energy at these frequencies can still travel down-current. In the SWAN model, all propagation schemes are fully implicit so that the model is always stable and the ad hoc measure of arbitrarily removing energy at these frequencies is avoided. By this, wave energy is propagated in the SWAN model through spectral space in a manner that is consistent with the linear theory for surface gravity waves. The proper kinematics are retained: wave energy travelling against the current can propagate to the blocking frequency where it is reflected in geographic space. Wave energy that is travelling down-current above the blocking

frequency is present in the model and can propagate through the blocking frequency to lower frequencies. Wave-current interactions through radiation-stresses are taken into account by formulating the wave evolution in terms of the action balance equation rather than the energy balance equation (e.g. Hasselmann et al., 1973):

$$\frac{\partial}{\partial t} N + \frac{\partial}{\partial x} c_x N + \frac{\partial}{\partial y} c_y N + \frac{\partial}{\partial \sigma} c_\sigma N + \frac{\partial}{\partial \theta} c_\theta N = \frac{F}{\sigma} \quad (1)$$

where $N = N(\sigma, \theta)$ is the action density with σ as intrinsic frequency, θ as wave direction, x and y as cartesian geographical coordinates and t as time. The first term in the left-hand side of this equation represents the rate of change of action in time, the second and third term represent propagation of action in geographical space (with propagation velocities c_x and c_y respectively). The fourth term represents propagation through the intrinsic frequency domain due to variations in depths and currents (with propagation velocity c_σ). The fifth term represents propagation in directional space due to depth and current induced refraction (with propagation velocity c_θ). These velocities are all taken from the linear theory of surface gravity waves. The term $F (= F(\sigma, \theta))$ at the right hand side of the action balance equation is the source term in terms of energy density $E (= E(\sigma, \theta))$ representing the effects of generation, wave-wave interactions and dissipation. This spectral action balance equation is the basic equation of the SWAN model.

To investigate the effect of current-induced breaking in blocking conditions, a third-generation formulation for whitecapping is used. It is the *pulse-based model* of Hasselmann (1974) as adapted by Komen et al. (1984):

$$F_{br}(\sigma, \theta) = -\Gamma \bar{\sigma} \frac{k}{\bar{k}} E(\sigma, \theta) \quad (2)$$

where $\bar{\sigma}$ is an average frequency, k is the wave number, \bar{k} is an average wave number and

$$\Gamma = \Gamma_k = \alpha_1 \left[\frac{s}{s_{PM}} \right]^4 \quad (3)$$

where s is an overall wave steepness and s_{PM} is the value of s for the Pierson-Moskowitz (1964) spectrum (so that s/s_{PM} is a normalized overall steepness). Details of the model are given in Komen et al. (1984).

The proportionality coefficient α_1 has been calibrated by Komen et al. (1984) to attain the Pierson-Moskowitz (1964) limit situation of fully developed seas in deep water. This formulation has been implemented in the third-generation WAM model (Cycle 3, WAMDI group, 1988) to compute whitecapping. With the same coefficient and with the same formulations for the wind generation and the quadruplet interactions as in the WAM model, the SWAN model also attains the Pierson-Moskowitz limit (as interpreted by Komen et al., 1984, Fig. 1). It also reproduces well the evolution of the wave energy and the peak frequency in the

idealized deep water case of a constant wind blowing perpendicularly off a straight upwind coast (no ambient current). This is evident from the agreement shown in Fig. 1 with the compilation of several data sets by Wilson (1965) and Kahma and Calkoen (1992; derived for $5 \cdot 10^4 < X^* < 4 \cdot 10^6$, E^* is the total wave energy, f_p^* is the peak frequency and X^* is the fetch, all normalized with gravitational acceleration and wind friction velocity, assuming $u_* = U_{10}/24$? for the Wilson data).

Fig. 1 The evolution of the dimensionless wave energy and the dimensionless peak frequency as function of the dimensionless fetch in the idealized deep water case according to the compilation of Kahma and Calkoen (1992; *K & C*) and of Wilson (1965, envelope), Pierson-Moskowitz (1964; *P & M*, as interpreted by Komen et al., 1984) and as computed by the SWAN model with the dissipation model of Komen et al. (1984; Γ_K), with and without the supplementing model of Battjes and Janssen (1978; Γ_{BJ}).

THE EXPERIMENT

A well documented experiment with waves travelling against a current in blocking conditions with violent breaking has been carried out in a laboratory flume by Lai et al. (1989). The waves with incident significant wave height $H_s = 0.019$ m and a mean wave period $T_{m01} = 0.51$ s are blocked in the flume by an opposing current that increases in down-wave direction ($U_{max} = -0.22$ m/s). This variation in the current speed was obtained with an elevated bottom over part of the flume in relatively deep water, see Fig. 2. The wave conditions have been computed with the SWAN model with a very narrow directional distribution of the wave energy (directional standard deviation 2.5°) and with all formulations for generation, dissipation and wave-wave interactions disabled except the above described whitcapping formulation.

In Fig. 2 the observed and computed evolution of the significant wave height along the flume are shown. It is obvious that the computed wave height reduction is considerably underestimated. In fact, the significant wave height increases some distance down the flume where the observations show a decrease. The whitewater formulation of Komen et al. (1984) apparently permits a wave steepness that is considerably larger than observed. As noted above, the coefficient α_1 in this formulation has been calibrated for deep water wave generation where the wave steepness is rather limited. In the present experiment it is apparently used for higher

Fig. 2 The observed evolution of the significant wave height and the mean wave period in the opposing current experiment of Lai et al. (1989) and the computational results of the SWAN model with the dissipation model of Komen et al. (1984; Γ_K), with and without the supplementing model of Battjes and Janssen (1978; Γ_{BJ}).

values of the wave steepness. It therefore seems that either another value for the coefficient is needed for higher wave steepness or that another formulation is required. We speculate that the total dissipation of the steeper waves can be better modelled with the *bore-based model* of Battjes and Janssen (1978). If this total dissipation is distributed over spectral space as in the pulse-based model, then the formulation of Γ becomes:

$$\Gamma = \Gamma_{BJ} = \alpha_2 Q_b \left(\frac{s_{\max}}{s} \right)^2 \quad (4)$$

in which Q_b is the fraction of breaking waves and s_{\max} is the maximum steepness of an individual breaker (so that s_{\max}/s is a normalized maximum steepness of an individual breaker). The maximum steepness is set at $s_{\max} = 0.14$ and the value of α_2 is taken from Battjes and Janssen (1978). The fraction of breakers Q_b increases very quickly as function of the overall steepness s above $s = 0.08$ so that the dissipation is relatively large for steep waves. This is shown in Fig. 3 with Γ_K and Γ_{BJ} as a function of overall steepness s . In the SWAN model this bore dissipation of Battjes and Janssen (1978) is added to the whitecapping dissipation of Komen et al. (1984).

Fig. 3 The coefficient of whitecapping as a function of overall wave steepness according to Komen et al. (1984) and the expression of the present study that is based on Battjes and Janssen (1978).

The evolution of the waves in the idealized fetch-limited conditions is hardly affected by this addition of the bore-based model except for very short fetches where the SWAN results now agree slightly better with the compilation of Wilson (1965) for $X^* < 10^4$ (Fig. 1; not considered by Kahma and Calhoun, 1992). In the experiment of Lai et al. (1989) the agreement between the computed and observed evolution of the waves has improved (see Fig. 2) but the observed continued reduction in wave height up-current from the location where the current speed attains a constant speed (at the down-current end of the elevated bottom), is not reproduced. This continued reduction is unexpected since the wave steepness decreases to rather low values and breaking is expected to be insignificant. This continued dissipation needs further investigation.

CONCLUSIONS

The numerical schemes in the third-generation spectral wave model SWAN allow a treatment of the kinematic characteristics of wave-blocking and wave reflections against an opposing current that is consistent with the linear theory for surface gravity waves without any ad hoc assumptions. Numerical simulations of wave-

blocking experiments in a flume show that the pulse-based whitecapping formulation of Hasselmann (1974), adapted by Komen et al. (1984) is not adequate in representing the process of energy dissipation in the blocking situation that was considered. Supplementing this formulation with the bore-based model of Battjes and Janssen (1978) shows an improvement but the observed continued reduction in wave height in the region of constant current has not been resolved.

ACKNOWLEDGEMENTS

We gratefully acknowledge receiving additional information on the flume experiment from Steven R. Long of NASA, Wallops Flight Facility (USA).

New York, New York 10017-2398

Abstract:

This proceedings contains over 370 papers presented at the 25th International Conference on Coastal Engineering which was held in Orlando, Florida, 2-6 September, 1996. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation, erosion and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and professionals in related fields with a broad range of information on coastal engineering.

CONTENTS

Part I Characteristics of Coastal Waves and Currents

CHAPTER 1	
Experimental Study of Breaking Waves over a Shoal	2
<i>Arun Chawla, H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 2	
A Method for Estimating Standardized Bimodal Directional Spectra	16
<i>Ryuichi Fujiwara, Masahiko Isobe</i>	
CHAPTER 3	
The Effects of Currents on Estimations of Directional Wave Spectra	30
<i>Yasuyuki Nakagawa, Hiroichi Tsuruya, Noriaki Hashimoto</i>	
CHAPTER 4	
A Method for Estimating Directional Spectra in a Field of Incident and Reflected Waves	43
<i>Hiromune Yokoki, Masahiko Isobe</i>	
CHAPTER 5	
Active Absorption of Multidirectional Waves	55
<i>Hemming A. Schaffer, Jesper Skourup</i>	
CHAPTER 6	
Time-Averaged Wave Field Evolution in Coastal Zone	67
<i>Jianlu Xu, Rodney J. Sobey</i>	
CHAPTER 7	
Quality Control of GEOSAT Wave Data for Engineering Applications	81
<i>M. Siddabathula, Vijay G. Panchang</i>	
CHAPTER 8	
Boussinesq Type Equations with High Accuracy in Dispersion and Nonlinearity	95
<i>P.A. Madsen, B. Banijamali, H.A. Schaffer, O.R. Sorensen</i>	
CHAPTER 9	
Wave Kinematics Computations Using Boussinesq Models	109
<i>J. Bosboom, G. Klopman, J.A. Roelvink, J.A. Battjes</i>	
CHAPTER 10	
Effects of Mode Truncation and Dissipation on Predictions of Higher Order Statistics ..	123
<i>James M. Kaihatu, James T. Kirby</i>	
CHAPTER 11	
Field Observation of Movement of Sand Body Due to Waves and Verification of Its Mechanism by Numerical Model	137
<i>Takaaki Uda, Yoshimichi Yamamoto, Naoki Itabashi, Kosuke Yamaji</i>	

CHAPTER 12	
Wave Groups in the Surf-Zone: Model & Experiments	151
<i>J. Veeramony, I. A. Svendsen</i>	
CHAPTER 13	
Simulation of Propagating Nonlinear Wave Groups	165
<i>Paul de Haas, Maarten Dingemans, Gert Klopmann</i>	
CHAPTER 14	
Cross-Shore Momentum Flux Due to Shear Instabilities	175
<i>Ad Reniers, Jurjen A. Battjes</i>	
CHAPTER 15	
Modelling Post-Wave Breaking Turbulence and Vorticity	186
<i>T.C.D. Barnes, M. Brocchini, D.H. Peregrine, P.K. Stansby</i>	
CHAPTER 16	
A Turbulent Flow Model for Breaking Waves	200
<i>Nguyen The Duy, Tomoya Shibayama, Akio Okayasu</i>	
CHAPTER 17	
Turbulence Structures in the Surf Zone	214
<i>T.R. Haydon, D.B. Hann, P. Davies, C.A. Greated, T.C.D. Barnes</i>	
CHAPTER 18	
Experiments on Design Wave Height in Shallow Water	221
<i>J. William Kamphuis</i>	
CHAPTER 19	
Time-Dependent Quasi-3D Modeling of Breaking Waves on Beaches	233
<i>Entin A. Karjadi, Nobuhisa Kobayashi</i>	
CHAPTER 20	
Models of Wave Height and Fraction of Breaking Waves on a Barred Beach	247
<i>Yoshiaki Kuriyama</i>	
CHAPTER 21	
A Parametric Model for Random Wave Deformation by Breaking on Arbitrary Beach Profiles	261
<i>Hyuck-Min Kweon, Yoshimi Goda</i>	
CHAPTER 22	
Generation Characteristics of Wave Sounds as a Factor of Beach Amenity	275
<i>Hitoshi Murakami, Sadahiko Itoh, Yoshihiko Hosoi, Hideo Araki and Tsuyoshi Koyabu</i>	
CHAPTER 23	
Measurements of Wave Breaking in the UK Coastal Research Facility	286
<i>Howard N. Southgate, Stuart Stripling</i>	
CHAPTER 24	
A New Type Breaker Forming a Giant Jet and Its Decaying Properties	300

CHAPTER 25	
Wave Climate Cycles and Coastal Engineering Practice	314
<i>Douglas L. Inman, Scott A. Jenkins, M. Hany S. Elwany</i>	
CHAPTER 26	
Stability of Design Wave Estimates	328
<i>Jan Rossouw, Josep R. Medina</i>	
CHAPTER 27	
An Evaluation of Two Wave Forecast Models for the South African Region	340
<i>M. Rossouw, D. Phelp</i>	
CHAPTER 28	
A Comprehensive Wind, Wave, and Current Measurement Program in the South China Sea	354
<i>Jagat N. Sharma, S. Tryggestad, J. Bian</i>	
CHAPTER 29	
Wave Height and Period Distributions from Long-Term Wave Measurement	368
<i>Chung-Chu Teng, Ian M. Palao</i>	
CHAPTER 30	
Interference of Small Structures in the Vicinity of Large Structures	380
<i>Subrata K. Chakrabarti, Sumita Chakrabarti</i>	
CHAPTER 31	
Wave Dynamics at Coastal Structures: Development of a Numerical Model for Free Surface Flow	389
<i>Zoheir A. Sabeur, N. William H. Allsop, Robert G. Beale, John M. Dennis</i>	
CHAPTER 32	
Scale Effects in Oxygenation in the Breaker Zone of Coastal Structures	403
<i>V.K. Tsoukala, C.I. Moutzouris</i>	
CHAPTER 33	
Wave Actions on a Vertical Cylinder in Multi-Directional Random Waves	415
<i>Yu-xiu Yu, Ning-chuan Zhang, Qun Zhao</i>	
CHAPTER 34	
Wind/Wave Relation and the Pressure Gradient Effect	429
<i>Spiros M. Gouloumis</i>	
CHAPTER 35	
Non-Reflected Multi Directional Wave Maker Theory and Experiments of Verification ..	443
<i>Kazumori Ito, Hidehiro Katsui, Masashi Mochizuki, Masahiko Isobe</i>	
CHAPTER 36	
Fifty Years of Wave Growth Curves	457
<i>Paul C. Liu</i>	

CHAPTER 37	
Development of a Third Generation Shallow-Water Wave Model with Unstructured Spatial Meshing	465
<i>Michel Benoit, Frederic Marcos, Francoise Becq</i>	
CHAPTER 38	
New Optimization Method for Paddle Motion of Multi-Directional Wavemaker	479
<i>Akira Matsumoto, Minoru Hanzawa</i>	
CHAPTER 39	
Generation of Second-Order Long Waves by a Wave Group in a Laboratory Flume and Its Control	493
<i>M. Mizuguchi, H. Toita</i>	
CHAPTER 40	
Kinematic Predictions in Large Shallow Water Waves	502
<i>Susan Smith, Christopher Swan</i>	
CHAPTER 41	
Fetch Limited Spectral Evolution in Finite Depth Water	516
<i>I.R. Young, L.A. Verhagen</i>	
CHAPTER 42	
Measurement of Breaking Waves Using Particle Image Velocimetry	527
<i>Kuang-An Chang, Philip L.-F. Liu</i>	
CHAPTER 43	
Computation of the Near-Bottom Kinematics of Shoaling Waves	537
<i>Luc Hamm</i>	
CHAPTER 44	
Formulation and Validation of Vertically 2-D Shallow-Water Wave Model	551
<i>Bradley D. Johnson, Nobuhisa Kobayashi, Daniel T. Cox</i>	
CHAPTER 45	
Particle Velocity Distribution in Surface Waves	565
<i>Geir Moe, Oivind A. Arntsen</i>	
CHAPTER 46	
A Comparison of Analysis Methods for Wave Pressure Data	575
<i>Murray Townsend, John D. Fenton</i>	
CHAPTER 47	
A Nonlinear Model for Wave Propagation	589
<i>Ting-Kuei Tsay, Philip L.-F. Liu, Nan-Jing Wu</i>	
CHAPTER 48	
Application of a Digital Particle Image Velocimetry (DPIV) System to Breaking Waves in the Surf Zone	602
<i>Kenneth R. Craig, Robert J. Thieke</i>	

CHAPTER 49	
Wave Gauging Networks Worldwide - An Overview616
<i>J. Michael Hemsley</i>	
CHAPTER 50	
Improvement of Submerged Doppler-Type Directional Wave Meter and its Application to Field Observations629
<i>Noriaki Hashimoto, Masao Mitsui, Yoshimi Goda, Toshihiko Nagai, Tomoharu Takahashi</i>	
CHAPTER 51	
Comparison of Directional Wave Data Quality from Two Different Monitoring Systems643
<i>Lihwa Lin, Sidney Schofield, Hsiang Wang</i>	
CHAPTER 52	
The Digital Simulation of Non-Linear Random Waves657
<i>Kyungmo Ahn</i>	
CHAPTER 53	
The “SWAN” Wave Model for Shallow Water668
<i>N. Booij, L.H. Holthuijsen, R.C. Ris</i>	
CHAPTER 54	
Generation Depths from Water Wave Data677
<i>J. Ernest Breeding, Jr.</i>	
CHAPTER 55	
Wave Climate Assessment in the South Aegean Shelf689
<i>Spiros Christopoulos, Christos Solomonidis</i>	
CHAPTER 56	
Sea State Parameterisation Using Empirical Orthogonal Functions703
<i>Witold Cieslikiewicz, Jerzy Graff</i>	
CHAPTER 57	
Fully Nonlinear Properties of Periodic Waves Shoaling over Slopes717
<i>Stephan T. Grilli, Juan Horrillo</i>	
CHAPTER 58	
Water Wave Fluctuations Induced by Irregular Bathymetry731
<i>Lulin Guo, Robert A. Dalrymple</i>	
CHAPTER 59	
Integral Control Data Assimilation in Wave Predictions743
<i>L.H. Holthuijsen, N. Booij, M. van Endt, S. Caires, C. Guedes Soares</i>	
CHAPTER 60	
Two-Dimensional Analysis of Wave Transformation by Rational-Approximation-Based, Time-Dependent Mild-Slope Equation for Random Waves754
<i>Toshimasa Ishii, Masahiko Isobe, Akira Watanabe</i>	

CHAPTER 61	
Nonlinear Wave Transformation Due to a Submerged Breakwater767
<i>Masahiko Isobe, Akira Watanabe, Shogo Yamamoto</i>	
CHAPTER 62	
Observed and Modeled Wave Results from Near-Stationary Hurricanes781
<i>Charles L. Vincent, Robert E. Jensen</i>	
CHAPTER 63	
Estimation of Persistence Statistics of the Waves Observed on Japanese Coast in the Light of Recent Studies794
<i>Hajime Kato, Hisamichi Nobuoka</i>	
CHAPTER 64	
Probabilistic Modeling of Long-Term Wave Climate808
<i>V.M. Leyden, W.R. Dally</i>	
CHAPTER 65	
Monte Carlo Simulation for Nearshore Wave Statistics in Southern California822
<i>Chia-Chi Lu, R. Rea Strange III</i>	
CHAPTER 66	
Bottom Friction Dissipation in the Belgian Coastal Regions836
<i>Weimin Luo, Jaak Monbaliu, Jean Berlamont</i>	
CHAPTER 67	
Weakly non-Gaussian Model of Wave Height Distribution for Nonlinear Random Waves .	.850
<i>Nobuhito Mori, Takashi Yasuda</i>	
CHAPTER 68	
An Attempt at Applying the Chaos Theory to Wave Forecasting864
<i>Takao Ohta, Akira Kimura</i>	
CHAPTER 69	
Transition of Stochastic Characteristics of Waves in the Nearshore Zone878
<i>David J. Robillard, Michel K. Ochi</i>	
CHAPTER 70	
Monitoring and Modelling on Shallow Water Wave Propagations in “El Saler” Beach ..	.889
<i>Jose C. Santos, Jose M. de la Pena, Jose Lozano</i>	
CHAPTER 71	
Intercomparison of Parameter Estimation Methods in Extremal Wave Analysis900
<i>Masataka Yamaguchi</i>	
CHAPTER 72	
Influences of Spectral Shapes on the Statistical Properties of Simulated Random Waves .	.914
<i>John Z. Yim, M.-Y. Lai</i>	
CHAPTER 73	
Second-Order Interaction between Random Wave and Submerged Obstacle927

CHAPTER 74	
A Uniform Mild-Slope Model for Waves over Varying Bottom941
<i>Libang Zhang, Billy L. Edge</i>	
CHAPTER 75	
Bragg Reflection of Shallow-Water Waves on a Sloping Beach955
<i>Yong-Sik Cho, Jong-In Lee, Jong-Kyu Lee</i>	
CHAPTER 76	
Reflection Analysis with Separation of Cross Modes968
<i>John Gronbech, Thomas Jensen, Henning Andersen</i>	
CHAPTER 77	
Wave Runup on Beaches981
<i>John P. Ahrens, William N. Seelig</i>	
CHAPTER 78	
Field Study on Wave Run-Up on Seadykes994
<i>Joachim Grune</i>	
CHAPTER 79	
Wave Run-Up on Revetments with Composite Slopes1008
<i>Zeya Wang, Joachim Grune</i>	
CHAPTER 80	
Landward Transport of Spray Generated from a Wave Absorbing Sea Wall1022
<i>Misao Hashida, Nobuhiro Matsunaga, Isao Irie</i>	
CHAPTER 81	
Irregular Wave Kinematics from a Pressure Record1034
<i>Christopher H. Barker, Rodney J. Sobey</i>	
CHAPTER 82	
Nonlinear Refraction-Diffraction of Surface Waves over Arbitrary Depths1048
<i>Serdar Beji, Kazuo Nadaoka</i>	
CHAPTER 83	
Boussinesq Equations with Improved Doppler Shift and Dispersion for Wave/Current Interaction1060
<i>Qin Chen, Per A. Madsen, Ole R. Sorensen, David R. Basco</i>	
CHAPTER 84	
The Propagation of Water Waves in Prismatic Channels1074
<i>Li Li, Robert A. Dalrymple, Jeffrey M. Mlynarski</i>	
CHAPTER 85	
A Statistical Approach for Modeling Triad Interactions in Dispersive Waves1088
<i>Y. Eldeberky, V. Polnikov, J. A. Battjes</i>	

CHAPTER 86	
A Fully Nonlinear 3D Method for the Computation of Wave Propagation	1102
<i>Andrew B. Kennedy, John D. Fenton</i>	
CHAPTER 87	
A Fourth Order Boussinesq-Type Wave Model	1116
<i>Mauricio F. Gobbi, James T. Kirby</i>	
CHAPTER 88	
Fast Methods for Computing the Shoaling of Nonlinear Waves	1130
<i>J.D. Fenton, A.B. Kennedy</i>	
CHAPTER 89	
Structure of Frequency Domain Models for Random Wave Breaking	1144
<i>James T. Kirby, James M. Kaihatu</i>	
CHAPTER 90	
A Hamiltonian Model for Nonlinear Water Waves and Its Applications	1156
<i>A.K. Otta, M.W. Dingemans, A.C. Radder</i>	
CHAPTER 91	
The Role of Wave-Induced Shear Stresses in the Momentum Balance Equations	1168
<i>Francisco J. Rivero, Agustin S.-Arcilla</i>	
CHAPTER 92	
Nonlinear Wave Dynamics in the Surf Zone	1178
<i>O.R. Sorensen, P.A. Madsen, H.A. Schaffer</i>	
CHAPTER 93	
A Boussinesq Breaking Wave Model with Vorticity	1192
<i>I.A. Svendsen, Ke Yu, J. Veeramony</i>	
CHAPTER 94	
Roller Contributions as Inferred from Inverse Modelling Techniques	1205
<i>D.J.R. Walstra, G.P. Mocke, F. Smit</i>	
CHAPTER 95	
Wave-Current Interaction in Inlets	1219
<i>Michael J. Briggs, Zeki Demirbilek, Debra R. Green</i>	
CHAPTER 96	
Wave Climate of Large Reservoirs and a Revised Wave Hindcast Formula	1233
<i>Pierre Dupuis, Jean-Pierre Tournier, Octave Caron</i>	
CHAPTER 97	
Spectral Modelling of Current Induced Wave-Blocking	1247
<i>R.C. Ris, L.H. Holthuijsen</i>	

Part II Long Period Waves, Storm Surges and Wave Groups

CHAPTER 98	
Uncertainties in the Validation of Harbor Wave Models	1256
<i>Zeki Demirbilek, Bingyi Xu, Vijay Panchang</i>	
CHAPTER 99	
Field Measurements and Numerical Modeling of Harbor Oscillations During Storm Waves	1268
<i>W.M. Jeong, J.W. Chae, W.S. Park, K.T. Jung</i>	
CHAPTER 100	
Performance of a Resonator Designed by the Wave Filter Theory - Applicability to a Harbor	1280
<i>Takayuki Nakamura, Hitoshi Mochizuki, Satoshi Morita</i>	
CHAPTER 101	
The Generation of Waves by a Landslide: Skagway, Alaska - A Case Study	1293
<i>Fredric Raichlen, Jiin Jen Lee, Catherine Petroff, Philip Watts</i>	
CHAPTER 102	
Laboratory Experiment on Long Wave Generation by Time-Varying Breakpoint	1307
<i>Satoru Nagase, Masaru Mizuguchi</i>	
CHAPTER 103	
Laboratory Experiments on Generation of Long Waves in the Surf Zone	1321
<i>Akio Okayasu, Teruki Matsumoto, Yasuyuki Suzuki</i>	
CHAPTER 104	
Generation of Infragravity Waves	1335
<i>A. R. van Dongeren, I.A. Svendsen, F.E. Sancho</i>	
CHAPTER 105	
Responses of Coastal Topography to Sea-Level Rise	1349
<i>Nobuo Mimura, Eiichi Kawaguchi</i>	
CHAPTER 106	
Numerical Study of Low Frequency Surf Zone Motions	1361
<i>H. Tuba Ozkan-Haller, James T. Kirby</i>	
CHAPTER 107	
Neptune - An Integrated Approach to Determining NW European Coastal Extremes ...	1375
<i>Jerzy Graff, Witold Cieslikiewicz</i>	
CHAPTER 108	
A Stochastic Typhoon Model and Its Application to the Estimation of Extremes of Storm Surge and Wave Height	1389
<i>Yoshio Hatada, Masataka Yamaguchi</i>	

CHAPTER 109	
Design of Vertical Walls Against Storm Surge	1403
<i>A. Kortenhaus, C. Miller, H. Oumeraci</i>	
CHAPTER 110	
Nearshore, Wave and Topographic Effects in Storm Surges	1417
<i>Gary Watson, Takao Yamashita</i>	
CHAPTER 111	
The Swash Zone: A Focus on Low Frequency Motion	1431
<i>Adam M. Shah, J. William Kamphuis</i>	
CHAPTER 112	
The Development of an On-Line, Interactive, Tsunami-Information Resource	1443
<i>Benjamin Cook, Catherine Petroff</i>	
CHAPTER 113	
Long Wave Runup on Coastal Structures	1452
<i>Utku Kanoglu, Costas Emmanuel Synolakis</i>	
CHAPTER 114	
Offshore Tsunami Profiles Observed at the Coastal Wave Stations	1465
<i>Toshihiko Nagai, Noriaki Hashimoto, Kazuyoshi Shimizu, Fujio Kitamura</i>	
CHAPTER 115	
A Realistic Model for the 1992-96 Tidal Waves	1478
<i>Srinivas Tadepalli, Costas Emmanuel Synolakis</i>	
CHAPTER 116	
Long-Period Oscillations in a Harbour Caused by Typhoon	1491
<i>Wataru Kioka</i>	
CHAPTER 117	
Estimation of Wave Groups Parameter from Wave Climate Statistics	1503
<i>Satoshi Nakamura</i>	

Part III Coastal Structures

CHAPTER 118	
Reflection Coefficients of the Step-Shaped Slit Caisson on the Rubble Mound	1516
<i>Sung Mo Ahn, Ryuichi Fujiwara, Hiroshi Matsunaga, Katsuhiko Kurata, Shohachi Kakuno</i>	
CHAPTER 119	
Berm Breakwater Trunk Exposed to Oblique Waves	1528
<i>A. Alikhani, G.R. Tomasicchio, J. Juhl</i>	
CHAPTER 120	
Interaction Between Main Armour and Toe Berm Damage	1542
<i>P. Aminti, A. Lamberti</i>	

CHAPTER 121	
Stability of Artificial Roughness Elements and Run-Up Reduction	1556
<i>M. Klein Breteler, K.W. Pilarczyk</i>	
CHAPTER 122	
Wave Induced Velocities at a Rubble Mound Breakwater	1569
<i>Bruno Brunone, Giuseppe R. Tomasicchio</i>	
CHAPTER 123	
Natural Periods of Armor Stones	1583
<i>Fred E. Camfield</i>	
CHAPTER 124	
Reliability Based Optimal Design of Vertical Breakwaters Modelled as a Series System of Failure	1589
<i>E. Christiani, H.F. Burcharth, J. Dalsgaard Sorensen</i>	
CHAPTER 125	
Overall Slope Stability Analysis of Rubble Mound Breakwaters	1603
<i>Julien De Rouck, Luc Van Damme</i>	
CHAPTER 126	
Interactions in the Stability of Toe-Berm and Main-Armour for Rubble-Mound Breakwaters: An Experimental Study	1617
<i>Philippe Donnars, Michel Benoit</i>	
CHAPTER 127	
Potential Uses for the Rapidly Installed Breakwater System	1631
<i>Jimmy Fowler, Donald Resio, Michael Briggs, Cheryl Pollock</i>	
CHAPTER 128	
Stability of Reshaping Breakwaters with Special Reference to Stone Durability	1640
<i>P. Frigaard, T. Hald, H.F. Burcharth, Sigurdur Sigurdarson</i>	
CHAPTER 129	
Field Investigations on Wave-Dissipating Concrete Blocks Covering Vertical Wall Breakwater	1652
<i>Michio Gomyoh, Kazuhiko Sakai, Tomotuka Takayama, Kojiro Suzuki, Shigeo Takahashi</i>	
CHAPTER 130	
New Stability Formula for Wave-Dissipating Concrete Blocks Covering Horizontally Composite Breakwaters	1665
<i>Minoru Hanzawa, Hirokazu Sato, Shigeo Takahashi, Kenichiro Shimosako, Tomotsuka Takayama, Katsutoshi Tanimoto</i>	
CHAPTER 131	
Breakwater Stability under Regular and Irregular Wave Attack	1679
<i>Thomas Jensen, Henning Andersen, John Gronbech, Etienne P.D. Mansard, Michael H. Davies</i>	
CHAPTER 132	
Roundhead Stability of Berm Breakwaters	1693

CHAPTER 133	
Improvement of Composite Breakwater on Solid Bottom Against Severe Tsunamis	1707
<i>Yoshiaki Kimura, Hideo Kondo, Shinji Kuwabara, Akira Kawamori</i>	
CHAPTER 134	
Hydraulic Stability Analysis of Leaside Slopes of Overtopped Breakwaters	1721
<i>M.D. Kudale, N. Kobayashi</i>	
CHAPTER 135	
Influence of the Core Configuration on the Stability of Berm Breakwaters	1735
<i>Nikolay Lissev, Alf Torum</i>	
CHAPTER 136	
Model Study of Reservoir Riprap Stability	1748
<i>Etienne P. D. Mansard, Michael H. Davies, Octave Caron</i>	
CHAPTER 137	
Prototype Measurements of Wave Pressures on a Wave Screen: Comparison to Physical and Analytical Models	1762
<i>F.L. Martin, M. A. Losada, C. Vidal, J.L. Diaz Rato</i>	
CHAPTER 138	
Velocity Field Measurements over Breakwater Heads under 3D Waves	1776
<i>Yoshiharu Matsumi, Akira Kimura, Kenichi Ohno</i>	
CHAPTER 139	
Wave Climate Simulation and Breakwater Stability	1789
<i>Josep R. Medina</i>	
CHAPTER 140	
Incipient Motion of Breakwater Armor Units	1803
<i>J. A. Melby, N. Kobayashi</i>	
CHAPTER 141	
Overtopping Reduction in Crownwall Design	1816
<i>Jose Luis Monso, Alfonso Vidoar, Cristina Cadevall, Cristina Garcia</i>	
CHAPTER 142	
Stable Profiles of Reshaping Breakwaters with a Berm Below the Water Level	1826
<i>C.I. Moutzouris</i>	
CHAPTER 143	
Experiments on a Non-Wave Overtopping Type Seawall	1840
<i>Keisuke Murakami, I. Irie, Y. Kamikubo</i>	
CHAPTER 144	
A Condition and Performance Rating System for Breakwaters and Jetties	1852
<i>John Oliver, Don Plotkin, John Lesnik, Douglas Pirie</i>	

CHAPTER 145
Wave Overtopping and Stability of Armor Units under Multidirectional Waves1862
T. Sakakiyama, R. Kajima

CHAPTER 146
Numerical Modeling of Breach Growth in a Sanddike1876
Guus S. Stelling, Willem T. Bakker, Christine van Kuik, Christel Somers

CHAPTER 147
Aging and Stability of Placed Block Revetments1888
Theo Stoutjesdijk, Hans Johanson, Mark Klein Breteler

CHAPTER 148
Experimental Analysis of the Settlement Failure Mechanism Shown by Caisson-Type Seawalls1902
Shigeo Takahashi, Kojiro Suzuki, Katsumasa Tokubuchi, Ken-ichiro Shimosako

CHAPTER 149
Full Scale Measurements of Wave Attenuation Inside a Rubble Mound Breakwater ...1916
Peter Troch, Marc De Somer, Julien De Rouck, Luc van Damme, Dierik Vermeir, Jean-Pierre Martens, Conan van Hove

CHAPTER 150
Numerical Modelling of Wave Interaction with Dynamically Stable Structures1930
Marcel R.A. van Gent

CHAPTER 151
Monitoring of Zeebrugge Breakwaters1944
Luc van Damme, Julien de Rouck

CHAPTER 152
Influence of Rock Shape and Grading on Stability of Low-Crested Structures1957
Jentsje W. van der Meer, W.H. Tutuarima, G. Burger

CHAPTER 153
Toe Stability of Rubble Mound Breakwaters1971
Ton van der Meulen, Gerrit J. Schiereck, Kees d'Angremond

CHAPTER 154
Seawall Effects on Historically Receding Shorelines1985
Bryan N. Jones, David R. Basco

CHAPTER 155
Control of Wave Propagation Angle by Tapered-Submerged Breakwater1998
Satoshi Takewaka, Isao Irie

CHAPTER 156
Multidirectional Wave Loads on Vertical Breakwaters2008
Claudio Franco, Jentsje W. Van der Meer, Leopoldo Franco

CHAPTER 157	
Modelling the Impact of Detached Breakwaters on the Coast	2022
<i>K.J. Bos, J.A. Roelvink, M.W. Dingemans</i>	
CHAPTER 158	
Evaluation of Beach Modelling Techniques Behind Detached Breakwaters	2036
<i>Philip Axe, Suzana Ilic, Andrew Chadwick</i>	
CHAPTER 159	
Numerical Modelling of Bed Evolution Behind a Detached Breakwater	2050
<i>Philippe Pechon, Charles Teisson</i>	
CHAPTER 160	
Combined Diffraction and Transmission of Water Waves around a Porous Breakwater	
Gap	2063
<i>Xiping Yu, Hiroyoshi Togashi</i>	
CHAPTER 161	
Prediction of Wave Reflection from Rock Structures: An Integration of	
Field & Laboratory Data	2077
<i>Mark A. Davidson, Paul A.D. Bird, David A. Huntley, Geoff N. Bullock</i>	
CHAPTER 162	
Performance Evaluation of Buoy-Membrane Wave Barriers	2087
<i>M.H. Kim, B. L. Edge, S.T. Kee, L. Zhang</i>	
CHAPTER 163	
An Improved Design Method for the Riprap of Earthfill Dams of Large Reservoirs ...	2101
<i>Jean-Pierre Tournier, Pierre Dupuis, Raymond Ares</i>	
CHAPTER 164	
Geotextile Systems in Coastal Engineering - An Overview -	2114
<i>Krystian W. Pilarczyk</i>	
CHAPTER 165	
Groynes on the East Frisian Islands: History and Experiences	2128
<i>Hans Kunz</i>	
CHAPTER 166	
Permeable Pile Groins	2142
<i>Thomas Trampenau, Frank Goricke, Arved J. Raudkivi</i>	
CHAPTER 167	
The Effect of Groundwater on Scour Near Structures	2152
<i>John H. Loveless, Geoffrey T. Grant, Robert I. Karlsson</i>	
CHAPTER 168	
Abrasion of Steel Pipe Piles by Sediment Motion in Coastal Zones	2166
<i>Gaku Matsuoka, Shinichi Ito, Toshihiko Yamashita, Hiroshi Saeki, Yoshihisa Kariyazono, Koichi Sato</i>	

CHAPTER 169	
A Viscous Rotational Model for Wave Overtopping over Marine Structure	2178
<i>Fei Zhuang, Jiin-Jen Lee</i>	
CHAPTER 170	
Overtopping of Waves at a Wall: A Theoretical Approach	2192
<i>M. Jervis, D.H. Peregrine</i>	
CHAPTER 171	
Wind Effects on Runup and Overtopping of Coastal Structures	2206
<i>Donald L. Ward, Jun Zhang, Christopher G. Wibner, Charles M. Cinotto</i>	
CHAPTER 172	
Wave Overtopping of Vertical Structures Including Wind Effect	2216
<i>Johannes P. de Waal, Patrick Tonjes, Jentsje W. van der Meer</i>	
CHAPTER 173	
Bridge Pier Scour Assessment for the Northumberland Strait Crossing	2230
<i>C.D. Anglin, R.B. Nairn, A.M. Cornett, L. Dunaszegi, J. Turnham, G.W. Annandale</i>	
CHAPTER 174	
Wave Setup at River Entrances	2244
<i>David J. Hanslow, Peter Nielsen, Kevin Hibbert</i>	
CHAPTER 175	
Scour at Coastal Inlet Structures	2258
<i>Steven A. Hughes, J. William Kamphuis</i>	
CHAPTER 176	
Probability Distribution of the Maximum Wave Height along a Sea Wall with Finite Width	2272
<i>Akira Kimura, Takao Ohta</i>	
CHAPTER 177	
Beach Response in Front of Wave-Reflecting Structures	2284
<i>Roy C. Seaman, Tom O'Donoghue</i>	
CHAPTER 178	
Fundamental Characteristics of Wave Transformation around Artificial Reefs	2298
<i>Toshio Aono, Eric C. Cruz</i>	
CHAPTER 179	
Performance of a Submerged Breakwater for Shore Protection	2312
<i>Albert E. Browder, Robert G. Dean, Renjie Chen</i>	
CHAPTER 180	
Nonlinear Wave Transformation over a Submerged Triangular Breakwater	2324
<i>Lifen Dong, Akira Watanabe, Masahiko Isobe</i>	
CHAPTER 181	
Breaking Limit, Breaking and Post-Breaking Wave Deformation Due to Submerged	

Structures	2338
<i>Koichiro Iwata, Koji Kawasaki, Do-Sam Kim</i>	
CHAPTER 182	
Italian Experience on Submerged Barriers as Beach Defence Structures	2352
<i>Alberto Lamberti, Alessandro Mancinelli</i>	
CHAPTER 183	
Resonant Reflection and Refraction-Diffraction of Surface Waves Due to Porous Submerged Breakwaters	2366
<i>Hajime Mase, Akira Kimura, Hiroshi Sakakibara</i>	
CHAPTER 184	
BEM-FEM Combined Analysis of Nonlinear Interaction between Wave and Submerged Breakwater	2377
<i>N. Mizutani, W.G. McDougal, A.M. Mostafa</i>	
CHAPTER 185	
Regulation of Nearshore Circulation by Submerged Breakwater for Shore Protection .	2391
<i>Hisamichi Nobuoka, Isao Irie, Hajime Kato, Nobuo Mimura</i>	
CHAPTER 186	
Submerged Breakwaters for the Defence of the Shoreline at Ostia - Field Experiences, Comparison	2404
<i>Ugo Tomasicchio</i>	
CHAPTER 187	
Wave Transmission of Low-Crested Structures	2418
<i>Kees d'Angremond, Jentsje W. van der Meer, Rutger J. De Jong</i>	
CHAPTER 188	
Effect of Submerged Breakwater on Profile Development	2428
<i>Martin D. Groenewoud, Jan van de Graaff, Edward W.M. Claessen, Stephan C. van der Biezen</i>	
CHAPTER 189	
Cause and Characteristics of Impact Pressure Exerted by Spilling and Plunging Breakers on a Vertical Wall	2442
<i>Seyed Ali Azarmsa, Takashi Yasuda, Hidemi Mutsuda</i>	
CHAPTER 190	
Dynamic Response of Vertical Elastic Walls to Breaking Wave Impact	2456
<i>Masatato Hattori, Nobuaki Tsujioka</i>	
CHAPTER 191	
Wave Transmission Past Vertical Wave Barriers	2470
<i>David L. Kriebel, Chad A. Bollmann</i>	
CHAPTER 192	
Physical Study of the Nature of High Peak Wave Pressures	2484
<i>Jordan Marinski</i>	

CHAPTER 193	
A Design Short-Crested Wave Force Model for Vertical Deep-Water Breakwaters2494
	<i>S.-Y. Tzang, S.-R. Liaw</i>
CHAPTER 194	
New Design Methods for Wave Impact Loadings on Vertical Breakwaters and Seawalls . .	.2508
	<i>N.W.H. Allsop, J.E. McKenna, D. Vicinanza, T.T.J. Whittaker</i>
CHAPTER 195	
Scale Effects of Wave Impact Pressures on Cob Armour Units2522
	<i>M.W. Howarth, N.W.H. Allsop, A.M. Vann, R.J. Jones, J.P. Davis</i>
CHAPTER 196	
Wave Impact Loading of Vertical Face Structures for Dynamic Stability	
Analysis - Prediction Formulae -2534
	<i>P. Klammer, A. Kortenhaus, H. Oumeraci</i>
CHAPTER 197	
Analysis on the Interaction of Waves with Flexible Floating Structure	
by BE-FE Combined Method2548
	<i>Xiaodong Liu, Shigeki Sakai</i>
CHAPTER 198	
Design Wave Height Related to Structure Lifetime2560
	<i>Zhou Liu, Hans F. Burcharth</i>
CHAPTER 199	
Wave Impact Beneath a Horizontal Surface2573
	<i>D.J. Wood, D.H. Peregrine</i>
CHAPTER 200	
Wave Impulse Prediction for Caisson Design2584
	<i>Michael J.A. Walkden, Peter J. Hewson, Geoffrey N. Bullock</i>
CHAPTER 201	
Wave Overtopping Rate and Reflection Coefficient for Obliquely Incident Waves2598
	<i>Yoichi Moriya, Masaru Mizuguchi</i>
CHAPTER 202	
Sediment Transport and Wave Reflection near a Seawall2612
	<i>Jonathon R. Miles, Paul E. Russell, David A. Huntley</i>

Part IV Coastal Processes and Sediment Transport

CHAPTER 203	
Wave Energy Dissipation in Kelp Vegetation2626
	<i>Alfonse Dubi, Alf Torum</i>
CHAPTER 204	
Experimental Study on the Effect of Gravity Drainage System on Beach Stabilization . .	.2640
	<i>Hiroshi Kanazawa, Fumihiko Matsukawa, Kazumasa Katoh, Iwao Hasegawa</i>

CHAPTER 205
Field Experiment on the Effect of Gravity Drainage System on Beach Stabilization ...2654
Kazumasa Katoh, Shin-ichi Yanagishima

CHAPTER 206
On the Change of Velocity Field in Nearshore Zone Due to Coastal Drain and the Consequent Beach Transformation2666
Michio Sato, Tadahiro Fukushima, Ryuichiro Nishi, Masahiko Fukunaga

CHAPTER 207
Evaluation of a Beach Dewatering System: Nantucket, USA2677
William R. Curtis, Jack E. Davis, Ian L. Turner

CHAPTER 208
Sediment Transport Processes at Ocean Beach, San Francisco, California2691
Robert T. Battalio, Dilip Trivedi

CHAPTER 209
Two Treatments of Shore Erosion in Extreme Floods on U.S. Great Lakes2705
Robert J. Hallermeier

CHAPTER 210
Long-Term Beach Response to Shore Stabilization Structures on the Oregon Coast ...2718
G.E. Hearon, W.G. McDougal, P.D. Komar

CHAPTER 211
Profile Volumes as a Measure of Erosion Vulnerability2732
Timothy W. Kana, Ram Krishna Mohan

CHAPTER 212
Breach Growth: Experiments and Modelling2746
Harry de Looff, Henk J. Steetzel, Arie W. Kraak

CHAPTER 213
The Impact of an Extreme Event on the Sediment Budget: Hurricane Andrew in the Louisiana Barrier Islands2756
Jeffrey H. List, Mark E. Hansen, Asbury H. Sallenger, Jr., Bruce E. Jaffe

CHAPTER 214
Beach Maintenance Strategies, a Comparison for a Recreational Beach2770
M. Pluijm, G. Kant, R. Nolten, A.P. de Looff

CHAPTER 215
Littoral Impact of Ocean City Inlet, Maryland, USA2779
Julie Dean Rosati, Bruce A. Ebersole

CHAPTER 216
Extreme Water Levels, Wave Runup and Coastal Erosion2793
P. Ruggiero, P.D. Komar, W.G. McDougal, R.A. Beach

CHAPTER 217	
A Morphological “Mixed-Type” Model for the Ebro Delta Coast	2806
<i>Agustin Sanchez-Arcilla, Jose A. Jimenez</i>	
CHAPTER 218	
Sea Dike Erosion and Coastal Retreat at Nam Ha Province, Vietnam	2820
<i>Ton That Vinh, G. Kant, Nguyen Ngoc Huan, Z. Pruszek</i>	
CHAPTER 219	
Beach Profile Analysis around Indian River Inlet, Delaware, U.S.A	2829
<i>Kirk F. Bosma, Robert A. Dalrymple</i>	
CHAPTER 220	
Improved 3-D Beach Evolution Model Coupled with the Shoreline Model (3D-SHORE)	2843
<i>Takuzo Shimizu, Takahiro Kumagai, Akira Watanabe</i>	
CHAPTER 221	
Evaluation of Shoreface Nourishments by Line Modelling	2857
<i>Martin D. Groenewoud, Willem T. Bakker, Jan van de Graaff, Ruud Spanhoff, Christian Laustrup</i>	
CHAPTER 222	
Beach Monitoring Program of Valencia (Spain)	2871
<i>Jose Serra, Josep R. Medina</i>	
CHAPTER 223	
Bar Migration and Duneface Oscillation on Decadal Scales	2884
<i>Marcel J.F. Stive, Jorge Guillen, Michele Capobianco</i>	
CHAPTER 224	
Morphological Development of the Terschelling Shoreface Nourishment in Response to Hydrodynamic and Sediment Transport Processes	2897
<i>P. Hoekstra, K.T. Houwman, A. Kroon, B.G. Ruessink, J.A. Roelvink, R. Spanhoff</i>	
CHAPTER 225	
Justification for Beach Nourishment	2911
<i>John G. Housley</i>	
CHAPTER 226	
Beach Nourishment Versus Shore Protection Structures	2918
<i>Alexander Khabidov, Yuri Bazhenov, Marina Glodenis, Nadya Ivanova, Liya Kaskevitch, Oleg Rybak, Valery Savkin, Anatoly Trizno, Grigory Zelensky, Veniamin Yedapin</i>	
CHAPTER 227	
Comparison of Beach and Shoreface Nourishment Torsminde Tange, Denmark	2927
<i>Christian Laustrup, Holger Toxvig Madsen, Per Sorensen, Ida Broker</i>	
CHAPTER 228	
Mathematical and Physical Modeling of Beach Nourishment Projects	2941
<i>W. Eric Rogers, Paul A. Work</i>	

CHAPTER 229	
Coastal Zone Dynamics during Artificial Nourishment	2955
<i>Elzbieta Zawadzka</i>	
CHAPTER 230	
Dune Damage Curves and Their Use to Estimate Dune Maintenance Costs	2969
<i>David R. Basco, Cheol S. Shin</i>	
CHAPTER 231	
Hurricane Opal Induced Changes on Natural and Nourished Beaches, West-Central Florida	2982
<i>Richard A. Davis, Jr., Ping Wang</i>	
CHAPTER 232	
Modelling Sand Transport and Profile Evolution on Macrotidal Beaches	2994
<i>Paul R. Fisher, Tim J. O'Hare</i>	
CHAPTER 233	
Beach Evolution Under Random Waves	3006
<i>Patrick Holmes, Thomas E. Baldock, Ray T.C. Chan, M. Ahmad L. Neshaei</i>	
CHAPTER 234	
Beach Profile Surveys Along the U.S. Pacific Coast 1945-1947	3020
<i>Nicholas C. Kraus, Robert L. Wiegel, Willard N. Bascom</i>	
CHAPTER 235	
Mechanism and Calculation of Sand Dune Erosion by Storms	3034
<i>Ryuichiro Nishi, Nicholas C. Kraus</i>	
CHAPTER 236	
Simulation of Coastal Profile Development Using a Boussinesq Wave Model	3048
<i>K.A. Rakha, R. Deigaard, P.A. Madsen, I. Broker, J.K. Ronberg</i>	
CHAPTER 237	
Cross-shore Sediment Transport and Beach Deformation Model	3062
<i>RattanapitikonWinyu , Tomoya Shibayama</i>	
CHAPTER 238	
Experimental Study on Sediment Transport in Surf and Swash Zones Using Large Wave Flume	3076
<i>Takao Shimizu, Masaaki Ikeno</i>	
CHAPTER 239	
The Influence of Long Waves on Macrotidal Beach Morphology	3090
<i>David J. Simmonds, Tim J. O'Hare, David A. Huntley</i>	
CHAPTER 240	
Mathematical Models for Waves and Beach Profiles in Surf and Swash Zones	3104
<i>Akira Watanabe, Mohammad Dibajnia</i>	

CHAPTER 241
Comparisons of Erosion Models for Storms at Ocean City, Maryland3115
Jie Zheng, Robert G. Dean

CHAPTER 242
Measurements of Wave Generated Bedforms3129
Christopher D. Jette, Daniel M. Hanes

CHAPTER 243
Field Measurement of Bed Roughness for Waves on an Offshore Reef3143
Raymond C. Nelson

CHAPTER 244
Effect of Wave-Induced-Pressure on Seabed Configuration3155
Tetsuo Sakai, Hitoshi Gotoh

CHAPTER 245
The Measurement of Bed Form Shapes in Hydraulic Models3169
Ian E. Shepherd

CHAPTER 246
Asymmetric Boundary Layer Flow above Sand Ripples under Progressive Waves3183
Takao Toue, Kazuo Nadaoka, Hidehiro Katsui

CHAPTER 247
Undertow Profiles in the Bottom Boundary Layer under Breaking Waves3194
Daniel T. Cox, Nobuhisa Kobayashi

CHAPTER 248
A Comparison of Field Observations and Quasi-Steady Linear Shear Instabilities of the Wave Bottom Boundary Layer3207
D.L. Foster, A.J. Bowen, R.A. Beach, R.A. Holman

CHAPTER 249
Wave Boundary Layer Flows and Pore Pressures in Permeable Beds3219
H.H. Hwang, K.S. Hwang, B.H. Lee

CHAPTER 250
Backfilling of Trenches Exposed to Waves3231
Jacob Hjelmager Jensen, Jorgen Fredsoe

CHAPTER 251
A Closed-Form Solution for Turbulent Wave Boundary Layers3244
Magnus Larson

CHAPTER 252
Observed Suspended Sediments in Storm Conditions3257
J.J. Williams, C.P. Rose, P.D. Thorne, L.E. Coates, J.R. West, P.J. Harcastle, J.D. Humphery, S.P. Moores, D.J. Wilson

CHAPTER 253	
Ebb Tidal Delta Evolution of Coastal Inlets	3270
<i>Michael R. Dombrowski, Ashish J. Mehta</i>	
CHAPTER 254	
Adjustments toward Equilibrium of a Large Flood -Tidal Delta after a Major Dredging Program, Tauranga Harbour, New Zealand	3284
<i>Terry Healy, Joseph Mathew, Willem de Lange, Kerry Black</i>	
CHAPTER 255	
Laboratory Mobile Bed Model Studies on Ebb Tidal Shoal Evolution	3295
<i>Xu Wang, Lihwa Lin, Hsiang Wang</i>	
CHAPTER 256	
Interaction of the Colorado River Project, Texas, with Longshore Sediment Transport ..	3309
<i>Daniel J. Heilman, Billy L. Edge</i>	
CHAPTER 257	
A Comprehensive Field Study of Tidal Inlet Processes at Ponce de Leon Inlet, Florida ..	3323
<i>Gary L. Howell</i>	
CHAPTER 258	
Transport of Fluid Mud Generated by Waves on Inclined Beds	3337
<i>Thijs van Kessel, C. Kranenburg, J.A. Battjes</i>	
CHAPTER 259	
Wave on Pebble Beach and Deformation of Pebble Beach	3349
<i>Ichiro Deguchi, Masanobu Ono, Toru Sawaragi</i>	
CHAPTER 260	
Wind-Induced Waves and Currents in a Nearshore Zone	3363
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroshi Kawakami</i>	
CHAPTER 261	
Predicting Large-Scale, Cross-Shore Sediment Movement from Orbital Speeds	3378
<i>Edward B. Hands, John P. Ahrens, Donald T. Resio</i>	
CHAPTER 262	
Small-scale Morphology Related to Wave and Current Parameters Over a Barred Beach	3391
<i>A.F. Garcez Faria, E.B. Thornton, T.P. Stanton</i>	
CHAPTER 263	
Prediction of Shoreline Change Considering Cross-Shore Sediment Transport	3405
<i>Yoshimichi Yamamoto, Kiyoshi Horikawa, Katsutoshi Tanimoto</i>	
CHAPTER 264	
The Influence of Rollers on Longshore Currents	3419
<i>Daniel A. Osiecki, William R. Dally</i>	

CHAPTER 265	
Velocity Field Measurements in a “Coastal Buffer Zone”	3431
<i>Hiroshi Yagi, Hirofumi Hinata, Kazuo Nadaoka</i>	
CHAPTER 266	
Development of Underwater Beach Profile by Monochromatic and Random Waves ...	3442
<i>Karsten Peters, Jurgen Newe, Hans-H. Dette</i>	
CHAPTER 267	
Turbulent Stresses in the Surf-Zone: Which Way Is Up?	3453
<i>John W. Haines, Guy Gelfenbaum</i>	
CHAPTER 268	
Asymmetric and Irregular Wave Effects on Bedload: Theory Versus Laboratory and Field Experiments	3467
<i>Leszek M. Kaczmarek, Rafal Ostrowski</i>	
CHAPTER 269	
Kinematics and Shear Stresses from Combined Waves and Longshore Currents in the UK Coastal Research Facility	3481
<i>Richard R. Simons, Ruairi D. MacIver, Wameidh M. Saleh</i>	
CHAPTER 270	
Movable Bed Roughness in the Flow of Irregular Waves and Currents Over Movable Beds	3495
<i>Zai-Jin You, Peter Nielsen</i>	
CHAPTER 271	
Seabed and Foundation Response to Wave Loading	3507
<i>Michael H. Davies</i>	
CHAPTER 272	
Interannual Shoreline Variations at Duck, NC, USA	3521
<i>Nathaniel Plant, Rob Holman</i>	
CHAPTER 273	
Long Term Behaviour of the Sediment Volume inside a Tidal Basin after Poldering ...	3534
<i>Ernst Schroeder, Roland Goldenbogen, Hans Kunz</i>	
CHAPTER 274	
Wave Groups in a Barred Nearshore	3546
<i>B. Boczar-Karakiewicz, W. Romanczyk, J.L. Bona, B. Greenwood</i>	
CHAPTER 275	
Coastal Morphodynamic Instabilities	3560
<i>Albert Falques, Amadeu Montoto, Vicente Iranzo</i>	
CHAPTER 276	
On Validation of a Sand Waves and Sand Banks Model	3574
<i>Suzanne J.M.H. Hulscher</i>	

CHAPTER 277	
Transverse Bars in Duck, North Carolina	3588
<i>Kathryn M. Konicki, Rob A. Holman</i>	
CHAPTER 278	
On the Systematic Offshore Decay of Breaker Bars	3600
<i>Kathelijne M. Wijnberg</i>	
CHAPTER 279	
Longshore Bed-Load Transport	3614
<i>Jesper S. Damgaard, Richard L. Soulsby</i>	
CHAPTER 280	
Design Capacity of a Longshore Current Recirculation System for a Longshore Sediment Transport Laboratory Facility	3628
<i>David G. Hamilton, Julie D. Rosati, Jimmy E. Fowler, Jane M. Smith</i>	
CHAPTER 281	
Influence of Nearshore Hardbottom on Regional Sediment Transport	3642
<i>Paul C.-P. Lin, R. Harvey Sasso</i>	
CHAPTER 282	
Improvement of the Most Accurate Longshore Transport Formula	3652
<i>J.S. Schoonees, A.K. Theron</i>	
CHAPTER 283	
Cross-shore Structure of Longshore Currents during Duck94	3666
<i>Falk Feddersen, R.T. Guza, Steve Elgar, T.H.C. Herbers</i>	
CHAPTER 284	
Three-Dimensional Hydrodynamics on a Barred Beach	3680
<i>Tae-Myoung Oh, Robert G. Dean</i>	
CHAPTER 285	
Rip Current Generation on a Plane Beach	3694
<i>D.A. Suriamihardja, Yoshito Tsuchiya</i>	
CHAPTER 286	
Nearshore Placement of Sand	3708
<i>Scott L. Douglass</i>	
CHAPTER 287	
Influence of Nearshore Berm on Beach Nourishment	3722
<i>Paul A. Work, Emre N. Otay</i>	
CHAPTER 288	
Accuracy of Sand Volumes as a Function of Survey Density	3736
<i>Jennifer L. Irish, W. Jeff Lillycrop, Larry E. Parson</i>	
CHAPTER 289	
Shoreline Analysis Using Digital Photogrammetry	3750

CHAPTER 290	
Application of Satellite Images to the Detection of Coastal Topography	3762
<i>Ji Wu, Jea Tzyy Juang</i>	
CHAPTER 291	
Sediment Transport in Swash Zone under Obliquely Incident Waves	3770
<i>Toshiyuki Asano</i>	
CHAPTER 292	
Sheet Flow Modelled As Pure Convection	3784
<i>Stephen Clark, Peter Nielsen</i>	
CHAPTER 293	
A Transport Rate Formula for Mixed-Size Sands	3791
<i>Mohammad Dibajnia, Akira Watanabe</i>	
CHAPTER 294	
Modelling of 3D Sediment Transport in the Surf Zone	3805
<i>Berry Elfrink, Ida Broker, Rolf Deigaard, Erik Asp Hansen, Peter Justesen</i>	
CHAPTER 295	
A Numerical Model of Sheet Flow Sediment Transport	3818
<i>Sadakazu Katori, Masaru Mizuguchi, Akira Watanabe</i>	
CHAPTER 296	
Numerical Modeling of Nearshore Morphological Changes under a Current-Wave Field	3830
<i>Taerim Kim, Hsiang Wang</i>	
CHAPTER 297	
An Analysis of Particle Saltation Dynamics	3846
<i>Michael R. Krecic, Daniel M. Hanes</i>	
CHAPTER 298	
Sediment Movement and Stress Condition in Sea Bed	3860
<i>Yoshihiko Maeno, Motoyasu Ishikawa, Kozo Bando, Yoshinobu Akiyama, Kouichi Yabe</i>	
CHAPTER 299	
Application of the Depth of Closure Concept	3874
<i>Robert J. Nicholls, William A. Birkemeier, Robert J. Hallermeier</i>	
CHAPTER 300	
Numerical Modeling of Sediment Transport for Various Mode	3888
<i>Masanobu Ono, Ichiro Deguchi, Toru Sawaragi</i>	
CHAPTER 301	
Nearbed Sediment Concentration from Tracer Studies	3901
<i>Zbigniew Pruszek, Ryszard Wierchnicki, Andrzej Owczarczyk, Ryszard B. Zeidler</i>	

CHAPTER 302	
A Sloping Duct for the Study of Sediment Transport	3913
<i>Jesper S. Damgaard, Richard J.S. Whitehouse, Richard L. Soulsby</i>	
CHAPTER 303	
Sediment Dynamics and Profile Interactions: DUCK94	3921
<i>Donald K. Stauble, Mary A. Cialone</i>	
CHAPTER 304	
A Study on Flow Structure and Suspended Sediment Concentration over Seaweed Bed .	3935
<i>Gozo Tsujimoto</i>	
CHAPTER 305	
An Energetics Approach for Suspended Sand Transport on Macrotidal Ridge and Runnel Beaches	3948
<i>George Voulgaris, Travis Mason, Michael B. Collins</i>	
CHAPTER 306	
Field Tests of Suspended-Load Transport Theories Used in Numerical Models	3962
<i>Thomas E. White</i>	
CHAPTER 307	
Shore Protection Studies for Ras-Elbar Area, Egypt	3976
<i>John B. Herbich, Abd-Elfattah Elfiky, Abd-Elmohsen Elmongy; Ali Elbahrawy, Gamal Elsaeed</i>	
CHAPTER 308	
Stabilizing Beaches Downcoast of Harbor Extensions	3986
<i>John R.C. Hsu, Richard Silvester</i>	
CHAPTER 309	
Observation of Nearshore Currents and Beach Changes around Headlands Built on the Kashimanada Coast, Japan	4000
<i>K. Saito, T. Uda, K. Yokota, S. Ohara, Y. Kawanakajima, K. Uchida</i>	
CHAPTER 310	
Nourished Beach Control Between Balis and Arenys Harbours (Spain)	4014
<i>F. Javier Escartin, Alfonso Vidoar; A.M. Castaneda, Nuria Lupon</i>	
CHAPTER 311	
Numerical Simulation of Shoreline Change with Longshore Sand Waves at Groins	4024
<i>Hans Hanson, Michelle M. Thevenot, Nicholas C. Kraus</i>	
CHAPTER 312	
Erosive Waves in Shoreline Change Due to the Reduction of a River Delta	4038
<i>Yoshito Tsuchiya</i>	
CHAPTER 313	
DELILAH, DUCK94 & SandyDuck: Three Nearshore Field Experiments	4052
<i>William A. Birkemeier, Charles E. Long, Kent K. Hathaway</i>	

CHAPTER 314	
Eulerian Mean Velocities under Non-Breaking Waves on Horizontal Bottoms	4066
<i>Peter Nielsen, Zai-Jin You</i>	
CHAPTER 315	
Reynolds Stress and Small-Scale Morphology Measurements during DUCK94	4079
<i>Timothy P. Stanton, Edward B. Thornton</i>	
CHAPTER 316	
Studies on the Suspended Concentration in the Surf Zone	4088
<i>Ching-Her Hwang, Li-Hung Tsai, Po-Ching Lin, Chin-Chi Tsai</i>	
CHAPTER 317	
Suspended Sediment Mixing in the Surf Zone	4098
<i>Jose A. Jimenez, Francisco J. Rivero, Agustin Sanchez-Arcilla, Vicente Gracia, Andres Rodriguez</i>	
CHAPTER 318	
Sand Suspension Events and Intermittence of Turbulence in the Surf Zone	4111
<i>R.D. Kos'yan, H. Kunz, S.Yu. Kuznetsov, N.V. Pykhov, M.V. Krylenko</i>	
CHAPTER 319	
Mechanisms of Beach Ground Water and Swash Interaction	4120
<i>Andrew J. Baird, Travis E. Mason, Diane P. Horn</i>	
CHAPTER 320	
The Equations for Integral and Mean Flow Properties in the Swash Zone	4134
<i>M. Brocchini, D.H. Peregrine</i>	
CHAPTER 321	
Wave Overwash of Subaerial Dunes	4148
<i>Yukiko Tega, Nobuhisa Kobayashi</i>	
CHAPTER 322	
Pressure Gradients Within Sediment Beds	4161
<i>Thomas E. Baldock, Patrick Holmes</i>	
CHAPTER 323	
Analysis of Mud Mass Transport under Waves Using an Empirical Rheological Model . .	4174
<i>Qin Jiang, Akira Watanabe</i>	
CHAPTER 324	
Countermeasures Against Wind-Blown Sand on Beaches	4188
<i>Shintaro Hotta, Kiyoshi Horikawa</i>	
CHAPTER 325	
Sea Breeze Effects on Nearshore Coastal Processes	4200
<i>Charitha Pattiaratchi, Gerhard Masselink</i>	
CHAPTER 326	
Wind Blown Sand at Castroville, California	4214
<i>Douglas J. Sherman, Bernard O. Bauer, Paul A. Gares, Derek W.T. Jackson</i>	

Part V Coastal, Estuarine and Environmental Problems

CHAPTER 327	
Pipeline Protection in the Surf Zone	4228
<i>Gerrit J. Schiereck, Henri L. Fontijn</i>	
CHAPTER 328	
Modeling Tidal Circulation in Florida Bay	4242
<i>Y. Peter Sheng, Justin Davis</i>	
CHAPTER 329	
Recent Developments in Coastal Defence Policy and Guidance in England	4253
<i>Reg Purnell</i>	
CHAPTER 330	
Structural Restoration of Coral Reefs Damaged by Vessel Groundings	4261
<i>Kevin R. Bodge</i>	
CHAPTER 331	
Dredging and Disposal within the Limits of a National Park	4274
<i>H. A. Manzenrieder, J.M. de Vries</i>	
CHAPTER 332	
Storm-Derived Bar/Sill Dynamics in a Dredged Channel	4289
<i>Sean O'Neil, Keith W. Bedford, David P. Podber</i>	
CHAPTER 333	
Bivalve Habitat Based on Sediment-Transport Mechanics	4300
<i>Hitoshi Gotoh, Tetsuo Sakai</i>	
CHAPTER 334	
Hydraulic Controls on Tidal Wetlands	4314
<i>R. Eric Katmarian, Philip A. McKee, Timothy W. Kana</i>	
CHAPTER 335	
Enhanced Mixing Through Perforated Discs on Round Buoyant Jet	4325
<i>Lilun Wu, Jiin-Jen Lee</i>	
CHAPTER 336	
Assessing Coastal Flood Risks	4339
<i>Roger Maddrell, Chris Fleming, Chris Mounsey</i>	
CHAPTER 337	
Experimental Study on the Behavior of Bivalves by Oscillatory Flow	4353
<i>Toshihiko Yamashita, Akira Wada, Gaku Matsuoka, Kenji Yano, Sadamitsu Akeda</i>	
CHAPTER 338	
Wind- and Sea Level-Induced Shore Evolution in Poland	4364
<i>Ryszard B. Zeidler, Marek Skaja, Grzegorz Rozynski, Jarka Kaczmarek</i>	

CHAPTER 339	
Ashdod Port's Effect on the Shoreline, Seabed and Sediment	4376
<i>Abraham Golik, Dov S. Rosen, Arik Golan, Maxim Shoshany Dan DiCastro, Pinkhas Harari</i>	
CHAPTER 340	
Tweed River Sand Bypass: Concepts and Progress	4390
<i>Russell J. Murray, R.P. (Jock) Brodie, Mark Porter, David A. Robinson</i>	
CHAPTER 341	
Design Considerations for Coastal Projects in Cold Regions	4397
<i>Craig B. Leidersdorf, Peter E. Gadd, Kennon D. Vaudrey</i>	
CHAPTER 342	
Experimental Study on Deformation and Fracture of Ice Sheet by Propagating Water Wave	4411
<i>Shigeki Sakai, Xiaodong Liu, Makoto Sasamoto, Shigeo Kanada and Koh Izumiyama</i>	
CHAPTER 343	
An Attempt to Determine the Spanish Public Domain Border	4418
<i>R. Medina, I.J. Losada, F. Mendez, A.J. Fernandez</i>	
CHAPTER 344	
Education of Coastal Engineers for the 50th ICCE	4431
<i>Henk Jan Verhagen</i>	
CHAPTER 345	
Risk-Based Analysis of Coastal Projects	4440
<i>Edward F. Thompson, Michael Wutkowski, Norman W. Scheffner</i>	
CHAPTER 346	
Designing for Propeller Action in Harbours	4451
<i>G.A. Hamill, J.A. McGarvey</i>	
CHAPTER 347	
Modeling Inlet Sand Bypassing	4464
<i>Christopher G. Creed</i>	
CHAPTER 348	
An Approach to Modeling Inlet and Beach Evolution	4477

CHAPTER 98

Uncertainties in the Validation of Harbor Wave Models

Zeki Demirbilek¹, Bingyi Xu & Vijay Panchang²

Abstract

Various sources of uncertainties contributing to the difficulties in the validation of harbor wave models with field measurements are discussed in this paper. Some aspects of a new theoretical formulation for removing these uncertainties for estimates of waves in harbors are presented. Implementation of the new formulation is illustrated for waves incident on a planar beach by comparing numerical model predictions to the closed-form analytical solution for normal incident waves and to the results from an one-dimensional Helmholtz equation for oblique waves.

Introduction

Reliable modelling of coastal hydraulic phenomena is vital for commercial and military activities, including harbor design, shoreline evolution, navigation, ship motion during loading/unloading operations, dredging, design of structures, harbor wave agitation, contaminant transport, just a few to name. Military coastal hydraulics deals with amphibious operations, mooring forces, mine movement, and others. Computer models presently play an important role in the ever-increasing coastal activities in some countries, and in the past two decades, industrial activity in the coastal and offshore environment worldwide has witnessed a phenomenal growth. Many nations have quite liberal policies to promote the development of new ports and harbors to meet the need for growing exploration and transport of petro-products, aquaculture, and commerce by shipping. Ongoing and future investment by governments, international participants, and the private sector will further accelerate the use of numerical wave prediction models for coastal projects and design studies.

Although a number of mathematical models have been successfully developed

¹U.S. Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199

²Department of Civil and Environmental Engineering, University of Maine, Orono, ME 04469-5706

worldwide for coastal hydraulics, wave modelling confronts us with numerous complexities in the physics and the numerics. Many available models have been developed in a somewhat ad-hoc manner with the immediate needs of a project in mind, and time and budgetary constraints have often taken priority over rigorous model evaluation and systematic development. In fact, many model solutions are perforce accepted at face value, even though model sensitivity to grid resolution, open boundary conditions, parameters associated with various mechanisms, model assumptions, etc. are almost never tested.

This paper addresses a general discussion of some of the key uncertainties in the validation of harbor wave models. Using a state-of-the-art wave model called "CGWAVE", model uncertainties are discussed for a simple application, waves transforming over a plane sloping beach. The CGWAVE model is developed by the US Army Corps of Engineers and the US Navy in collaboration with the University of Maine, for civil and military applications. CGWAVE is a comprehensive and sophisticated finite-element nearshore wave prediction model that can be used for predicting wave climate either in open-coast type applications or in harbors of irregular bathymetry which are surrounded by complex land boundaries and protective structures such as jetties, breakwaters, or islands.

The model CGWAVE is based on the elliptic mild-slope wave equation and can simultaneously simulate the effects of refraction, diffraction, reflections by bathymetry and structures, dissipation due to friction and breaking, and nonlinear amplitude dispersion. The computational capabilities of CGWAVE model permit the modeling of large coastal regions. The model has been compared to several academic test-cases and laboratory data for complex bathymetries (e.g. Panchang et al. 1990, 1991, 1996; Xu and Panchang 1993; Panchang et al. 1993; Panchang & Xu 1995; Xu et al. 1996). The governing equations of CGWAVE pass, in the limit, to the deep and shallow water equations, making this model applicable to a wide range of frequencies, including short wind waves, swell, and infra-gravity waves.

Harbor Models and Applications

The three most widely-known elliptic wave models are HARBD (Chen and Mei 1974; Mei 1983; Chen & Houston 1987), PHAROS (Kostense et al. 1986), and CGWAVE (Panchang et al. 1991; Xu, Panchang & Demirbilek 1996). These steady-state models may either use finite-element or finite-difference schemes for solving the governing equations and associated boundary conditions for calculating the linear wave oscillations in harbors of arbitrary configuration and variable bathymetry. Effects of bottom friction and boundary absorption (reflection) are included. Boundary reflection is based on a formulation similar to the impedance condition in acoustics, expressed as a function of the wavenumber and reflection coefficient.

For modeling waves over an arbitrary depth, these models divide the water domain into near- and far-regions. The near-region, also known as the model domain

(Fig. 1), that includes the actual harbor, is bounded by an offshore boundary, in the form of a semi-circle for HARBD and PHAROS models, and a semi-circle or rectangular-box boundary for CGWAVE. The offshore boundary is a mathematical artifice and typically is located some distance offshore of the harbor entrance. The near-region encompasses the entire harbor area and all its protective marine structures, and part or all of the entrance and approach navigation channels. Water depth in the near-region is generally variable, overlaid with a finite-element triangular-mesh whose grid resolution is determined by the project-specific design wave conditions. Element attributes such as water depth and bottom friction are specified at the centroid of each element. For those elements along the solid boundaries (land or structure), a reflection coefficient is assigned to each element.

Figure 1. Near- and Far-regions (Model & Exterior Domain) & Open Boundary, Γ .

The far-region, also known as the exterior domain (Fig. 1), of the elliptic wave models covers the domain outside the offshore boundary of the near-region, and is bounded by the coastline and deepwaters of the sea, extending to infinity (Fig. 2). Water depth in the far-region is assumed to be constant for HARBD and PHAROS models, whereas it is treated as variable depth in the CGWAVE model (Fig. 3). Bottom friction and reflection are neglected in the far-region. The constancy of water depth in the far-region for HARBD and PHAROS models permits a simpler analytical solution of waves at the expense of introducing some undesirable depth-discontinuities at the interface between the near-region and the coastlines on either side of the harbor entrance. These discontinuities are one of the major source of difficulties in the validation of elliptic wave models. CGWAVE avoids this problem by considering the water depth in the far-region to be piece-wise continuous by allowing the water depth to change in the cross-shore direction as waves approach the coastlines and the harbor. This is one of the major differences between CGWAVE

and all other existing elliptic models. In CGWAVE, the wave field in the far- and near-regions is obtained by solving the one- and two-dimensional Helmholtz equations, respectively. These two solutions are mathematically coupled along the offshore boundary of the modeling domain to obtain the complete wave field estimates in the combined regions.

Figure 2. Collinear and Fully-reflective Exterior Coastlines.

Elliptic wave models require a wave period and direction as input, as well as the three-dimensional coordinates for the near-region finite-element mesh. For CGWAVE, grid coordinates for the far-region are also required. In addition, models may require certain parameters for their numerical solvers, which vary from model to model depending on the specific numerical algorithms used to solve the linear system of equations. CGWAVE model uses a Galerkin formulation for discretizing its equations. The resulting matrix equations are solved iteratively using the so-called conjugate gradient method (CGM). The CGM (Panchang et al. 1991; Li 1994) is a powerful, iterative scheme for solving system of equations without any matrix inversion. The iterative solution scheme of CGWAVE significantly improves our wave modelling capabilities in the nearshore when large domains have to be modelled using highly refined grids. While the basic model developed so far incorporates all the nearshore wave transformation mechanisms noted earlier and also includes a graphical user interface, a number of important questions remain. These remaining issues introduce uncertainties into the predictions of models as described in the following sections of this paper.

Uncertainties due to Model Assumptions

Traditional elliptic harbor wave models such as HARBD and PHAROS are based on the assumptions that the exterior sea region outside the computational finite-element grid is of constant depth and that exterior coastlines are collinear and fully reflecting (Figs. 2 & 3). These assumptions are generally not true for most practical applications and their effects on model predictions are substantial (Xu, Panchang, and Demirebilek 1996), resulting in unreliable simulations. This is not surprising since the exterior geometry varies arbitrarily, and the unrealistic bathymetric representation used by modelers should invariably have an adverse influence on model predictions.

Figure 3. Exterior Domain Bathymetry Representation for CGWAVE model.

A solution to this problem has been to extend the near-region as far as possible to minimize the effects of these assumptions. But, this practice in turn introduces some prohibitive computational resource demands that are difficult to meet. An alternative solution has been developed (Xu, Panchang, and Demirebilek 1996) that eliminates such demands by invoking the use of parabolic approximation as the open boundary condition for the scattered waves. Theoretical details and implementation of this innovative method are omitted here since several illustrations of its practical applications have been presented in that paper.

The requirement that exterior coastlines are fully reflecting is particularly troublesome, almost always giving rise to extremely large wave amplitude estimates and rapidly varying wave patterns in the exterior region of the modeling domain. This has been illustrated by the authors (see Fig. 2 in Xu, Panchang, and Demirebilek 1996), in which CGWAVE predictions for Toothacher Bay, Maine were obtained by forcing CGWAVE to mimic a HARBD-like solution. In this application, using full

reflection from exterior coastlines of low reflectivity did clearly lead to erroneous model results, and made the said assumption very problematic. The parabolic approximation treatment of the scattered waves developed by Xu, Panchang, and Demirbilek (1996) does in deed overcome this requirement and allows the modeler much greater flexibility for tackling realistic applications.

In fact, there are a number of sources that give rise to uncertainties in the predictions of elliptic models, including:

- model set-up/open boundary location
- coastal reflectivity
- grid resolution
- parameters (dissipation, etc.)
- forcing (input)

These uncertainties make the validation and comparison of models to field measurements difficult. A brief discussion of the role played by the open boundary in these uncertainties is presented next.

Uncertainties due to Open Boundary

Figure 2 depicts the open boundary Γ , shown as a semi-circular boundary that separates the near-region Ω from the far-region Ω' . The solution of problem, expressed in term of the velocity potential Φ , in the far-region (exterior region) consists of the incident (Φ_i), reflected (Φ_r), and scattered (Φ_s) components, respectively. Both HARBD and PHAROS make use of the Bessel-Fourier series for representation of Φ_s . This traditional approach for determining Φ_s requires (1) depths in the exterior-region Ω' be constant, (2) exterior coastlines A_1D_1 and A_2D_2 be fully-reflecting, and (3) exterior coastlines A_1D_1 and A_2D_2 be collinear. All three requirements which are unrealistic for practical applications, can be avoided using the parabolic representation of Φ_s (Xu, Panchang, and Demirbilek 1996). Advantages of this new approach are that it eliminates requirements (2) and (3). A novel approach for eliminating requirement (1) has also been developed by the same authors and was presented in the ICCE'96. Their proposed solution for eliminating the requirement #1 was to represent the bathymetry in the far-region by a piece-wise continuous one-dimensional (1-D) bathymetry (Fig. 3) to solve the 1-D Helmholtz equation for $\Phi_0 = \Phi_i + \Phi_r$ in the exterior domain. This 1-D solution for Φ_0 and the parabolic solution of Φ_s are then used along the open boundary Γ for coupling of the solutions of the near- and far-regions. Figure 4 presents an illustration of this method for predicting waves on a 3-km long planar beach with a slope of about 1:50 and offshore depth of 54 m. CGWAVE predictions for this problem are next discussed for different incident wave conditions, for both normal incident and oblique waves, and model predictions are compared to the closed-form analytical J_0 -solution (Mei 1983) of this problem.

Figure 4. CGWAVE Model Setup for a Planar Beach of About 1:50 Slope.

Discussion of Waves on a Sloping Beach

In the comparison of CGWAVE to the analytical solution, we examine the performance our model CGWAVE for different sizes of the semi-circle and the cross-shore extent of the exterior domain. Due to space limitations, model results will only be presented at three on-offshore cross-sections. We choose cross-sections 1 and 3 at 500 m from the left- and right-edge of the semi-circle, respectively, and cross-section 2 at the center of the semi-circle. Since the open-boundary related effects manifest themselves mainly near that boundary, the greatest differences between the model predictions and the analytical solution should occur at cross-sections 1 and 3, and the least difference at cross-section 2. In addition, as the size of the semi-circle decreases, the effect of the boundary should become more dominating throughout the entire domain. Conversely, for a larger semi-circle, these effects should be localized in the vicinity of the open boundary.

Figures 5 and 6 represent model versus the analytical solution results for a 3-km domain (i.e. diameter of the semi-circle is 3 km) for normal and oblique incident waves, respectively, of 260 sec period. The agreement between the model and J_0 solution in all three cross-sections is excellent for both normal and oblique incident waves. Since the J_0 -solution is for normal incident waves, we provide in Figure 6 a true comparison of the CGWAVE model estimates to the solution from a one-dimensional Helmholtz equation, the exact solution of this problem for 30-degrees

Figure 5. Comparison of CGWAVE Model Predictions versus Analytical Solution at Three Cross-sections for a 3-km Planar Beach (Normal Incident).

Figure 6. Comparison of CGWAVE Model Predictions versus 1-D Solution (Helmholtz Equation) at Three Cross-sections for a 3-km Planar Beach (Oblique Incident).

oblique waves from left of the normal to the boundary. Model compares extremely well to this solution also at all three sections.

Figure 7. Comparison of CGWAVE Model Predictions versus Analytical Solution at Three Cross-sections for a 2-km Planar Beach (Normal Incident).

The results of CGWAVE model for a 2-km domain are presented in Figs. 7 and 8. For this smaller domain, model estimates still compare exceptionally well to the predictions from the J_0 -solution and 1-D Helmholtz equation even though the modeling domain has been reduced by 30 percent. This shows that CGWAVE results are robust and do not vary as the domain size varies.

Figure 8. Comparison of CGWAVE Model Predictions versus 1-D Solution (Helmholtz Equation) at Three Cross-sections for a 2-km Planar Beach (Oblique Incident).

Lastly, model results at cross-section 1 are shown for a domain size ranging from 1.5 to 6 km in Fig. 9. We can clearly see a slight change in the model results when the domain size is varied four-fold, but overall, CGWAVE predictions do not show any strong dependence to the size of the modeling domain.

Figure 9. Comparison of CGWAVE Model Predictions versus Analytical Solution at Cross-section 1 for Varying Widths of Beach (Normal Incident).

Conclusions

Elliptic wave models that use the traditional mathematical formulation for wave estimates in the offshore and inside the harbors impose some unrealistic demands as described earlier in this paper. Exterior depth variations in the outside areas of the harbor neglected by these models and the position of the semi-circular open boundary become rather problematic in the field application of these models. Presented here is a discussion of some solutions for eliminating the effects of these undesirable demands. We have demonstrated here the implementation of the proposed solutions for waves on a plane sloping beach by providing a comparison of the model predictions and analytical and approximate solutions.

Our proposed solutions are compromises between an account of the effects of the field bathymetry and radiation boundary condition. The presented model results show that the proposed solutions work very well and that a negligible contamination occurs due to relaxation of the open boundary condition. The suggested solutions eliminate the need to select a constant depth in the exterior region. Our new formulation of the scattered waves greatly reduces the sensitivity of model predictions to the position of the open boundary. Efforts are underway now to evaluate these new ideas implemented in the CGWAVE model for Kahului, Barbers Point, and Oceanside harbors using field measurements.

This work was carried out under the Coastal Research Program of Civil Works Research and Development. The Office of the Chief of Engineers, U.S. Army Corps of Engineers is acknowledged for authorizing publication of this paper.

CHAPTER 99

FIELD MEASUREMENTS AND NUMERICAL MODELING OF HARBOR OSCILLATIONS DURING STORM WAVES

W. M. Jeong¹, J. W. Chae², W. S. Park¹, and K. T. Jung²

Abstract

A series of simultaneous field measurements for long and short-period waves under storm and calm wave conditions were made to understand harbor resonances in a partially enclosed harbor. During storm condition the frequency spectra show peaks of considerable magnitude around the wave period of 1 ~ 5 minutes, which are bounded long waves and their harmonics. They are strongly related with storm waves but longer period (free long) waves are not in the harbor. Numerical tests were also carried out by using the hybrid element model including entrance separation losses in a simple rectangular harbor to validate the model for a mostly constricted entrance case. Further the model was used to simulate the long period oscillation in Muko harbor. Comparisons were made between field data and numerical results to discuss the effect of storm waves on the long period oscillations. Tests demonstrate the effect of input parameters on model results and proper choice of them are stressed.

INTRODUCTION

Long-period wave oscillations in a harbor could create unacceptable vessel motions, excessive mooring forces and fender reactions leading to the breaking of mooring lines and fender system. The typical natural periods of a reasonable sized harbor or a moored vessel are of the order of magnitudes of minutes (Nagai *et al.*, 1994). One of the sources that generate the long-period waves of 2 ~ 3 minutes in the offshore side is the wave set-down travelling with the wave groups. In a partially enclosed harbor attacked by short waves through the narrow entrance, free long waves can be generated, and the waves further resonate the natural modes of the harbor basin (Mei and Agnon, 1989; Wu and Liu, 1990). Recently Girolamo (1996), and Okihiro and Guza (1996) showed that irregular short waves generate bounded long waves and free long waves which excite harbor resonance with extensive analyses of experimental and field measured data, respectively.

²Principal Research Scientist

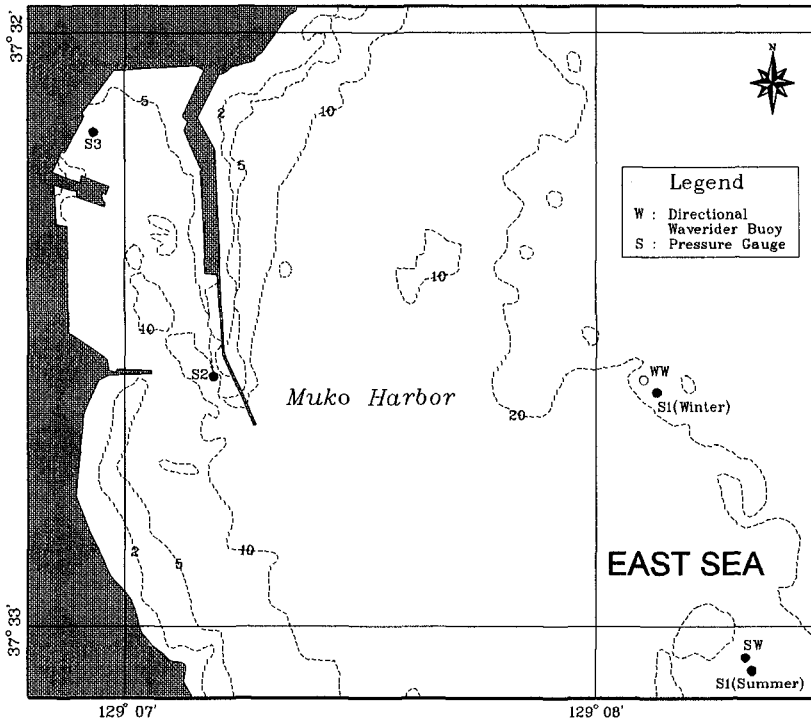

Figure 1: Location map for field measurements around Muko harbor.

Most of previous studies are restricted to theoretical analysis with limited number of narrow frequency waves, and a few experimental and field measurement works taking into account irregular frequency-directional waves during storm conditions. As actual wind waves do not lie in a narrow frequency band, the resonance process is different. In order to investigate the effect of storm short waves to long-period harbor oscillations, a series of field measurements were conducted for both random sea waves and long-period waves inside and outside a small harbor. Harbor amplifications were calculated using HARBD linear model (Chen, 1986) including entrance loss and directional effects (Sand, 1982).

FIELD MEASUREMENTS AND ANALYSIS

Such phenomena of long-period oscillations were observed in the Muko harbor located at the east coast of Korea where north-eastern storm waves are dominant in winter season. The harbor is of a partially-enclosed rectangular shape with dimensions of 1 km long, 410 m wide, and entrance width of 250 m as shown in figure 1. The averaged water depth in the harbor is about 8.5 m.

4	07/09 01:08	18.0~27.8	13.3~14.6, 5.8	13.3	0.43	4.4	N19 ° E
5	07/10 11:16	20.4~27.8	20.4, 13.3	11.4~13.3	0.37	5.2	N54 ° E

* Each record length is 34.1 hr.

** Shaded numeral denotes peak period corresponding to peak spectral density.

Figure 3: Typical directional spectrum of a short-period wave condition.

To investigate the relationship of short-period storm waves and long-period waves in a harbor, field measurements were performed at three reference stations as shown in figure 1. Using a Datawell directional waverider buoy short-period waves were measured at offshore stations WW and SW for 26.7 minutes at every hour in the interval of 0.78125 second. The frequency of the waves is in the range from 0.04 Hz (25 sec) to 0.25 Hz (4 sec). Using pressure-type wave gauges long-period waves were simultaneously measured at three stations S1, S2 and S3 (figure 1) for March 18 ~ 21 and July 7 ~ 12, 1993. Five sets of data (Table 1) were chosen for the analysis which show typical storm and calm wave conditions. Each set was recorded at 5 second intervals and recording length is approximately 34 hours. Typical time series of measured long-period waves for storm and calm sea conditions are presented in figure 2. It can be clearly found that the long period waves are amplified in a harbor and modulated with tide.

Directional-frequency spectra were obtained from the short-period wave analyses using Maximum Entropy Method (Kobune and Hashimoto, 1986), which show spreading of wave energy in both frequency and directional bands (figure 3). They are different from the narrow frequency banded waves used in the theoretical analysis. After filtering low-frequency waves from long-period wave signals using Butterworth high-pass filter in MATLAB, spectral analyses were made for each record of 4096 data points (at 30 second intervals averaged over 6 raw data). Standard spectral analysis based on FFT provides wave parameters and frequency spectrum that was herein obtained averaging over 16 raw harmonics. Two typical frequency spectra of storm and calm seas corresponding to time series of figure 2 in 128 frequency bands are shown in figure 4. Several peak frequency bands can be found around the wave period of 1 ~ 5 minutes in the frequency spectrum for the storm wave condition, which may be resulted from group-bounded long waves and their harmonics resonated in the harbor (refer to Girolamo, 1996).

(a)

(b)

Figure 4: Power spectra measured around Muko harbor; (a) Storm sea; (b) Calm sea.

LONG-PERIOD WAVES AND HARBOR RESONANCE

Several resonant peaks are clearly seen in the frequency spectrum of long-period waves in the harbor when the storm waves occurred outside the harbor (figure 4(a)). However, only primary resonant peak can be seen in the calm sea condition (figure 4(b)). The observations reveal that long-period waves in the harbor are excited due to the nonlinear resonance by the groups of short waves.

On the basis of case studies of Wu and Liu (1990), it is possible to analyse approximately the characteristics of the oscillations. A little difference in the bounded long waves across the harbor mouth could generate free long waves of small amplitude in the neighbourhood of the first mode. But bounded long waves could be dominant at frequencies beyond the first mode because the harbor entrance is relatively large in comparison with the dimension of the harbor basin. The bounded long waves are mainly affected by short waves (swell) and resonated in the small harbor, but the first resonant mode and free long waves are not dependant on them. It may be because of nonlinear energy dissipation in the harbor entrance even with the increase of the bounded long wave energy.

NUMERICAL MODELING

Mild slope equation of Berkhoff (1972) was adopted for simulating the harbor oscillations. There are three major energy dissipating processes in harbor resonance problem, i.e., bottom friction, energy absorption at solid boundaries, and entrance separation. Chen (1986) considered first two terms in his hybrid element model by introducing frictional loss parameter in governing equation and partial absorbing boundary condition. The governing equation and boundary conditions of Chen's model are summarized in figure 5. In the figure, ϕ is the complex-valued velocity potential in finite element region; ϕ^s is the velocity potential for scattered waves in the far field region; λ is the frictional parameter; α is a coefficient related to the wave reflection characteristics on solid boundaries; and C and C_g are celerity and group velocity, respectively.

Harbor Entrance Energy Loss

In this study, entrance separation losses were considered by introducing two matching conditions at the harbor mouth depicted as a dashed line in figure 6 as follows.

Continuity equation:

$$u_1 = u_2 = u_e \quad (1)$$

Dynamic equation:

$$\frac{p_1}{\rho} = \frac{p_2}{\rho} + \frac{1}{2} f_e u_e |u_e| + l \frac{\partial u_e}{\partial t} \quad (2)$$

in which u_1 and u_2 are water particle velocities in open sea region, A_1 and inner harbor region, A_2 , respectively; u_e is the velocity of water particle at harbor entrance; f_e is loss coefficient; and l is the length of the jet flowing through the harbor mouth.

Figure 5: Hybrid element model, HARBD (Chen, 1986).

The second term of right hand side of equation (2) is generally nonlinear. To solve the boundary value problem efficiently in frequency domain, it should be linearized. Using Lorentz's transformation and averaging power along the water depth, it can be linearized as

$$\frac{1}{2} f_e u_e |u_e| \approx \gamma u_e \tag{3}$$

in which γ is the linearized loss coefficient including amplitude of water particle velocity at the interface of A_1 and A_2 , which is given by

$$\gamma = \frac{4}{3\pi} f_e \bar{u}_e \frac{\sinh kh}{\cosh kh} \frac{2(5 + \cosh 2kh)}{3(2kh + \sinh 2kh)} \tag{4}$$

in which \bar{u}_e is the amplitude of u_e ; k is the incident wave number; and h is the depth of water.

Using complex valued velocity potential, the linearized matching conditions can be rewritten as

$$\frac{\partial \phi_1}{\partial n} = - \frac{\partial \phi_2}{\partial n} \tag{5}$$

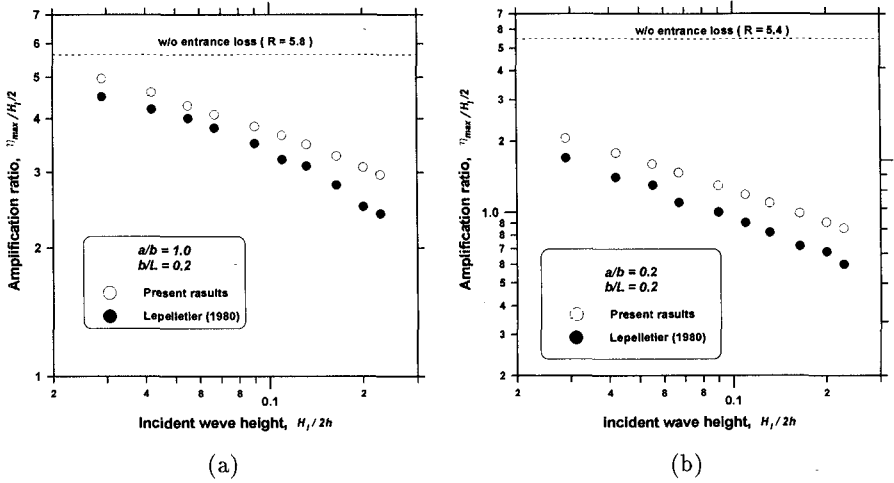

Figure 6: Variation of amplifications varying with incident wave heights; (a) fully opened case; (b) partially opened case.

$$\phi_1 = \phi_2 + \left(\frac{i\gamma}{\omega} + l \right) \frac{\partial \phi_2}{\partial n} \tag{6}$$

The entrance loss coefficient, f_e , are determined from the empirical formulation developed by Lepelletier (1980) given by

$$f_e = \begin{cases} CS & \text{for } S \leq 1 \\ C & \text{for } S \geq 1 \end{cases} \tag{7}$$

in which S is Stroul number ($=u_e/a\omega$); C is empirical coefficient, 0.8 for fully opened harbor ($a/b = 1.0$) and 1.15 for partially opened harbor ($a/b \leq 0.8$); a is the width of entrance; and b is the width of harbor.

Comparison with Experimental Data

With reference to Lepelletier's (1980) laboratory tests a simple rectangular harbor was chosen for numerical calculation of amplification factors. The harbor bottom is flat and widths of the entrance gap are 0.2 (partially open) and 1.0 (fully open) times the harbor width. Using the values of K_r and β (discussed in Thompson et al., 1993), the modified Chen's model was run for the two cases (figure 6). The amplification factor is half as big as Lee's (1969). As shown in the figures the amplification factors taking into account of harbor entrance loss effects are reasonably in good agreement with the data for the most constricted entrance case (figure 6(b)). It can be said that the linear model (HARBD) with linearization of nonlinear dissipation term due to flow separation in the harbor entrance will be a good tool for the estimation of the amplification of a restricted harbor. In case of Muko harbor the entrance energy loss may be not significant because the harbor is relatively wide opened.

No. of Nodes = 7,408
 No. of Elements = 14,379

Figure 7: Finite element mesh for Muko harbor.

Model Application

The modified model was applied to calculate the harbor amplification due to group bounded and free long waves generated during the storm wave condition and resonated in the Muko harbor. Model boundary was taken large enough to cover offshore measurement station S1 as shown in figure 7. The water depth of far field area (analytic solution region in HARBD model) is assumed to be constant. Reflection coefficients vary from 0.95 (natural beach) to 0.99 (vertical sea wall) and also vary depending on the magnitude of frequency (i.e., from 0.4 for 15 sec to 0.98 for 180 sec waves at energy absorbing boundary). The numbers of triangular elements are 14379 and its size is small in order to resolve 30 sec period wave in water of 8.5 m depth. Numerical computation has been made for the 54 component waves of period range from 60 sec to 1400 sec. Some comparison was made with experimental data. The amplification ratio is $\sqrt{S_i(f)/S(f)}$, where $S_i(f)$ is spectral density at the i -th point in the domain and $S(f)$ at offshore station. Figure 8 shows the amplification ratio at C7 (measurement station S3), and computation results are in reasonably good agreement with measured data, where water depth is chosen as mean depth of 17.2m. The water depth effects are dominant on the waves around the first resonant peak. The incident wave direction is also very important on the estimation of harbor amplification especially in high frequency range below 350 sec in Muko harbor (figure 9). Those wave periods are related with bounded long waves. Upon the test results of partial wave reflection (figure 10) the coefficient should vary depending on the wave length up to a certain wave period. With proper choice of parameters the modified numerical model performs reasonably well in relation to field data.

Figure 8: Comparison of normalized amplification ratios obtained by measurements and numerical calculation with various water depths in far field region.

Figure 9: Variation of normalized amplifications with incident wave directions.

Figure 10: Comparison of normalized amplification ratios obtained by measurement and numerical calculation with different reflection coefficients.

CONCLUSIONS

Field measurements of short- and long-period waves were made to understand long-period oscillations generated by storm waves in a partially enclosed harbor. In a storm wave condition the frequency spectrum shows several resonant peaks, which are free long waves in the neighbourhood of the first mode, and bounded long waves and harmonics in the other modes. The bounded long waves are strongly dependent on short wind waves but the longer waves may be not. Chen's linear model was modified to cope with entrance energy losses due to flow separation. The model provided a good approximation to the harbor amplification of major resonant modes in the Muko harbor.

CHAPTER 100

PERFORMANCE OF A RESONATOR DESIGNED BY THE WAVE FILTER THEORY – APPLICABILITY TO A HARBOR

Takayuki Nakamura¹, Hitoshi Mochizuki² and Satoshi Morita³

ABSTRACT

A wave resonator, which has a comparatively wide opening and still keeps effectiveness for a wider range of wave frequency, is newly developed based on the Wave Filter Theory. Applying this resonator both to a long channel and a harbor entrance, the sheltering effect for incoming waves was examined by the numerical and physical experiments. It was confirmed that the Wave Filter theory is very effective to design a wave resonator for required conditions, such as an effective band width of wave frequency.

INTRODUCTION

In the 1950s, Valembouis(1953) has already presented an idea of resonators to reduce incoming waves to harbors and canals by installing resonators at the entrance. In this attempt, the shape of a resonant basin is fixed to the definite one; the ratio of a length to a width of the resonant basin is 2:1. It was reported that the effective range of a wave frequency is comparatively narrow. In order to expand the effective range, he has proposed a series of resonators with different dimensions instead of a single resonator. However, in his study, the influence of an opening length between the two facing resonators on the sheltering effect has not been clarified. Consequently, it may be very hard to out find the total geometry of a resonator-type breakwater.

Recently, Mochizuki et al.(1990) have developed a new method to design a resonator that is effective for wider frequency range based on the electric filter theory, which is called the Wave Filter Theory. Nakamura et al.(1994) may be very hard to out find the total geometry of a resonator-type have conducted a series of experiments on a resonator designed by the theory in a long wave flume. However, applicability of the resonator to a fully three-dimensional wave field, such as harbor tranquility problems, has not been verified sufficiently.

In this study, using the Wave Filter Theory, a resonator that is effective for a wider range of wave frequency is first obtained. Especially, intending the resonator at harbor entrances, a resonator with a wider opening is presumed for passing ships. Experimental verification of this resonator was carried out in a long wave channel to check the principal validity of the Wave Filter Theory. Finally, for protecting a harbor from incoming waves of wider frequency range, the designed resonator is installed at the entrance. Numerical experiments on the wave height distributions in the harbor were carried out to examine the effectiveness of the resonator. Some additional case studies were also given to compare with the result of a resonator case.

(b) Equivalent electric circuit to the wave resonators.

Fig.1 Analogy between the wave resonators and the electric filter.

RESONATOR DESIGNED BY THE WAVE FILTER THEORY

Mochizuki et al. (1990) have presented a rational way to determine a geometrical shape of the resonator that is effective for a specified wave frequency range. The basic idea is to consider the analogy between a wave resonator and its equivalent electric filter. In the field of an electric filter, filter actions of various electric filters are well known. Consequently, considering the corresponding parts between the resonator and its equivalent electric filter, we can easily find out the geometrical shape of the resonator.

In the theory, a resonator model as shown in Fig.1(a) is assumed. The corresponding electric filter to the resonator is given in Fig.1(b). In the latter figure, L_a and L_b =inductance, R_0 =resistance, and C_b =capacitance. This equivalent electric circuit is known as a derived m-type low-pass filter. By considering the analogy between the two models and also the frequency characteristics of the electric filter, we can derive design equations of a wave resonator for required conditions.

Here, we made some simplifications for convenience of practical designs. At first, we assume that the long wave approximation can be used. Secondly, a longitudinal length of the first and third resonant basin in Fig.1(a) is equal to a half of that of the center one, i.e., $b_2=b_3/2$. By use of these assumptions, the following equations are given (Mochizuki et al. 1990)

$$\left. \begin{aligned} b_3 &= \frac{m b_0}{\sqrt{2(1-m^2)}} \\ l_2 &= \frac{1}{\pi f_c} \sqrt{\frac{gh(1-m^2)}{2}} \\ \frac{l_1}{b_1} &= \frac{m\sqrt{gh}}{2\pi f_c b_0} \end{aligned} \right\} \quad (1)$$

where g =gravitational acceleration, h =water depth, and m is a function of the critical frequency f_c and the pole frequency f_∞ of an effective frequency band ($f_c < f < f_\infty$) of a wave resonator and is defined by

$$m = \sqrt{1 - \left(\frac{f_c}{f_\infty}\right)^2} \quad (2)$$

The pole frequency f_∞ is a frequency at which wave transmissions through a resonator become the lowest.

Fig.2 shows a typical result by use of Eq.(1), which is designed under the required conditions given in Table 1: In the figure, however, only the center part of a series of resonators is adopted. Nakamura et al.(1994) have reported that such a single resonator has similar filter actions to a series of resonators as seen in Fig.1(a). They also pointed out that the aligned resonators have a sharper cutoff feature of filtering actions than the single resonator. For economical and practical designs, it might be said that a single resonator is much more acceptable than the aligned resonators. Therefore, in the followings, we will use the single resonator as shown in Fig.2 as a model.

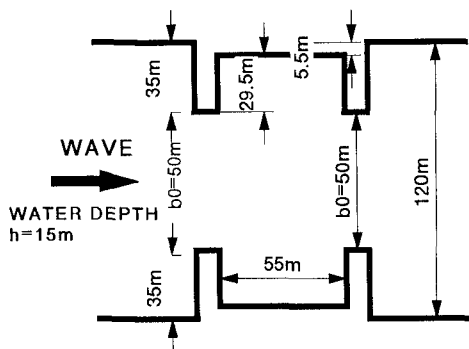

Table 1 Design conditions for a resonator

Critical frequency f_c	1/20 Hz
Pole frequency f_p	1/11 Hz
Opening length b_0	50 m
Water depth h	15 m

Fig.2 A resonator designed by the Wave Filter Theory.

EXPERIMENTAL RESULTS IN A CHANNEL

Experimental setup

In order to check the validity of the Wave Filter Theory, we carried out a model test in a long channel with a width of 1m, a height of 1.2m and a length of 26m. Using the 1/60 model of the resonator shown in Fig.2, wave transmission and reflection characteristics were examined. In the experiment, as shown in Fig.3, we built a half of the single resonator in the channel. There are two different types of model structures with the same dimensions, but having different reflection characteristics. One model is made of plywood and shows a high reflective nature. The other model is made of steel nets and pebbles and shows a low reflective nature.

Considering the mirror image effect of side walls of a channel, the wave field in the channel described above is equivalent to the one around an infinite array of identical resonators. In the above case, an allocation pitch length λ of arrayed structures is equal to double of a channel width.

According to the recent studies (Darlymple et al. 1990; Nakamura 1994), it has become known that the wave pattern around an arrayed bodies is short-crested, especially under the condition in which a wave length L is less

than a pitch length λ of the array. This is due to the generation of obliquely transmitted and reflected wave trains about the arrayed bodies in addition to the usual scattered waves as seen in a vertical two-dimensional wave field.

In order to be able to analyze the short-crested wave pattern in the channel, we set a linear array of five wave gauges in the transverse direction to measure transmitted waves through a resonator. Wave conditions used in the experiment are as follows; a wave period T_m ranges from 0.9 sec to 2.6sec (in prototype scale $T=7\sim 20$ sec) and a wave height H_m is fixed at about 4cm (in prototype scale $H=2.4$ m). Above conditions of a wave period T_m correspond to the dimensionless parameter λ/L being from 0.5 to 1.8.

Fig.3 Experimental setup (model scale 1/60).

Fig.4 Ratio of a RMS transmitted wave height to an incident wave height.

Wave transmission characteristics

Fig.4 shows typical results, where the dimensionless transmitted wave height K_T is plotted as a function of a wave period T in the prototype scale. A parameter λ/L is also specified as the second horizontal axis.

Where K_T is defined by

$$K_T = (H_T)_{rms} / H \quad (3)$$

$(H_T)_{rms}$ is a root-mean-square(RMS) value of transmitted wave height along the array direction, which is consistent with the transverse direction of a channel. The RMS value is necessary to account for the short-crested wave pattern in the transmission side of the channel, especially under the condition $\lambda/L > 1$. In other condition where $\lambda/L < 1$, the definition of K_T coincides with that of a well known transmission coefficient.

In the figure, two different experimental results are shown. One is for the resonator consisting of high-reflective walls. Other is for dissipative walls made of steel nets and pebbles. Further, in the figure, the calculated result by the Green's function method is also plotted. Nakamura(1992) has developed a method of numerical analysis to analyze wave transformations about an infinite array of vertical bodies by the wave source distribution method.

From this figure, we can see reasonable agreements between the calculated and experimental results, except near the condition $\lambda/L = 1$. The spike-like variation of K_T is caused by the wave resonance in the transverse direction. It is seen that there is little influence of the different wall types on the wave transmission. As an important point, we can say that the Wave Filter Theory is useful to design a resonator for required conditions, such as a target band width of wave frequency ($f_c < f < f_\infty$) and a necessary opening length. A small discrepancy of the pole frequency f_∞ between the Wave Filter Theory and the calculated and experimental results may be due to the assumption of the long wave approximation as described in the Wave Filter Theory.

Wave height variations in a resonator

Figs.5 and 6 show typical measurement results of wave height distributions in a resonator, in which the wave height is normalized by the incident wave height. These two figures correspond to the two different wall-type cases, i.e., a high-reflective wall case and a low-reflective wall case, respectively. The condition of a wave period T used in these figures is approximately consistent with that where K_T becomes minimum as seen in Fig.4.

From these figures, we can see that K_T becomes comparatively small when a node of two-dimensional standing waves appears at the transmission-side mouth of a resonator. It is also seen that the maximum wave height in

Fig.5 Wave height distributions in a resonator of high-reflective walls .

Fig.6 Wave height distributions in a resonator of low-reflective walls .

the resonator becomes about two times as high as the incident wave height when the wall-type is high reflective. By changing the wall-type of a resonator to the low reflective one, it is possible to reduce the maximum wave height effectively, say by one half. For the practical use of a wave resonator at a harbor entrance, it may be required to reduce the maximum wave height in a resonant basin to the order of an incident wave height for safety operation of ships. Therefore, a resonator consisting of low-reflective walls is highly recommended, especially for the use at a harbor entrance.

NUMERICAL EXPERIMENT ON THE HARBOR TRANQUILITY

Numerical method

In order to check the applicability of the resonator described above to a harbor, numerical experiments were carried out for a harbor with a typical shape in Japan. The vertical line source Green's function method developed by Isaacson (1978) was mainly adopted. Nakamura et al. (1985) precisely examined singular functions included in the wave source function and modified the numerical method so that a thin-walled structure can be treated as compared to a wave length. In the numerical analysis, reflection characteristics from harbor boundaries can be treated generally by using

partially absorbing boundary conditions (Engquist et al. 1977) instead of well-known no-flux conditions.

Fig.7 Layout of a harbor and wave reflection characteristics of the boundary.

Fig.8 A harbor entrance with a resonator.

Fig.9 A harbor entrance with a detached breakwater.

Model harbors

Fig.7 shows a layout of an original harbor used in the numerical experiment. It is assumed that a water depth h inside and outside a harbor is constant and equal to 15m. Reflection characteristics of harbor boundaries are specified in the figure by using reflection coefficients C_R . We presume that the boundary outside the harbor of $C_R=0.4$ is covered with dissipative concrete blocks. Further, the boundary inside the harbor with the same

Fig.10 Wave height distributions around the original harbor ($T=9\text{sec}$).

Fig.11 Wave height distributions around the harbor with a resonator of high-reflective walls ($T=9\text{sec}$).

Fig.12 Wave height distributions around the harbor with a resonator of low-reflective walls($T=9$ sec).

Fig.13 Wave height distributions around the harbor with a detached breakwater($T=9$ sec).

C_R is an inclined quay. Other boundaries of $C_R=0.8$ are vertical sea walls. In the experiment, three different models are examined; an original harbor as shown in Fig.7, a harbor with resonators at harbor entrances (Fig.8) and a harbor with detached breakwaters outside harbor entrances (Fig.9). Regarding the resonator case, we have adopted the same shape specified in Fig.2. Two different reflection characteristics from inside walls of a resonator are again used, a high reflective wall case of $C_R=1.0$ and a low

reflective wall case of $C_R=0.6$, respectively. In all cases, an opening length of each harbor entrance is fixed at 50m.

Inter-comparisons of wave height distributions among different cases described above are shown in Figs.10 to 13 by the use of normalized wave height contours. A normal incidence of plane waves to harbor entrances is presumed. Further, the wave period T is fixed at 9sec, which corresponds to the condition of minimum wave transmission for the case of arrayed resonators as shown in Fig.4.

Fig. 14 Averaged wave height ratio in a harbor for various types of breakwaters.

Fig. 15 Averaged wave height ratio in a harbor for obliquely incident waves; 60-degree incidence.

We can see that the resonator with high-reflective walls is the most effective breakwater to reduce wave heights in the harbor. The resonator with low-reflective walls is also very useful as compared to the detached breakwater case. However, it must be noted that the maximum wave height in a resonant basin reaches more than twice as high as an incident wave height for the resonator case with high-reflective walls. Therefore, it is again confirmed that a resonator with low-reflective walls is highly recommended. In this case, the maximum wave height in a resonant basin is reduced to the order of an incident wave height.

Fig. 14 shows the variation of a representative wave height ratio $(K_d)_{av}$ in a harbor with a wave period T for each case described above. Where $(K_d)_{av}$ is a spatially averaged wave height ratio in a harbor. It can be seen that a resonator designed by the Wave Filter Theory is very effective to reduce incoming waves for a comparatively wide range of wave period. It is also seen that the resonator with low-reflective walls has a wider effective range of wave period than the one with high-reflective walls, especially for longer waves.

Fig. 15 also shows the variation of $(K_d)_{av}$ with T , but under the condition of obliquely incident waves (incident angle of waves is 60-degree from the x axis). From this figure, it is confirmed that the resonator is still effective for obliquely incident waves to harbor entrances. The reduction of a wave height in a harbor is almost the same for the case of normally incident waves as shown in Fig. 14.

CONCLUSIONS

The Wave Filter Theory is very useful to design a resonator for required conditions, such as an effective range of wave frequency ($f_c < f < f_w$) and a necessary opening length. It was confirmed that the resonator designed by the Wave Filter Theory plays an effective protector for reducing incoming waves to harbors and canals.

A resonator consisting of low-reflective walls is highly recommended for the use at a harbor entrance because of safety operations of ships. It is also possible to expand the effective range of wave frequency of a resonator by the use of low-reflective walls.

CHAPTER 101

The Generation of Waves by a Landslide: Skagway, Alaska—A Case Study

Fredric Raichlen¹, Jiin Jen Lee², Catherine Petroff³, and Philip Watts⁴

1. Introduction

On November 3, 1994, at about 7:10 p.m. Alaska time, a combined aerial and sub-aerial landslide, which was not seismically induced, occurred at a railway dock on the eastern side of the harbor at Skagway, Alaska. A small portion of the landslide, consisting in part of rip-rap, was initially above water. The submerged landslide material was composed of loose alluvium accumulated along the eastern side of the harbor on an underwater slope with an average angle between 0 deg. and 30 deg. Witnesses reported waves 30 ft to 36 ft high at the eastern side of the harbor. The slide and the generated water waves claimed the life of one construction worker and caused an estimated \$21 million damage. A map of the Skagway Harbor is presented in Fig. 1 showing the location of the landslide and the surrounding area including the Taiya Inlet which is an arm of the much longer Lynn Canal.

A floating dock used as an Alaska state ferry terminal is located in the middle of the harbor at the end of a 660 ft long jetty, and a small boat harbor is located near the east side of the harbor. The chains which moored the floating dock were broken during the event.

At the time of the landslide the tide elevation was at about -4 ft MLLW; the tide range at Skagway varies from about 9.8 ft to about 24.6 ft over a month. The record from a tide gage located at a dock on the west side of the harbor is presented in Fig. 2 showing the waves generated by the landslide. The tide gage trace is truncated for extremely low water surface elevations because, for those readings, the travel of the gage recording pen was stopped by the chart paper guide.

The purpose of the study reported in this paper was to more fully understand the wave events which could have taken place in Skagway Harbor after the landslide. The interest is not in precisely modeling the landslide, but in defining the response of the harbor and of the moored floating ferry dock to waves generated by a moving boundary which is used as an analogy to the landslide for purposes of wave generation.

¹Prof. C.E., Calif. Inst. of Tech., Pasadena, CA 91125; ²Prof. C.E., Univ. of So. Calif., Los Angeles, CA 90089; ³Asst. Prof. C.E., Univ. of Wash., Seattle, WA 98195; ⁴Grad. Stud., Calif. Inst. of Tech., Pasadena, CA 91125

Three aspects of the problem will be investigated and will be discussed in subsequent sections. The first deals with the dynamics of a gas-purged nitrogen bubbler tide gage which was of the same type as used in Skagway. The dynamics of the tide gage were determined experimentally in the laboratory, and the response is presented in this discussion. The second aspect is the response of Skagway Harbor to the waves generated by the transient motion of a section of the harbor boundary. This was investigated primarily to simplify the problem of the generation mechanism for landslide induced waves. The transient waves generated by the moving boundary have a similar ability to induce oscillations in the harbor as waves generated by an aerial and a sub-aerial landslide. With the harbor connected to a large open region, i.e., the Taiya Inlet, the questions are how energy generated by a moving boundary (representing the landslide) propagates across the harbor and into the inlet and what is the frequency content of this energy at various locations within Skagway Harbor. The third portion of the overall problem deals with the failure of the floating ferry dock mooring chains. An analytical model was developed for the response of the moored-floating dock to incident waves, and combined with wave spectra determined from the harbor response model, the parting of the mooring chains which was observed at Skagway was investigated qualitatively.

2. The Landslide Event

In this section the characteristics of the landslide and the generated waves will be discussed along with some observations made by witnesses of the event (see Watts and Petroff (1995)). There were four major docks in Skagway Harbor prior to the landslide: an Ore Loading Dock situated adjacent to a jetty that forms the west side of the harbor and is the site of the tide gage location; the Ferry Terminal Floating Dock located in the middle of the harbor at the end of a 660 ft long landfill jetty; the Broadway Dock immediately west of the Ferry Terminal Dock and jetty; and the White Pass Company Railway Dock located along 1312 ft of the eastern shore of the harbor and immediately south of the small boat harbor. (These can be seen in the map presented as Fig. 1.)

The underwater landslide on November 3, 1994 destroyed the southern 984 ft of the White Pass Company Railway Dock. Construction work was underway at the White Pass Company Railway Dock, and the northern quarter (328 ft) of the dock had been cut away from the southern three quarters (984 ft) to replace wooden piles with steel sheet pile cells. Several construction workers standing on the northern quarter of the dock watched the landslide and the southern part of the dock disappear into the water. The job superintendent estimated the total time from the beginning of the slide to the total loss of ground at between 15 to 20 seconds. The wave generated by the landslide was described as a "wall of water" by the survivor who escaped from one of the sheet pile cells that disappeared in the landslide. At about the same time it was observed by two of the three witnesses that a barge alongside the White Pass Company Railway Dock appeared to be level with the remaining northern portion of the dock, providing evidence of a positive wave generated by the landslide and/or a wave reflecting off the shoreline.

The Ferry Terminal Dock located at the center of the Skagway Harbor was moored with thirteen chains each with a scope such that it would allow for the relatively large vertical movement of the dock caused by the tide range. The chains consisted of both 1.5 in. diameter and 2.5 in. diameter chain links (a submerged unit weight of about 48 lbs/ft), and links were broken on all thirteen chains as a result of the dock movement. Observers reported that the dock was not overtopped

by waves. However, tall lamp posts located on the dock were all buckled at the base with the poles bent westward indicating that there must have been either a significant eastward acceleration of the dock or large westward deceleration.

3. The Tide Gage Response

The tide record shown in Fig. 2 was measured using a gas-purged nitrogen bubbler gage (see Young, 1977). The gage records the change in water level by sensing the change in hydrostatic pressure at the open end of a gas filled tube, termed the orifice chamber, which is secured beneath the still water level. For the case of a steady water surface the pressure of the gas throughout the tube is approximately equal to the pressure of the water at the gas-water interface at the end of the tube. For example, as the pressure increases with the rising tide, the gas in the tube compresses to reach equilibrium and shifts the gas-water interface. By supplying a regulated flow of gas the interface is kept at the end of the tube throughout the tidal range. The other end of the tube is connected to a bellows and through a mechanical linkage to a pen recorder. A needle valve located between the end of the tube and the bellows can be adjusted to damp out pressure fluctuations due to normal short period wave activity. The adjustment is subjective and is determined on-site by the gage operator depending on the ambient wave conditions. Thus, as the pressure at the open end of the tube changes the bellows expands or contracts thereby providing a tide record or marigram. The tube length for the Skagway bubbler tide gage was about 150 ft. Due to effects of compressibility, the bellows arrangement, the linkages, and especially the setting of the damping valve this type of transducer has a dynamic response which varies as a function of the frequency of the pressure fluctuation at the open end. To correctly interpret the tide gage record presented in Fig. 2 for waves with periods much shorter than the tide, it was necessary to independently calibrate the bubbler tide gage.

A calibration system was designed to determine the dynamic response of the nitrogen bubbler tide gage to an imposed sinusoidal pressure. The orifice chamber was immersed in a partially water-filled pressure chamber which could have a time-varying air pressure impressed above the water surface. The air pressure was varied sinusoidally with an adjustable period from 10 sec to about 1200 sec. The dynamic response of the gage obtained with this calibration system is presented in Fig. 3. The ratio of the maximum wave amplitude indicated on the chart to the imposed wave is the ordinate and the period of the oscillation is the abscissa. Based on information that the ambient wave condition on the day of the landslide was 3 to 4 foot waves of 10 sec, the gage was adjusted so that the response from this wave condition was barely observable. This corresponded to a needle valve opening of $3/4$ turns. Additionally, the responses at other valve positions were tested including $1/2$ and $3/8$ turns as suggested by NOAA field personnel. For excitation periods greater than about 1,000 sec (16 min) the response is nearly unity, but as the excitation frequency increases, i.e. the wave period decreases, the signal is damped dramatically. For example, at a period of about 3 min, the response, a/a_0 , varies from 40 % to 75 % depending on the needle valve setting. At a wave period of approximately 20 to 30 sec the response is between 5 % and 25 %.

4. A Numerical Model for Harbor Response

A finite element model based on the depth averaged equations of motion was developed to determine the wave response of Skagway Harbor to a moving section of the boundary corresponding to the region of the observed landslide. This

somewhat simplified numerical model was chosen, since it was believed that the important elements of the landslide-induced waves could be generated in this manner. Indeed the object of this study was to investigate the wave motions induced by a transient disturbance in this harbor and to develop wave spectra at various locations. These results will help to explain how the floating ferry dock mooring system was damaged.

As a guide to the concept of using a boundary motion to represent a material landslide, simple experiments were conducted in a laboratory channel (with depth $h = 28.2$ cm) by a two-dimensional triangular solid block (with horizontal and vertical edges 12.4 cm long) moving on a 45° slope. The horizontal face was initially 3 cm above and submerged 3 cm below the still water surface. The water-surface time histories recorded at the toe of the slope are presented in Fig. 4 with the nondimensional wave amplitude plotted as a function of nondimensional time. Offshore of the generation region, a lead positive wave is followed by a negative wave with the part-aerial landslide producing a larger positive wave than the sub-aerial one. The positive wave is generated by the forward advancing vertical front face of the block while the negative wave is generated by the downward moving horizontal face. For both model landslides the wave has some similarity to one cycle of a sinusoid. Therefore, in the numerical model, a boundary motion was chosen that would generate a similar wave near the source.

Three motions were considered for a 984 ft section of the east boundary of Skagway Harbor corresponding in length to the section of the White Pass railway dock's foundation which failed. The motions were: a combined positive and negative motion with a period of 20 sec and an amplitude of 20 ft/sec, and separately, a positive motion and a negative motion alone each with a maximum amplitude of 20 ft/sec and a duration of 10 sec. The maximum velocity was based on the both the estimated time of the landslide event and the thickness of the slide. Since the equation of motion was depth averaged, the boundary generator moved as a piston.

The governing equations used for the present finite element model are similar to those used by Leendertse (1967). (Leendertse (1967) used a finite difference method for his solution.) The equations of motion used in the two propagation directions are as follow:

$$\text{for the x-direction: } \frac{Du}{Dt} = -g \frac{\partial \eta}{\partial x} + 2\Omega(\sin \Phi)v - \frac{\tau_{bx}}{\rho(h+\eta)} \quad (1)$$

$$\text{and for the y-direction: } \frac{Dv}{Dt} = -g \frac{\partial \eta}{\partial y} + 2\Omega(\sin \Phi)u - \frac{\tau_{by}}{\rho(h+\eta)} \quad (2)$$

where u and v are the velocity components in the x and y directions, g is the acceleration of gravity, η is the amplitude of the wave, Ω is the earth's rotational speed, Φ is the latitude, τ_b is the bottom shear stress with direction indicated by the subscript, and ρ is the fluid density. The second term on the right in Eqs. 1 and 2 is termed the Coriolis acceleration. The last term is the bottom friction expressed in terms of the shear stress along the bottom. The continuity equation for a long wave in the x and y directions is:

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} [(h+\eta)u] + \frac{\partial}{\partial y} [(h+\eta)v] = 0 \quad (3)$$

These equations have been solved using a finite element technique with finite difference in time. The grid used is shown in Fig. 5. For this model, the shoreline is considered perfectly reflecting. The portion of the shoreline which was impulsively moved to represent the landslide is shown. Along the region of the model denoted as ABCDE the boundary of the numerical model is non-reflecting and represents the so-called "open sea". Wave energy can pass through this boundary but will not be reflected back to the harbor. However, at the limit of the modeled Skagway Harbor, due to the change in width of the harbor entrance compared to the width of the outer region, reflection occurs. This "mis-matching" at the entrance is one reason for the "ringing" which was seen in the tidal record presented in Fig. 2. An open harbor entrance acts to some extent like a leaky closed boundary allowing energy to escape and some to be reflected back into the harbor; this is the basis for resonance. Although the model is three-dimensional the velocities are depth-averaged. Thus, it is expected that the information obtained from the model may be more qualitative than would be obtained from a more general set of equations developed from the equations of motion incorporating a moving sediment mass. A velocity time history imposed along a section of the grid which corresponds to the location of the moving boundary was used as the forcing function for the model.

In Fig. 6 water surface contours corresponding to the ratio of the wave amplitude to the boundary motion are shown in the harbor at two different times after generation by the combined positive and negative boundary motion. An outline of the planform of Skagway Harbor is incorporated so that one can better appreciate the general outward spreading of the wave from the generation source; the ordinate is oriented north-south and the abscissa east-west. The upper plot corresponds to the time of the completion of the boundary motion. It is seen that the waves generally propagate toward the north-northwest as a spreading cylindrical wave. The positive maximum wave can be seen propagating toward the site of the Floating Ferry Dock while the negative wave is still relatively close to the generation boundary. As the wave spreads the wave amplitude decreases. The lower portion of the Fig. 6 corresponds to 40 seconds after motion begins. Toward the western side of the harbor, near the site of the tide gage, the waves propagate into the Ore Dock slip moving generally northward. Near the entrance to Skagway Harbor the wave amplitudes become very small; wave energy will propagate north and south in the inlet reducing further the wave energy which may reach the far shore of Taiya Inlet.

Three water surface time histories corresponding to three locations are presented in Fig. 7: at the Tide Gage (Location 8), at the Floating Ferry Dock (Location 6), and at the head (landward end) of the Ore Dock slip (Location 2). At Location 6, both the wave amplitude and the wave frequency are larger than at either Locations 2 or 8. Apparently at the head of the Ore Dock slip the impulsive wave generated excites a mode of oscillation with a frequency much smaller than at Location 6. This also appears near the site of the Tide Gage (Location 8). The proximity of Location 6 to the boundaries must influence the frequency of the waves. Skagway Harbor does not reach steady state due to the leakage of energy past the entrance. The difference between the tide gage record presented in Figs. 2 and 7 is probably due to several factors. First, the boundary motion used in this model is a highly simplified; some features are reasonably represented while others are not. In addition, during the movement of the slide, the bathymetry within the

harbor changes and the numerical model does not incorporate these time-varying changes. Finally, and perhaps most important, the numerical model is depth averaged, and although some aspects of the waves are well represented by shallow water wave theory others are not. Therefore, the results from this model can only be considered an approximate representation of the events observed on November 3, 1994. It is believed that they do show the frequency characteristics of the waves in the harbor.

The energy spectra obtained at Locations 2, 6, and 8 are presented in Fig. 8 with frequency as the abscissa, and the energy normalized by the area under the spectrum is the ordinate. At each location, spectra corresponding to each of the three different boundary motions are presented. At the head of the Ore Dock slip and at the location of the Tide Gage, Locations 2 and 8, respectively, the major component is at about 0.007 Hz (wave period of 143 sec). It is recalled from Fig. 3 that the dynamics of the nitrogen bubbler tide gage will attenuate most high frequency energy so that only low frequencies will be present in the tide gage record. The most important feature of Fig. 8 is that in the vicinity of the floating ferry dock the predominant frequency is much larger than that observed at either Location 2 or 8. The frequency of the peak energy is about 0.045 Hz (a period of 22 sec). This change in frequency as a function of location will be shown to be important with regard to the excitation of the floating dock.

5. The Response Of The Floating Ferry Dock

A schematic is presented in Fig. 9 showing the Floating Ferry Dock moored by chains, each with a submerged weight of approximately 48 lbs/ft. As shown in the lower portion of Fig. 9 these chains are arranged so the dock can rise and fall with the tide. The dock and the chains form a dynamic system with the chains and their catenary shape defining the restraining and restoring force associated with dock motion. As the chain lifts up from the seabed or is laid down the changing weight and resultant tension in the suspended portion of the chain provide a non-linear restoring force. This is shown in Fig. 10 for one typical chain. The abscissa is the horizontal displacement of the mooring point on the barge, and the ordinate is the restraining force associated with this displacement.

A simplified analytical model of the moored Floating Ferry Dock was developed primarily to determine the important range of frequencies for the excitation of the dock. These could then be compared to the spectrum corresponding to Location 6 in Fig. 8 to assist in inferring the cause of the observed chain failure. The method used to develop the equation of motion of the dock was presented by Raichlen (1965). The floating body was excited by a volume averaged acceleration and velocity, i.e. the average over the displaced volume of the dock of the acceleration and velocity in a small amplitude long wave. It was assumed that viscous damping and wave damping were small and could be neglected, and that dock motion was controlled primarily by inertial forces. Resistance to motion was due to the varying weight of the mooring chains. Although waves approach the barge obliquely in the harbor model, for the motion analysis, it was assumed that waves approach from an easterly direction and that the barge's motion would then be east-west and defined as the x-direction. Considering the shape of the curve of restoring force vs. displacement, the simplified equation of motion in the absence of damping is as follows:

$$\frac{d^2x}{dt^2} + \alpha x + \beta x^3 = \frac{dU}{dt} \quad (4)$$

The constants α and β in Eq. 4 which define the restoring force are based on a total of five chains acting simultaneously. The volume averaged acceleration dU/dt is determined from small amplitude wave theory as:

$$\frac{dU}{dt} = \frac{ag}{kLD} \left[\frac{\sinh kh - \sinh ks}{\cosh kh} \right] \sin kL \cos \sigma t \quad (5)$$

where a is the amplitude of the wave, k is the wave number, L is the length of the barge in the direction of wave propagation, i.e. 120 feet, D is the draft, h is the depth, s is the distance from the bottom to the keel of the barge, and σ is a circular wave frequency. For long waves Eqs. 4 and 5 become:

$$\frac{d^2x}{dt^2} + \alpha x + \beta x^3 \approx a \sqrt{\frac{g}{h}} \sigma \cos \sigma t \quad (6)$$

This equation has the form of the Duffings equation with the exception that the forcing function is linearly proportional to the circular frequency, σ . This equation is evaluated by assuming a motion for the horizontal displacement of the vessel from the at-rest-position of:

$$x = X \cos \sigma t \quad (7)$$

as discussed by Stoker (1963). Although this may be a significant simplification, the assumption of Eq. 7 leads to the development of the response curves to show the important forcing frequencies for this problem.

The response curves for this non-linearly moored body obtained in this manner are presented in Fig. 11 where the amplitude of motion of the dock is plotted as a function of excitation frequency for given wave amplitudes. A so called "backbone" curve represents a zero wave amplitude. The response to the right of this curve is out-of-phase with the excitation and to the left it is in-phase. Referring to Fig. 8, the important wave frequency present at Location 6 (the location of the floating ferry dock) is approximately 0.045 Hz ($\sigma = 0.283$ rad/sec), i.e., a wave period of 22.2 sec. The response curve in Fig. 11 shows that this excitation frequency is near the resonant frequency of the moored dock. For a wave amplitude of one foot and a circular frequency of 0.283 rad/sec, the response of the barge is approximately four times the forcing function. Perhaps more important, as the wave height increases from zero at this frequency the motion increases until a minimum of the response curve is reached for the given excitation amplitude. The motion will jump to the higher branch of the curve changing suddenly from out-of-phase to in-phase. This can create significant dynamic chain stresses. Thus, it is believed that although the observed wave periods at the tide gage were relatively large, because of the influence of the geometry and the proximity of the dock to the harbor boundaries, the higher frequency which is observed at the site of the floating ferry dock might have led to the mooring line and lampost failures.

An example of the motion time history of the dock is shown in Fig. 12 for an excitation based on the spectrum presented in Fig. 8 using Eq. 6 to represent the excitation spectrum by the superposition of forcing functions :

$$\frac{d^2x}{dt^2} + \alpha x + \beta x^3 \approx \sum_{i=1}^N \left[a_i \sqrt{\frac{g}{h}} \sigma_i \cos \sigma_i t \right] \quad (8)$$

where i is the frequency component of the forcing function varying from $i = 1$ to N , and the phase angles have been arbitrarily set equal to zero. The frequencies and the amplitudes of the components are shown in the table accompanying the figure. Significant motions approaching amplitudes of ± 10 ft can be seen for the assumed waves. This corresponds to an amplification factor, i.e., the ratio of the amplitude of the horizontal dock motion to the average of the amplitudes of the wave components, of approximately fifteen. Thus, the dynamics of the mooring system could have been a major contributor to the failure of the mooring chains at Skagway.

5. Conclusions

The following major conclusions can be drawn from this study:

1. The gas-purged pressure recording (bubbler) tide gage with normal operating settings has a response (measured amplitude/actual amplitude) of 40 % to 75 % for waves with periods of 3 min and 5 % to 25 % for waves with periods of 20 sec.
2. An impulsive wave generated in Skagway Harbor by the simple motion of a section of the coast can induce groups of complex waves composed of a wide range of frequencies.
3. The frequency content of the transient waves generated by the boundary motion is strongly dependent on location.
4. Different forms of the boundary motion tend to generate similar spectral energy distributions at the same location in the harbor.
5. The damage to the floating ferry dock observed at Skagway may have occurred due to the combined effect of the mooring dynamics of the dock and the frequency content of the waves at that location.

CHAPTER 102

Laboratory experiment on long wave generation by time-varying breakpoint

Satoru Nagase¹ and Masaru Mizuguchi²

Abstract

Laboratory experiment is conducted to investigate the long waves generated by time-varying breakpoint. We focus our attention on the variation of plunging point as well as the variation of breaking point. The results show that free long waves (BFLW) are really generated by the variation of the starting point of wave set-up which coincide with the plunging point and that the BFLW observed can be quantitatively evaluated by Mizuguchi(1995) model, which is more direct and realistic model. The generation mechanisms of long waves of other origins, such as bound long waves to wave groups and free long waves generated during shoaling process of wave groups, are also discussed.

1. Introduction

Some lively discussions have been going on concerning the origins of the free long waves (of typical time scale 1 to 3 minutes) observed in the nearshore zone. It is well known that the generation of long waves is closely related with wave groups. However the characteristics of long waves, which may be free or bound, are still not well understood because of the difficulty of detailed measurements. One of the possible mechanism for the generation of free long waves is that the breaking of wave groups generates free long waves.

Longuet-Higgins and Stewart (1962) suggested that the bound long wave to a positive wave group is freed as a set-down wave when the wave group disappears by wave breaking. This concept has been used

¹Engineer; Taisei corp., Nishi Shinjuku Shinjuku-ku, Tokyo 163-06, JAPAN (Formerly graduate student, Chuo Univ.)

²Professor; Dept. of Civil Eng., Chuo Univ., Kasuga, Bunkyo-ku, Tokyo 112, JAPAN

for a long time without any physical or mathematical explanation. In fact, little is known about the behavior of the bound long waves when the primary waves break. Symonds et al.(1982) showed theoretically that time-varying breakpoint generates free long waves by playing a role of time-varying forcing term in the long wave equation. Schaffer(1993) extended their approach by including both the effect of bound long waves to wave groups and the behavior of wave groups in the surf zone. This topic has been studied mainly in a theoretical manner. Most studies have concluded that the model of Symonds et al.(1982) is in qualitative agreement with experimental results. For example, Kostense(1984) in laboratory experiment, Nakamura and Katoh(1992) in field observation. However they have neither measured the variation of breaking point nor the behavior of long waves around the breaker zone. More direct experimental measurements are needed to support or to reject the theoretical modeling.

Here we report a carefully conducted experiment, where the long waves generated by time-varying breakpoint can be quantitatively estimated. Based on the experimental results, we show that the modeling proposed by Symonds et al.(1982) is really valid and the analytical solution for bound long waves by Longuet-Higgins and Stewart (1962) is still correct even in shallow water. Then we show another treatment applicable to non-periodic wave group for the generation of free long waves in the nearshore zone, proposing a simple formula to estimate the magnitude of the free long waves generated by time-varying breakpoint.

2. Experiment

Figure 1 shows our laboratory flume. The wave flume is 20m long and

Fig.1 Experimental setup and the origin of x coordinate
The location of water depth 13.5cm is taken to be the origin of x coordinate.

30cm wide. It is equipped with a flap-type wave maker controlled by a personal computer. The slope of 1/20 with a constant depth area in the shoreward is set in a wave flume so that all waves can break on a uniformly sloping beach and then reform on a constant depth area in the shoreward. The wave absorber is installed at the end of the wave flume in order to dissipate the energy of reformed waves. Incomplete absorption of reformed waves at the shore end may cause unstable breakpoint variations due to wave reflection. The water depths at location A in the offshore, location B on a sloping beach and location C on a constant depth area in the shore are 33.5cm, 10.0cm and 2.0cm, respectively. The wave gages and current meter are moved in the nearshore zone so that detailed measurements of the process of long wave generation may be possible.

In order to investigate the simplest case of long wave generation in as much detail as possible, a single hump-type grouping waves are selected. A single wave height variation signal is given by Eq.(1).

$$H(t) = \begin{cases} H_M(1 + \beta(1 - \cos(2\pi(t-t_0)/T_g))) & t_0 \leq t \leq t_0 + T_g \\ H_M & t < t_0, t_0 + T_g < t \end{cases} \quad (1)$$

where H_M is the steady wave height, T_g is the wave group period and β is the wave height ratio. The experiments are conducted on the following conditions. Both $T=1.0s$ for the wave period of the primary waves and $T_g=8.0s$ are fixed in all cases. The steady wave height at location A in Fig. 1, $H_M=5.5cm, 4.5cm, 4.2cm, 3.7cm, 2.8cm$ and the wave height ratio, $\beta=0.2, 0.1, -0.2, -0.1$, which introduce the variation of breaking point, are varied. Total of experimental cases are fourteen.

Figure 2 shows examples of a single hump-type grouping waves, a positive wave group and a negative wave group. For generating stable grouping waves, first, the amplitude of the wave maker board is increased very slowly, then the steady uniform waves are maintained for a while (about 40s) and finally a single hump-type grouping waves are added. However, we did not apply the control method either to suppress the generation of the second-order free long waves or to absorb free long waves coming back from the shore. At each location, waves are measured during 180s from the start of wave making with a sampling time of 0.02s.

3. Experimental results

Figure 3 shows the wave height variation of individual waves when a positive single hump-type grouping waves are incident into the surf zone. In this study, individual waves are defined by applying the zero-down crossing method. The breaking point clearly moves offshoreward

(a) A positive wave group ($H_M=4.5\text{cm}$, $\beta=-0.2$)

(b) A negative wave group ($H_M=5.5\text{cm}$, $\beta=-0.2$)

Fig.2 A single hump-type grouping waves (measured at location A)

Fig.3 Wave height variation of individual waves in the positive wave group shown in Fig.2(a)

as the wave height increases gradually. As a wave starts to break, its height decreases very rapidly while maintaining an approximately constant ratio of wave height to water depth, in other words, the wave group tends to disappear in the surf zone.

The time variation of the breaking position of individual waves is visually measured using a high-speed video camera. The solid squares in Fig.4 denote the measured variation of breaking position. The variation shows good correspondence with the wave height variation measured outside the breaking zone. Spilling breakers are observed in all cases.

Figure 5 shows the measured wave group structure and the generated long waves for a positive wave group. The long wave components are obtained by applying a numerical filter, by which the short-period components less than 4 second are removed perfectly. The wave group shows stable propagation up to the breaking zone and then disappears or shows slightly negative wave group during the breaking process (between $x=90$ to 130 cm). Low-pass filtered long waves show that the set-down wave propagates at the group velocity of primary waves without significant amplification with a slight delay to the wave group up to the breaking point. Since the wave maker is not controlled to suppress the generation of the second-order free long waves, a free wave (a positive single hump) generated at the wave maker travels just ahead. See the data at location A. As the wave group disappears while breaking, a set-up wave is formed in the surf zone and propagates in the shoreward direction. A set-down wave also appears to be generated and

Fig.4 Time variation of breaking position of individual waves in the positive wave group

travel offshoreward outside the breaking zone.

When a negative single hump-type grouping waves is generated, the bound long wave as a set-up wave is observed in the offshore shown in Fig.6. When the primary waves in a negative wave group break, a set-down wave is observed in the surf zone and propagates in the shoreward direction.

These two experimental results are just opposite in the phase of the long waves as are expected. This shows the reliability of the experiment.

Fig.5 Low pass filtered data (solid line) and time history of wave height (broken line) in the positive wave group

Reference level for long waves is the mean water level of steady state at each location. Wave heights are nondimensionalized by mean wave height of steady state at each location. Scales of vertical axis for long waves and nondimensionalized wave heights are 0.2cm and 1.0, respectively, for an interval of two horizontal lines.

Fig.6 Low pass filtered data (solid line) and time history of wave height (broken line) in the negative wave group shown in Fig.2(b). (See Fig. 5 for explanation.)

4. Discussion

4.1 Generation of long waves

The generation mechanism of long waves in the laboratory experiment may be illustrated schematically as shown in Fig.7.

Long waves in this experiment consist of, ① free long waves generated at the wave maker, ② bound long waves to wave group, ②' bound long waves being freed at the breaking point, ③ free long waves generated during the shoaling process of wave group and ④ time-varying breakpoint forced (free) long waves (BFLW). Wave groups are assumed to disappear after their breaking.

Free waves generated at the wave maker (①) can be identified as the leading positive hump on a sloping beach. Then a point to be noted is

that the transforming wave group due to wave shoaling does accompany free long waves (③) in addition to the bound long waves (②). Any change of wave group may result in the generation of free long waves, simply because the new bounded solution is different from the old one and free waves are needed to satisfy the old condition. This free waves have the opposite sign to the bound waves and travel only a little faster as schematically illustrated in Fig.7(b). This is the reason why in shallow water the long waves appear to lag behind the wave group, as is also pointed out by List(1992) and Van Leewen(1992), and why its magnitude is not so large as the analytical solution by Longuet-Higgins and Stewart (1962).

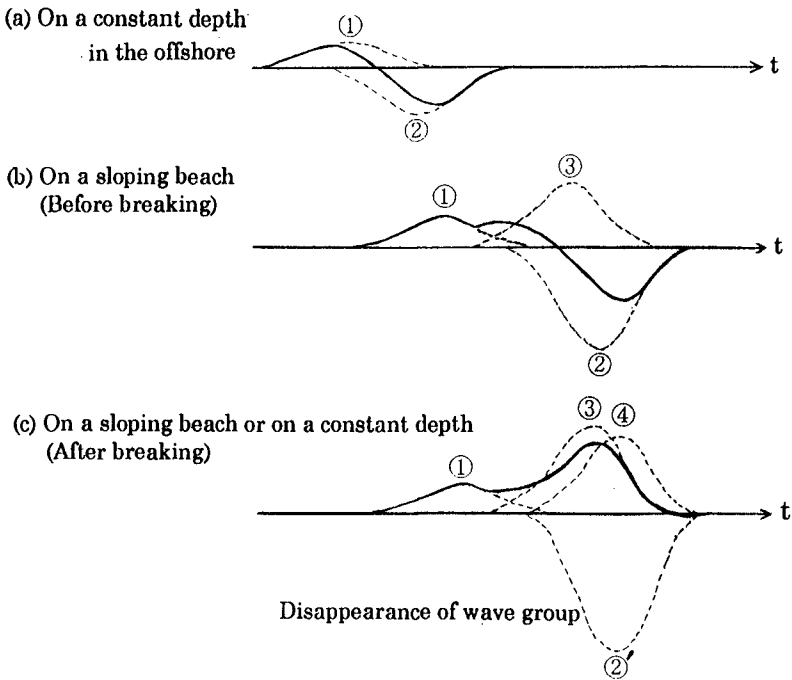

Fig.7 Schematic illustration of generation and propagation of long waves(time profile) in the positive wave group
 Solid lines denote the observed long waves, which can be resolved into,
 ① Free long waves generated at the wave maker
 ② Bound long waves to wave group
 ②' Bound long waves being freed at the breaking point
 ③ Free long waves generated during the shoaling process of wave group
 ④ Time-varying breakpoint forced (free) long waves (BFLW)

It has been quoted in various studies that the LHS solution predict unreasonably large wave heights in shallow water and cannot be applied in the nearshore. The fact is that the LHS solution is a particular solution and the physical situation must include general solutions, which nearly cancel the particular solution. For more detailed discussion, see Mizuguchi and Toita(1996). In addition to these long waves, free outgoing long waves (set-down waves) generated by time-varying breakpoint may have an effect on both the phase and the magnitude of long waves observed in the offshore. However this free waves were difficult to evaluate separately and are neglected in Fig.7.

At the breaking point, bound long wave (②') to a positive wave group is freed as a set-down wave due to sudden disappearance of the wave group, and the free wave generated while shoaling (③) continues to propagate as a free wave. In addition to these waves, the BFLW is generated. The shoreward propagating BFLW has the same phase with the wave group, that is, a positive wave group produces a set-up wave.

4.2 Magnitude of the BFLW

We discuss the generation mechanism of the BFLW, trying to evaluate its magnitude. First, in Fig.8 we plot the change of mean water level of individual waves in the nearshore zone when the positive wave group is generated. Figure 8 shows the starting points of the rise of mean water level, that is, the plunging points of individual waves move offshoreward corresponding to the offshoreward movement of the breaking points. The mean water level rises in the shoreward region with approximately constant gradient. This is what the generation of the BFLW really is. Thus the variation of the plunging point is essential. In Fig.8 the theoretical results (Bowen et al.,1968) on wave set-down and wave set-up for regular waves are also shown. The value of the wave height to water depth ratio, γ , is typically taken to be 0.8. Here the gradients of mean water level of individual waves in the transition region between the breaking point and the plunging point are neglected. The gradient of the measured set-up shows good agreement with the predicted value. As mentioned later, the vertical difference shown in Fig.8 is taken to be the magnitude of the BFLW traveling shoreward measured just after breaking.

Symonds et al.(1982) first proposed the model for the long waves generated by time-varying breakpoint. Figure 8 supports their modeling. However their approach assumes the periodicity in time of the breaking point variation and cannot be applied to a single hump-type grouping waves employed with this experiment. Recently, Mizuguchi(1995) shows more direct and realistic modeling with much simpler solution in the time domain. The modeling may be illustrated as shown in Fig.9.

Fig.8 Change of mean water level of individual waves in the positive wave group

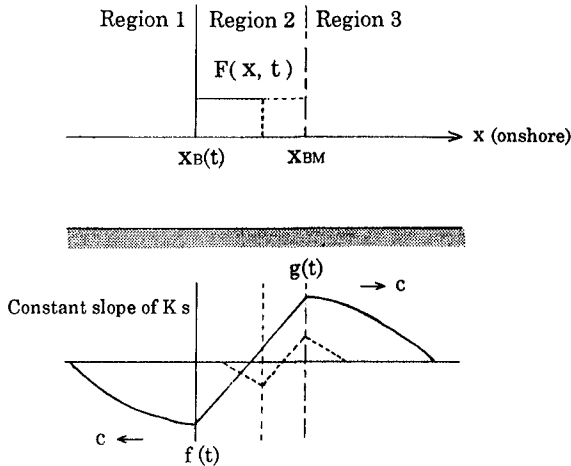

Fig.9 Schematic illustration of forcing term (top) and local profiles of long waves (bottom) after Mizuguchi(1995)

The well-known linear long wave equation with a forcing term is solved analytically on the following assumptions. First, the water depth around the breaking point is taken to be constant as far as the long waves are concerned. Second, a bounded solution for region 2 may be given by the steady version of the momentum equation, as is observed in this experiment.

The solutions obtained are so simple as shown in Eq.(2).

$$\begin{aligned} g(t) &= K s(x_{BM} - x_B(t)) / 2 \\ f(t) &= -K s(x_{BM} - x_B(t)) / 2 \end{aligned} \quad \text{at } x = x_{BM} \quad (2)$$

where $g(t)$ and $f(t)$ are the functional form of the long waves propagating toward the shore and that propagating toward the offshore, respectively, $x_B(t)$ is the time-varying breaking point, x_{BM} is the mean (or steady) breaking point, K is the constant given by γ , wave height-water depth ratio in the surf zone (Bowen et al., 1968) and s is the local bottom slope around the breaking point. Therefore, the magnitude of the BFLW, which radiate both shoreward and offshoreward, can be expressed as follows.

$$\Delta \bar{\eta} = K s \Delta x_B / 2 \quad (3)$$

where Δx_B is the width of breaking variation.

In order to evaluate the magnitude of the BFLW with Eq.(3), it is necessary to estimate the variation of breaking points. Here a very crude model for the variation of breaking points is employed. That is, by assuming that the structure of wave group incident on a shallow water region can be expressed by Eq.(1), and by applying Green's formula for shoaling up to wave breaking, Δx_B , is simply given by Eq.(4).

$$\Delta x_B = 1.6 \beta h_{BM} / s \quad (4)$$

where h_{BM} is the mean (or steady) breaking depth. In Eq.(4) $\beta \ll 1$ is assumed.

Figure 10 shows the comparison of the width of breaking point variation predicted by Eq.(4) with that measured. In spite of a crude approximation, the model predicts the width of breaking point variation reasonably well. The measured width of plunging point variation are also compared in Fig.11. The measured values show surprisingly good agreement with the predicted ones.

Fig.10 Comparison of width of breaking point variation predicted with that measured

Fig.11 Comparison of width of plunging point variation predicted with that measured

As was already discussed using illustration in Fig.7, one needs care to evaluate the BFLW separately. Here, as marked in Fig.8, the maximum height of long waves measured just after breaking is simply assumed to correspond to the magnitude of the BFLW. Because, around the breaking zone, the new free waves due to wave shoaling(③) and the new bound waves being freed(②') may cancel each other and may not exceed the old bound waves in the offshore(②), which may be negligible compared to the BFLW, as shown in Fig.7. Thus evaluated magnitude of the long waves traveling shoreward is plotted in Fig.12 with solid lines which denote Mizuguchi(1995) model. Good quantitative agreement between the experimental values and theoretical ones is observed. The experimental values show linear dependency on the mean breaking depth, h_{BM} , and the wave height ratio, β , as is also predicted by the model.

The quantitative discussions on free long waves in the offshore direction is rather difficult as the separation between the incoming bound waves and the outgoing free waves was not possible in the nearshore area. However the data at location A in Fig.5 and 6 shows long period motion with the opposite sign for the first motion of reflected mode, supporting the results in Eq.(2) at least qualitatively.

Fig.12 Magnitude of the BFLW traveling shoreward

5. Conclusions

In this study the main conclusions are as follows.

- (1) Careful experiments with both detailed measurements and elaborate data analysis reveal that free long waves, which radiate both shoreward and offshoreward, are really generated by time varying breakpoint.
- (2) The generation of the BFLW result from the variation of the starting point of wave set-up which coincide with the plunging point.
- (3) The BFLW observed in this experiments can be quantitatively evaluated by Mizuguchi(1995) model, although the measured data may be contaminated with long waves of other origins.

CHAPTER 103

LABORATORY EXPERIMENTS ON GENERATION OF LONG WAVES IN THE SURF ZONE

Akio Okayasu¹, Teruki Matsumoto² and Yasuyuki Suzuki³

Abstract

Laboratory experiments were performed to investigate generation of long waves in the surf zone. Amplitude of long waves generated by time-varying breaking points was found to be nearly same as that of incoming bounded long wave. The generated long waves showed phase difference with the incoming long waves. The difference of the phases reached to $3/4 \pi$ through π at the shoreline.

1. Introduction

In order to predict the sediment transport in the nearshore area, the mechanism of generation and propagation of long period waves in the surf zone must be clarified. Long waves observed in the surf zone consist of three major components. The first component is free long wave (FLW) coming from outside of the surf zone which includes both of wave group bounded long wave (BLW) released at the breakpoint and free long waves generated by the wave maker. The second component is breakpoint forced long wave (BFLW) which is generated by moving breakpoint due to wave group. The third one is outgoing long wave which is formed by reflection of the former two components at the shoreline.

Long wave outside the surf zone can be basically explained by the mechanism proposed by Longuet-Higgins and Stewart (1962) (see *e.g.* Sato *et al.*, 1989, Nagase and Mizuguchi, 1996). Long wave generated by moving breakpoint was also theoretically investigated by Symonds *et al.* (1982), Schäffer (1993) and others. On the qualitative description of long wave sources in the surf zone, Mizuguchi (1982) wrote that the long wave coming from outside of the surf zone

³Graduate Student, Department of Civil Engineering, Yokohama National University.

was predominant among observed onshore propagating long waves in the surf zone. On the other hand, Nakamura and Katoh (1992) considered that BFLW should be predominant.

Nagase and Mizuguchi (1996) observed BFLW by putting a single packet of wave group into stable regular wave field in a wave flume. However, quantitative analysis for generation of BFLW should be difficult by the single packet experiment. Shibayama *et al.* (1992) pointed out that phase relation between wave group and long waves in the surf zone is important for suspended sediment movement due to low-frequency velocity change. Statistic analysis of phase shift also requires the measurement under usual random wave condition in the surf zone.

In the present study, generation and propagation of long waves in the surf zone are investigated on a step, 1/30, 1/20 and 1/10 uniform beaches in a flume under irregular wave conditions. Amplitude and phase variation of the long waves in the surf zone are quantitatively investigated. The experimental results are compared with a theory proposed by Mizuguchi (1995).

2. Experimental Procedures

2.1 Experimental setup and condition

The experiments were performed in a wave flume which was 17 m long and 0.5 m wide. A random wave generator with absorption control for reflected waves was equipped at one end of the flume. Beach topography were a step, 1/30, 1/20 and 1/10 uniform beaches. The step beach consisted of the first 2 m of 1/10, the next 1 m of 1/20, 6 m of flat bed and the last 2 m of 1/10 slopes. The 1/30 and 1/20 slopes had an 1 m of 1/10 slope at the toe. The beaches were made of 15-mm-thick plywood on stainless steel base.

Surface elevation and cross-shore velocity were measured by wave gages and a optic-fiber laser Doppler velocimeter (FLV). A wave gage was set 3 m onshore of the wave paddle in the offshore constant depth region. Seven (step and 1/30) or eleven (1/20 and 1/10) measuring stations were located from the offshore side of the breaking point to the shoreline. The elevation of the velocity measuring point was 1 cm from the local bottom of the slope. Figure 1 shows the setup of the flume with the step and 1/30 beaches. The x -axis was set to be onshoreward from the shoreline at the still water level.

The experiments were performed for total 14 wave conditions. Random incident waves were designed to have the Bretshneider-Mitsuyasu spectrum. The experimental conditions are listed in Table 1. In the table, h_i is the still water depth in the offshore region, h_s the still water depth on the step, $H_{1/3}$ is the significant wave height offshore, $T_{1/3}$ is the significant wave period. $H_{1/3}$ and $T_{1/3}$ were obtained by using the zero-down cross method. The "breaking point" in the table shows the mean location of wave breaking denoted by the measuring station (St.) numbers. The positions on the x -axis of the measuring stations are listed in Table 2.

2.2 Data acquisition

Since only one FLV was used, the velocity measurement was repeatedly done for each measuring station with the same incident wave signal. Wave generation was started with still water condition at each time. Preparatory generation of wave was done for 600 seconds which was considered to make the wave field enough stable. Measurements of velocity and water surface elevation were conducted after this moment.

The wave profile data were sampled at the rate of 20 Hz and were stored in a digital data recorder. The velocity signal was also acquired more than 20 valid data per second. Since the time intervals of velocity records are not equal, the data were resampled every 50 ms. 300 seconds of cross-shore velocity and water surface elevation data were used for analysis.

3. Experimental Results

3.1 Extract of BFLW

Long wave components of velocity and water surface elevation of long waves were extracted by a numerical filter with the cut-off frequency of 0.25 Hz. Then the long wave components were separated into incident and reflected low frequency components by using the water surface elevation and velocity after Mizuguchi (1991).

Figure 2 shows a result of incident and reflected wave separation on the step beach for Case 1-2. In the figure, t is the time-axis, the origin of which was the start of data acquisition, and η is water surface elevation change around the mean water level. The incident component is given by the solid line and the reflected component is shown by the dotted line. The chain and the chain with 2 dots lines respectively show paths of incident and reflected free long wave calculated by the shallow water wave theory. The separation of incident and reflected long waves are found to be fairly good on the step part.

In Case 1-2, the breaking point was around St. 3 ($x = -710$ cm). By following a prominence along the incident wave path in Fig. 2, significant change

Figure 2: Incident and reflected long waves in the surf zone (chain line: path of free incident long wave, chain with 2 dots line: path of free reflected long wave)

of the amplitude and phase of the incident long wave can be seen between St. 2 and St. 4. This should be caused by generation of free long wave due to moving breakpoint.

In the present study, incoming long wave is given at a measuring station just offshore the breaking point after the separation of onshore propagating component. Onshore propagating free long wave in the surf zone can be calculated by using the shallow water wave theory from the coming long wave from the offshore-side of the boundary, the breaking point. In the present study, this calculated onshore propagating FLW is termed as "predicted free long wave (in the surf zone)". It can be considered that the deviation of observed onshore propagating FLW from this "predicted FLW" is caused by long wave generated at the breaking point. Therefore, the "measured BFLW" was obtained by "observed onshore propagating FLW" - "predicted FLW".

The dotted line in Fig. 3 shows predicted FLW for Case 1-2. This free long wave is calculated from the observed incoming long wave at St. 2. The solid line gives BFLW evaluated by subtracting the predicted FLW (dotted lines in the figure) from the observed onshore propagating long wave at each station (solid lines in Fig. 2).

The random wave field in a flume is not the same as that on the natural beach, because the seiche and multi-reflection of long waves at the flume ends as well as the unexpected free long wave generated by the wave maker affects the wave field. However, all incoming long waves from outside into the surf zone can be considered as free long waves at the breaking point. On the other hand, BFLW should be essentially the same as that on the natural beach, if the incident short wave component can be regarded as the same. Therefore, by excluding the incoming free long waves (with any origin) from the onshore propagating free long waves observed in the surf zone, the breakpoint generated long wave can be extracted with basically the same condition in the field.

The figure shows generation of relatively large long wave between St. 2 and St. 4. This generated long wave propagates onshoreward on the step as free long wave. The form of it doesn't change so much after St. 4.

3.2 Estimation of BFLW amplitude

The amplitude of BFLW was investigated quantitatively with a model proposed by Mizuguchi (1995). The displacement of water surface $\Delta\eta$ caused by onshore propagating long wave generated by the moving breakpoint is given by

$$\Delta\eta = -Ks[x_b(t) - x_{bm}]/2 \quad (1)$$

in the model. K is a constant and given by 0.194 with wave height to water depth ratio at breaking point = 0.8. s is the mean bottom slope around the breakpoint and $[x_b(t) - x_{bm}]$ the moving distance of breakpoint.

By giving $0.8\delta(1 - \kappa)h_{bm}/s$ for the moving distance of breakpoint after

Figure 3: Predicted free long wave and generated long wave which obtained from the difference between the predicted and observed long waves

Table 3: Observed r.m.s. values of BFLW and those predicted by Mizuguchi (1995)

case	bottom slope s	breakpoint water depth h_{bm} (cm)	estimated r.m.s. value η_{crms} (cm)	measured r.m.s. value η_{mrms} (cm)	measured r.m.s. for incident wave η_{irms} (cm)
1-1	1/20	8.30	0.228	0.283	0.205
1-2		6.96	0.191	0.215	0.172
1-5		8.13	0.223	0.317	0.179
1-6		6.70	0.184	0.216	0.192
2-1	1/30	5.69	0.156	0.188	0.224
2-2		4.74	0.130	0.149	0.169
2-5		5.59	0.153	0.196	0.256
2-6		4.64	0.127	0.154	0.160
3-1	1/20	8.86	0.243	0.276	0.299
3-2		11.3	0.309	0.328	0.370
3-3		13.0	0.357	0.346	0.395
4-1	1/10	8.84	0.243	0.260	0.267
4-2		11.3	0.310	0.509	0.343
4-3		13.3	0.364	0.392	0.359

Mizuguchi (1994), Eq. 1 is obtained as

$$\Delta\eta = 0.8K\delta(1 - \kappa)h_{bm} \quad (2)$$

where δ is modulation parameter for the short waves and κ the degree of transmission of short wave grouping which are taken to be here as 0.5 and 0, respectively. h_{bm} is the mean water depth at breaking point which is approximately given by $H_{1/3}/0.7$ in the present study.

Amplitude of BFLW was calculated with above described conditions. Root-mean-square (r.m.s.) value of variation is $1/\sqrt{2}$ of the amplitude, if sinusoidal change can be assumed. Comparison between $1/\sqrt{2}$ of the calculated BFLW amplitude and observed r.m.s. value of BFLW are listed in Table 3 together with measured r.m.s. values of onshore propagating FLW (including BFLW) in the surf zone. The observed value in the table shows the mean value through the surf zone. The value 1/20 of s in Series 1 is the local bottom slope at St. 3 which was the breakpoint for the cases.

The calculated values for BFLW shown in the table are slightly smaller than the measured values. However, it can be considered that the Mizuguchi's model can predict the BFLW variation fairly well. The table also shows that the amplitude of BFLW is comparable to that of FLW coming from outside the surf zone.

Figure 4: Phase delay of observed and generated long waves from predicted free long wave for Case 1-2

3.3 Phase shift between BFLW and incoming FLW

Cross-shore variations of phase shifts between the long wave components in the surf zone for Case 1-2 are shown in Fig. 4. θ in the figure is the phase delay from the predicted FLW (dotted line in Fig. 3) in the surf zone. The solid line in the figure gives phase delay of the observed onshore propagating long wave (solid line in Fig. 2). The broken line shows phase delay of the observed BFLW (solid line in Fig. 3).

The phase shifts were defined as mean value of Fourier components around the frequency of 0.1 Hz in spectrum analysis. The right end of the figure shows the shoreline on the beach. The phase of the observed long wave delays $\pi/2$ on the step and that of the generated long wave reaches to π . The result supports the theoretical value of phase shift π given by Mizuguchi (1995). The figure shows that the phase shifts change between St. 2 and St. 4 and quite stable on the flat bed.

Figure 5 shows phase shifts between the observed BFLW and the predicted FLW for other 3 cases on the step beach. The phase shifts are stable on the step and take values around π in all cases.

Figure 6 shows phase shifts between the observed onshore propagating long wave from the predicted FLW for Series 2, 3 and 4 which were the measurements on 1/30, 1/20 and 1/10 constant slopes. The horizontal axis in the figure is non-dimensionalized by the surf zone width x_b . The straight bold broken line in the figure shows $\theta = 0.4\pi x/|x_b|$. Although the deviation of the phase shifts near the shoreline is large, this bold broken line shows good agreement with the phase shift variations in the surf zone for all cases.

Figure 7 shows phase shifts between the observed BFLW from the predicted FLW on 1/30, 1/20 and 1/10 constant slopes. The phase shift just onshore the

Figure 5: Phase delay of generated long waves from predicted free long waves on the step beach

Figure 6: Phase delay of observed long waves from predicted long waves on the constant slope bottoms

Figure 7: Phase delay of generated long waves from predicted long waves on the constant slope bottoms

breaking point takes various value. However, the value near the shoreline is within the range of $0.6 - 0.9 \pi$. The average is around $3/4\pi$.

As mentioned before in this section, the theoretical phase shift between BFLW and bounded long wave at the breaking point which should be transferred to free long wave in the surf zone is π (Mizuguchi, 1995). Near the breaking point, the measured values in the figure show wide variation and is far smaller than π . In the case of large short wave modulation, the generated long wave (BFLW) is relatively small near the mean breakpoint. This causes poor separation of generated long wave, then results in a large error in the phase calculation. Since the generated long wave becomes enough large, the stable phase shift close to π can be obtained near the shoreline. On the step, where the generation of BFLW is almost finished, the phase shifts show values close to π as seen in Fig. 5.

4. Calculation of BFLW by a Numerical Wave Model

It is considered that BFLW can be numerically simulated by presenting momentum flux change due to wave breaking in time and space. The concept is basically the same as Symonds *et al.* (1982) or Mizuguchi (1995) did in their theoretical models.

Watson *et al.* (1994) numerically simulated propagation and run-up of BFLW caused by a single wave group with a non-linear shallow water equation. In the

Figure 8: Comparison of r.m.s. values of calculated and measured long waves in the surf zone (Case 2-1)

present study, numerically simulated long waves in the surf zone were compared with the observed waves under random short wave conditions. Information on phase shifts can be examined with the random waves.

Boussinesq-type nonlinear dispersive wave model was used for the numerical simulation. Wave energy dissipation was expressed by a surface roller model which had been proposed by Deigaard (1989). Advantages for using the surface roller model in the simulation is: 1) Breakpoints are determined for individual short waves. Characteristics of wave groupiness can be reflected in the numerical calculation. 2) Momentum flux of surface rollers is included in the calculation. 3) Since the surface roller area is determined from the surface geometry, catching up of a wave crest to the previous wave crest can be simulated in the calculation, *etc.*

An example of the results of numerical simulations is shown in Fig. 8. Comparisons of r.m.s. values of the simulated and measured long waves for Case 2-1 are given. The solid line in the figure shows calculated onshore propagating long wave and the chain line gives measured onshore propagating long wave. The broken line is calculated BFLW and the chain with 2 dots line is measured BFLW. The calculated values at the shoreline show good agreement with measured values.

Figure 9 gives calculated and measured phase shifts between onshore propagating long wave and BFLW for Case 2-2. The solid line in the figure is calculated phase delay of onshore propagating long wave (including BFLW) from incoming long wave. The broken line is calculated phase delay of BFLW from incoming long wave. The chain line shows observed phase delay of onshore

Figure 9: Comparison of phase shifts of calculated and measured long waves in the surf zone (Case 2-2)

propagating long wave and the chain with 2 dots line is observed phase delay of BFLW. Calculated phase shifts near the shoreline are slightly smaller than the observed values. However, it is considered that the numerical simulation can be used for evaluation of BFLW with phase information.

5. Conclusions

In the present study, laboratory experiments were performed for long waves observed in the surf zone under random incident wave conditions. Breakpoint forced long wave (BFLW) was evaluated from the measured cross-shore velocity and surface water elevation. Phase relation between incoming long wave and BFLW was also investigated for various wave conditions and beach topography.

The conclusions of this study are as follows:

1. With propagation of random waves onshore in a flume, long wave generated near the breaking point was observed in the surf zone. This long wave is considered to be generated by time-varying breakpoint.
2. Root-mean-square value of the generated long wave was comparable to that of incoming long wave propagating from outside of surf zone. Predicted amplitude of generated long wave calculated after Mizuguchi (1995) showed good agreement with the observed value.
3. Phase shift was found between the observed long wave in the surf zone and predicted free long wave which was calculated by using shallow water approximation. The phase delay of the onshore propagating long wave was roughly

evaluated by $\theta = 0.4\pi x/|x_b|$. Phase delay of the generated long wave from that of the incoming free long waves was around $3/4 \pi$ (for constant slopes) through π (for step-type beach) at the shoreline.

4. Boussinesq-type nonlinear dispersive wave model with the surface roller model can quantitatively simulate BFLW. The phase information can be also evaluated by the numerical model.

CHAPTER 104

Generation of Infragravity Waves

A.R. Van Dongeren, I.A. Svendsen and F.E. Sancho¹

ABSTRACT: In this paper the depth-integrated, short wave-averaged nearshore circulation model SHORECIRC is used to study the generation of infragravity waves due to normally incident short wave groups on a plane beach. After linear separation of the incident and reflected long waves, it is shown that the incoming long wave shoals faster than Green's Law predicts for free waves. This indicates that energy is transferred from the short wave groups to the long wave. However, it does not shoal as quickly as Longuet-Higgins & Stewart's (1962) steady state theory for bound waves suggests. The outgoing long wave deshoals according to Green's Law but it is shown that energy is traded back and forth with the incoming short wave groups. Different shoaling and deshoaling curves can be found for different parameter choices. The work term in the long wave energy equation is used to explain these differences and ratio of the number of short wave groups to the surf zone width is confirmed to be an important parameter. As a consequence, the energy of the outgoing long wave can be larger or smaller than that of the incoming long wave, depending on the value of that parameter. Finally, the nonlinear version of the model shows the importance of the mean set-up on the generation of long waves, in particular very close to the shoreline.

INTRODUCTION

It is well-known that a forced long wave propagates with short wave groups at the group speed (Longuet-Higgins & Stewart, 1962) [LHS62 in the remainder]. When these groups propagate onto a beach, the short waves shoal and break. In the shoaling process the incoming, bound long wave gains energy and is released from the groups. The incoming long wave propagates shoreward, interacts with the breaking process, eventually reflects off the beach and propagates seaward as a free wave. The principle of this process is generally agreed upon, but the precise mechanisms by which energy is transferred to the long (or infragravity) waves are not.

For the case of normally incident waves, two different infragravity wave generation mechanisms have been proposed for the interaction with the breaking. Symonds *et al.* (1982) assumed that the groupiness which existed outside the

¹Center for Applied Coastal Research, Ocean Engineering Lab, University of Delaware, Newark, DE 19716, USA. Correspondence e-mail: apper@coastal.udel.edu

breaker zone is destroyed by the breaking and that the short waves inside the surf zone will decay with a saturated wave height. This implies a time-varying break point which generates long waves while no long wave generation takes place inside the surf zone.

Schäffer & Svendsen (1988) [SS88] examined the other extreme where all short waves regardless of their height are assumed to break at a fixed break point. This means that the groupiness outside the surf zone is transmitted into the surf zone where long wave generation can take place.

It is likely that neither mechanism is exclusively responsible for long wave generation but that it is due to a combination of both effects. Therefore Schäffer (1993) [S93] merged the two extreme mechanisms into one hybrid analytical solution and showed the effects of parameter variations.

Some field studies suggest that there is more energy in the free (outgoing or trapped) waves than in the incoming bound waves (Munk, 1949; Tucker, 1950; Elgar *et al.*, 1992; Herbers *et al.*, 1995 to name a few). This indicates that in the nearshore region energy has been transferred from the short waves to the long waves. However, other observations (Guza & Thornton, 1985; Kostense, 1984) show that the energies of the in- and outgoing long waves are about equal, which means that no net long wave energy was gained.

In this paper the nearshore circulation model SHORECIRC (Van Dongeren *et al.*, 1994) is applied to study the generation of infragravity waves on a plane beach with normally incident short wave groups. In the next section, the general governing equations of nearshore circulation are stated. Then, the linearized version of the model is used to study the growth of the amplitude of the incoming and outgoing long waves for different parameter choices. The linear long wave energy equation is used to explain the characteristics of the shoaling and deshoaling curves. It is shown that net energy can either be gained or lost depending on the values of certain parameters. Finally, the nonlinear version of the model reveals the importance of the nonlinear terms, in particular the mean set-up of the surface elevation.

GOVERNING EQUATIONS

The depth-integrated, time-averaged mass and momentum equations read (Van Dongeren *et al.*, 1994; Svendsen & Putrevu, 1996):

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{\partial}{\partial x_\alpha} \left(\int_{-h_0}^{\bar{\zeta}} V_\alpha dz + Q_{w\alpha} \right) = 0 \quad (1)$$

$$\begin{aligned} \frac{\partial \bar{Q}_\beta}{\partial t} + \frac{\partial}{\partial x_\alpha} \left(\frac{\bar{Q}_\alpha \bar{Q}_\beta}{h} \right) + \frac{\partial}{\partial x_\alpha} \int_{-h_0}^{\bar{\zeta}} V_{1\alpha} V_{1\beta} dz + \frac{\partial}{\partial x_\alpha} \int_{\zeta t}^{\bar{\zeta}} \overline{u_{w\alpha} V_{1\beta} + u_{w\beta} V_{1\alpha}} dz \\ + g(h_0 + \bar{\zeta}) \frac{\partial \bar{\zeta}}{\partial x_\beta} + \frac{1}{\rho} \frac{\partial}{\partial x_\alpha} \left(S_{\alpha\beta} - \int_{-h_0}^{\bar{\zeta}} \tau_{\alpha\beta} dz \right) - \frac{\tau_\beta^S}{\rho} + \frac{\tau_\beta^B}{\rho} = 0 \end{aligned} \quad (2)$$

where the total current has been split into depth uniform and depth varying components:

$$V_\alpha = \frac{\bar{Q}_\alpha}{h_0 + \bar{\zeta}} + V_{1\alpha}(x, y, z, t) \quad (3)$$

which implies

$$\int_{h_o}^{\bar{\zeta}} V_{1\alpha} dz = -Q_{w\alpha} \quad (4)$$

It turns out that in this formulation the radiation stress $S_{\alpha\beta}$ is defined as by Mei (1983). For a discussion of the details see Svendsen & Putrevu (1996).

In (1) and (2), V_α and $\bar{\zeta}$ represent the horizontal current velocity and the mean surface elevation, respectively. u_w is the short wave velocity defined so that $\bar{u}_w = 0$ below through level, \bar{Q}_α represents the total volume flux and $Q_{w\alpha}$ is the volume flux due to the short wave motion. ζ_t is the elevation of the wave trough, $\tau_{\alpha\beta}$ is the Reynolds stress, h_o is the still water depth, while τ_β^S and τ_β^B represent the surface and the bottom shear stress, respectively. The overbar denotes short wave averaging and the subscripts α and β denote the directions in a Cartesian coordinate system. Fig. 1 shows the definitions.

Figure 1: Definition sketch.

For the present purpose we will consider depth-uniform long waves in the shore-normal x -direction, which reduces the set of equations to:

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{\partial \bar{Q}}{\partial x} = 0 \quad (5)$$

$$\frac{\partial \bar{Q}}{\partial t} + \frac{\partial}{\partial x} \left(\frac{\bar{Q}^2}{h} \right) + g(h_o + \bar{\zeta}) \frac{\partial \bar{\zeta}}{\partial x} + \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} + \frac{\tau_x^B}{\rho} = 0 \quad (6)$$

These equations correspond to the forced nonlinear shallow water equations where the radiation stress gradient provides the forcing on the long waves. The equations are solved by finite differences using a second-order predictor-corrector method for time and horizontal space on a fixed rectangular grid. On the seaward side we specify an absorbing-generating boundary condition as derived by Van Dongeren & Svendsen (1996). In the linear version of the model a no-flux boundary condition is specified at the still water line while in the nonlinear version a moving shoreline condition is used (Van Dongeren *et al.*, 1995).

LINEAR ANALYSIS

The simplest possible case to analyze is a plane beach with a shelf and forcing generated by a bichromatic short wave group while using the linearized version of the model. This case provides valuable insights into the long wave generation mechanisms.

Following SS88 and S93 we can write the radiation stress forcing as:

$$S_{xx} = \frac{1}{2} \rho g \left(2n - \frac{1}{2} \right) \begin{cases} a_1^2 \left(1 + 2\delta \cos \left(f \frac{\Delta\omega}{c_g} dx - \Delta\omega t \right) \right), & h \geq h_b \\ \gamma^2 h_o^2 \left(1 + 2\delta(1 - \kappa) \cos \left(f \frac{\Delta\omega}{c_g} dx - \Delta\omega t \right) \right), & h \leq h_b \end{cases} \quad (7)$$

where κ is the parameter controlling the generation mechanism: $\kappa = 0$ corresponds to the case of a fixed break point, while $\kappa = 1$ represents the time-varying break point case. $n = c_g/c$ where c_g is the group speed. a_1 is the amplitude of the primary short wave in the group while the groupiness $\delta = a_2/a_1$ is the ratio of the amplitude of the secondary wave and the primary wave. $\Delta\omega = \omega_1 - \omega_2$ is the difference frequency between the two short waves which is also the long wave frequency. $\gamma = 2a_1/h$ is the saturated wave height over water depth ratio. h_b is the breaking depth. It is important to notice that the forcing consists of a steady part - which causes a steady set-up - and a time-varying part which forces a long wave. In our analysis we are only interested in the latter and in the rest of the paper we show only the time varying part of the solution.

It is assumed that the shelf is wide enough so that at the toe of the beach the incoming long wave corresponds to the equilibrium bound long wave for the flat shelf:

$$\bar{\zeta}_i = -\frac{1}{\rho} \frac{S_{xx}^{(1)}}{g h_s - c_{gs}^2} \quad (8)$$

where the subscript s corresponds to conditions on the shelf and $S_{xx}^{(1)}$ is the time-varying part of the forcing of (7). The outgoing wave is absorbed using the absorbing-generating boundary condition referenced above.

Case 1: fixed breakpoint

The first case considered is that of a fixed breakpoint ($\kappa = 0$) corresponding to the mechanism proposed by SS88. In the example studied, the following parameter values are used: forcing frequency $\Delta\omega = 0.422 \text{ s}^{-1}$, primary wave amplitude $a_{1,s} = 0.4415 \text{ m}$ on the shelf, groupiness $\delta = 0.1$, saturated breaking parameter $\gamma = 0.7$, beach slope $h_x = 1/30$ and shelf depth $h_s = 3 \text{ m}$.

The solid line in Fig. 2a shows the envelope of the long wave versus the depth, nondimensionalized by the shelf depth. The surface elevations are normalized by $a_{1,s}^2 \delta / h_s$, so that the incoming bound long wave of (8) is $O(1)$ at the offshore boundary. In the Figure, the still water line is on the left-hand side while the toe of the beach is on the right-hand side. Notice the agreement of the model with the dashed line which corresponds to the analytical solution by SS88. The break point is located at $h/h_s = 0.45$ and is indicated in the Figure.

The long wave can be separated into an incoming and an outgoing long wave

Figure 2: Case 1: (a) Envelope of the total long wave motion vs. depth : present model (—) and analytical solution (- -); (b) Envelope of the incoming long wave: present model (—), Green's Law (- -) and LHS62's steady state solution (-·-); (c) Envelope of the outgoing long wave: present model (—) and Green's Law (- -); (d) Reflection coefficient.

using linear superposition of the surface elevation and the flux

$$\bar{\zeta} = \bar{\zeta} + \bar{\zeta}_i + \bar{\zeta}_r \quad \text{and} \quad \bar{Q} = \bar{Q}_i + \bar{Q}_r \quad (9)$$

where $\bar{\zeta}$ is the steady set-up, subscript i denotes the incoming wave and subscript r denotes the outgoing wave. Also, we know the following relationships between the surface elevation and the flux of the incoming and outgoing wave, respectively:

$$\bar{Q}_i = c_g \bar{\zeta}_i \quad \text{and} \quad \bar{Q}_r = -\sqrt{g h_o} \bar{\zeta}_r \quad (10)$$

which implies that the incoming wave essentially propagates with group speed c_g and the free outgoing wave propagates with the shallow water wave speed.

This is confirmed by the computations. Solving for $\bar{\zeta}_i$ and $\bar{\zeta}_r$ from these four equations yields

$$\bar{\zeta}_i = \frac{\sqrt{g h_o} (\bar{\zeta} - \bar{\zeta}) + \bar{Q}}{c_g + \sqrt{g h_o}} \quad \text{and} \quad \bar{\zeta}_r = \frac{c_g (\bar{\zeta} - \bar{\zeta}) - \bar{Q}}{c_g + \sqrt{g h_o}} \quad (11)$$

The solid line in Fig. 2b shows the envelope of the *incoming* long wave. Note that the long wave shoals faster than as predicted by Green's Law ($\hat{\zeta} \propto h^{-1/4}$, the dashed line), which means that energy must have been transferred to the long wave. Also shown is the shoaling curve according to LHS62's steady state theory, Eq. (8) (the dash-dotted line, $\hat{\zeta} \propto h^{-5/2}$ outside the surf zone), which grows much faster than the actual wave. This indicates that on a sloping beach the bound long wave does not have "time" to attain local equilibrium but that it depends on its history. Therefore, on the slope the forced long wave does not increase with depth as $h^{-5/2}$ as is assumed in the analysis of field data in some papers (e.g., Elgar *et al.*, 1992; Herbers *et al.*, 1995).

In Fig. 2c the outgoing long wave (solid line) closely follows Green's Law (dashed line) which indicates that this wave is a free long wave. There are some oscillations noticeable around the dashed line because energy is traded back and forth with the incoming short wave group, as will be explained below.

Figure 2d shows the ratio of the amplitude of the outgoing wave and the incoming wave (the "reflection coefficient"). This ratio is by definition equal to unity at the shore. For the chosen parameter values, the ratio is larger than unity everywhere else, meaning that there is more energy in the outgoing wave than in the incoming wave, which indicates that energy has been transferred from the short waves to the long waves.

As a tool to study this energy transfer in more detail we can use the linear long wave energy equation

$$\frac{\partial E}{\partial t} + \frac{\partial E_f}{\partial x} + \frac{\bar{Q}}{h_o} \frac{\partial S_{xx}}{\partial x} = 0 \quad (12)$$

where E is the long wave energy, $E_f = \rho g \bar{\zeta} \bar{Q}$ is the energy flux and the third term represents the work the short waves do on the long wave through the radiation stress. Averaging over the IG-wave period (denoted by the double overbar) eliminates the temporal variation and yields a balance between the energy flux and the work

$$\frac{\partial \overline{\overline{E_f}}}{\partial x} + \frac{\overline{\overline{Q}}}{h_o} \frac{\partial \overline{\overline{S_{xx}}}}{\partial x} = 0 \quad (13)$$

The two terms can be each split into an incoming and outgoing part

$$\frac{\partial \overline{\overline{E_{f,i}}}}{\partial x} + \frac{\partial \overline{\overline{E_{f,r}}}}{\partial x} + \frac{\overline{\overline{Q_i}}}{h_o} \frac{\partial \overline{\overline{S_{xx}}}}{\partial x} + \frac{\overline{\overline{Q_r}}}{h_o} \frac{\partial \overline{\overline{S_{xx}}}}{\partial x} = 0 \quad (14)$$

Figure 3a shows the balance between the energy flux term (dashed line) and the work term (solid line) in (13) across the domain for the same parameter

Figure 3: Case 1: (a) Work done on total long wave (—) and energy flux (- -); (b) Work on incoming long wave; (c) Work on outgoing long wave; (d) Energy flux of incoming wave (—), energy flux of outgoing wave (- -), and energy flux of total long wave (- .).

values as in Fig. 2. Both terms are normalized by $\rho g \sqrt{gh_s} \delta^2 a_{1,s}^4 / h_s^3$. Figure 3b shows the work done on the incoming wave which is the third term in (14). It is negative across the whole domain, which means that energy flux is gained. This is consistent with the finding of Fig. 2 that the incoming long wave increases faster in amplitude than a free long wave. Conversely, Fig. 3c reveals that the work done by the short waves on the outgoing long wave oscillates around zero, which means that energy is traded back and forth but that over the whole domain the long wave loses or gains very little energy. It essentially deshoals as a free long wave as was already seen in Fig. 2c.

In Fig. 3d the energy fluxes of the incoming, the outgoing and the total long wave motion are shown, normalized by $\rho g \sqrt{gh_s} \delta^2 a_{1,s}^4 / h_s^2$. Notice that the incoming wave already gains about 30% of energy flux seaward of the break point. The incoming long wave reaches its maximum energy flux at the shore-

line where it is fully reflected. The outgoing wave shows an oscillating energy flux. The total energy flux therefore becomes increasingly negative seawards as a consequence of the net transfer of energy from the short waves to the long wave.

Case 2a: moving breakpoint

The second case considered is that of a moving breakpoint ($\kappa = 1$) corresponding to the mechanism proposed by Symonds *et al.* (1982). The same parameter values as in case 1 are used.

Figure 4: Case 2a: labels as Fig. 2. The breaking region is indicated by the vertical lines.

Figure 4a shows the comparison of the long wave envelope as predicted by the model and the analytical solution by S93. The differences are due to the fact that in the analytical solution the breaking region (ranging from $0.41 \leq h/h_s \leq 0.48$) is contracted into a point at $h/h_s = 0.45$ whereas the model is capable of reproducing the breaking region itself.

Up to the point where breaking starts, the incoming long wave in Fig. 4b gains energy flux as before. Over the breaking region, however, the energy flux is now decreasing, a feature which is investigated in more detail below. Inside the surf zone ($h/h_s \leq 0.41$) a standing long wave occurs due to the absence of forcing in that region, see Figs. 4b and c. Figure 4c shows that outside the surf zone the long wave again deshoals according to Green's Law.

Finally, the ratio of the amplitudes of the outgoing wave and the incoming wave is shown in Fig. 4d. Though the long wave energy is reduced through the breaking region the amplitude of the outgoing wave is still about equal to or larger than that of the incoming wave.

Figure 5: Case 2a: (a) Work on incoming long wave; (b) Work on outgoing long wave; (c) Energy flux of incoming wave (—), energy flux of outgoing wave (---) and energy flux of total long wave (-.-); The breaking region is indicated by the vertical lines.

This is further illustrated by the direct analysis of the energy transfer in Fig. 5. Panel (a) shows that in case 2a the work done on the incoming wave by the short waves in the breaking region itself is positive, which indicates an energy flux loss. This is consistent with the loss of amplitude shown in Fig. 4b. Inside the surf zone no forcing occurs, so the work is zero.

Fig. 5b shows that through the breaking region the work done on the outgoing wave is negative so that energy flux is *gained* (in magnitude) when the wave propagates out. Seaward of breaking the work is oscillating around zero as in case 1. The according energy fluxes of the incoming, outgoing and total wave are plotted in Fig. 5c.

Case 2b: moving breakpoint with halved forcing frequency

The results of case 2a are valid only for the chosen set of parameters. It turns out that a profound change occurs when the forcing frequency or the beach slope are varied. Either of these parameters control the number of wave groups in the surf zone, which is an important parameter, as will be shown below.

Figure 6: Case 2b: labels as Fig. 2. The breaking region is indicated by the vertical lines.

The conditions of case 2a are repeated except that the forcing frequency is halved, $\Delta\omega = 0.211 \text{ s}^{-1}$. Again the deviation between the model and the slightly simpler analytical solution is negligible (Fig. 6a). Fig. 6b shows that the amplitude of the incoming wave increases outside of the breaking region and decreases in the breaking region itself, similar to the previous case. Inside the surf zone forcing is absent and a standing wave occurs, see Figs. 6b and c. In this case, however, the outgoing long wave *loses* amplitude when propagating out through the breaking region (Fig. 6c). This results in a reflection coefficient less than unity outside the surf zone, i.e. the long waves have *lost* energy in the breaking process (Fig. 6d).

Figure 7: Case 2b: labels as Fig. 5. The breaking region is indicated by the vertical lines.

Analysis of the energy transfer using the terms in (14) confirms this result. Figure 7a is similar to Fig. 5a, but Fig. 7b shows that contrary to the previous case the work the short waves do on the outgoing long wave is now positive, which means that the energy flux decreases in magnitude as the long wave propagates out through the breaking region.

The reason for this different behavior is the phase difference between the short wave groups and the incoming and outgoing long waves. As the short waves propagate onto the beach, the phase shift between the associated incoming long wave and the groups grows from 0.5π to about 0.6π . This phase shift causes the work (which is the time-averaged product of the radiation stress gradient and the incoming long wave) to be negative so energy is transferred to the long waves. In the breaking region the forcing is varying in time (when the short waves in the group are smaller and break closer to shore) or constant (when the waves are larger and break further offshore). This causes the long wave-averaged work done on the incoming long wave to be positive in the breaking region. This behavior is independent of the period of the incoming wave groups.

With the destruction of the wave groups by the varying break point, the long wave is released in the breaking region and propagates shoreward as a free wave, where it is reflected and propagates seaward. The sign of the work that the short waves do on the outgoing wave is then dependent on the relative phase between them, which is a function of the time it takes the long wave to propagate through the surf zone and back. For a plane beach this time lag can be calculated as

twice the propagation time from the shore to the mean break point h_b :

$$\Delta T = 2 \int_0^{h_b} \frac{dh}{h_x \sqrt{gh}} = \frac{4}{h_x} \sqrt{\frac{h_b}{g}} \quad (15)$$

where $\Delta T = 44.5$ s in the cases considered here. In case 2a the ratio of the time lag ΔT to the group period $T_g = 2\pi/\Delta\omega$ is

$$\frac{\Delta T}{T_g} = \frac{2}{h_x} \sqrt{\frac{2a_b}{\gamma g}} \frac{\Delta\omega}{\pi} = 3 \quad (16)$$

This integer value means that the outgoing long wave is "in phase" with the incoming long wave in the breaking region (which is short relative to the long wave length). Because these waves propagate in opposite directions, the signs of the work terms are opposite as well. In case 2b the ratio $\Delta T/T_g$ is 1.5, which means the incoming and outgoing waves are in "anti-phase", which causes the work on the incoming and outgoing waves to have the same sign. The ratio $\Delta T/T_g$ essentially specifies the number of wave groups in the surf zone. As can be seen from (16) it depends on the forcing frequency, the beach slope and on the short wave amplitude at breaking. Instead of changing the forcing frequency, an equivalent variation of the beach slope would yield the same result.

This ratio is equivalent to the parameter \mathcal{X} which was already found by Symonds et al. (1982) and the slope parameter $S_b = h_x L_b/h_b$ used by SS88 where L_b is the length of the surf zone and h_b is the depth at breaking. Rewriting those parameters yields

$$\mathcal{X} \equiv \frac{\Delta\omega^2 h_b}{g h_x^2} = \frac{\pi^2}{4} \left(\frac{\Delta T}{T_g} \right)^2 = 4\pi^2 S_b^{-2} \quad (17)$$

IMPORTANCE OF NONLINEAR TERMS

To investigate the importance of nonlinearities on the results, the model is rerun with the parameters of case 2a but now using the nonlinear Equations (5) and (6). In this case it is impossible to linearly separate the incoming and outgoing long waves. Therefore, we will examine the terms in the nonlinear long wave equation, averaged over the IG-wave period

$$\frac{\partial}{\partial x} \overline{\left(\frac{1}{2} \rho \frac{Q^3}{h^2} + \rho g \zeta Q \right)} + \frac{\overline{Q}}{h} \frac{\partial \overline{S_{xx}}}{\partial x} + \overline{U \tau_{b,x}} = 0 \quad (18)$$

which is the nonlinear extension of (13). The work that the bottom friction is small and is neglected in the following. The energy flux and the work balance each other, as can be seen in Fig. 8a. It turns out that for the particular set of parameter values used here the same case run with the linearized equations (Fig. 8b) shows a change of sign of the terms. This is due to the fact that in the nonlinear version of the model the travel time ΔT is dependent on the still water depth h_o as well as the set-up $\bar{\zeta}$. In short, the set-up effectively changes the beach slope in the surf zone experienced by the long waves. Artificially including the mean set-up $\bar{\zeta}$ in the linear model reverses the sign of the terms, see Fig. 8c. In fact, it can be seen that Figs. 8a and c agree well, which indicates that the mean set-up is the most important nonlinear term.

Figure 8: Work done on total long wave (—) and energy flux (- -): (a) Nonlinear version; (b) Linear version; (c) Linear version with mean set-up included in the depth.

CONCLUSIONS

The SHORECIRC model has been used to study infragravity wave generation. In the linear version of the model, the incoming and outgoing long waves can be separated. As expected, the incoming long wave already gains energy flux outside the surf zone due to the changing forcing but not nearly as fast as the local value of the LHS62 steady state theory for bound waves suggests. In the case of a fixed break point the energy flux gain continues inside surf zone, whereas in the case of a moving break point, it is found that the incoming wave loses energy flux in the varying break point region.

In the case of a fixed break point the outgoing long wave is seen to exchange energy flux with the short waves with very little net gain over the domain, so that it essentially deshoals according to Green’s Law. When the breakpoint is allowed to move, however, the outgoing wave either gains or loses flux depending on the phase between the short wave forcing and the outgoing wave. This gain or loss is dependent on a parameter which represents the number of wave groups in the surf zone. This result may explain the variation in the ratio of outgoing to ingoing wave energy found in field data.

Extending the model to include the nonlinear terms shows the importance of the steady set-up over the other nonlinear terms.

CHAPTER 105

RESPONSES OF COASTAL TOPOGRAPHY TO SEA-LEVEL RISE

Nobuo Mimura¹, Member ASCE and Eiichi Kawaguchi²

ABSTRACT

The impacts of sea-level rise induced by global warming on sandy beaches and sediment deposition around the river mouth are assessed. The exacerbated erosion by sea-level rise is evaluated in a national scale for Japan, on the basis of the Bruun Rule assuming the existence of the equilibrium beach profile. The eroded area reaches 56.6, 81.7, and 90.3% of the total area of the existing beaches for the sea-level rises of 30, 65, and 100cm, respectively. The effects on sandy beaches is extremely large, since such erosion superposes on the already existing erosion. The effect of sea-level rise on the river mouth is also examined by a numerical model. The place of sand deposition changes from the river mouth to the upper reaches along the river as the mean sea level rises higher. Higher risk of flooding is anticipated because of the rise of river floor and the backwater effect of sea-level rise.

INTRODUCTION

It is anticipated that global warming will bring about accelerated sea-level rise through thermal expansion of ocean water and melting of land-based glaciers, and climate change such as changes in precipitation and tropical cyclones. IPCC(1990) projected that the mean sea level would rise 65cm by the year 2100, with an uncertain range of 30 to 110cm in its first report. The best estimate for the sea-level rise has been revised to 50cm by 2100 in the second assessment report(IPCC, 1996), as shown in Fig.1. If climate change and sea-level rise occur in future as estimated, they can impose a variety of impacts on the natural environment and human society in the coastal zones. Since most coasts in the world consist of natural geographic features, such as sandy beach, dune,

¹ Professor and ² Graduate student, Department of Urban and Civil Engineering, Ibaraki University, 4-12-1 Nakanarusawa, Hitachi, Ibaraki 316, Japan

Fig.1 Projections of global sea level(IPCC, 1996)

delta and river mouth, wetlands and coral reef, a concern has arisen about what and how serious the impacts of sea-level rise and climate change on them will be. As the natural geographic features show particular adaptive responses to the changes in external conditions, it is necessary to estimate such responses of the coastal topography in order to evaluate the impacts of sea-level rise and climate change. This paper is an attempt toward this direction focusing on sandy beaches and river mouth.

IMPACTS ON SANDY BEACHES

Outline of the predictive model

Topographic changes of sandy beaches are caused by cross-shore and longshore sediment transport. Sea-level rise due to global warming acts uniformly on the world coasts, though the amount of the rise relative to the land differs place to place because of the uneven distributions of sea temperature rise, plate movement, and local land subsidence, etc. Therefore, it is assumed, as the first step of assessment, that local factors for the beach topographic change, such as sources of sediment supply and the longshore transport, can be neglected. Under such assumption, the response of sandy beaches to the sea-level rise is considered to take place only in the cross-shore direction, i.e. as beach profile change.

A sandy beach is eroded by sea-level rise more than simple inundation. If there is an equilibrium form of the beach profile, the sandy beach changes toward forming a new equilibrium profile for the increased sea level, as shown in Fig.2. This concept is known as the Bruun Rule (Bruun, 1962), and a number of predictive models have been developed on its basis. The Bruun Rule-based models has been calibrated by Mimura et al.(1995) by correlating the land subsidence due to pumping up ground water, i.e. relative sea-level rise, and the resultant retreats of the shoreline in Niigata, Japan. Equation (1) is often

Fig.2 Response of the beach profile to sea-level rise

used to represent the equilibrium beach profile.

$$h = Ay^{2/3} \quad (1)$$

where, h is water depth at an offshore distance y from the shoreline, and A is a shape coefficient determined for the individual beach. The amount of shoreline retreat, Δy , can be calculated by balancing the sediment volumes eroded in the foreshore and transported offshore (Dean, 1991; Mimura et al., 1993). The formula derived by Dean is as follows.

$$\Delta y + \frac{3}{5} \frac{h_* W_*}{B} \left(1 + \frac{\Delta y}{W_*}\right)^{5/3} = \frac{3}{5} \frac{h_* W_*}{B} - \left(\frac{S}{B} W_*\right) \quad (2)$$

Mimura et al. (1993) took into account the foreshore slope in the calculation, whereas Dean (1991) assumed that the foreshore above the mean sea level was vertical. However, as there were no significant difference in the shoreline retreat calculated by the two formulas, Eq. (2) was used in this study.

Data and Calculation

In order to apply the Bruun Rule-based model, it is necessary to know the height of berm, B , critical depth of sediment movement in the offshore region, h_* , and the median diameter of sand to determine A . The first two parameters, i.e. B and h_* , can be estimated by the existing studies such as Takeda and Sunamura (1983) and Hallermeier (1981) if the wave conditions and the average slope of the beach are given. Therefore, the necessary data for the calculation are at least the dimensions of incident waves, the sediment diameter and the average beach slope.

Fig.3 Nation-wide average of erosion rate with sea-level rise

Table 1 Present situation of Japanese coasts and impacts of sea-level rise

Total coastline	34,386 km
Sandy beaches	
Length	5,508 km
Area	191 km ²
Ave. Width	35 m
Sandy beaches eroded (past 70 yrs)	125 km ²
Impact of SLR	
0.3 m	108 km ²
0.65 m	156 km ²
1 m	173 km ²

The Japanese coastline of about 34,000 km in length is divided into 9,688 segments for the purpose of management by four governmental ministries and agency. About one sixth of the total length is occupied by sandy beaches as indicated in Table 1. It was fortunate for us to be able to use the results of a national coastal survey carried out by the related ministries in 1993. The coastal survey covered the length, width and average slope of the beach. The data of incident waves were collected from this survey, Sugahara et al.(1986), and field measurements where available. These data were used to determine the height of berm, B , the critical depth of sediment movement, h_c , and the shape-factor, A . Then the amounts of shoreline retreat, Δy , was calculated for each sandy beach using Eq.(2).

Fig.4 Distribution of erosion rate with prefectures

Regarding the sea-level rise, three scenarios of 30, 65, and 110cm rise were used according to IPCC(1990). The best estimate of sea-level rise by the year 2100 has been revised from 65 cm in IPCC(1990) to 50cm in IPCC(1996) as mentioned above. However, the scenarios used in this study are still useful to examine the possible range of the impacts.

Sea level rise-induced erosion estimated for the Japanese beaches

The results of the estimation for the area of erosion are shown in Fig. 3 and 4. Figure 3 shows the national summary of the percentage of eroded area, which is called the erosion rate here. A 30 cm sea-level rise would erode 11,775 ha or 56.6% of the present sandy beaches in Japan. The total area eroded for the past about seventy years was 12,880 ha, which was estimated by the comparison between old and the present topographic maps by Tanaka et al. (1993). Therefore, the area to be eroded by a 30 cm sea-level rise is comparable to that occurred for the past several tens years. It is surprising that even a 30cm rise of mean sea level would cause such severe erosion. If the sea-level rise becomes 65cm and 100cm, 81.7% and 90.3% of the present sandy beaches will disappear by erosion, respectively. Table 1 shows a summary of the present situation of the Japanese coasts and the estimated impacts.

In Fig. 4, the distributions of the estimated erosion rate are shown with coastal prefectures which are thirty-nine out of forty-seven prefectures in total. The areas eroded by 30cm sea-level rise range from 24 to 95% of the existing beaches. If the sea-level rise reaches 1 m, most prefectures would lose more than 90% of their beaches. Large differences in the erosion rate can be seen among prefectures in Fig. 4. Figures 5 and 6 show the relationships between the erosion rate, and the significant wave height of the incident waves and beach width of the coastal segments. There is no apparent correlation between the erosion rate and the significant wave height, while it decreases clearly with the beach width. Such tendencies indicate that there are no large differences in the amount of the shoreline retreat among beaches for the same sea-level rise, and that narrow beaches tend to disappear early as the sea-level rise proceeds.

It is quite natural that beach erosion due to sea-level rise will superpose on those by other mechanisms such as lack of sediment supply and imbalance of the longshore transport. Therefore, the role of sea-level rise is to exacerbate the present trend of beach erosion.

Fig.5 Relationship of erosion rate and incident wave height

Fig.6 Relationship of erosion rate and beach width

IMPACTS ON RIVER MOUTH

Applied model

The topographic change of river mouth consists of complicated interactions of river and marine forces, and topography, so the response to sea-level rise must vary widely from place to place. Therefore, it seems more appropriate to take a simple case to study the basic phenomena related to the sea-level rise. In this study, a small-scaled and simplified model of the river mouth was studied on a basis of the numerical simulation.

The numerical model developed by Sawai et al.(1993) was used, since it has been verified to simulate the results of laboratory experiments well. The model consists of two sub-models; one is to calculate the flow field based on the equations of continuity and momentum, and the other the sediment transport and topographic changes. The equations are as follows.

1) Flow field

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} [(\zeta + h)u] + \frac{\partial}{\partial y} [(\zeta + h)v] = 0 \quad (3)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} - fv + g \frac{\partial \zeta}{\partial x} - A_h \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) + \frac{gu\sqrt{u^2 + v^2}}{(\zeta + h)C^2} = 0 \quad (4)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + fu + g \frac{\partial \zeta}{\partial y} - A_h \left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) + \frac{gv\sqrt{u^2 + v^2}}{(\zeta + h)C^2} = 0 \quad (5)$$

where, ζ is elevation of water surface, u and v components of velocity, h local water depth, f the Coriolis factor, A_h vertical eddy viscosity, C Cezy's coefficient of friction, and g the gravitational acceleration.

2) Topographic change

$$\frac{\partial z}{\partial t} + \frac{1}{1-\lambda} \left(\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} \right) = 0 \quad (6)$$

where, q_x and q_y are sediment transport rates, and λ is the void ratio of the sand layer.

Regarding the sediment transport rate, the longitudinal and transverse components are given separately for bed and suspended loads. In the calculation of topographic change by bed load, the effect of gravity was taken into account to prevent the slope of the local topography from becoming too steep.

The model of river mouth consists of a straight river and rectangular sea as shown in Fig. 7. The conditions of flow rate and sediment discharge were given at the uppermost boundary of the river, and were kept constant for all the calculations. Three scenarios of sea-level rise were assumed as shown in Fig. 8, i.e. no sea-level rise, slow and fast rise scenarios.

Results of calculations

The calculated profiles along the river channel are indicated in Fig. 9 (a)~(c), while three-dimensional pictures of the results are shown in Fig. 10. Figure 9 (a) is for the case

Fig.7 Model of river mouth

Fig.8 Assumed scenarios of sea-level rise

case of no sea-level rise, showing that a terrace is forming around the river mouth as time proceeds. After the terrace reached some length in the cross-shore direction, it stopped growing in that direction and started to expand in the longshore direction. In the case of no sea-level rise, little deposition of sand takes place on the river floor.

Figures 9(b) and (c) show the results for the cases of slow and fast sea-level rise. The water surface of the river tends to increase due to the backwater effect as the sea level rises. The significant feature of these cases is that the deposition of sediment occur along the river channel with the increase of river water surface, even in the upper reach. As the deposition on the river floor takes place, the terrace to be formed around the river mouth stay small compared with the no sea-level rise case. When the elevation of river floor is increased by sand deposition, this makes the river surface higher in addition to the backwater effect. According to such feedback mechanism, the area of sediment deposition moves further upstream.

(a) Scenario 1 (No sea-level rise)

(b) Scenario 2 (Low sea-level rise)

(c) Scenario 3 (High sea-level rise)

Fig.9 Topographic changes of river mouth with different sea-level rise scenarios

(a) No sea-level rise

(b) High sea-level rise

Fig.10 Three-dimensional picture of the topographic changes around river mouth

The combined effects of sea-level rise and sand deposition along the river floor exacerbate the potential danger of river flood. Attention has to be paid to this phenomena, as a possible impact of sea-level rise.

CONCLUSIONS

In the present paper, responses of coastal topography to sea-level rise and related impacts have been examined. Regarding the beach erosion, the nation-wide assessment revealed that the effect of sea-level rise is extremely large; even a 30 cm sea-level rise may cause beach erosion comparable with that took place for the past 70 years. Keeping

such fact in mind that the sea level rise-induced erosion superposes on the existing erosion, it is necessary to pay careful attention to the future trend of sea-level rise.

Regarding the impacts on the river mouth, sea-level rise has two effects; one is the backwater effect to increase the water level along the river, the other the changes in the place of sediment deposition. If the scale of sea-level rise is large, the deposition of sand transported by rivers will move upstream. Both effects act to increase the water level along the river, suggesting that the risk of river flooding would increase. Since the analyses performed in this study were rather simple, further studies are needed to evaluate the impacts of sea-level rise on the complicated situation of real river mouths.

The authors wish to thank the Ministries of Transport, Public Works, and Agriculture and Prof. Yamaguchi of Ehime University for providing the coastal data, and Prof. Sawai of Setsunan University for giving advice on the calculation of river mouth topography.

CHAPTER 106

Numerical Study of Low Frequency Surf Zone Motions

H. Tuba Özkan-Haller¹ and James T. Kirby²

Abstract

This paper describes the application of a model of the two dimensional shallow water equations to the growth of instabilities of the longshore current at SUPERDUCK on October 18th. Simulations are carried out using two initial current profiles. In the first case the initial longshore current profile results from a balance between bottom friction, the radiation stress gradient and lateral mixing due to turbulence. In the second case lateral mixing is neglected. The shear wave climates resulting from both simulations are analyzed and compared to data. In the first case the energy in the shear wave band is underpredicted whereas in the second case, it is overpredicted. In both cases, the initial longshore current profile changes due to lateral mixing induced by the shear instabilities. The resulting longshore current profile after shear instabilities have reached finite amplitude is found to be very similar for both cases.

Introduction

Surf zone current measurements from experiments such as SUPERDUCK, Delilah, NSTS at Leadbetter beach, and others show that a variety of low frequency motions, such as edge waves, leaky waves, surf beat, rip currents and shear waves exist in the surf zone. These motions coexist and interact with each other as well as the short wave climate. Among these low frequency motions shear waves have been identified most recently. They were seen in current data from the SUPERDUCK experiment by Oltman-Shay *et al.* (1989) as a meandering of the longshore current over time scales up to $O(1000\text{ s})$. During the SUPERDUCK experiment a longshore array of current meters was positioned in the surf zone of a predominantly north-south tending beach at Duck, NC. A storm hit Duck on the 15th of October and caused a fairly stationary short wave field from the north quadrant through the 18th of October. During this four day period the shear wave climate was very energetic.

Time series of current measurements from one of the current meters in the surf zone for the 18th of October clearly show the meandering character of the

¹Graduate Student, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA. E-mail: ozkan@coastal.udel.edu

²Professor, Center for Applied Coastal Research, University of Delaware, Newark, DE 19716, USA.

longshore current (Figure 1). Using five current meters from the longshore surf zone array, frequency-longshore wavenumber spectra can be computed. Such a spectrum for the longshore current velocities on the 18th of October is shown in Figure 2. Shear waves are readily distinguishable from edge waves due to the low range of frequencies they occupy as well as their nearly nondispersive character.

Figure 1: Time series of longshore velocity from gage LS07, SUPERDUCK field experiment, October 18th.

Figure 2: Frequency-longshore wavenumber spectrum for longshore velocity, SUPERDUCK field experiment, October 18th.

Bowen and Holman (1989) attributed these disturbances to instabilities of the longshore current. Analytical and numerical linear instability analyses were carried out by various investigators such as Dodd and Thornton (1990), Dodd *et al.* (1992), Dodd (1994), Putrevu and Svendsen (1992) and Falqués and Iranzo (1994). In these studies an initial current over a given bottom bathymetry is analyzed. Results show that longshore currents are unstable to longshore periodic perturbation in many cases.

In order to study these disturbances as they reach finite amplitude, a non-linear analysis needs to be employed. Such analyses were, to date, carried out by Dodd and Thornton (1992), Falqués *et al.* (1994), Özkan and Kirby (1995) and Allen *et al.* (1996). In these studies the spirit of a linear instability analysis is preserved since an initial current is generated and subsequently the temporal growth of the instabilities to finite amplitude is observed. In addition, Deigaard *et al.* (1994) performed a study where the longshore current was generated by ramping the short wave forcing. In their study the strengthening of the longshore current and the spatial growth of the instabilities were observed simultaneously.

In this study, we seek to find out whether or not instabilities of the longshore current are the source of the low frequency energy observed during the SUPER-DUCK experiment and to assess the importance of lateral mixing caused by shear instabilities. For this purpose we choose to simulate the low frequency climate on October 18th. Linear instability calculations for this day were previously carried out by Dodd *et al.* (1992) assuming straight and parallel bottom contours and a stationary wave field. Their results showed good agreement between the range of linearly unstable wavenumbers with observation as well as agreement between the linear prediction for the speed of propagation of the disturbances with observation.

Here, the analysis by Dodd *et al.* (1992) is taken one step further by carrying out a similar analysis using nonlinear computations. The assumption of straight and parallel bottom contours is retained, and it is also assumed that a stationary wave field forces an initial longshore current profile that subsequently becomes unstable. The instabilities are observed to grow to a finite amplitude and comparisons to data are made.

In the following, the governing equations of the model and their solution technique are discussed briefly. The generation of the initial longshore current profile is also documented along with results for the shear wave calculations and comparisons to data. For a detailed description of the numerical methods employed the reader is referred to Özkan-Haller and Kirby (1996a) where the application of the model to subharmonic edge waves is also documented.

Governing Equations

The governing equations are the nonlinear shallow water equations with added short wave forcing and bottom friction terms.

$$\begin{aligned}
 \frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x}[u(h + \eta)] + \frac{\partial}{\partial y}[v(h + \eta)] &= 0 \\
 \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} &= -g \frac{\partial \eta}{\partial x} - \tau_{bx} \\
 \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} &= -g \frac{\partial \eta}{\partial y} + \tau_y - \tau_{vy}.
 \end{aligned} \tag{1}$$

Here, η is the water surface elevation above the mean water level, h is the depth with respect to the mean water level, u and v are the depth-averaged current velocities in the x and y directions, respectively, where x points offshore and y points in the longshore direction. The parameter τ_y represents the effect of the

short wave forcing in the y direction. The bottom friction is modeled using a linear representation assuming a small angle of wave incidence and weak mean longshore currents in relation to the horizontal wave orbital velocities, such that τ_{bx} and τ_{by} are given by

$$\tau_{bx} = \frac{\mu}{h + \eta} u, \quad \tau_{by} = \frac{\mu}{h + \eta} v, \quad (2)$$

where

$$\mu = \frac{2}{\pi} c_f u_0. \quad (3)$$

Here, u_0 is the horizontal orbital velocity of the short waves and can be expressed in terms of the wave height (Dodd *et al.*, 1992).

In order to estimate the term τ_y the short wave climate has to be considered. The bottom bathymetry at SUPERDUCK on October 18th is depicted in Figure 3a. It is characterized by a steep foreshore slope, a sand bar about 60 m offshore, and a milder offshore slope. The bathymetry on this day was fairly uniform in the longshore direction (Dodd *et al.*, 1992). The incident wave field measured at 8 m water depth consisted of waves from the north quadrant at about 15° to the beach inducing a southward longshore current. The root-mean-square (rms) wave height was about 1 m with a peak period around 5 sec.

In order to simulate the transformation of these random waves into shallow water, the wave height transformation model by Whitford (1988) which is based on Thornton and Guza (1983) is used. This model assumes random waves with Rayleigh distributed wave heights as well as wave stationarity and straight and parallel contours. The applicability of these assumptions to the SUPERDUCK experiment is discussed in Whitford (1988). The results of this model for the conditions on October 18th are given in Figure 3b. The waves are predicted to break at the seaward side of the bar, the breaking process stops at the shoreward side and strong breaking occurs on the foreshore slope.

Model Setup

The radiation stress gradient resulting from the short wave motion can now be computed. In the presence of this steady forcing and in the absence of any fluctuating motions a steady longshore current $V(x)$ would result, representing a balance between the radiation stress gradient, bottom shear stress, and lateral momentum mixing. The simplest formulation of the longshore balance neglects turbulent momentum exchange and incorporates a linearized bottom stress. The longshore current profile that would result from such a balance will have two peaks, one around the location of the bar crest and another close to the shoreline. This is due to the prediction that waves break as they approach the crest of the bar, cease to break as they travel into the trough region of the bar and break again on the shore. This mechanism causes two distinct areas of radiation stress forcing, hence the two peaks in the current which can be seen in Figure 3c.

In reality, however, significant currents are observed in the trough regions of barred profiles. A mixing mechanism is required to model such a case. The mixing can be due to many factors such as turbulent momentum mixing (Battjes,

1975), the contribution to the radiation stress by the rollers of breaking waves (Lippman *et al.*, 1995) and effects of depth variations of the nearshore currents (Svendsen and Putrevu, 1994). All of these mechanisms have the tendency to smooth the longshore current profile. As a simple but representative case of the effect of such mechanisms on the shape of the longshore current profile, turbulent momentum mixing is considered. The addition of a lateral mixing term (Battjes, 1975) into the mean longshore current balance decreases the magnitude of both peaks and introduces a significant current in the bar trough region. The current profile resulting from choosing a mixing coefficient of unity is depicted in Figure 3c and represents a good agreement with the current maximum as dictated by measurements. It should be noted that the amount of turbulent momentum mixing introduced here is unrealistically high, but it is anticipated that total mixing induced by the Taylor mixing process described by Svendsen and Putrevu (1994) added to a realistic treatment of turbulence and wave rollers is of comparable magnitude. A detailed discussion of the model and parameters used in obtaining these results can be found in Özkan-Haller and Kirby (1996b).

Figure 3: (a) Bottom bathymetry, (b) Wave height transformation, computed (solid) and measurements (o) and (c) Current profiles for October 18th, Case 1 (solid), Case 2 (dashed) and measurements (o).

The short wave forcing term in the y -momentum equation can now be expressed as

$$\tau_y = \frac{\mu}{h + \eta} V(x) \quad (4)$$

since the profile $V(x)$ is computed such that it is balanced with the steady

radiation stress gradient and the lateral mixing. Simulations with this forcing function result in the generation of the current $V(x)$ initially. It subsequently becomes unstable and finite amplitude shear instabilities develop.

In the following, two distinct initial current profiles will be used. The first case, hereafter referred to as Case 1, involves the initial current profile $V(x)$ depicted by the solid line in Figure 3c. In the second case, hereafter referred to as Case 2, any momentum mixing in the surf zone is neglected in the short wave forcing terms resulting in a $V(x)$ profile with two distinct peaks seen in Figure 3c (dashed line).

The shear wave climate for both of these forcing functions is computed for a given friction coefficient of $c_f=0.004$. This value has previously been used by Dodd *et al.* (1992). Linear instability analysis gives the wavenumber corresponding to the maximum growth rate in Case 1 as 0.0315 rad/m. The length of the modeling domain in the longshore direction L_y is chosen to be 16 times the wavelength that corresponds to this wavenumber. This longshore length scale is used in both cases since the most unstable wavenumber for Case 2 occurs at higher wavenumbers due to the presence of the highly unstable shoreline jet. The modeling domain extends 400 m offshore. An absorbing boundary condition is used at the offshore boundary (Özkan-Haller and Kirby, 1996a). Periodicity is assumed in the longshore direction. The current profile $V(x)$ corresponding to the each case is specified as an initial condition.

Results for Case 1

The simulation for the forcing profile including the effects of additional mixing is presented first. Time series taken in the trough region of the bar (about 35 m offshore) are shown in Figure 4. The longshore averaged longshore velocity is also shown and is defined as

$$\bar{v}(x, t) = \frac{1}{L_y} \int_0^{L_y} v(x, y, t) dy. \quad (5)$$

It can be observed that the instabilities gain energy about one hour into the simulation, the time series display an intermittent character where periods of higher frequency oscillations are followed by periods of low frequency oscillations. A mean longshore current already exists in the trough region; it is seen to increase slightly after the shear instabilities reach finite amplitude.

The intermittent character of the motion is also evidenced by plots of the potential vorticity defined as

$$q = \frac{v_x - u_y}{h + \eta}. \quad (6)$$

The patterns of potential vorticity shown in Figure 5 are propagating in the $+y$ direction and show that features with longer longshore scales are followed by packets of features with shorter longshore scales.

To aid the interpretation of the potential vorticity a plot of the circulation pattern in a portion of the domain depicted in Figure 5 is shown in Figure 6a. The shear instabilities can be observed to cause flow across the bar crest which is located about 60 m offshore. Also of interest are the offshore directed velocities

Figure 4: **Case 1** Time series of u and v in the bar trough region (solid) and longshore averaged longshore velocity \bar{v} (dashed).

Figure 5: **Case 1** Contour plot of potential vorticity (solid for $q > 0$, dashed for $q < 0$) at $t=10$ hrs.

occurring further offshore. These features can be seen to be active up to about 250 m offshore corresponding to about 3 times the surf zone width.

The change in the mean longshore current profile that occurs as the shear instabilities reach finite amplitude is documented in Figure 7a where the initial current profile is shown along with the mean current profile after the instabilities develop. It can be noted that the value of the current maximum as well as the value of its slope on the seaward side have decreased. Multiplying the longshore momentum equation (1) by the total water depth, longshore averaging, and assuming stationarity of the mean quantities identifies the dominant terms and leads to a balance between lateral mixing induced by the shear instabilities and the change in the mean longshore current profile given by

$$\overline{(Duv)_x} = -\mu(\bar{v} - V), \quad (7)$$

where subscripts denote differentiation and $D = h + \eta$ is the total water depth. The initial current profile is denoted by V and \bar{v} is the current profile after the development of the shear instabilities. Any change in the longshore current profile is, therefore, directly due to lateral momentum mixing induced by the shear instabilities.

Figure 6: Circulation pattern at $t=10$ hrs (a) Case 1 (b) Case 2.

Figure 7: Initial (solid) and final (dashed) mean current profiles (a) Case 1 (b) Case 2.

Results for Case 2

Results for the simulation involving the forcing function with no mixing involved are discussed next. Time series for the velocity components (see Figure 8) show that the instabilities reach finite amplitude in a shorter amount of time than in Case 1. Higher frequency oscillations are evident but there is no evidence of intermittent behavior. It can be noted that there is no mean current at this location initially but a mean current of about the same magnitude as in Case 1 is created after the instabilities reach finite amplitude. The oscillations also appear to be more energetic in this case.

A contour plot of the potential vorticity at the end of the simulation (see Figure 9) shows that the organized layers of positive and negative potential vorticity are being mixed. Features with positive and negative potential vorticity can be seen to pair up. Some pairs that have previously been released are seen about 300 m offshore. The resulting pattern is similar to results obtained by

Figure 8: **Case 2** Time series of u and v in the bar trough region (solid) and longshore averaged longshore velocity \bar{v} (dashed).

Slinn *et al.* (1995) for a generic barred beach in a regime they called “eddy formation”.

An interesting feature can be seen in Figure 9 around $y = 400$ m. It resembles a “rip-head”. A plot of the circulation pattern associated with this feature is given in Figure 6b and exhibits strong offshore directed velocities across the bar crest extending offshore, much like a rip current. Flow across the bar trough is also evident.

Figure 9: **Case 2** Contour plot of potential vorticity (solid for $q > 0$, dashed for $q < 0$) at $t=10$ hrs

The change in the mean longshore current profile due to the shear instabilities can be observed in Figure 7b. The peak longshore current has decreased significantly due to the presence of the shear waves. In addition, an appreciable current is introduced in the trough region of the bar.

Comparisons with data

The predictions for the final mean longshore current for the two cases are plotted in Figure 10 along with data points from sequential measurements from a measurement sled that was pulled onshore during an experimental run, collecting data for 35 minutes at each stop. It should be noted that the current profiles

resulting from the two cases are remarkably similar. They exhibit similar maximum current values, the seaward slope of the current profiles are also similar. However, the current profile resulting from simulations for Case 2 shows a strong shoreline jet. The maximum longshore current is underpredicted by about 20 %. However, caution should be used in interpreting the data to model agreement in this case since the measurements were carried out sequentially and sled data and model data are based on very different averaging periods.

Figure 10: Final mean current profiles for Case 1 (solid) and Case 2 (dashed), measurements (o)

Time series obtained from the model can be compared to velocity measurements from one of the current meters located in the surf zone. Three hour segments of computations for the two cases as well as measurements of cross-shore and longshore velocities are shown in Figure 11. The time scales involved in Case 1 are much longer than what is seen in the data. The intermittent character is also not repeated in the data. In turn, simulations for Case 2 exhibit more high frequency activity than Case 1, but the fluctuations have higher amplitudes than the fluctuations seen in the data.

Frequency spectra for the longshore velocities confirm that the energy in high frequencies is underpredicted in Case 1 (see Figure 12a). The shape of the spectrum in Case 2 (see Figure 12b) is similar to that of data but the energy in the motions is overpredicted. The same trend can be seen in frequency spectra of the cross-shore velocities shown in Figure 13.

In order to determine if the propagation speeds of these motions are predicted well, comparisons of frequency-longshore wavenumber spectra for the longshore velocities are made. Frequency-longshore wavenumber spectra are obtained using the high resolution Iterative Maximum Likelihood Estimator (IMLE) utilizing time series from five sensors in the surf zone (Oltman-Shay *et al.*, 1989) (see Figure 14a). Since model computations are carried out with high resolution in both space and time a direct Fourier Transform in both space and time is used to obtain the two-dimensional spectra from the computed time series (see Figure 14b and c).

Results for Case 1 show that the wavenumber range in which shear instabilities are present is underpredicted as is expected after analyzing frequency spectra. The predicted spectra displays a nondispersive character. The two-dimensional spectra for Case 2 predicts a wider range of wavenumbers where

Figure 11: Three hour segments of time series (a) Case 1 (b) Case 2 (c) Data from gage LS07 at SUPERDUCK, October 18th.

shear instabilities are present. The slight increase in the speeds with increasing frequency is also reproduced. The propagation speeds are similar in both cases and correspond to an underprediction of the propagation speed seen in the data by about 20 %. This is likely to be a direct consequence of the fact that the peak mean longshore current velocity is underpredicted by about 20 %, since the shear instabilities propagate at a fraction of the maximum mean longshore current velocity (Bowen and Holman, 1989).

Summary and Conclusions

In this study, a comprehensive model of low frequency motions has been used to study the shear wave climate on October 18th at SUPERDUCK. Two cases including and neglecting a simple lateral mixing mechanism, respectively, are simulated. Time series, frequency spectra, frequency-longshore wavenumber spectra and time variations of the mean longshore current profiles are analyzed for both cases, the results are compared to measurements where possible.

It is seen that when intensive mixing is considered in the forcing function (Case 1) the mean current profile only changes slightly, therefore the lateral mixing caused by the shear instabilities is small. The resulting shear wave climate is not very energetic, underpredicting what is seen in data. In turn, if mixing due to mechanisms related to the short wave climate and turbulence is neglected entirely in the forcing function (Case 2), the initial profile undergoes drastic changes, therefore lateral mixing induced by the shear instabilities is appreciable and the shear wave climate is very energetic, overpredicting what is seen in data. The final longshore current profiles resulting from the simulations

Figure 12: Frequency spectra for v , measured (solid), computed (dashed-dotted) (a) Case 1 (b) Case 2.

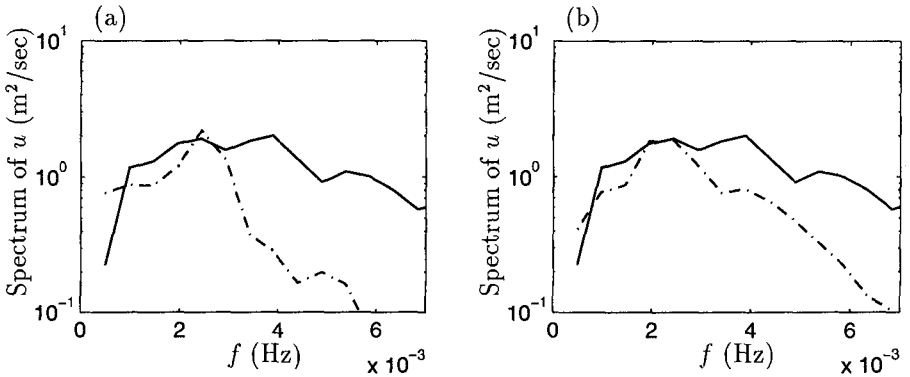

Figure 13: Frequency spectra for u , measured (solid), computed (dashed-dotted) (a) Case 1 (b) Case 2.

are remarkably similar regardless of the shape of the initial current profile. If the short wave forcing is far removed from producing this final current profile, shear instabilities arise, causing enough lateral mixing to redistribute the momentum in the surf zone.

In conclusion, the results of this study suggest that in this model the final mean longshore current profile is not a function of how much lateral mixing is initially included into the model, but only a function of the friction factor. If no (intensive) mixing due to the turbulence or Taylor dispersion is initially considered, the shear wave climate responds by creating intensive (minimal) mixing. Therefore, in this model the amount of energy in the shear wave band is a function of how much lateral mixing due to other considerations is already present in the initial forcing function. Hence, it is anticipated that the accurate prediction of the amount of energy present in the shear wave band in data is strongly linked to an accurate representation of the mixing processes due to turbulence, depth variations in the current or additional physics in the breaking process.

CHAPTER 107

NEPTUNE—AN INTEGRATED APPROACH TO DETERMINING NW EUROPEAN COASTAL EXTREMES

Jerzy Graff^{1) 2)} and Witold Cieřlikiewicz¹⁾

Abstract

NEPTUNE is an EU-research project under the MASTII framework. It involves seven partners: British Maritime Technology, Delft Hydraulics, Department of Mathematics & Statistics, University of Lancaster, Climate Research Unit, University of East Anglia, Econometrics Institute, Erasmus University, National Institute for Coastal and Marine Management of Rijkswaterstaat (RIKZ), and Forschungszentrum Geesthacht GmbH (GKSS). The purpose is to investigate *a new integrated approach for modelling the statistics of NW European coastal extremes* by first characterising the coastal impact and then *linking it through a process model chain with the causative storm involved*. The project methodology recognises that the North-European storm climate is made of several different storm types which impact on the coastline in different ways. The project strategy is described and some of the main results are presented.

1. Introduction

Information requirements for modern coastal management and engineering design need a statistical characterisation of the impact of storms on the shoreline or coastal structure. The impact is related to the combined influence of waves, tides and surges which are the hydraulic parameter inputs into functional relationships that describe the loading and response of the structure. The relationships describe the *limit-state* conditions that provide for the *design formulae* which are the basis of the modern approach to structural design and risk analysis (CUR/TAW 1990). Traditionally, estimates of the frequency distribution of extreme sea levels are based on analysis of historical tide gauge measurements of still water levels. These data are always site-specific and cover historical periods which are rarely consistent from site-to-site. The principal extreme value methods used to compute the *return periods* are the *annual maxima method* (Wemelsfelder 1961, Lennon 1963 a, Suthons 1963, Führböter 1976, Graff 1981) and the *joint probability method* (Pugh and Vassie 1980, Walden *et al.* 1982, Tawn 1992). Although the statistical methods have been extensively developed over recent years (de Valk 1991, Smith 1994, Coles and Tawn 1994) they are applied only to sea state observations without consideration to the influence and variability of the causative storm events involved.

The NEPTUNE project originated from the conviction that an integrated approach allowing for storm climate influence is called for. Changes in global weather climate

¹⁾ British Maritime Technology Limited, 7 Ocean Way, Ocean Village, Southampton SO14 3TJ, England

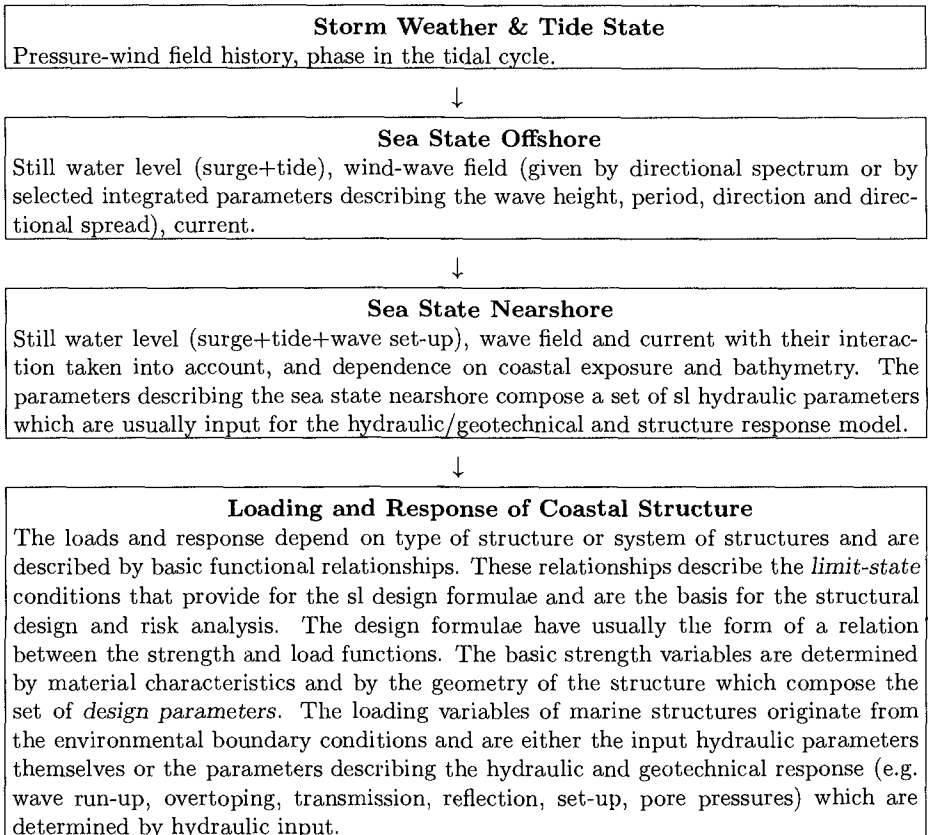

²⁾ Project Co-ordinator

will naturally influence storm climate which will induce consequential changes in the severity and frequency of regional coastal extremes. This may help explain the historical time variation in the probability of extreme sea levels around Great Britain and along the German coast identified independently by Graff (1978, 79) and Führböter (1976, 78) in the late 1970's. Ultimately, a stochastic description of the regional storm climate could form the common basis for the required joint statistics of coastal extremes, in which a combination of numerical models is used to parameterise the transformation from storm climate to local statistics. Such a description can serve as a solid basis for assessment of the consequences of changes in storm climate. Recently this same philosophy has been adopted by a number of other European research project groups (WASA, IMPACT) which will no doubt help to accelerate progress and development.

2. Project Methodology

The methodology seeks to develop an integrated approach for modelling the statistics of coastal extremes by first characterising the coastal impact and then linking it through a process model chain with the causative storm involved which in turn is attributed a statistical form within the global climate of storms.

The cause-consequence process chain linking the causative storm with impact on a coastal structure can be summarised in the following diagram:

The cause-consequence chain is represented as follows:

$$\mathbf{W}_t \xrightarrow{\mathcal{F}_1} \mathbf{X}_t \xrightarrow{\mathcal{F}_2} \mathbf{Y}_t \xrightarrow{\mathcal{F}_3} D_t \quad (1)$$

where \mathbf{W}_t , \mathbf{X}_t , \mathbf{Y}_t and D_t denote the random wind field, offshore variables, nearshore variables and design variable respectively, each indexed by time t . \mathcal{F}_1 is the superposition of the offshore tide-surge model and numerical wave generation model run on deep water up to 20 m depth. \mathcal{F}_2 is the superposition of the tide-surge model and wave model that transforms the offshore variables to the nearshore environmental variables (hydraulic parameters). Finally, \mathcal{F}_3 is a function of the nearshore variables which gives the design parameter D_t , assumed to be scalar. The function \mathcal{F}_3 (design formula) is usually determined by a *boundary function* of a failure region defined as a sub-set of \mathbf{Y}_t space. In order to develop a statistical model integrating the \mathbf{W}_t , \mathbf{X}_t , \mathbf{Y}_t and D_t variables the simplified versions of \mathcal{F}_1 and \mathcal{F}_2 need to be developed; in the case of \mathcal{F}_3 we assume that it is a known function. These are simple parametric models $\tilde{\mathcal{F}}_1 : \mathbf{W}_t \rightarrow \mathbf{X}_t$ and $\tilde{\mathcal{F}}_2 : \mathbf{X}_t \rightarrow \mathbf{Y}_t$. The parametric models $\tilde{\mathcal{F}}_1$ and $\tilde{\mathcal{F}}_2$ are designed and calibrated based on the data hindcast for the storms selected for both demonstrator zones.

NEPTUNE assumes that, on a European coastal cell scale, the extreme water levels generated at the shoreline are due to the impact of a particular type of storm. These storm types may vary for different coastal cell regions. Because wave effects play a critical role in maximising the water level at the shoreline it is obvious that storm directionality is important. It is assumed that the different coastal storm types which arise can be characterised into sub-classes of the overall climate of European storms.

Two distinct demonstrator zones were established, one on the west coast of Great Britain and the other on the north coast of Holland as shown in Fig. 1. Each zone has a particular type of region-specific storm climate associated with the generation of extreme coastal impact events and each is characterised by different physiography which would be used to investigate the relative influence of regional features affecting the storm-wave transformation to shore. In each demonstrator zone a review was made of the historical coastal flood events within the period 1955–1993 and the worst 20 events were selected independently for each region. The period 1955–1993 was chosen because high quality gridded digital meteorological data covering the NE Atlantic were available from DNMI—Norwegian Meteorological Institute. The DNMI data would provide a consistent set of boundary conditions both for analysing the storm weather directly and for modelling the sea state processes \mathcal{F}_1 and \mathcal{F}_2 associated with each of the 40 storm events.

3. Structure of Project

The project objectives span four main task areas of which three cover detailed research and investigation namely:

T100 Identify and analyse extreme sea state data

Establish a database of field measurements and information describing coastal physiography and sea state associated with historical coastal flood events in two selected coastal zones. One demonstrator zone was chosen on the west coast of Great Britain and the other on the Dutch coast. The extreme flood events in each zone are characterised by different types of storm.

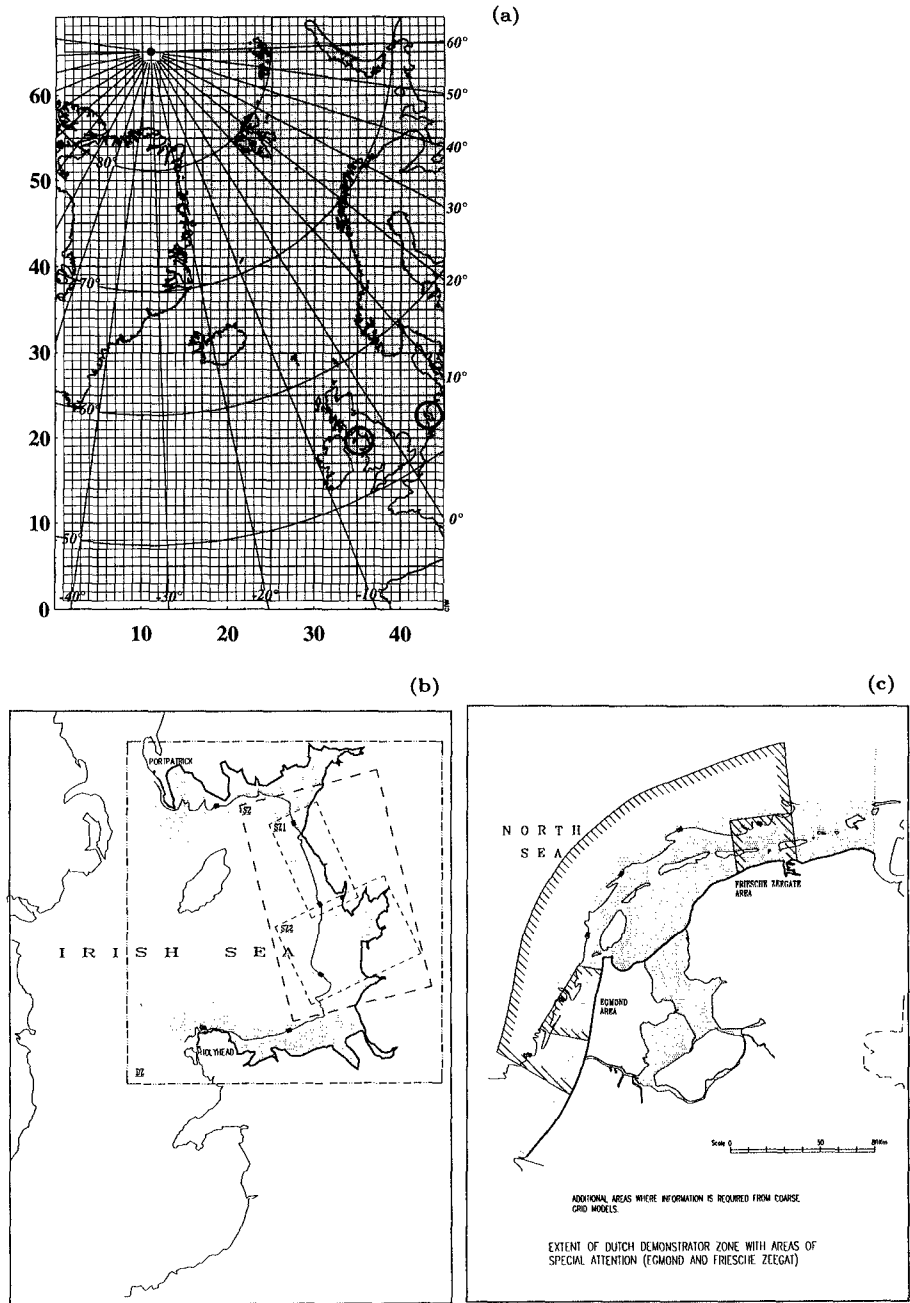

Fig. 1. (a) DNMI grid co-ordinates and study demonstrator zones; (b) UK demonstrator zone; (c) Dutch demonstrator zone.

T200 Identify and analyse storm weather data

Investigate the local and regional storm climate associated with generation of extreme coastal impact in respective demonstrator zones. The aim is to develop a parametric representation of the storm weather for input to sea state models and evaluate trends in storm character and frequencies of occurrence of different types of storms.

T300 Simulate extreme sea state processes and coastal impact

Use established operational hydrodynamic models to simulate the storm generated sea states offshore and their transformation to shore and investigate ways to parameterise the model responses and assess modelling uncertainties.

T400 Develop methods for determining joint statistics

The main goal is to develop, using the results from the two different demonstrator zones, a generic framework and associated multivariate models for describing joint statistics of coastal extremes allowing for relationships between storm climate and coastal response.

4. Key Features and Results

T100 Identify and analyse extreme sea state data

For each demonstrator zone the criteria for individual storm selection differed between the UK and Holland. The UK events were selected on the basis of regional coastal tide gauge records and documented public reports of the flood impact whereas the Dutch coast selection was made directly from available full scale measurements of winds, waves and tides monitored at a number of offshore platforms. The Dutch storm selection procedure is described in Dunsbergen (1994) and is based on metocean measurements recorded near Den Helder which was selected as representative location for the Dutch demonstrator zone. Many of the UK Irish Sea storm-surge events have been extensively studied and modelled at the Institute of Oceanographic Sciences (IOS), Bidston Observatory—now Proudman Oceanographic Laboratory (POL) (e.g. Amin 1982, and Heaps 1983) however, supporting wave measurement were rarely available.

T200 Identify and analyse storm weather data

Storm weather data

The primary data set used is the North Sea – NE Atlantic gridded pressure and wind data prepared by the DNMI covering the period 1955–1993. The coverage is shown in Fig. 1 (a) and represents a rectangular grid on a polar stereographic projection with grid size 75km at 60° N. These data were processed to provide coverage for all storm events in the study and were also used as common boundary data to model both the storm surge and storm wave simulation.

Storm classification and parameterisation

A key objective of NEPTUNE is to identify, characterise and classify storms affecting the two different demonstrator zone and seek to develop a parametric link between the causative storm features and the resulting hydraulic response (waves, tides and surges) at the shoreline. In part, this requires a need to parameterise the storms in order to exploit the digital DNMI database. The approach adopted was based on the recent work of Ferrier *et al.* (1993) which assumes that the storm pressure field (affecting

the Dutch coast) can be represented as a Gaussian bell of elliptical cross section whose geometry and motion are determined by a set of 11 parameters. The DNMI gridded data were processed to produce colour contoured pressure field maps at 6hrly intervals extending over a 20 day period for each of the 40 selected storms. These maps were used to study and classify the storms and to determine the parameters required for their characterisation and modelling. Preliminary analysis of the storms suggests that they can be divided into three classes each characterised by specific features associated with track and form of isobar distribution and dynamics. The assumption of a generic form of elliptic bell shaped storm structure proves to be an oversimplification. The findings reaffirm the view that UK west coast extremes are associated with a particular type of storm first identified by Lennon (1963 b) and that the great 1953 storm does in fact characterise the worst-case storms affecting the Dutch coast. The contrasting structure of the two types of storm at moment of maximum coastal impact are shown in Fig. 2.

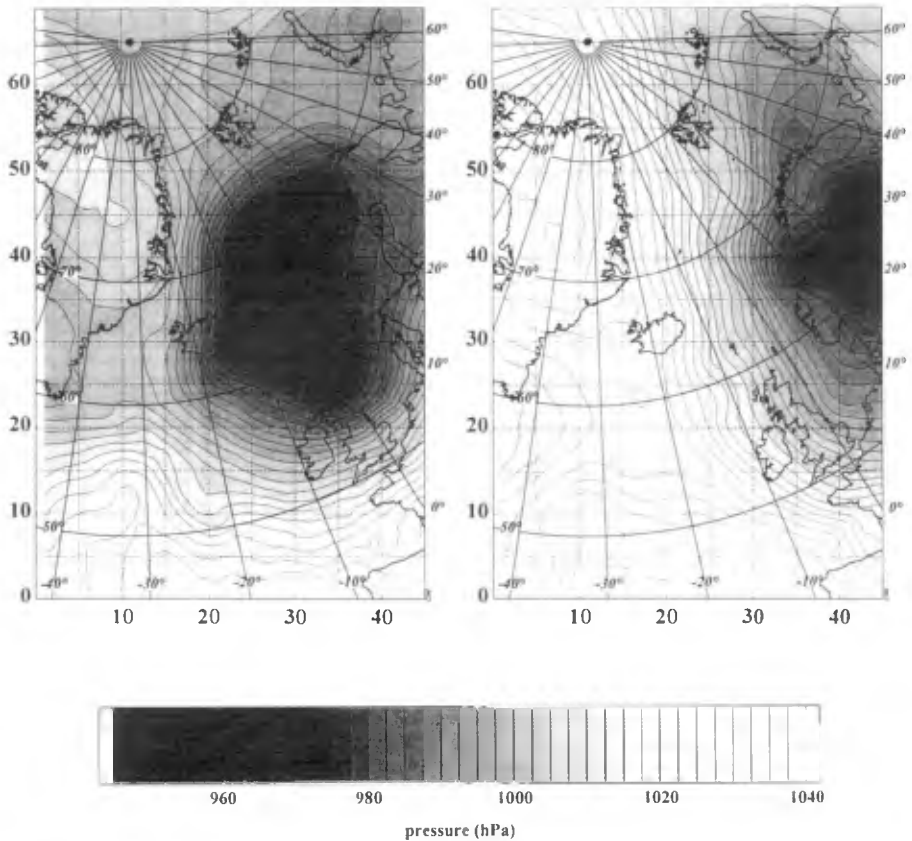

Fig. 2. Pressure distribution at time of coastal extreme for two contrasting storm types; Irish Sea extreme at 0:00h on 12/11/77 (left) and Dutch coast extreme at 6:00h on 13/02/62 (right).

T300 Simulate extreme sea state processes

Simulate offshore extremes

A conventional hybrid scheme involving the separate modelling of tide-surge and wave-current interaction processes was used to simulate the offshore storm induced sea state in each demonstrator zone. The DNMI gridded data were used to provide the boundary conditions associated with the forty storms selected. Storm surge levels were computed by POL using their CSX model and the associated wind-wave field was computed by GKSS using their hybrid parametrical surface wave prediction model (HYPA) in a nested model chain. The POL CSX model has a uniform grid resolution of $1/3^\circ$ latitude by $1/2^\circ$ longitude (approximately 36km) whereas the GKSS HYPA model chain coupled grid resolutions of 150km, 30km and 10km. HYPA (Günther *et al.* 1979) is a second-generation wave forecasting model that includes parametric prediction of the one-dimensional wind-sea spectrum with the mean wave direction as an additional prediction parameter. At each grid point the model generates the directional wave spectra as well as a set of 24 integrated spectral parameters.

Verification of hindcast wave and still water levels has been performed in detail for nine severe storm events using the independent field measurements available at five Dutch zone monitoring stations. The results were extremely good and an example of surge and wave comparison for a Dutch zone station is shown on Fig. 3.

Fig. 3. Comparison of surge hindcast (solid line) and observed (circles) at SON, 21–28 Nov, 1981. Time is counted from 00h of first day of storm period.

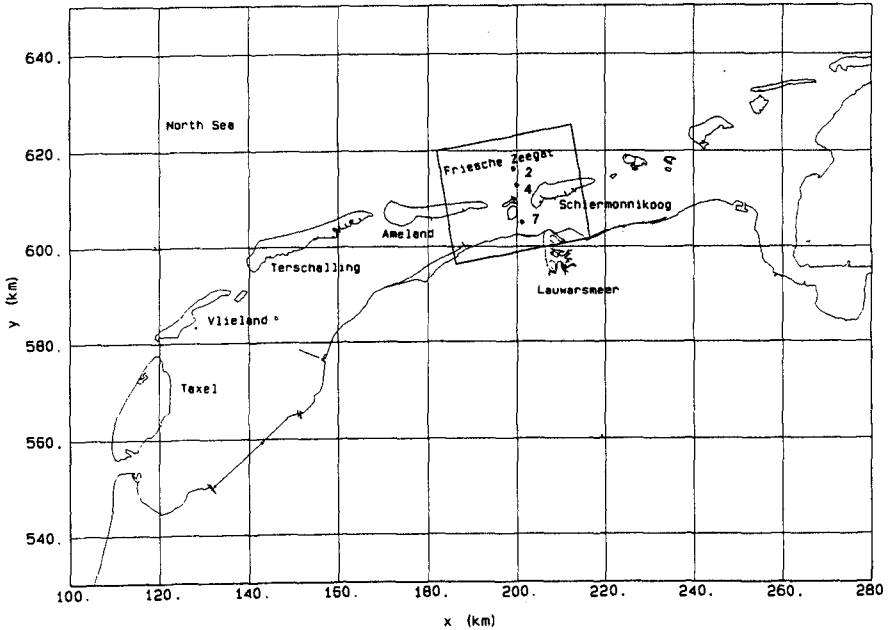

Fig. 4. Friesche Zeegat modelling area (ref. Spaan *et al.* 1996).

Transfer offshore extremes to shore

The transfer of offshore extremes to shore represents a strategic task since it forms the basis for developing the parametric relationships \tilde{F}_2 between physical parameters which are required to develop appropriate statistical models for the transfer of statistics to shore.

The Friesche Zeegat area in the Dutch demonstrator zone shown in Fig. 4 was used to undertake a number of detailed simulations and sensitivity studies involving different state-of-the-art models. The area is a special focus for ongoing coastal research modelling trials and associated field measurement experiments. The two principal models were HISWA (Holthuijsen *et al.* 1989) a 2nd generation stationary wave model and SWAN (Holthuijsen *et al.* 1993, 1994) another stationary but fully spectral 3rd generation wave model. Additionally the more advanced 3rd generation non-stationary wave model PHIDIAS (van Vledder *et al.* 1994) which is still under development was also used. The models were configured to provide grid cell resolution over various scales down to 100m. The results (Dunsbergen 1995, Otta 1995, van Vledder 1994, van Endt 1996) show that in complex coastal regions such as Friesche Zeegat it becomes necessary to employ the very latest advances in shallow water wave modelling in order to approach the degree of reality needed to correctly simulate wave transfer processes.

In association with the HYDRA project a special study was performed (Booij *et al.* 1996) to investigate in detail the nearshore wave conditions in the Friesche Zeegat during

a suprestorm. The superstorm (Bijl 1995) was an adapted version of the parameterised 1953 storm. The wave simulation was carried out using two models. First the SWAN model was used to compute the wave conditions at the height of the storm when the highest still water levels occurred in the central part of the Friesche Zeegat. The PHIDIAS model was then used to compute the time variation of the wave conditions over a period of 8 hours around the peak of the storm. The results show that the wave field along the Friesche Zeegat shoreline is mainly determined by local winds and by depth limitation on the tidal flats in the Waddensea. The offshore storm wave boundary conditions have little or no effect on the nearshore wave effects. Figs. 5 (a)–(c) show the storm wave spectra computed at the three locations marked on Fig. 4. The results clearly illustrate the form of double-peak spectra which may be associated with shallow water non-linear wave interaction.

Parameterisation of the modelling response

It has been assumed that full scale modelling of the process chain described in section 2 may lead to relatively simple parametric relationships linking \mathbf{W}_t , \mathbf{X}_t , \mathbf{Y}_t and design variables D_t . The objective is to represent the model responses \mathcal{F}_1 , \mathcal{F}_2 in simplified form $\tilde{\mathcal{F}}_1$, $\tilde{\mathcal{F}}_2$ to allow transformation not only of input data but also of statistics.

For the $\mathbf{W}_t \rightarrow \mathbf{X}_t$ link a parametrisation scheme has been developed (Cieřlikiewicz and Graff 1996) which can effectively relate the NE Atlantic wind and pressure field with the consequential NW European coastal surge and wave climate response. The novel approach involves use of empirical orthogonal functions (EOF) to transform the DNMI based NE Atlantic wind field into principal components targeting the UK and Dutch demonstrator zones and system identification techniques (SI) to develop the wave and surge field response. The scheme which involves linear system simulation techniques such as ARX and ARMAX has been trialed successfully for the Dutch demonstrator zone where 13 years of offshore metocean measurements are available in addition to the hindcast modelled data. Some results showing EOF wind field transformation and subsequent wave climate simulated using the SI technique are presented in Figs. 6 and 7. The scheme provides a potentially powerful tool for fast and efficient simulation of sea state parameters in response to weather field input.

A simple parameterisation scheme for the $\mathbf{X}_t \rightarrow \mathbf{Y}_t$ link specific to the Pettemer Zeewering shoreline was also developed. In this case available wave measurements were used to develop a parametric transformation matrix linking offshore storm waves with their shoreline response. The wave transform relationship needed to develop the multi-regression based matrix was determined using the 1-D version of the HISWA model. The transform matrix was then used to synthesise multivariate hydraulic parameters and associated statistics required to develop the $\mathbf{X}_t \rightarrow \mathbf{Y}_t$ association. Subsequently a family of seventy storms consisting of 22 historical storms and 48 fictitious conditions were used to compute $\mathbf{X}_t \rightarrow \mathbf{Y}_t$ wave transforms in the Friesche Zeegat region (Spaan *et al.* 1996) as a basis for the transfer of hydraulic parameter statistics.

T400 Determining joint statistics of extremes

The project methodology has been already outlined in section 2 and relations between the fields of random variables \mathbf{W}_t , \mathbf{X}_t , \mathbf{Y}_t and design variable D_t were discussed. The integration of a suitable multivariate extreme value model is dependent on the success of developing simple parametric models $\tilde{\mathcal{F}}_1$ and $\tilde{\mathcal{F}}_2$ of low dimension.

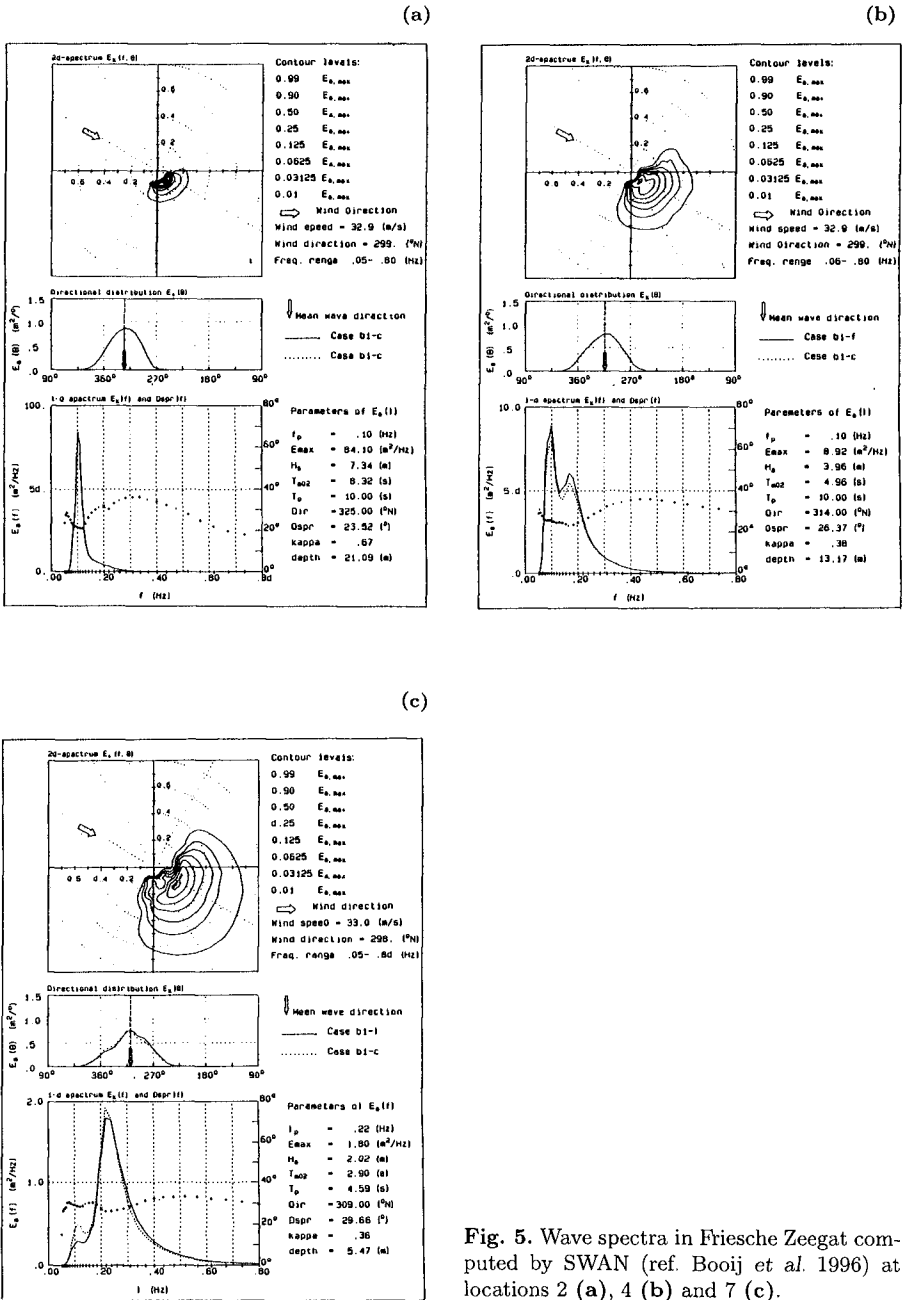

Fig. 5. Wave spectra in Friesche Zeegat computed by SWAN (ref. Booij et al. 1996) at locations 2 (a), 4 (b) and 7 (c).

Fig. 6. Comparison between spatial distribution of DNMI wind velocity field at 12h on 16 May, 1988 and wind obtained via EOF analysis; original distribution (to left), and recalculated using first eight principal components (in the middle) and first four (to right).

Fig. 7. Comparison between modelled (solid line) and recorded at EUR station (stars) time series of significant wave height for storm periods 15–22 Jan, 1983 (top) and 11–18 Feb, 1989 (bottom).

The hydraulic parameters $Y_{1,t}, Y_{2,t}, \dots, Y_{d,t}$, which compose the d -dimensional random vector \mathbf{Y}_t , determine the design variable D_t through \mathcal{F}_3

$$\mathbf{Y}_t = [Y_{1,t}, Y_{2,t}, \dots, Y_{d,t}] \xrightarrow{\mathcal{F}_3} D_t \quad (2)$$

If we assume that the marginal distributions of $Y_{1,t}, Y_{2,t}, \dots, Y_{d,t}$ are known then we can analyse the joint dependent structure of the multivariate data $[Y_{1,t}, Y_{2,t}, \dots, Y_{d,t}]$ and extrapolate, or create a structure variable D_t through $\mathcal{F}_3(\mathbf{Y}_t)$ and study the univariate structure data. One aim of the project has been to compare the accuracy of

joint probability models (analysis of \mathbf{Y}_t) to the structure variable approach (analysis of D_t) in estimating the return level for given probabilities of failure for D_t .

Considerable progress has been made in advancing both theoretical and practical aspects of the alternative approaches namely, the structured variable approach favoured by the Dutch research partners de Valk (1995, 1996) and Draisma and de Haan (1995, 1996) and the joint probability method favoured by the UK research partners Ledford and Tawn (1996 a, b) and Bruun and Tawn (1996). Issues examined cover multivariate dependency between the different parameters, temporal behaviour of the joint distributions and spatial dependency.

A practical case study application of the Structure Variable approach was developed and trialed by de Valk (1996) for a seawall dyke structure at Pettemer Zeewering in Holland. Only one failure mechanism was considered namely, wave overtopping of the crest of the seawall. Based on the expression for the 2 percent run-up level $z_{2\%}$ from Van der Meer (1993) a reliability function z was defined as the difference between the crest level z_{crest} and $z_{2\%}$; $z = z_{\text{crest}} - z_{2\%}$. If z is positive the overtopping is acceptable, whereas if z is negative, the structure fails. Contours of the reliability function involving nearshore wave height and period for two different still water levels are shown in Fig. 8.

Fig. 8. Contours of run-up reliability function z as function of nearshore significant wave height and nearshore peak wave period for sea level 3.0 m (left) and 5.0 m (right) at Pettemer Zeewering (ref. de Valk 1996).

CHAPTER 108

A Stochastic Typhoon Model and its Application to the Estimation of Extremes of Storm Surge and Wave Height

Yoshio Hatada¹ and Masataka Yamaguchi²

Abstract

This paper presents a system for estimating extremes of storm surge height and wave height associated with typhoons, which consists of a Monte-Carlo simulation model for probabilistic generation of typhoon characteristics, termed a stochastic typhoon model, a parametric typhoon model for wind estimation, numerical models for the computation of storm surges or waves and an extreme analysis model for estimation of their return values. The system is applied to the estimation of 50 to 1000-year return values and their confidence intervals based on the computations over a period of 1000 years for storm surge heights in Ise Bay connecting to the Pacific Ocean, and for wave heights at some representative locations around the Pacific coast of Japan.

1. Introduction

Japanese coasts facing the Pacific Ocean and the East China Sea have frequently been hit by powerful typhoons and consequently have suffered severe damage by typhoon-generated storm surges and high waves. Design heights of sea water level and waves in the area are conventionally estimated based on statistical analysis of their extreme data hindcasted for typhoons which occurred in the past several decades. Extremes of typhoon-generated storm surges and waves are strongly dependent on the strength and track of a typhoon, because the severe wind

2 Professor of Civil and Environmental Eng., Ehime Univ., Bunkyocho 3, Matsuyama 790, Japan.

area in a typhoon is limited, the radius being usually less than about 200 km and typhoon-generated winds greatly vary in space and time. Thus, the problem is whether the above-mentioned method could properly evaluate great variability of storm surge height and wave height associated with the contingency of typhoon characteristics. As an alternative and complementary method, this paper presents a system for estimating extremes of storm surge height and wave height around the concerned sea area, which consists of a stochastic typhoon model, a parametric typhoon model, numerical models for the computation of storm surges or waves and an extreme analysis model for the evaluation of their return values and confidence intervals.

2. Estimation System for Extremes of Storm Surge and Wave Height

(1) Stochastic typhoon model

Atmospheric pressure distribution in a typhoon is approximated with the Meyers formula such as

$$p = p_{\infty} - (p_{\infty} - p_c) \exp(-R/R_a)$$

$$R^2 = (X - X_c)^2 + (Y - Y_c)^2 \quad (1)$$

where p_c (hPa) is the central pressure, p_{∞} (=1013 hPa) the pressure of the far field, (X_c, Y_c) the position of the typhoon center in km unit and R_a (km) the typhoon radius. The stochastic typhoon model is a Monte-Carlo simulation model for probabilistic generation of typhoon parameters which are represented with the position of the typhoon center, the central pressure and the typhoon radius.

Data of typhoon parameters used in the modeling were gathered every 6 hours for 320 typhoons which passed through the Northwestern Pacific Ocean area during the period of 1951 to 1991 and had a central pressure of less than 980 hPa in the area, with 15 typhoons generated within the area being excluded in the modeling due to data scarcity. The data set consists of 7 parameters such as X_c , Y_c , p_c , their incremental change rates dX_c , dY_c , dp_c , and R_a . Fig. 1 shows the domain covered with the north latitude of about 23° to 44° and the east longitude of about 120° to 149° , which is divided into a grid system of 34 by 35 with a grid distance of 80 km.

The basic idea in the modeling is that each typhoon parameter may be represented by the sum of its mean value and the deviation from the mean value. Mean variation of each typhoon parameter along the boundary is approximated with use of a one-dimensional weighted spline function,

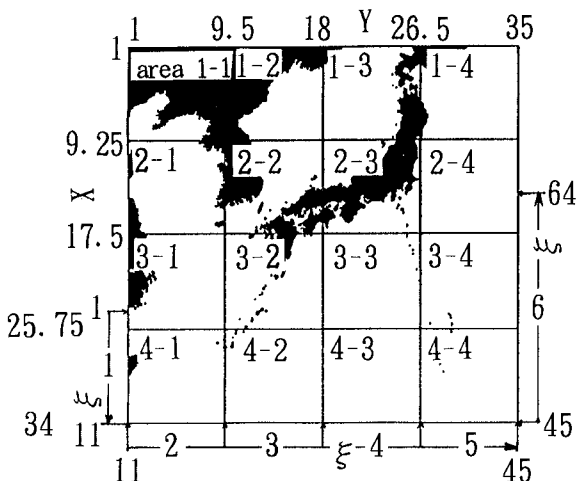

Fig. 1 The Pacific Ocean area where modeling of stochastic typhoons is made.

and correlations between typhoon parameters in the area as well as those between incremental change rates of typhoon parameter are taken into account with use of linear regression equations. Deviations from averaged typhoon parameters along the boundary and in the area are represented with empirical probability distribution functions obtained by data analysis. In order to improve reproducibility of the stochastic typhoon model, regression equations and empirical distribution functions are separately constructed at 6 sub-divided boundaries and in 16 sub-divided areas shown in Fig. 1.

Modeling of stochastic typhoon and Monte-Carlo simulation are conducted according to the following procedure.

(a) The annual occurrence rate of typhoons is fairly well approximated with the Poisson distribution for a mean value of 7.8, as shown in Fig. 2. So, it is determined with use of a computer-generated Poisson-type random number.

(b) The position where a typhoon generates is defined as the position where the typhoon crosses the boundary. Data of typhoon occurrence position and the other typhoon parameters are obtained from linear interpolation between the data before and after crossing the boundary. In order to describe the typhoon occurrence position on the boundary, a one-dimensional co-ordinate system ξ which is taken from the west boundary to the east boundary through the south boundary is introduced as indicated in Fig. 1. Fig. 3 shows the cumulative distribution of typhoon occurrence position. In the simulation, the occur-

Fig. 2 Annual occurrence rate of typhoons and approximation with Poisson distribution.

Fig. 3 Cumulative distribution of typhoon occurrence positions on the boundary.

rence position of a typhoon is obtained from the linear interpolation for cumulative distribution curve by giving a uniformly-distributed random number between 0 and 1 generated by computer.

(c) Mean variation of incremental change rate of typhoon position dX_{c0} along the boundary is approximated with a one-dimensional weighted spline function and then the deviation of individual data from the mean variation is separately expressed in the form of a cumulative distribution every sub-divided boundary. Fig. 4 illustrates the smoothing effect for scattered data by use of a one-dimensional spline function and an example of the cumulative distribution. Similar figures are prepared for the typhoon parameters such as dY_{c0} , p_{c0} and dp_{c0} .

In the formulation of typhoon radius, correlation with central pressure of the typhoon is taken into account using the regression equation such as

$$R_{a0} = a \cdot p_{c0}^n + b \quad (2)$$

Fig. 4 Smoothing of dX_{c0} data along the boundary with spline function and cumulative distribution of deviation from mean variation.

Fig. 5 Regression equation for R_{a0} and cumulative distribution of deviation from mean value in a sub-boundary.

where a , b and n are the coefficients to be determined by the least square method. Typhoon radius is expressed as the sum of mean value obtained from the above regression equation and its deviation from mean value for each sub-boundary. Fig. 5 indicates an example of the correlation diagram and the cumulative distribution.

Now typhoon parameters on the boundary X_{c0} , Y_{c0} , dX_{c0} , dY_{c0} , P_{c0} , dP_{c0} and R_{a0} can be successively simulated by using the regression equations and the cumulative distribution diagrams for each of which uniformly-distributed random number is given as input, and then position and central pressure of the typhoon at the next step can be determined from the relations such as

$$\begin{aligned}
 X_{c1} &= X_{c0} + dX_{c0}, & Y_{c1} &= Y_{c0} + dY_{c0} \\
 P_{c1} &= P_{c0} + dP_{c0} & & (3)
 \end{aligned}$$

Some restraint conditions are imposed on the generated typhoon parameters, and simulation is repeated until the conditions are satisfied.

(d) Regression equations are used to describe change of typhoon parameters every 6 hours associated with the typhoon movement in the simulation area. These are written as

$$\begin{aligned}
 X_{ci+1} &= a \cdot X_{ci} + b, & Y_{ci+1} &= c \cdot Y_{ci} + d \\
 P_{ci+1} &= e \cdot P_{ci} + f
 \end{aligned}
 \tag{4}$$

where i is the time step and a to f are the regression coefficients to be determined by the least square method. Change of typhoon radius is formulated with the following multiple regression equation including the effect of central pressure of the typhoon.

$$R_{ai+1} = a \cdot R_{ai} + b \cdot P_{ci+1} + c
 \tag{5}$$

Variability of each typhoon parameter is taken into account with use of the cumulative distribution for the deviation from mean value obtained from the regression equation as before. Regression equations and cumulative distribution diagrams are separately constructed for 16 sub-areas shown in Fig. 1. Examples of the correlation diagram and the cumulative distribution of the deviation from mean value for X_c , and those for R_a in the sub-

Fig. 6 Regression equation for X_c and cumulative distribution of deviation from mean value in a sub-area.

Fig. 7 Correlation diagram for R_a and cumulative distribution of deviation from mean value in a sub-area.

Fig. 8 Regression equation for dX_C and cumulative distribution of deviation from mean value in a sub-area.

area 2-3 are given in Fig. 6 and Fig. 7. Only eq.(5) is used to generate data of typhoon radius in the simulation area, because inclusion of the deviation gives rise to rapid and unnatural change of the typhoon radius with typhoon movement. Another reason is that correlation between data of typhoon radius and data calculated with eq. (5) is usually high to the extent that addition of the deviation is not required.

(e) Incremental change rates of the typhoon parameters dX_C , dY_C and dp_C are formulated in the same way as before. The regression equations are written as

$$\begin{aligned} dX_{Ci}^+ &= a \cdot dX_{Ci}^- + b, & dY_{Ci}^+ &= c \cdot dY_{Ci}^- + d \\ dp_{Ci}^+ &= e \cdot dp_{Ci}^- + f \end{aligned} \quad (6)$$

where

$$\begin{aligned} dX_{Ci}^+ &= X_{Ci+1} - X_{Ci}, & dX_{Ci}^- &= X_{Ci} - X_{Ci-1} \\ dY_{Ci}^+ &= Y_{Ci+1} - Y_{Ci}, & dY_{Ci}^- &= Y_{Ci} - Y_{Ci-1} \\ dp_{Ci}^+ &= p_{Ci+1} - p_{Ci}, & dp_{Ci}^- &= p_{Ci} - p_{Ci-1} \end{aligned} \quad (7)$$

Superscripts '+' and '-' mean change of typhoon parameter occurring from i step to $i+1$ step and from $i-1$ step to i step respectively. Both are defined at i step. Fig. 8 indicates the correlation diagram for dX_C and the cumulative distribution of the deviation from mean value based on the regression equation in the sub-area. Critical values of incremental change rates are used to restrict excess change over one time step of simulated typhoon parameters. Each critical value is calculated as the sum of the mean values obtained from the regression equation and deviation corresponding to 3% or 97% non-exceedance probability of the cumulative distribution. No restriction on typhoon radius is imposed because the

regression equation gives high correlation with the original data of typhoon radius.

(f) Monte-Carlo simulation of typhoon parameters for a typhoon is continued until the typhoon center moves out of the simulation area or the center pressure rises more than 1008 hPa. Simulation is repeated by the annual occurrence rate of typhoons and then by the number of years arbitrarily given as input condition.

(2) Parametric typhoon model

The estimation of typhoon-generated winds relies on the application of a simple parametric model. The model computes the spatial distribution of wind speed and wind direction in a typhoon by composing axisymmetrical gradient wind components and wind components related to the movement of the typhoon. Eq. (1) is assumed for the pressure distribution in a typhoon. Correction factor to wind speed at the height of 10 m is generally taken as 0.6, but some adjustment is made to improve the reproductiveness of storm surge computation.

(3) Storm surge model

Storm surge computation is based on a finite difference model for the vertically-integrated momentum and continuity equations, in which constant bottom friction factor and wind speed-dependent surface drag coefficient are used. Astronomical tides are not included in the storm surge computation because there is no way to determine phase relation between astronomical tides and storm surges associated with simulated typhoons. The domain of Ise Bay whose location is given in Fig. 9 is divided into a grid system of 38 by 34 with a grid size of 2.5 km. The time steps in wind and storm surge computations are 15 min and 45 s respectively. Although the topographical resolution is not sufficient for the storm surge computation in this area, the present grid system is necessary in order to save enormous computer processing time required for the computations of storm surges associated with more than 2300 typhoons.

(4) Wave model

Wave computation is performed with a shallow water wave model (Yamaguchi et al., 1987) which belongs to a decoupled propagation model, tracing the change of directional spectrum along a refracted ray of each component focused on a prescribed point. The usage of a nesting grid system with high topographical resolution results in a reasonable estimate of waves in coastal sea water. Fig. 9 shows a nesting grid system composed of the Northwestern Pacific Ocean area divided with a grid size of 5 km and a small sea area off Shikoku Island divided with a grid size of 0.5 km. The figure includes

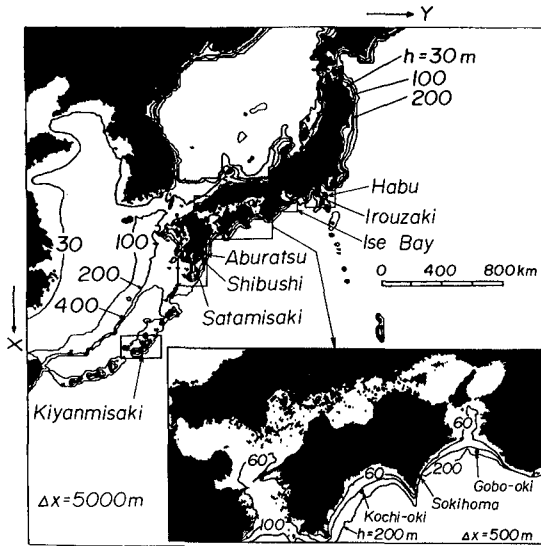

Fig. 9 Nesting grid used in wave computation, location of wave computation points and contour plot of water depth.

the location of Ise Bay where storm surge computation is conducted, the location of 9 wave computation points along the Pacific coast of Japan and contour plot of water depth. The numbers of frequency and direction data are 23 and 19 respectively, and the time step in wind and wave computations is 1 hour.

(5) Extreme analysis model

Return storm surge height and its standard deviation are evaluated applying the extreme analysis model based on the least square method (Goda, 1988) to data of its peak value during a typhoon. The optimum distribution is chosen among the Gumbel distribution and the Weibull distributions, shape parameters of which are 0.75, 1.0, 1.4, and 2.0, based on the largest correlation coefficient between the ordered data and its reduced variate.

Return wave height and its standard deviation are estimated with the extreme analysis model based on the PWM method (Yamaguchi et al., 1995), which was found from a numerical simulation study by the authors to be an excellent parameter estimation method. A sample of data is obtained from peak wave height during a typhoon in the case of simulated data and from typhoon-generated annual maximum wave height in the cases of observed and hindcasted data. Candidate distributions are the Gumbel and 3-parameter Weibull distributions, and choice of the

optimum distribution is due to a criterion of the correlation coefficient. A jackknife method is applied to estimate the standard deviation of return wave height.

3. Reproductiveness of Stochastic Typhoon Model, Storm Surge Model and Wave Model

Table 1 shows an example of the comparison between mean values and standard deviations of simulated typhoon parameters and those of observed typhoon parameters for each sub-area, and Fig. 10 illustrates the courses and radius of simulated typhoons in a representative year.

Fig. 11 Comparison of hindcast and observation for maximum storm surge height during a typhoon.

The stochastic typhoon model reasonably reproduces not only overall properties of typhoon characteristics but also their space-time variation associated with northward movement. It is natural that the model underestimates the standard deviation of typhoon radius because the effect of the deviation from mean value on the typhoon radius is neglected in the simulation.

Examples of the comparison between hindcasts and observations for typhoon-generated maximum

storm surge height in Nagoya Harbor and for maximum significant wave height at 4 wave observation points are indicated in Fig. 11 and Fig. 12 respectively. Applicability of the storm surge model and wave model are verified by satisfactory agreement between computation and observation for many typhoon cases.

Fig. 12 Comparison of hindcast and observation for maximum wave height during a typhoon.

4. Estimation of Extremes of Storm Surge in Ise Bay

A Monte-Carlo simulation for the generation of typhoon parameters is carried out over a period of 1000 years. The number of typhoons generated is about 7800. The associated storm surges in Ise Bay are computed for 2347 influential typhoon cases.

Fig. 13 shows the relation between return storm surge height with standard deviation at Nagoya Harbor and return period, where they are estimated based on the simulated data and the observed data over a period of 42 years from 1950 to 1991. It should be noted that the standard deviation estimated using the observed data for a shorter period becomes increasingly larger than that based on the simulated data for a longer return period. It can be said that estimates of return storm surge heights for return periods of less than 100 years by this system are close to those evaluated from the observed data, and that even for longer return periods, the re-

Fig. 13 Relation between return storm surge height with standard deviation and return period.

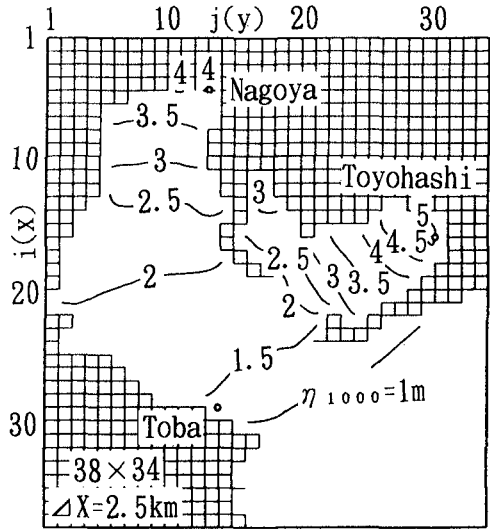

Fig. 14 Distribution of 1000-year return storm surge height in Ise Bay.

sults correspond well with each other, when their standard deviations are taken into account.

Spatial distribution of the 1000-year return storm surge height in Ise bay is given in Fig. 14, where the standard deviation ranges from 2.4 to 4.0 % of the return value and the maximum is 0.2 m. Return storm surge height rapidly increases from the entrance of the bay toward the inner most areas, in which case the maximum value exceeds 4 m at Nagoya Harbor and 5 m at Toyohashi point.

5. Estimation of Extremes of Wave height at the Pacific Coast of Japan

Two types of Monte-Carlo simulation are conducted. One is the simulation over a period of 1000 years as well as the case of storm surge computation, and the other is 100 times reiteration of the simulation over a period of 50 years. This is done for the purpose of directly computing standard deviation of each return wave height and investigating the applicability of a jackknife method to the evaluation of standard deviation based on the comparison between both estimates. Wave heights are calculated for about 3000 influential typhoon cases at 9 wave observation points indicated in Fig. 9.

Fig. 15 illustrates the effect of the number of iterations on mean and standard deviation of return wave height, in which statistically stable results can be seen for more than 50 iterations. Table 2 is the results of extreme analysis, in which standard deviations with a jackknife method agree well with those by direct calculation.

Fig. 16 shows longshore variation of the 1000-year return wave height and its standard deviation (68 % confidence interval) estimated using two kinds of simulation data, hindcasted data and observed data. Wave hind-casting is conducted for more than 150 intense typhoons which occurred during 45 years from 1948 to 1992, and period of wave observation ranges from 10 years to 21 years up to 1993. The return wave heights estimated from 4 kinds of extreme wave height data are in general agreement in spite of a great difference between computation period and observation period, when their standard devi-

ations are taken into account, but the confidence intervals are much wider in the estimates based on observation data.

6. Conclusions

It should be emphasized that the system proposed in this study is very useful to estimate extremes of storm surge height and wave height for return periods of more than several hundred years and their confidence intervals around the Pacific coast and the East China Sea coast of Japan.

7. Acknowledgements

A part of this study was accomplished with the support of the Science Research Fund (No. 06680431) of the Ministry of Education, for which the authors express their appreciation. CHAPTER 109

DESIGN OF VERTICAL WALLS AGAINST STORM SURGE

A. Kortenhaus¹, C. Miller², H. Oumeraci³

ABSTRACT

A concept for the design of high water protection (HWP) walls under storm surge conditions has been developed and is applied to the geometry found in the harbour of Hamburg, Germany. However, the design methods used have been generalized so that they may be used for a wide range of cases with similar geometries. Many gaps in standard design formulae have been filled by developing engineering approaches or formulae as reflection by steep berms, new breaker criterion, design formulae for impact breakers, reduction of loads by overtopping and soil pressure distribution in front of the wall.

INTRODUCTION

Interest in protective structures against storm surges is expected to largely increase in the near future, mainly due to the increased rate of storminess in the last decades. In order to be able to react more rapidly and to better protect the coastal estuary zones of high economic, social and environmental value, the performance of existing structures and their design must be reconsidered. Especially in areas with limited space, where the construction of "classic" high water protection (HWP walls) is impossible, the HWP walls as commonly found for instance in Hamburg are very suitable protective structures. Such a study has recently been conducted for the city of Hamburg, reconsidering the safety margin of all vertical wall structures within the harbour area. The motivation for this study was the change of the wave climate and of the rising water level assessments in the Hamburg harbour. To date, no general formulae have been developed to account for (i) the complicated foreland geometries in the harbour area, (ii) the different processes of wave transformation on these types of foreland, (iii) breaking of waves on the foreland and

(iv) different breaker types occurring at the protective structures. The design of HWP walls is very often considered to be much simpler than other more classical protection works. The relatively small heights of the HWP walls and their "simplicity" constitute the main reason, why this research field was neglected in the past. In fact there are many important peculiarities showing the need to develop this research field. Among the peculiarities there is for instance the size of the areas to be protected by the HWP walls which often extend over considerable lengths (e.g. more than 100 km in Hamburg harbour). Further reasons showing the need for more research will be addressed below.

In the Hamburg harbour area four typical foreland geometries can be identified (Fig. 1) which illustrate the large variety of harbour protection works. Due to these different types, a general design procedure is necessary which (i) accounts for different foreland geometries, (ii) is suitable for engineering practice and therefore must be easy to use and (iii) takes into account the large differences in water levels during a tidal cycle.

Fig. 1: Typical foreland geometries in the Hamburg harbour area

It is the main purpose of this paper to suggest a new design philosophy for protection works consisting of a variable foreland geometry with a vertical wall on top. In particular, a method is described to evaluate the wave transformation on the foreland and to calculate the most critical forces and moments on the vertical wall with respect to the critical water level and breaker type.

DESIGN STRATEGY

A set of five parameters is defined which describes all typical wall and foreshore geometries in the harbour area (Fig. 1). The walls are built as sheet walls or concrete wall structures with free heights of up to three meters. The design strategy for these conditions can be principally summarized in Fig. 2. The variable water level in this figure requires an iteration procedure until the design water level is reached which yields the most critical load at the wall. Breaking wave criteria, wave overtopping and wave load forces are evaluated by using the most updated design formulae/diagrams. It can be seen from Fig. 2 that three different loading cases may be distinguished:

- Standing waves: standing waves are very rare under prototype conditions for irregular wave trains but may occur during high water levels. A modification of the MICHE-RUNDGREN procedure for standing or almost standing waves was found to give reasonable results (*SPM, 1984*).
- Broken waves: broken waves at the wall represent the most frequent loads in the harbour area and may carry floating bodies (empty containers) hitting the wall. The standard CERC procedure for broken waves will be used to predict these loads (*SPM, 1984*).
- Plunging breakers: plunging breakers are relatively rare and will only occur under particular storm surge conditions but represent the most dangerous situation for the protection works since breaking waves cause very high impact loads. Results of hydraulic model tests which have been performed under the Marine Science and Technology Programme (MAST III) of the European Communities and formulae most recently developed to account for these type of loads (*Klammer et al., 1996*) will be used.

The variety and complexity of the foreland geometry makes it more difficult to define the design wave in front of the wall. The reason for this is that there are no reliable tools to describe the wave transformation and breaking criteria for most of the conditions shown in Fig. 1. The same reason is also valid for the lack of general design formulae to calculate the wave load and overtopping under these conditions.

The problem becomes more difficult by the complexity of the dynamic interaction of the "wave-structure-soil"-system under the impact load of breaking waves. Very often it is impossible to simplify the problem so that a static design method can be used. Moreover, the design water levels, wave parameters, loading and overtopping conditions do vary along the structure implying that there is not the same safety along the HWP walls at equal wall height.

The four design steps shown in Fig. 2 may be briefly described in the following sections.

(a) Step 1: Determination of Input Parameters

First, all important input parameters have to be defined or determined, respectively. The relevant water levels and the geometry of the foreland as well as the construction can be summarized by five parameters: water depth at the toe of the berm h_s , slope of the berm m , width of the berm B_b , water depth at the wall d and the free wall height h_c (Fig. 1).

The significant wave height $H_0 = H_s$, the peak-period T_p and the wave direction θ are needed as deep water input parameters. These parameters can be determined from

Fig. 2: Design procedure for high water protection works

measurements or by numerical wave forecast (*van Vledder, 1995*). Furthermore, particular boundary conditions provided by harbour authorities must also be taken into account. In Hamburg "Strom- und Hafengebäude" is responsible for the protection works used to provide shelter against high storm surges. These authorities generally provide information regarding the design of the load by floating bodies (empty containers etc.) as well as detailed data about the geometry of the HWP wall segments and their alignment relative to the wind direction. The latter is important as the design of HWP walls on the lee side can be performed by considering only the highest possible hydrostatic pressure (water level at the top of the wall); i.e. without any wave load (*Kortenhaus and Oumeraci, 1996*).

(b) Step 2: Wave Transformation and Breaker Criteria

Incident waves approaching from deep water will be transformed on the berm by shoaling, refraction and reflection; i.e. the wave height H_d in the water depth d (at the wall) can be derived by:

$$H_d = \kappa_s \cdot \kappa_R \cdot \kappa_X \cdot H_{\max} \quad (1)$$

H_{\max} is the maximum wave height in deep water (Rayleigh distribution) which can be derived from $H_{\max} = 1.86 H_s$ (H_s from step 1).

κ_s , κ_R and k_x are the shoaling, the refraction and the reflection factor, respectively (determined by linear wave theory). The shoaling factor κ_s and the refraction factor κ_R can be calculated as follows:

$$\kappa_s = \frac{k_{s,W}}{k_{s,0}} \quad (2)$$

$$\kappa_R = \frac{k_{R,W}}{k_{R,0}} \quad (3)$$

where $k_{s,0}$ and $k_{s,W}$ are the shoaling coefficients in deep water (subscript 0) and at the wall (subscript W) and $k_{R,0}$ and $k_{R,W}$ are the refraction coefficients. The reflection factor k_x describes the reduction of wave energy by the reflection due to the steep berm and can be calculated as follows:

$$k_x = \sqrt{1 - \kappa_B^2} \quad (4)$$

The total reflection coefficient of the wall-berm-system κ_B can be estimated as follows:

$$\kappa_B = \sqrt{\frac{E_{01}}{E_0} \cdot \kappa_{01}^2} \quad (5)$$

where κ_{01} is the reflection coefficient at the berm, E_0 is the wave energy in deep water calculated from linear wave theory and E_{01} is the part of the wave energy in front of the berm which can also be estimated by linear wave theory. The reflection coefficient at the berm κ_{01} can be estimated as follows (ξ is the Iribarren number):

$$\kappa_{01} = 1 - \exp\left(-\frac{1}{7} \xi^2\right) \quad (6)$$

Fig. 3 shows the reflection factor k_x plotted against the relative water depth d/L_0 according to Eqs. (4)-(6). It can be seen that changes in effective reflection coefficients up to 25% may result for design water levels ($d \approx 2$ m; $L_0 \approx 20$ -25 m) in the Hamburg harbour area.

To determine the relevant loading case under storm surge conditions breaking criteria are needed which account for the reflection properties of the HWP wall and for the foreland geometry.

Assuming the reflection coefficient to be 0.9 for vertical HWP walls (Kondo *et al.*, 1986) the wave height of the breaking wave H_b can be determined by the following formula (Oumeraci *et al.*, 1993):

$$H_b \approx 0.10 L_0 \left[\tanh \left(2\pi \frac{d}{L_b} \right) \right]^2 \quad (7)$$

L_0 is the wave length in deep water and L_b is the wave length at the breaking point (water depth d) which can be calculated from linear wave theory as follows:

Fig. 3: Reflection nomogram for a vertical wall with a foreshore sloping berm

$$L_b \approx L_0 \left[\tanh \left(2\pi \frac{d}{L_0} \right)^{3/4} \right]^{2/3} \tag{8}$$

The comparison of the breaking wave height H_b from Eq. (7) and the wave height H_d from Eq. (1) allows a first distinction into two loading cases. If H_b is smaller than H_d the waves will not break and the 'Standing wave' loading case can be applied.

If H_b is larger than H_d loading cases 'plunging breaker' or 'broken wave' can be applied. To check for 'plunging breaker' conditions a 'breaker type nomogram' in Fig. 4 has been developed on the basis of existing experimental data (Takahashi *et al.*, 1993). Comparison to results obtained in large-scale model tests showed that these breaking criteria give acceptable results (Oumeraci and Kortenhaus, 1996). A further comparison to another method recently published by Allsop *et al.* (1996) shows only slight differences. The relative berm width Bb/L_b , the relative berm height $h_r = (hs - d)/hs$ and the relative wave height H_d/d are needed as input parameters for the nomogram.

The 'plunging breaker' loading case occurs when the point is inside the corresponding H_d/d area. If the point is outside the loading case "Broken Wave" can be assumed. Two examples in Fig. 4 demonstrate the use of the breaker type nomogram.

Fig. 4: Nomogram for identification of loading case 'plunging breaker'

(c) Step 3: Calculation of Loading Cases

The wave pressure distribution at the wall, wave forces and moments for each of the loading cases described before have to be determined. For all cases a load reduction due to overtopping and the pressure distribution in the soil in front of the wall will be given. These calculations are described below in the third section of this paper.

(d) Step 4: Variation of Water Level

During storm surge conditions the water level will vary significantly in front of the wall. Therefore it is necessary to perform step 3 for a stepwise reduction of the water level (down to $d = 0$). As a result a critical water level and a corresponding load for each section of the wall along the HWP line are obtained.

This procedure can be used for the identification of the most critical spots along the HWP walls in the harbour area where impact loading may occur under particular water level and sea state conditions.

DETERMINATION OF LOADING CASES

This chapter summarizes the methods to estimate the pressure distributions, forces and moments due to the wave action in front of the structure for the three loading cases shown in Fig. 2. Due to the limited space for this paper, related references will be given in all cases where standard procedures have been used.

(a) Standing Waves

For the loading induced by standing waves the method of *Sainflou (1928)*, the method by *Rundgren (1958)*, modified by Miche and summarized in *SPM (1984)* and a more recent method based on a crest elevation proposed by *Goda (1985)* have been compared. As a result the method of Miche-Rundgren has been selected for the design, because of its simplicity in engineering use and because it accounts for both terms of higher order as well as for the reflection coefficient of the HWP wall (see design diagrams in *SPM, 1984*).

It is proposed to use a constant reflection coefficient for the Miche-Rundgren method. It is well known that a reflection coefficient of 1.0 is too conservative but to be on the safe side a constant reflection coefficient of $C_r = 0.9$ is proposed. In applying the method to the harbour of Hamburg this value was used.

(b) Broken Waves

This loading case is assumed to be the predominant loading case for HWP walls under storm surge conditions and geometric boundary conditions as for instance found in Hamburg harbour. The fast change from deep water conditions in front of the berm to shallow water conditions in front of the wall will induce wave breaking. A plunging breaker at the wall will occur under very special geometric conditions (relative berm height and width) as already shown in Fig. 4. Therefore broken waves are more likely to be expected. The design for this loading case may be combined with a load induced by floating bodies as it is most likely that floating bodies will be transported by broken waves. For the assessment of design load, the method by *CERC (SPM, 1984)* is proposed.

The input parameters for the SPM method are:

- the wave depth at the wall d
- the wave height of the breaking wave H_b according to Eq. (7)

(c) Plunging Breakers

For plunging breakers at the wall a new method was developed to calculate pressure distribution and forces at the vertical wall (*Klammer et al., 1996*). The latter formula takes into account the total duration and the rise time of the load.

From experiments on a large-scale breakwater model the following formula for the impact force has been derived for the design of the HWP walls in Hamburg:

$$F_{h,\max} = 8.0 \cdot \rho g H_b^2 \quad (9)$$

$F_{h,\max}$ is the maximum horizontal wave force, H_b is the height of the breaking wave in front of the structure and ρ is the density of the water. From statistical analysis it has been found that the non exceedance probability of the relative horizontal force $F_{h,\max}/\rho g H_b^2$ in Eq. (9) is about 10 to 15%. The point of application of the force is close to the height of the design water level. The pressure distribution at the time of the maximum horizontal force and further design details can be taken from *Klammer et al., 1996*.

To account for the dynamic behaviour of the system the load has to be multiplied by a dynamic load factor D . Dynamic load factors for caisson structures were principally investigated by *Oumeraci and Kortenhaus (1994)*. In the example case of the Hamburg harbour dynamic load factors were determined from prototype measurements at the protection walls in the Hamburg harbour area where D was found to be in the range from 0.85

to 1.2 (Kruppe, 1996). A conservative value for D of 1.5 can be used for each section along the HWP walls where no detailed information on the dynamic characteristics of the structure-soil-system are available. The force increased by the dynamic load factor has to be used for a static design approach instead of the values calculated by the method described before:

$$F_h = D \cdot \left(8,0 \cdot \rho g H_b^2 \right) \tag{10}$$

Fig. 5: Comparison of pressure distributions with and without overtopping

Reduction of wave impact at the wall due to oblique wave attack and short-crestedness may also be taken into account by using the results of extensive 3D hydraulic model tests (Franco et al., 1995). For short-crested waves almost no reduction of horizontal forces can be found whereas for long-crested waves, reductions in horizontal forces can be found only for higher wave obliquity.

OVERTOPPING

Overtopping will lead to a reduction of the horizontal loading. This phenomenon has not yet been addressed in detail in the literature. Generally, in the case of overtopping the pressure figure is cut at the top of the wall (Fig. 5b). The pressure ordinate at the top of the wall is then calculated by an interpolation between the ordinate at the height of the design water level (DWL) and the point above the water level where the pressure would be zero if the wall were high enough. However, this method particularly fails for higher DWL. Therefore an additional approach is suggested below.

In Fig. 5a the wave and the pressure distribution just reach the top of the wall whereas in Fig. 5c the design water level

(DWL) has reached the top of the wall. In the latter case the dynamic pressure induced by wave motion is relatively small as compared to the hydrostatic head. Hence, the governing load is the hydrostatic head related to the water depth at the wall.

Therefore the reduction of the loading on the wall due to overtopping is about zero at the top of the wall. Especially for impact loading this is not the case when the pressure distribution is simply cut off at the top of the wall. Contrarily this procedure would result in a significantly high pressure at the top of the wall.

Hence, a factor k_{Fh} has been introduced to reduce the loading by more than a simple 'cutting' of the pressure distribution. This factor accounts for the fact that the pressure distribution and the force in Fig. 5c has to be zero ($R_c \approx 0$) and has its maximum for an infinitely high wall (Fig. 5a):

$$F_{h,ov} = k_{F,h} \cdot F_h \tag{11}$$

with

$$k_{F,h} = 1 \quad \text{für } \eta_* \leq R_c$$

$$k_{F,h} = \sqrt[3]{\frac{R_c}{\eta_*}} \quad \text{für } \eta_* > R_c \tag{12}$$

$F_{h,ov}$ is the reduced force, F_h is the horizontal force according to the method valid for each loading case, η_* is the distance of the highest point of the pressure distribution to the design water level and R_c is the freeboard of the wall. Applying this procedure for the three loading cases shown will result in the lower curve related to the respective loading case in Fig. 6.

Fig. 6: Reduction of horizontal force by reduction factor k_{Fh}

SOIL PRESSURE IN FRONT OF THE WALL

(a) Standing Waves

For standing waves where the loading changes with the wave period T_p the pressure in the height of the berm p_s for a water depth d can be calculated by:

$$p_s = \rho_w g \left(1 + C_r\right) \frac{H}{2} \frac{1}{\cosh \frac{2\pi d}{L}} \quad (13)$$

For a berm made of *rubble material* it can be assumed that the decrease of pressure $p(z)$ in the soil still can be described by linear theory. Increasing depth in the soil z will result in:

$$p(z) = p_s \frac{\cosh \left[2\pi (t_B + z) \right]}{\cosh \left(\frac{2\pi d_b}{L} \right)} \quad (14)$$

For a berm made of *finer soil material* like sand the method of *Moshagen and Tørum (1975)* can be used. For $k_x = k_z$ (same permeability in horizontal and vertical direction) the method of *Moshagen and Tørum (1975)* can be simplified to:

$$p(z) = p_s \frac{\cosh \left[\mu (z + t_B) \right]}{\cosh \left[\mu t_B \right]} \quad (15)$$

n is the porosity of the soil material ($n \approx 0,4$); k_x is the permeability of the soil material in horizontal direction ($k_x \approx 10^{-4}$ m/s for sand); T is the wave period in s; L is the wave length in the water depth d in m and μ can be given by:

$$\mu = \left[\left(\frac{2\pi}{L} \right)^4 + \left(\frac{\frac{2\pi}{T} n \rho_w g}{k_x E_F} \right)^2 \right] \frac{1}{4} \quad (16)$$

Since *Moshagen and Tørum (1975)* assumed a total saturation of the soil E_F is set equal to E_{water} . This is not completely true as air and water will fill the pores of the soil. Therefore the following approach for E_F will be used in Eq. (16):

$$E_F = \frac{1}{\beta'} \quad (17)$$

In this β' is the compressibility of the pore fluid which can be calculated from:

$$\beta' = \beta + \frac{1-s}{p_a} \quad \text{für } (1-s) \ll 1 \quad (18)$$

β is the compressibility of the water ($\beta = 4.2 \cdot 10^{-7}$ m²/kN); s is the saturation of the soil; p_a is given by $p_a = p_{\text{atm}} + p_{\text{hydrostat}}$; p_{atm} is equal to 101.325 kN/m² and p_{hyd} is the hydrostatic pressure which is given by $p_{\text{hyd}} = \rho_w g d$.

The application of Eq. (18) to three typical water depths in the Hamburg harbour area is given in Tab. 1.

Tab. 1: Compressibility β' of the pore fluid as a function of the saturation of the soil s and the water depth d

Saturation s [-]	Compressibility of the pore fluid β' [m^2/kN]		
	$d = 0.5 \text{ m}$	$d = 1.0 \text{ m}$	$d = 2.0 \text{ m}$
1.00	$\beta' = \beta = 4.2 \cdot 10^{-7}$		
0.999	$9.83 \cdot 10^{-6}$	$9.42 \cdot 10^{-6}$	$8.96 \cdot 10^{-6}$
0.99	$9.45 \cdot 10^{-5}$	$9.04 \cdot 10^{-5}$	$8.31 \cdot 10^{-5}$
0.98	$1.89 \cdot 10^{-4}$	$1.80 \cdot 10^{-4}$	$1.66 \cdot 10^{-4}$
...
0.95	$4.71 \cdot 10^{-4}$	$4.50 \cdot 10^{-4}$	$4.14 \cdot 10^{-4}$

(b) Broken Waves and Impact Breakers

For impact loads and broken waves no method is yet available to assess the damping in fine soil material. For rubble material the respective pressure distribution can be extended in the soil. For fine soil materials (sand) it is proposed to neglect the pressure distribution in the soil due to the strong damping (highly frequent loading).

CONCLUDING REMARKS AND FUTURE RESEARCH WORK

A concept for the design of high water protection (HWP) walls under storm surge conditions has been developed. The concept was initially developed for the harbour of Hamburg (Germany) but the design methods have been generalized so that they may be used for a wide range of cases with similar geometries.

In the future however a more elaborated concept for the safe and economic design of this kind of protective structures is needed which requires both an integrative procedure by accounting for hydraulic, structural and soil mechanical aspects as well as for all possible failure modes and their probability of occurrence. Therefore it is necessary to use dynamic and probabilistic design methods where the 3D-character of the problem has to be taken into consideration.

This task has been undertaken in the "Marine Science and Technology"-programme (MAST III) of the European Union. This research project of 23 European institutes out of different disciplines (hydrodynamics, coastal engineering, soil mechanics, structural mechanics, applied mathematics, etc.) is coordinated by Leichtweiss-Institut, Braunschweig (Oumeraci, 1995) and is aiming for providing a basis for the design of vertical breakwaters under probabilistic aspects.

ACKNOWLEDGEMENTS

This study has been supported by the Hamburg harbour authority "Strom- und Hafengebäude". The support of basic research studies by the German Research Council (DFG) on monolithic breakwaters and by the European Union (contract no. MAS2-CT95-0041) on

vertical structures is also gratefully acknowledged. Without the latter basic research studies the results described in this paper would not have been achieved.

CHAPTER 110

NEARSHORE, WAVE AND TOPOGRAPHIC EFFECTS IN STORM SURGES

Gary Watson¹ and Takao Yamashita²

Abstract

Some ideas for improving the accuracy of storm surge prediction models are discussed. A detailed coastal flooding model is applied to the flooding of Chittagong in the April 1991 disaster, but results are only illustrative due to the lack of good topography data. The influence of waves on wind stress forcing and bottom friction is discussed. Some recent results from a coastal observation tower taken during a typhoon show enhanced stress compared with values from empirical formulae in the literature. A new model for improving the representation of typhoon wind fields in areas surrounded by mountains is presented. Its applicability for storm surge computation is demonstrated using observations of a typhoon and surge in Osaka Bay.

Introduction

Storm surges, abnormal rises in sea level caused by strong onshore winds, pose one of the most severe natural hazards in many coastal areas. As recently as 1991, 150,000 people died in Bangladesh, mostly by drowning in coastal floods caused by a severe cyclone and surge. Effective action to minimize the impact of such disasters depends on advance knowledge of the threat to any particular location. A number of numerical models have been developed for predicting surges, and in some countries they are used operationally for making surge warnings. However, there remains scope for improving the representation of a number of phenomena in the models and this paper describes some recent investigations. These include new work on modelling coastal flooding; modelling of the wave field and its effects

¹Cooperative Foreign Researcher, Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611, Japan

²Associate Professor, same address.

on wind stress, bottom friction and coastal set-up; and the effect of mountains on the wind field.

Surge models commonly use some form of the non-linear shallow-water equations for mass and momentum conservation, with appropriate forcing terms. Here we use the following:

$$\frac{\partial \zeta}{\partial t} + \frac{\partial(ud)}{\partial x} + \frac{\partial(vd)}{\partial y} = 0 \quad (1)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = f v - g \frac{\partial \zeta}{\partial x} - \frac{1}{\rho} \frac{\partial p_a}{\partial x} + \frac{1}{\rho d} \tau_{sx} - \frac{1}{\rho d} \tau_{bx} + A \nabla^2 u \quad (2)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -f u - g \frac{\partial \zeta}{\partial y} - \frac{1}{\rho} \frac{\partial p_a}{\partial y} + \frac{1}{\rho d} \tau_{sy} - \frac{1}{\rho d} \tau_{by} + A \nabla^2 v \quad (3)$$

where ζ is surface elevation, d is total water depth, and (u, v) is depth-averaged velocity. The terms on the right of the momentum equations (2) and (3) are due respectively to Coriolis force, surface slope, atmospheric pressure gradient, surface wind stress $\vec{\tau}_s = (\tau_{sx}, \tau_{sy})$, bottom friction stress $\vec{\tau}_b = (\tau_{bx}, \tau_{by})$, and eddy viscosity. A is an eddy viscosity coefficient.

If the wind field is reasonably well approximated, the storm surge predicted by models based on these equations is generally good enough to be useful. In principle however, it is possible to make improvements to the methods currently used. In the case of surges generated by tropical storms, the main limitation is the accuracy of storm forecasts. Prediction of the storm's track and speed are especially important, because landfall point and timing relative to local high tide strongly affect the location and depth of flooding (Flather, 1994). Storm intensity is also a primary factor determining surge height and this too is difficult to forecast, as it can change unexpectedly. Any progress in these respects would improve the surge forecasts.

Besides this, there are other improvements which could be made. Figure 1 illustrates some phenomena that occur during storm surges, which are not normally included in the models. Those discussed briefly in this paper are the flooding of rivers and low-lying coastal land, including the possibility of bore formation; the effect of waves on the wind stress, bottom stress and coastal set-up; and the effect of mountains on the wind field. Others that are not discussed here include coastal wave hazard, the drag effects of terrain, vegetation and buildings on flooding, changes in river levels (especially when in flood), and morphodynamic changes due to sediment transport during the surge. Ideally, all of these effects should be incorporated into future operational surge models.

Flooding of Rivers and Low-Lying Coastal Land

The most dangerous threat during a storm surge is the sudden flooding of inhabited areas on land near the coast. It is thus highly desirable to be able to model and predict such events in as much detail as possible. A standard surge model with a fixed boundary is able to make a reasonable prediction of the

Figure 1: Some phenomena that occur during storm surges.

increase in coastal sea level, but this does not tell us the extent of flooding to be expected in any particular area. For example, if there is a river or an extensive area of low-lying land, the flooding will reach further inland and pose a more severe hazard. For flooding studies, we can use a local model with a fine grid covering the area of interest. Here we present some preliminary results from a model which is under development, simulating the flooding of Chittagong during the April 1991 disaster in Bangladesh.

A number of reports have said that surges in the Bay of Bengal are sometimes observed as “walls of water”, suggesting that they may steepen and break in the same way as a tidal bore. Tides and tsunamis are well known for steepening into breaking bores in suitably-shaped estuaries and rivers. It is likely that this may also sometimes happen with storm surges. The sudden increase in water level and associated turbulence would increase the resulting danger, and it is thus important to understand and be able to predict the circumstances under which bore formation can occur.

We thus use a model for coastal flooding that is able to represent bore formation. It is based on the nonlinear shallow-water equations and uses a numerical method which accurately handles the formation of discontinuities (representing bores) in the solution. It is an extension into two horizontal dimensions of an earlier model used for waves on beaches (Watson et al., 1994). The boundary condition at the moving shoreline is satisfied, allowing flooding to be simulated properly. The model includes a bottom friction term but for these preliminary studies, the drag coefficient was set to zero. The model is applied to a detailed local area using a fine grid, with offshore boundary conditions provided by a surge model of a wider area including the continental shelf.

Here we show results from a simulation of the flooding of Chittagong in the

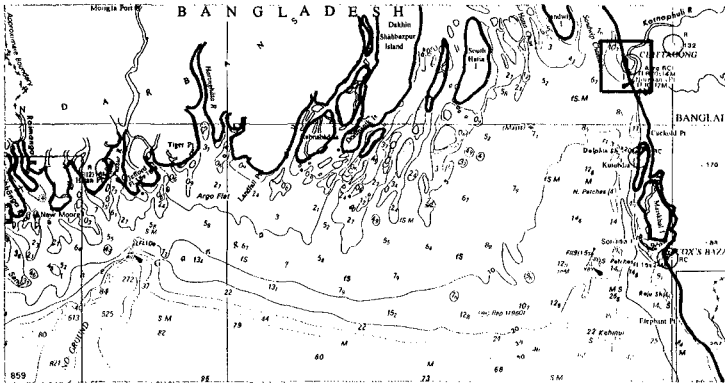

Figure 2: Map of the area showing the boundaries of the large-scale storm surge model and the small-scale flooding model.

Figure 3: The topography of Chittagong and the Karnaphuli River.

April 1991 cyclone disaster in Bangladesh. A surge model of the northern Bay of Bengal (grid size $1,700 \text{ m} \times 1,726 \text{ m}$) was run using idealized pressure and wind fields based on available data for the cyclone intensity and track (Katsura et al., 1992). A fine-grid model (grid size $0.1' = 170 \text{ m} \times 185 \text{ m}$) was then constructed for a small area around Chittagong including the Karnaphuli River, solving the nonlinear shallow-water equations. The areas covered by the two models are shown in Figure 2. A time series of water level from the surge model at the point closest to Chittagong was applied to the western boundary of the local model.

The bathymetry and topography of the local model are plotted in Figure 3.

Bathymetry data were read and interpolated manually from British Admiralty chart No. 84. It has not been possible to obtain good elevation data for the city of Chittagong, so for this preliminary study a very approximate topography was constructed. East and south of the Karnaphuli River, heights were interpolated between the water and the 25 m contour on the Admiralty chart. To the north, the 20 m contour on the Chittagong Guide Map (Govt. of Bangladesh, 1976) was used. Between coast and river, Chittagong airport was set to its elevation of 3 m. North of the airport, data were invented. This is of course an important limitation on these results, which should be taken only as an illustration of the method. An example of the results from this simulation is shown in Figure 4. Extensive flooding of Chittagong is seen, but according to Katsura et al. (1992), the flooding was not quite as extensive as is shown here.

Figure 4: Preliminary results of the model showing flooding of Chittagong. *N.B. This calculation uses inaccurate topography and the result is only illustrative of the method. This result is not considered to be a good representation of the flood which actually occurred, nor of possible future floods.* On the left, the initial undisturbed state. On the right, during the storm surge flooding. Land is white and higher water levels are lighter shades.

No bore occurred in the Karnaphuli River. This is not surprising since the river has no V-shaped estuary to concentrate the wave energy, as is common in rivers which have tidal bores. A tidal bore exists in the Meghna estuary, which was also affected by the 1991 surge, but it has so far not been possible to run the model there because of a lack of bathymetric data.

The combined model shows potential for making detailed flooding and bore formation predictions, but uncertainties remain such as how to treat buildings and different types of terrain. Unfortunately, no precise observations for testing the predictions are available. Accuracy is also limited by a lack of good topo-

graphic data for the sites of interest. Thus, it is not yet possible to apply the results with confidence to particular localities.

Wave Effects

For storm surge modelling, the most important forcing terms are the atmospheric pressure, surface wind stress and bottom friction stress. The former is of course theoretically well-defined and depends only on a reasonably accurate knowledge of the relevant time-dependent pressure field.

The stress terms represent the exchange of momentum between atmosphere and ocean, and between ocean and sea bed. Air-sea momentum exchange is a complex process involving turbulent boundary-layer flow over a changing rough surface, wave generation, non-linear energy transfer between wave components, and wave breaking. Waves also affect the bottom stress, by increasing bottom boundary layer turbulence and eddy viscosity, and hence momentum transfer. These processes are not very well understood theoretically, especially in strong winds and high waves, and so are not incorporated into the models. If they can be better understood, then in principle the accuracy of the corresponding forcing terms in the models could be improved.

Dependence of Surface Wind Stress on Wave Conditions

The mean force acting on the surface of a body of water due to wind stress is usually approximated as

$$\vec{\tau}_s = \rho_a C_{D10} \vec{U}_{10} |\vec{U}_{10}| \quad (4)$$

where $\vec{\tau}_s$ is the wind stress at the surface (the horizontal force per unit area acting on the surface), ρ_a the air density, \vec{U}_{10} the mean wind at 10 m and C_{D10} the drag coefficient for wind at 10 m. To represent the fact that surface roughness increases with windspeed, this coefficient is normally specified as a function of the windspeed at 10 m, $C_{D10}(U_{10})$. An example is the empirical relationship of Smith et al. (1992), which is based on data from the HEXOS experiment. This is a linear relationship given by $C_{D10} = (0.66 + 0.072U_{10}) \times 10^{-3}$. A number of similar relationships have been proposed, based on different data sets. Although the data are scattered, these empirical functions are all quite similar. This approach is a useful first approximation, and produces acceptable results in many circumstances. Note however that it applies only to well-developed seas in which the waves are approximately in equilibrium with the local wind, in deep water, and also mainly for wind speeds greater than about 5 ms^{-1} .

There may be important cases where this is inaccurate, especially if the wind is rapidly changing (such as in tropical storms), or near the coast where the water is shallow and the waves fetch-limited, or where the wave spectrum has more than one significant component. Higher values of C_D are found both in growing waves, such as during the onset of a storm, and in shallow water. Both of these conditions are necessary for the development of a storm surge, so the effect is po-

tentially important. An important parameter here is the ratio of dominant wave phase speed to wind speed, known as the wave age c_p/U , which is an indication of whether or not the wind and waves have reached equilibrium. However, what field data exist are hard to interpret because the effect is comparable in size with measurement errors, and therefore cannot be determined very accurately. It has not so far been possible to derive any empirical formulae based on the data, and so this effect is not usually incorporated into surge models. Such cases could potentially be more accurately represented by a theory which correctly accounts for momentum transfer between wind and waves, and between waves and the mean current, such as that of P. Janssen (1992). Note however that there is currently much debate on this subject, for example J. Janssen (1995) recently argued that the HEXOS data show no statistically significant dependence of wind stress on sea state.

Wind and Wave Data from the Observation Tower

This section discusses drag coefficient estimates made from observations taken by the Kyoto University DPRI Tanabe-Nakajima Storm Surge Observation Tower. The tower is located about 2 km offshore from the town of Tanabe in southern Honshu, mainland Japan. It stands at the mouth of Tanabe Bay, on a plateau about 10 m in depth, about 100 m in diameter, in an area where the depth is predominantly about 30 m. It is possible that this plateau will have some local influence on the waves, but this is difficult to determine. The tower measures wave elevation (using a downward-looking ultrasonic sea-surface height gauge), current (using an electromagnetic current meter at a depth of 10 m) and wind (using a 3-component ultrasonic anemometer at a height of 20 m). Data are recorded at 20 Hz for 20 minutes during each hour. This section discusses some drag coefficient estimates made from these data.

Because the largest surges are generated by storms, priority was given to the analysis of data from Typhoon 9426, which passed very close to the tower on 29 Sept. 1994. The lowest recorded pressure was 965 hPa at about 19:00, and the central pressure was estimated as about 950 hPa. The track was slightly south of the tower, so that the wind direction changed rapidly from east to west, also at about 19:00. Maximum recorded wind speed was 24 ms^{-1} at about 21:00. Wave height peaked at around 5 m near 17:00 and the wave period reduced from 13 s to 7 s as the typhoon passed. Direct measurements of wave direction are not available. These observations are reported in more detail by Yoshioka et al. (1995).

Following Yelland et al. (1994), wind stress was estimated from the anemometer data using the turbulent (or inertial) dissipation method. This is based on the assumption that the energy spectrum of the down-wind component is governed by the rate of dissipation of energy by high-frequency turbulence. In this case,

the spectrum is assumed to have the form:

$$S(f) = K \epsilon^{2/3} f^{-5/3} \left(\frac{U}{2\pi} \right)^{2/3} \tag{5}$$

where $S(f)$ is the power spectrum of the down-wind component, K is the 1-D Kolmogorov constant, taken as 0.55, and ϵ is the high-frequency turbulent dissipation rate. If the measured spectrum is found to obey the $f^{-5/3}$ law reasonably well, then an average value of $S(f)f^{5/3}$ over an appropriate frequency range may be used in (5) to estimate ϵ . The wind stress τ is then estimated from

$$\tau = \rho_a (k_\nu \epsilon z)^{2/3} \tag{6}$$

where k_ν is the von Kármán constant (taken as 0.4), and z is the measurement height (20 m). The drag coefficient is then obtained from (4) after correcting the observed mean wind to an estimated value at 10 m using the relation for a logarithmic boundary layer,

$$\frac{U(z)}{U(10)} = \frac{\ln(z/z_0)}{\ln(10/z_0)} \tag{7}$$

where z_0 is the roughness length $z_0 = ze^{-k_\nu/\sqrt{C_D}}$. Note that (5) applies to neutral atmospheric stability. A correction is possible for non-neutral conditions, but was found to be small in this case.

Figure 5: Wind Spectra $S(f)f^{5/3}$ at 19:00 and 23:00, 29 Sep 94 (T9426)

Figure 5 shows $S(f)f^{5/3}$ for two samples during the typhoon, at 19:00 (close to the point of closest approach) and 23:00 (a few hours after the typhoon centre passed). The plot for 19:00 is typical of those before 21:00, and the spectrum is almost constant over the frequency range used for the average (0.8–2.0 Hz, dotted

lines). This permits Eq. 5 to be used with some confidence. At 23:00 however, the spectrum exhibits a distinct slope throughout the frequency range, indicating that the $f^{-5/3}$ power law does not apply, and that (5) should not be used. Such data must be excluded from the analysis. This is unfortunate, since results just after a rapid change of wind direction are of particular interest. The reason for the different spectral slope (these data have much more high-frequency content) are not clear but may be caused by interference of the anemometer structure with the flow. One must also be aware that mean flow distortion around the tower will change the observed value of the mean wind, introducing an unknown error into the estimated drag coefficient.

Figure 6: Drag coefficient estimates against wind speed during the typhoon.

The final estimates of stress for this day, excluding the data from 22:00 and 23:00, are plotted against mean wind speed in Figure 6 and compared with the empirical relation of Smith et al. (1992). Particularly at intermediate wind speeds, the data lie well above this curve. There is no obvious trend with wind speed, and as with other such data, they are rather scattered. If anything, a constant drag coefficient of about 2.2×10^{-3} may be appropriate in this instance. These limited data appear to be an example of departure from the standard formulae, although the whole data set should be examined before drawing firm conclusions.

Dependence of Bottom Stress on Wave Conditions

Another effect of waves which may sometimes be important is their influence on the bottom stress. In shallow water, waves affect momentum exchange with the sea bed. The wave-induced oscillatory flow near the bottom produces

turbulence when flowing over the rough bed. This increases the rate of vertical transfer of horizontal momentum, and hence the mean drag force between the water and the sea bed. Theoretically, this is represented as an increase in eddy viscosity.

In models, the mean retarding force acting on a body of water due to bottom friction is usually approximated as

$$\bar{\tau}_b = \rho_w C_{Db} \bar{u} |\bar{u}| \quad (8)$$

where $\bar{\tau}_b$ is the bottom stress, ρ the water density, \bar{u} the wave-averaged bottom current and C_{Db} a bottom drag coefficient. For many applications, it is found good enough to use a constant value for C_{Db} .

The effect of wave-induced turbulence is to increase the effective value of C_{Db} . Mastenbroek (1992) estimated the size of this effect on surges in the North Sea using the relationship between drag coefficient and significant wave height, $C_{Db}(H_s)$, in Figure 3 of his paper. He found that in some shallow areas it could significantly affect the predicted surge, more so than the effect of a wave-dependent wind drag coefficient. However, the size of this effect is similar to that of geographical variations in C_{Db} due to variations in bed roughness. This makes practical implementation difficult because of the lack of sufficiently detailed data on bed roughness.

Wave Set-Up

For completeness, we also point out that another effect of waves on local water level at the coast is that of wave set-up. This may be evaluated using forcing by the gradient of radiation stresses of shoaling and breaking waves. The effect is significant in storm surges occurring on coastlines facing the open sea. Depending on the beach topography and wave conditions, this can be about 10% of the incident wave height or even more, sometimes up to about 1 m. Although not the subject of this paper, it is an effect that should also be taken into account when considering the flood risk during storms and surges.

Incorporation of Wave Effects into Surge Models

The next stage of this work, in addition to further analysis of the wind stress data, will be to incorporate wave effects into a surge model. The first step will be to use an ocean wave model suitable for the region in question, which for storm surges will usually mean shallow shelf regions with strong winds. After predicting the time-dependent wave field during the storm, the next step will be to use the results for wave height to modify the surface and bottom drag coefficients in the surge model, as outlined above. In this way, the size of wave effects on the surge prediction will be assessed.

Influence of Mountains on the Wind Field

In coastal areas with mountains, the simple formulae which are often used to

represent the wind field in tropical storms may become quite inaccurate and thus affect surge predictions. Both the shape of the mountains, and surface roughness have an effect. This is particularly so in a number of bays in Japan, such as Osaka Bay and Ise Bay, where storm surges pose a threat to low-lying urban areas. In order to reproduce the wind fields of typhoons in such places, empirical attenuation parameters have been used to decrease both the moving wind and the gradient wind, in a rough attempt to include the effects of land topography and surface roughness. However, the values have to be adjusted in each case to give results which best fit the observed wind - the best values are different for each typhoon and cannot be predicted in advance. This is unsatisfactory because it is impossible to make credible predictions for hypothetical typhoons, as for example would be desirable when planning coastal defences.

Here we improve the situation using Schloemer's equation for the typhoon pressure field, Yoshizumi's formula for the variation of wind with height in the friction layer, and a finite-difference model for air flow over topography based on mass conservation, called 'MASCON'. This model is based on Sasaki's (1970) theory and is similar to one developed by Sherman (1978), for interpolating wind vectors in complicated topography from limited wind observations.

The model works as follows. First, the equation of Schloemer (1954) is used for the atmospheric pressure as a function of distance r from the cyclone centre:

$$p = p_c + \Delta p e^{-r_m/r}. \quad (9)$$

The model of Yoshizumi (1968) is then used to evaluate the three-dimensional wind field which this would produce over a flat surface, considering the effects of surface friction (the Eckman spiral) and storm movement. This is the initial wind field for the MASCON model. The wind field is then corrected so as to satisfy the conservation of mass for an incompressible fluid, using the calculus of variations. The error of adjustment is expressed as,

$$E(u, v, w, \lambda) = \int_V \left[\alpha_1^2 (u - u_0)^2 + \alpha_1^2 (v - v_0)^2 + \alpha_2^2 (w - w_0)^2 + \lambda \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right) \right] dx dy dz \quad (10)$$

where (u, v, w) is the corrected wind field, λ is Lagrange's indeterminate coefficient and α_1, α_2 are Gauss precision moduli. Euler-Lagrange's equations have a solution minimizing (10) which can be written as,

$$u = u_0 + \frac{1}{2\alpha_1^2} \frac{\partial \lambda}{\partial x} \quad (11)$$

$$v = v_0 + \frac{1}{2\alpha_1^2} \frac{\partial \lambda}{\partial y} \quad (12)$$

$$w = w_0 + \frac{1}{2\alpha_2^2} \frac{\partial \lambda}{\partial z} \quad (13)$$

Differentiating with respect to x, y, z respectively, and substituting into the mass conservation equation gives the following Poisson-type partial differential equation:

$$\frac{\partial^2 \lambda}{\partial x^2} + \frac{\partial^2 \lambda}{\partial y^2} + \left(\frac{\alpha_1}{\alpha_2}\right)^2 \frac{\partial^2 \lambda}{\partial z^2} = -2\alpha_1^2 \left(\frac{\partial u_0}{\partial x} + \frac{\partial v_0}{\partial y} + \frac{\partial w_0}{\partial z}\right) \quad (14)$$

This is solved for $\lambda(x, y, z)$ subject to the boundary condition

$$\frac{\partial \lambda}{\partial n} = 0 \quad (15)$$

at the boundary, where n is the coordinate normal to the boundary (for the lower boundary, this is the shape of the mountains). The solution is obtained numerically using a successive over-relaxation method.

Figure 7: Observed and predicted wind speed, with and without MASCON. (Osaka, Typhoon 9426).

Wind speed and surge calculations with and without MASCON are compared with data from Typhoon 9426 in Osaka Bay (the same typhoon as in the previous section) in Figures 7 and 8. Figure 7 shows that MASCON does not so greatly overestimate the wind speed as does Yoshizumi's model, although there is still some disagreement. Figure 8 shows that although still overpredicted, the surge result from MASCON agrees better with the measured surge. The 20 cm shift of data relative to the model results is presumed to be a temporary increase in sea level due to some event in the coastal ocean dynamics, such as a change in the Kuroshio current. Similar improvements were found when this model was applied to other historical typhoons and surges in Japan.

Conclusions

The modelling of coastal flooding during storm surges may be achieved using a local model with a fine grid. This could be useful in the Bay of Bengal where the

Figure 8: Observed and predicted surge, with and without MASCON. (Osaka, Typhoon 9426).

land is low, coastal defences against flooding are weak, and precise predictions of danger areas could in principle save many lives. A test case was performed for the city of Chittagong, but the results are only indicative since good land topography data were not available.

The wave field in a storm surge influences both the surface drag and, in shallow water, the bottom friction coefficients. These effects are likely to influence the size of a storm surge in some circumstances, but are not normally included in surge models. There is room for improving our understanding of the physics of these processes, especially under what circumstances they are likely to be significant. For wind stress, this should come from further collection and analysis of comprehensive and accurate field measurements of wind stress in a range of wind and wave conditions. Having done so, the effects may in principle be incorporated into surge models using results from an ocean wave model. Waves may also produce a measurable set-up at the coast.

Data taken during storms are particularly important for the storm surge problem. One such dataset, from a new tower, shows enhanced stress during a typhoon, in comparison with empirical formulae from the literature. Data from this tower add to those currently in existence and should be thoroughly analyzed as they become available. Eventually, a more accurate formulation of wave effects in surge models should be possible.

If there are high mountains near the coast, the resulting distortion of the wind field may have a measurable effect on the predicted surge. Using Yoshizumi's Model and the MASCON Model, a typhoon model in which the effects of both land topography and surface roughness are introduced has been developed. Hindcasts of the wind field have been made for various typhoons. These show

that even without using empirical attenuation parameters, it is possible to estimate the wind field in areas surrounded by mountains, such as Osaka Bay and Kii Channel. The predicted storm surges, although sometimes still over-predicted, also agree better with the data than the predictions of models with empirical attenuation parameters.

Acknowledgments

Thanks are due to Dr. H. Nakagawa of DPRI for providing the Chittagong bathymetry data; Dr. H. Yoshioka of DPRI for discussion and help with analysis of the tower data; Prof. S. Nakamura of Kyoto University's Shirahama Oceanographic Observatory for making the wind data available; Ms. M. Yelland of Southampton Oceanography Centre for advice on the inertial dissipation method and Dr. S. Smith of Bedford Institute of Oceanography for advice on the eddy-correlation method.

CHAPTER 111

THE SWASH ZONE: A FOCUS ON LOW FREQUENCY MOTION

Adam M. Shah¹ and J. William Kamphuis²

ABSTRACT

This paper presents an analysis of physical model tests of the swash zone. A mild, impermeable slope was used to create a wide swash zone. Bichromatic and irregular waves with varying wave heights, wave periods and wave grouping were tested. The experiments showed the swash zone to be dominated by low frequency motions, which were closely related to the incident wave groups. The incident waves were still grouped in the surf and swash zones.

An empirical relationship was determined, relating the long wave height at the shoreline to the deep water wave parameters. The long waves were found to be partially reflected from the swash zone and this partial reflection was successfully simulated by the superposition of an absorbed and a reflected long wave. The generation of spurious long waves and the seiche at the natural frequency of the equipment were also investigated.

INTRODUCTION

The swash zone extends from the limit of run-down to the limit of run-up. Although the very shallow water and the low incident wave energy levels in the swash zone might suggest it to be of minor importance, Kraus *et al.* (1981) and Kamphuis (1991) have shown that it contains a peak in sediment transport rate. Thus the swash zone plays an important role in shaping natural beaches. Since very little is known about flow in the swash zone, all the numerical models of beach morphology use drastic simplifications within the swash zone. The goal of this paper is, therefore, to improve the understanding of swash zone flow so that eventually the computation of beach morphology can be improved.

Wave energy in the swash zone is concentrated in the infra-gravity band, at frequencies about one order lower than the incident waves. These low frequency motions are initially generated offshore by the distribution of wave

¹ MSc, Research Assistant, Dept. of Civil Engineering, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

heights within wave groups. A Bound Long Wave travels with the incident waves at their group velocity and with its trough located under the highest waves in the group (Longuet-Higgins and Stewart, 1964).

Inshore of the break-point, the behaviour of the long waves and their interaction with individual breakers is not fully understood. One theory states that the bound long wave shoals as it travels inshore. Upon reaching the breakpoint it becomes a free long wave which is reflected seaward once it reaches the shore (Longuet-Higgins and Stewart, 1964). Another theory suggests that the amplitude of long waves decreases from the break-point and if the breaking is gentle all of the long wave energy is absorbed along with the short wave energy (Ottesen - Hansen *et al.*, 1980). Symonds *et al.* (1980) present a completely different mechanism for long waves within the surf zone. They state that the long wave motion inside the breaker zone is driven by the spatial variation of the breakpoint. As the breakpoint location varies with the group frequency it generates a long wave at that frequency. The experimental results in this paper favour a modified Longuet-Higgins and Stewart (1964) approach.

The long waves inside the breaking zone are difficult to study in the field. But they are also difficult to study in the laboratory, where studies of long waves are plagued by undesired low frequency motions resulting from spurious long waves coming off the wave generator and from seiche. Most wave generators are driven by a signal that only generates the grouped short waves and does not generate the bound long wave that accompanies the wave groups. Since the bound long wave will physically accompany the short waves anyway, this simplistic wave generation procedure amounts to generation of a spurious, free long wave equal and opposite to the bound long wave, travelling at the shallow water wave speed. Seiche (an oscillation at the natural frequency of the laboratory flume) results from transfer of wave energy into the natural frequency band of the wave flume. Such an oscillation increases with time and may eventually dominate the low frequency motion, contaminating measurements. Since the predominant mode of oscillation for the natural frequency has an antinode at the shoreline, seiche has the greatest significance in shallow water. Flick and Guza (1980) developed an expression for the natural frequency of the first mode of oscillation for a composite section, consisting of a slope and a horizontal section:

$$\sigma_n = \frac{1}{4} \pi \frac{(g\beta x_s)^{1/2}}{x_L + x_s} \quad (1)$$

where β is the slope, x_s is the length of the slope and x_L is the total length of the flume.

In view of the confusion and lack of understanding of long wave motion and the difficulties in studying long waves in the field and in the laboratory, this study (described in more detail in Shah, 1996) has the following objectives:

1. To relate the long wave at the shoreline to the offshore wave climate by a simple expression,
2. To study the development of the long wave from the breakpoint to the swash zone,
3. To study the contamination of long wave measurements by incorrect wave generation and seiche.

EXPERIMENTAL PROCEDURE

Laboratory tests were conducted at the Queen's University Coastal Engineering Research Laboratory (QUCERL) and the National Research Council of Canada (NRCC). An impermeable 0.6 m wide ramp with a 1:50 slope was installed in a 2.1 m wide wave flume at QUCERL. The mean water depth at the wave generator was 0.7 m, 26.2 m from the still water line (Figure 1). The tests at NRCC were conducted in a larger facility and made use of their more sophisticated generators. The ramp in Figure 1 was extended by 5 m, at NRCC, increasing the test depth to 0.80 m. The distance from the wave generator to the toe of the ramp was also increased from 1.2 m to 5 m.

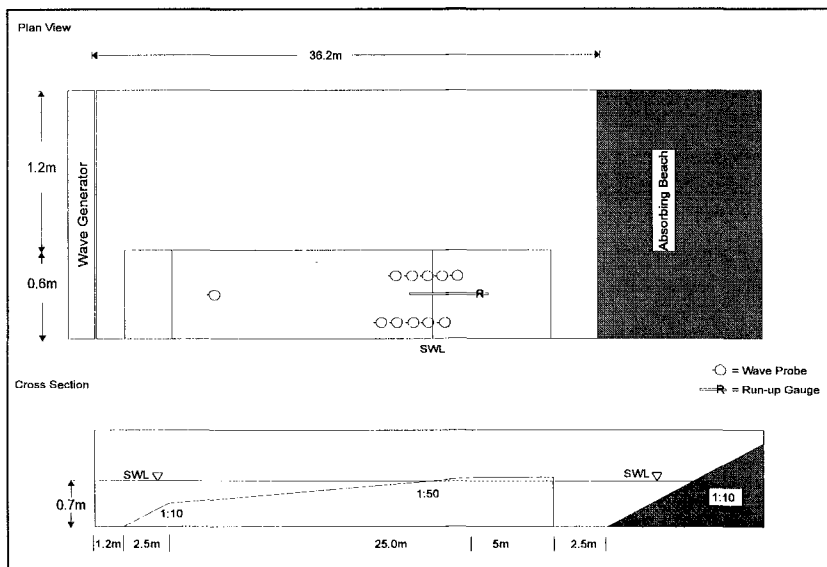

Figure 1 Experimental Setup at QUCERL

Table 1 summarizes the test series. For the irregular waves, H_s is the offshore significant wave height, T_p the peak period, and GF the groupiness factor (Funke and Mansard, 1979). For the bichromatic waves, H_1 and H_2 are the wave heights of the two components, T_{av} , the average period and T_g the group period.

Table 1 Wave Parameters Tested

Irregular Waves 19 tests at QUCERL 16 tests at NRCC			Bichromatic Waves 24 tests at NRCC			
H_s	T_p	GF	H_1	H_2	T_g	$T_{av.}$
.08 to .175 m	0.83 to 2.0 s	0.5 to 1.0	.05 to .25 m	.015 to .10 m	14 to 38 s	1.7 to 1.9 s

The effect on swash flow was measured at QUCERL by 11 capacitance wave gauges placed between 1.7 m offshore of the still water line and 0.5 m inshore. As well, a continuous run-up gauge was placed in the swash zone. At NRCC, 12 probes were placed between the breakpoint and the shoreline, to detect shoaling of the long waves and decay of the breakers through the surf zone.

The principal tool for data reduction was spectral analysis. Since all of the wave spectra showed a minimum spectral density at about one half the incident peak frequency, this was used to separate the high frequency and low frequency components. Wave heights were calculated as the zero spectral moment H_{moh} , for the high frequency ($f \geq f_p/2$) and H_{mol} , for the low frequency ($f < f_p/2$) components.

RESULTS

Swash Zone Wave Measurements

The QUCERL experiments provided high resolution measurements of water surface elevation within the swash zone. Figure 2 presents the first 50 seconds of sampling for four of the wave signals from an irregular wave test in which the initial conditions were $T_p=1.00$ s, $H_0=0.116$ m, $GF=0.94$. The heavy line is a low pass filtered signal to identify the long wave action. The low pass cut-off frequency was $f_p/2 = 0.50$ Hz. The importance of the low frequency motion ranges from minor at the offshore probe to near-total domination at the still water line.

The first panel shows the unbroken wave train for the furthest probe offshore. The groupiness of the wave train is clearly visible. In the second panel, Probe 1 was located 1.7 m offshore of the still water line, in the inner surf zone, and the wave train shows the saw-tooth profile indicative of broken waves. Though the waves are well inshore of the breakpoint they are still highly grouped and a high proportion of the incident waves are still intact. The final two panels show waves within the swash zone and present the final stages of wave decay. There are substantially fewer individual waves in the swash zone than there are incident waves as breakers coalesce into less frequent, more energetic uprush surges. The rate of decay is not the same for all the breakers. The waves that arrive at the swash zone during a strong downrush, characterized by a steep drop in water level, decay rapidly. For example, those waves arriving between 27 and 34 seconds at Probe 1 never reach Probe 2, which is only 1.2 m closer to the

Figure 2 Example Wave Trains with Low-Pass Filtering

shoreline. Waves that arrive during an uprush cycle, for example from 20 to 25 s at Probe 1, progress with much less energy dissipation and eventually correspond to the extreme uprushes.

In addition to the increase in amplitude of the low frequency motion, the phase of the low frequency motion relative to the wave groups shifts 180° as the waves approach shore. At the offshore probe, the troughs of the low frequency motion occur under the highest waves in the group, at 2, 10 and 45 s. But at the probes inshore of the breakpoint, the highest waves in the group are on the crest of the long waves. This phase shift of the low frequency motion relative to the incident wave groups is undoubtedly complicated and no satisfactory explanation or theory has yet been proposed.

Spurious Long Waves and Seiche

Some of the tests at NRCC were specifically aimed at studying the effect of undesirable, spurious long waves resulting from not generating the bound long wave in the wave generation process. Such spurious long waves were found to be negligible for the tests conducted at NRCC due to a relatively large water depth at the wave generator and the longer wave period (Ottensen-Hansen *et al.*, 1980). For the tests at QUCERL such waves were calculated to contribute 10-15% to the total measured long wave energy.

Seiche was measured by recording water levels after the wave generator was shut down. The natural period of the NRCC flume was found to be 55 s, which is somewhat larger than the value of 40 s calculated from Equation (1). The difference can be attributed to run-up. Equation (1) predicts the resonant period based on the still water dimensions of the flume, as if vertical walls existed at the generator and the still water line. In the experiments, run-up excursions of 2.5 m or more were typical and the time required for the long wave to travel this distance is significant, since the speed of propagation is very small in very shallow water. The travel time required from the original still water line to the limit of run-up and back may be approximated using an expression developed by Wilson (1966) for the natural frequency of a triangular basin:

$$t = 1.64 \frac{2L}{\sqrt{gh}} \quad (2)$$

For a typical wave set-up of 20 mm at the shoreline and a run-up excursion of 2.5 m, the additional time is 19 s and when this is added to the value calculated by Equation (1) the total of 59 s, is close to the measured value of 55 s.

Contamination by the seiche was evaluated from the energy at the natural frequency and its harmonics. Bichromatic waves excited seiche, even during short duration testing. When the group frequency approached the natural frequency, energy leaked into the natural frequency band of the flume. Figure 3 shows the energy leakage for a bichromatic test with $H_1=0.10$ m, $H_2=0.05$ m, $T_g=38$ s. The offshore spectral peak, at $X_s = 9.8$ m, is at the group frequency of 0.026 Hz while

Figure 3 Energy Leakage from Group to Natural Frequency

Figure 4 Subharmonic Excitement of the Natural Frequency

Figure 5 Build-up of Seiche Energy for Irregular Wave Testing

in the vicinity of the shoreline the spectral peak has shifted to the natural frequency of 0.018 Hz. Obviously the long wave measurements in this test were severely contaminated by seiche. Seiche was also generated when the group frequency matched a superharmonic of the natural frequency. Figure 4 shows a bichromatic wave test with $H_1=0.075$ m, $H_2=0.015$ m, $T_g=14$ s. The peak, at 0.07 Hz, is at the group frequency, the peak near 0.04 Hz is the first subharmonic and the peak near 0.018 Hz is the second subharmonic, which is also the natural frequency of the flume.

Irregular wave tests built up energy at the natural frequency over a longer duration; short duration tests did not excite appreciable seiche. Irregular waves have a broad band of group frequencies and can excite the natural frequency by a first-order interaction between any two incident group frequencies. Figure 5 presents three long wave spectra calculated at different times for the same irregular wave test with $H_o=0.175$ m, $f_p=0.5$ Hz, $f_g=0.05$ Hz. While the energy levels at and above the group frequency of 0.05 Hz were relatively constant, energy levels near the natural frequency of .02 Hz increased by a factor of six. This resulted in an incorrect increase of the calculated long wave H_{mo} from 0.04 m to 0.053 m.

Swash Zone Long Wave Height

The long wave height at the shoreline, $H_{mol,s}$ is a function of the beach slope and the deep water zero moment wave height, H_o , wave length, L_o , and Groupiness Factor. The effect of beach slope was not tested. One dimensionless expression that was found to satisfy the necessary conditions is:

$$\frac{H_{mol,s}}{L_o} = 0.078 \left(\frac{H_o}{L_o} \right)^{0.7} \quad (3)$$

It is based on the 31 irregular wave tests that were not contaminated by seiche and is shown in Figure 6. The correlation coefficient, r^2 is 0.81 and the different symbols represent ranges of groupiness. A consistent trend with groupiness is not apparent. This is, most likely because the calculation of the Groupiness Factor was affected by the reflected long wave at the offshore probe.

Long Wave Reflection Model

The cross-shore profiles of long wave height, H_{mol} , with distance offshore showed partial nodes and antinodes (the solid triangles in Figure 7). This indicates the long waves may be simulated by superimposing a reflected and absorbed long wave component. Thus, the Longuet-Higgins and Stewart (1964) development, suitably modified using partial long wave reflection is needed to explain the experimental results.

The fully reflected component was simulated by the solution presented in Lamb's (1932) for the reflection of a long wave over a sloping bottom. The height

Figure 6 Regression Results for All Irregular Wave Tests

Figure 7 Example Model Results for Bichromatic Wave Test

Figure 8 Example Model Results for Irregular Wave Test

of the standing wave envelope, ζ_r , is twice the absolute value of Lamb's Bessel function solution,

$$\zeta_r = 2\zeta_{r,s} \left| J_0 \left(\sqrt{\frac{4\sigma^2 x}{g\beta}} \right) \right| \quad (4)$$

where ζ_r is the local reflected long wave height, $\zeta_{r,s}$ is the reflected long wave height at the shoreline, J_0 is the zero order Bessel function, σ is the angular frequency of the long wave, g is the acceleration due to gravity, β is the beach slope and x is the distance offshore of the still water line. The reflected long wave is shown as the dashed line in Figure 7.

The absorbed portion of the long wave energy shoals as it travels inshore; the dotted line in Figure 7. Prior to breaking, the shoaling of the short waves will increase the height of the bound long wave. Theoretically this rate has been shown to vary with depth according to $h^{-3/2}$ by Longuet-Higgins and Stewart (1964). They assume, however, that the depth varies slowly enough that the shoaling long wave attains equilibrium. In practice the depth probably changes too rapidly for the long wave to reach equilibrium. Typically the distance from the wave generator to the breakpoint was less than one wavelength of the bound long wave and hence the actual shoaling rate was considerably smaller than $h^{-5/2}$. Since the focus of this research was on the swash zone, few probes were placed in the outer surf zone and for most tests the offshore probe was the only measured point on the bound long wave shoaling profile. Thus, a precise quantification of the bound long wave shoaling rate was not possible from these results.

If it is assumed that the bound long wave becomes a free long wave upon breaking, Green's Law, which states that the wave height of a free long wave varies with depth according to $h^{-1/4}$, can be used inside the breaker. The transition from bound to free long wave shoaling should begin where breaking is initiated. The present model assumes an abrupt transition between the two shoaling rates at the onset of breaking, as estimated using the criteria of Kamphuis (1991). This is an over-simplification; the transition is more gradual and will occur over the width of the breaking zone.

In very shallow water, wave set-up contributes to the effective depth and must be included. Theoretically, wave set-up increases linearly from the maximum set-down at the breakpoint to maximum set-up at the shoreline (Longuet-Higgins and Stewart, 1964). This relationship was a good approximation to the actually measured values of set-up. Thus, the local absorbed long wave height, ζ_a , inshore of the breaking point for a coordinate system with its origin at the still water line may be expressed, using a combination of wave set-up and wave shoaling according to Green's Law as:

$$\zeta_a = \zeta_{a,s} \left(\frac{h_o + \bar{\eta}_b + (\bar{\eta}_s - \bar{\eta}_b) \left(1 - \frac{h_o}{h_b}\right)}{\bar{\eta}_s} \right)^{-1/4} \quad (5)$$

where ζ_a is the local absorbed long wave height, $\zeta_{a,s}$ is the absorbed long wave height at the shoreline, h_o is the local still water depth, h_b is the breaking depth, $\bar{\eta}_s$ is the set-up at the shoreline and $\bar{\eta}_b$ is the set-down at the breakpoint. Offshore of the breaker

$$\zeta_a = \zeta_{a,s} \left(\frac{h_b + \bar{\eta}_b}{\bar{\eta}_s} \right)^{-1/4} \left(\frac{h_o}{h_b} \right)^{-k} \quad (6)$$

where k is the shoaling rate for the bound long wave (equal to $5/2$ if the depth is changing very slowly).

Superimposing the wave reflection analyzed from Equation (4) on Equations (5) and (6) produced Figure 7, a prediction of the local long wave height, representing the partially reflected standing wave system for a linear long wave over a sloping bottom, in the absence of losses:

$$\zeta_i = \zeta_a + \zeta_r \quad (7)$$

The model can calculate the long wave height profile if $\zeta_{a,s}$, $\zeta_{r,s}$, and σ are known. Figure 7 compares the results of the model (solid line) with measured data for a bichromatic wave test with $H_1 = 0.1$ m, $H_2 = 0.05$ m, $T_{av} = 1.9$ s, $T_g = 18$ s; the reflected and absorbed components are respectively the dashed and dotted lines. The predicted long wave profile, offshore of the first partial node, matches the observed standing wave pattern well. Inshore of this node, (at approximately $X = 2$ m), the model overpredicts the measured H_{mol} profile severely. This is because energy dissipation removes energy from the long wave system, since the extremely shallow depths make bottom friction significant. The measured profile peaks at about 1 m offshore and then abruptly decreases. Figure 8 shows similar results for an irregular wave test with $H_o = 0.175$ m, $T_p = 0.5$ Hz, $GF = 0.9$. More long wave energy is absorbed in the irregular wave test (Figure 8) than in the bichromatic wave test (Figure 7), which translates into less reflection. This may be due to the broad-bandedness of the irregular wave group frequency.

Comparable results to Figures 7 and 8 were obtained for all 15 of the 24 bichromatic tests and the 9 irregular tests at NRCC which were not contaminated by seiche.

Long wave height at the shoreline was represented by a simple empirical expression (Equation 3).

Long waves are partially reflected from within the swash zone. A model was developed that predicts the shape of the observed partial standing long wave envelope by adding the absorbed and reflected long waves (Equations 4-7). These equations take into account shoaling.

Seiche at the natural frequency of the basin was found to be a much more important laboratory effect in contaminating long wave experiments than the spurious long waves off the generator. Bichromatic tests were found to be contaminated by the seiche, when the group period approached the natural period of the flume or its superharmonics. Irregular wave tests were only contaminated when longer test durations were used.

Acknowledgments

This study was funded by the operating grants programme of the National Sciences and Engineering Research Council. The assistance of Etienne Mansard and the facilities provided by the National Research Council of Canada Hydraulics Laboratory are greatly appreciated. The funding for Adam Shah to attend ICCE '96 was provided by the Queen's University School of Graduate Studies.

CHAPTER 112

THE DEVELOPMENT OF AN ON-LINE, INTERACTIVE, TSUNAMI-INFORMATION RESOURCE

Benjamin Cook¹, Catherine Petroff²

ABSTRACT

Tsunami! (<http://www.geophys.washington.edu/tsunami/welcome.html>) is a WWW site developed at the University of Washington with collaborative support from the global tsunami research community. The site originated as an on-line documentation of the 1994 East Java tsunami survey. The field survey documentation was developed to serve as a prototypical WWW resource whose form can be amended and improved upon for future on-line tsunami survey documentation. Educational and hazard mitigation resources were added to the site to provide the general public with an on-line source of tsunami information. The site's content and interface design were strongly influenced by the wide range of network connections and browser applications utilized by the target audience.

INTRODUCTION

The World-Wide Web (WWW) can be thought of as the virtual network of information accessible over the Internet using the HyperText Transmission Protocol (HTTP), the WWW communication standard. A collection of WWW documents with a common theme served by a computer(s) is often called a WWW or Web site. *Tsunami!* is a prototypical WWW site developed at the University of Washington with collaborative support from tsunami researchers around the world. Multimedia-supported resources currently available through the site include the following: Explanations of the physics of tsunamis; case studies of significant historical

1) Hydraulic Engineer, WEST Consultants, 2101 4th Avenue, Suite 1050, Seattle, WA 98121, USA.

2) Assistant Professor, Department of Civil Engineering, University of Washington, Seattle, WA 98195, USA.

tsunamis; hazard management and prevention information; recent event documentation; and an index of tsunami-related WWW sites.

The site originated as an on-line documentation of the 1994 East Java tsunami survey. On June 3, 1994, a large earthquake occurred off the southeastern coast of Java near the east end of the Java Trench in the Indian Ocean (Figure 1). The 7.2 M_s earthquake generated a devastating tsunami that took the lives of approximately 200 East Java residents (Synolakis et al., 1995). An international tsunami survey team, which included tsunami scientists and engineers from Indonesia, Italy, Japan, and the United States, visited the impacted areas of Bali and Java from June 20 to June 25, 1994. Survey team members measured runup heights along the southwestern coast of Bali and the southeastern coast of Java (Figure 2), and examined tsunami-induced sedimentation and structural damage. They also interviewed coastal residents to determine the distribution of seismic intensity and collect eyewitness accounts of the tsunami attack (Tsuji et al., 1995). In addition to the quantitative data collected during the survey, visual data such as slides, photographs, and video footage were also gathered. The visual data include photographs that depict sedimentation and structural damage observed by survey team members (Figure 3), as well as water and debris marks noted in the runup surveys.

Figure 1. Locator map for the 1994 East Java survey.

Due to the limited number of tsunami scientists who were able to participate in the field survey, dissemination of the visual and quantitative data gathered during the survey was considered to be an important part of the documentation effort. Since the physical duplication and distribution of the visual data to tsunami scientists located throughout the world was logistically impractical, the feasibility of

distributing digitized visual data with an Internet information-exchange service was explored. It was found that the WWW allowed for an easily implemented and distributed multimedia presentation of the survey data. Non-platform specific, the WWW enables the electronic publishing of documents, which can include both text and graphics, to any computer connected to the Internet and equipped with browser software. Browser applications, through their graphical interface, allow users to access and view WWW documents, often referred to as WWW pages. A variety of media resources, including graphics such as survey maps, as well as audio and video clips, can be incorporated into a WWW page. Another WWW feature, interactive graphics called image maps, allows users to retrieve information associated with a particular region of an image.

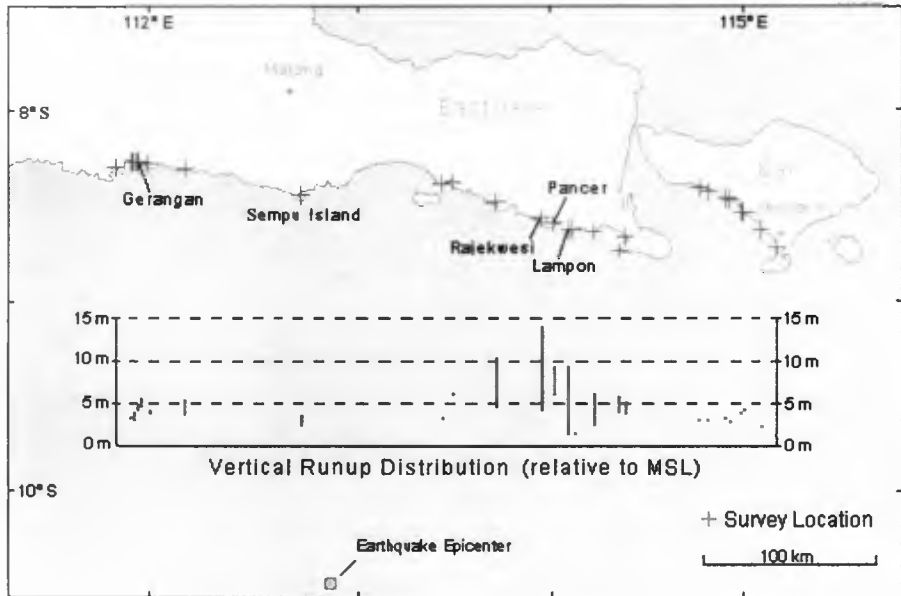

Figure 2. Interactive runup distribution map of 1994 East Java survey area.

FIELD SURVEY DOCUMENTATION

For the East Java survey, visual, damage, and runup data related to the event are accessed through an interactive runup distribution map of the survey area (Figure 2). Site-specific survey data are downloaded by selecting the survey location of interest from the image map. Runup data are presented in a tabular format including raw data (as recorded in the field) and corrected data that have been adjusted for the difference in the tidal level at the time of the tsunami attack and the time of the runup measurements (Tsuji et al., 1995). The visual data were prepared in two resolution formats. By default, the user is presented with small, low-resolution annotated

Figure 3. Sample digitized slide showing a scarp in Rajekwesi, East Java formed by tsunami-induced erosion.

digital images called in-line images. Relatively small in file size (less than 10 kilobytes), the in-line images are more quickly transferred over the Internet, facilitating the rapid navigation of the visual data. The in-line images function as links to higher-resolution images, which can be accessed by clicking on the in-line image of interest.

The East Java tsunami survey documentation was developed to serve as a prototypical document whose form can be amended and improved upon for future WWW tsunami-survey documentation. As shown schematically in Figure 4, a more comprehensive on-line documentation is proposed for future tsunami surveys that would serve as a data source for tsunami scientists and hazard management professionals. An event overview section could provide summary information about the event, the survey itinerary and team members, as well as links to other related WWW documents. Data sections accessible through the event overview could include earthquake source information provided by seismologists, historical data pertaining to local seismic and tsunami activity, and instrument records (when available) from tide gauges, deep-ocean pressure transducers, and remote sensing.

Data pertaining to specific survey sites could be accessed through an interactive survey area map, such as the one used in the East Java documentation (Figure 2). Survey site overviews could provide brief descriptive summaries of the observed local runup and flow characteristics, and tsunami-induced sedimentation and structural damage. A local map could be presented in conjunction with audio-visual data gathered at the survey location. Site-specific runup, sedimentation, damage, and emergency management data could be presented in subordinate sections. For example, a runup data section for a specific survey site might include an

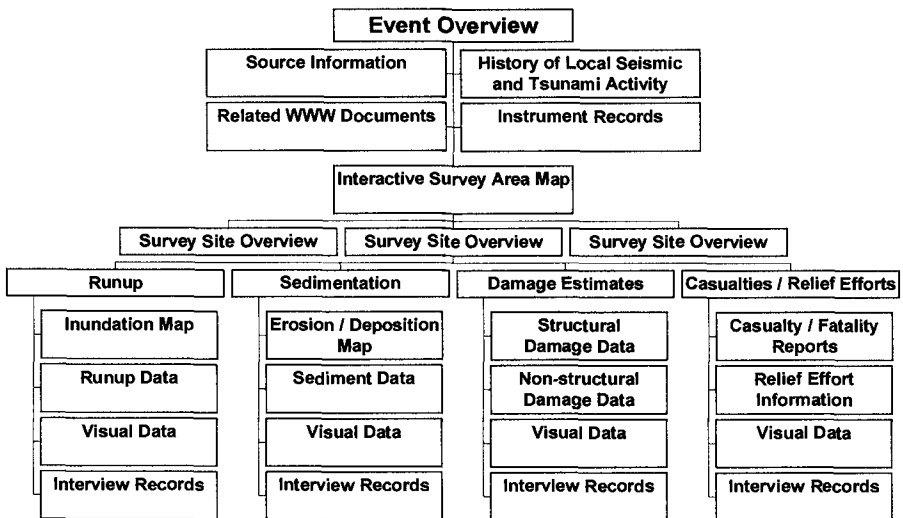

Figure 4. Resource hierarchy tree for tsunami survey documentation.

inundation map, surveyed runup measurements, annotated visual data showing water marks, trace evidence, and indicative debris, and interview records. Borrowing on the multimedia capabilities of the WWW, interview records could be presented in written form and as audio clips, both in the native language of the interviewee and in English.

At present, the preparation of an on-line multimedia survey documentation is technically challenging and labor intensive. Emerging software and hardware technologies should greatly facilitate future tsunami survey documentation efforts. For example, the use of digital cameras in field surveys would allow for the direct uploading and WWW publication of visual data. The level of detail of future documentation will vary as a function of the perceived scientific importance and human impact of a particular tsunami event. With limited public funding available for tsunami field surveys, the WWW enables the cost-effective documentation and world-wide dissemination of field survey data to tsunami scientists and emergency management professionals.

SITE RESOURCES

Additional resources were added to the site to meet the general public's broader needs for hazard mitigation and educational information. In addition to researchers and hazard management professionals interested in recent event data, the site's audience includes secondary and university students, and residents of tsunami-threatened coastal communities. In recognition of the diverse information needs of this group, *Tsunami!*'s on-line resources include educational information about the physics of tsunamis, significant historical tsunamis, the Tsunami Warning System and hazard mitigation. A top-level flow chart of the subject material presented on the site is shown in Figure 5. Referred to as a resource hierarchy tree, it represents, in a general sense, the logical order in which the site developers attempted to present the resources. The site's directory structure reflects the resource hierarchy tree, assuring continuity for inter-linked documents throughout the development process.

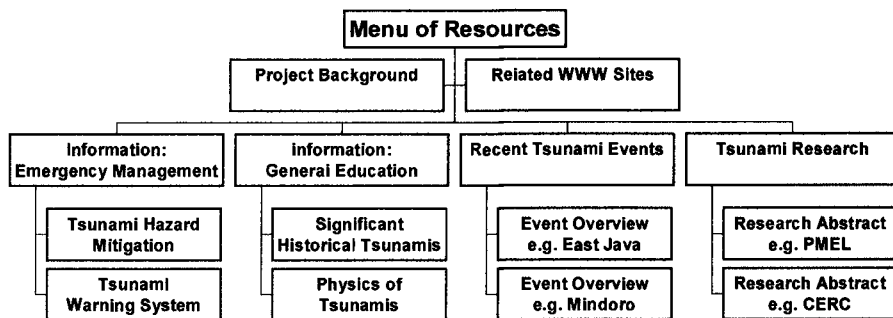

Figure 5. Top-level resource hierarchy tree for the WWW tsunami site.

With roughly 500 animation, audio, image, and text files accessible through the site, link management was an important issue that had to be addressed in site development. Similar subordinate flow charts were conceived for several of the more extensively-developed sections shown in Figure 5, including the "Physics of Tsunamis" and "Event Overview" sections (for example, see Figure 4).

CONTENT AND INTERFACE DESIGN

The site's content and interface design were strongly influenced by the technical constraints imposed by the wide range of network connections and browser applications utilized by the target audience. At present, there are some inherent technical limitations, such as network bandwidth, that strongly impact the design of a WWW site. Restricted local and global network bandwidth often prevents the rapid transfer of information necessary to allow the interactive navigation of the WWW. WWW-related computer hardware, software, protocols, and languages are also swiftly changing.

Several types of Internet connections exist. The fastest connections, commonly available on university campuses and at large corporate facilities, are Ethernet connections. Users accessing the Internet over Ethernet connections can consistently realize file transfer rates, or throughput, of over 100 kilobytes per second (KB/s). However, many of site's potential users are limited to dial-up Serial Line Internet Protocol (SLIP) or Point-to-Point Protocol (PPP) connections through modems, with typical baud rates (bits per second) of 9,600 - 28,800, limiting theoretical throughput over these dial-up connections to between one and three KB/s (Krol, 1994). Throughput can be further diminished by heavy local and regional network traffic.

This wide range in throughput poses a significant development problem as multimedia resources are information-rich and hence inherently large in file size. Image files, even when stored in the compressed formats cited later in this paper, can be well over 100 KB in size. Animations, even relatively short clips several seconds in length, can be one or more megabytes. Considerable effort was taken to present information on the site in the least data-intensive format for the primary links. Additional link-options, intended for users on high-bandwidth connections, are available to provide access to data-rich resources such as high-resolution images and animations. With the exception of the high-resolution images and animations, most of the site's pages have been kept to well under 50 KB, allowing even dial-up users to quickly download and browse through pages containing in-line images.

Compounding the at least two order of magnitude difference in throughput experienced by the site's target audience, the language used to format documents, HyperText Markup Language (HTML), continues to evolve. At the time of the site's initial development (summer 1995), most graphics-capable browsers supported HTML 2.0, but did not support the then newly-proposed standard, HTML 3.0. HTML 3.0 implemented several features, including table formatting and sophisticated image formatting, not available with HTML 2.0, and was used exclusively for the site's page development because of these advanced features. For site resources to be easily accessed and properly displayed, developers need to

accurately assess the hardware and software capabilities of their site's prospective audience. Following this assessment, document formatting standards and multimedia content can be appropriately selected.

RESOURCE DEVELOPMENT AND SITE IMPLEMENTATION

The site presents a variety of media resources, including graphics, sounds, and animations. These resources were originally delivered to users over the Internet by a dedicated server set up specifically to support the site. It is beyond the scope of this paper to discuss in detail the digitization techniques and editing employed in the development of the site's multimedia resources. Digitization considerations include data preparation (e.g., cleaning of slides), digitization device and resolution selection. Post-digitization filtering, such as image sharpening, can greatly improve digital image quality. Various compression algorithms are available that significantly reduce file size while preserving visual and audio quality. The interested reader is referred to numerous on-line resources or in-print publications (see, for example, Murray, 1994).

Digitization Techniques

A variety of digitization devices are currently available for converting hard-copy images and analog audio and video signals into digital data. For this project, flatbed scanners were used to digitize hard-copy images such as slides and photographs. A Macintosh Quadra with hardware-assisted compression provided by a Digital Film frame-grabber board was used to capture video footage. *Adobe Premier* was used as the software interface for the capture board and served as a powerful editing environment for the acquired digital clips. Sounds were digitized with an analog-to-digital converter supported by the Macintosh's built-in sound capabilities.

Two types of graphics file formats were used to store the images presented on the site; the Joint Photographic Experts Group (JPEG) format is used for in-line and high-resolution digital images produced from photographic images, while the Graphic Interchange Format (GIF) format is used for maps, image maps, and icons that were digitally generated. JPEG images, with their 24-bit pixel depth, can contain over 16 million colors, while GIF images are limited to 256 colors because of the format's 8-bit pixel depth. Digital movies were stored in the cross-platform flattened QuickTime format with Cinepak compression. Lastly, the AU file format was used for audio clips.

HTTP Server Setup

WWW documents are distributed over the Internet by HTTP servers. In many cases, organizations may have an existing HTTP server, and the publication of WWW documents simply requires that newly-developed HTML files be transferred to the HTTP server. Although a departmental HTTP server was available with limited storage space, for this project a Macintosh HTTP server was initially set up to facilitate site development. The creation of the dedicated server allowed for the autonomous administration of the WWW tsunami site during the development

period. The HTTP server consisted of a Macintosh SE-30 running *MacHTTP 2.2* that was connected to the University of Washington's Ethernet network. Remarkably, this somewhat outdated configuration performed almost flawlessly for one year, distributing data to the more than 10,000 users who accessed the site over this period. Increased server demand during the summer of 1996 necessitated the site's move to a UNIX-based workstation.

FUTURE WORK

As the tsunami research and hazard management community's information exchange and dissemination needs become better defined, *Tsunami!* can be easily expanded and revised. Future development efforts that have been considered include real-time tsunami warning dissemination, event management, and post-event survey administration. In cooperation with the Pacific Tsunami Warning System, tsunami warnings and preliminary event information could be globally disseminated over the WWW. Event information could be complemented by regional hazard management resources, including inundation maps and evacuation procedures. Post-event data collection could be facilitated with the on-line distribution of survey guidelines, survey itineraries, and preliminary visual and runup data. Finally, educational offerings could be expanded to include interactive demonstrations, which could be developed in the Java programming language, of tsunami generation, propagation, and inundation mechanisms.

ACKNOWLEDGMENTS

Funding for *Tsunami!*'s development was provided by the U.S. Department of Defense, through the National Defense Science and Engineering Graduate (NDSEG) Fellowship Program. Researchers who contributed to the development of the site are acknowledged individually at the following on-line location: (<http://www.geophys.washington.edu/tsunami/background/acknow.html>).

CHAPTER 113

LONG WAVE RUNUP ON COASTAL STRUCTURES

Utku Kânoğlu¹ and Costas Emmanuel Synolakis²

Abstract

We present a general method for determining the runup and the amplification explicitly for nonbreaking long waves propagating over piecewise linear topography, using the linear shallow water wave equations. We associate each constant-depth segment and each linearly-varying depth segment with (2×2) matrices and we calculate the transmitted wave amplitude after propagating over any number of segments explicitly. We then extend our methodology to the three dimensional topography of a conical island. Our method is applicable in the design of dikes, sea-walls and other coastal structures.

INTRODUCTION

The September 2, 1992 Nicaragua tsunami, the December 12, 1992 Flores island tsunami, the July 12, 1993 Hokkaido tsunami, the June 2, 1994 East Java tsunami, on October 2, 1994 Kuril Islands, Shikotan tsunami, the November 11, 1994 Mindoro Island tsunami, the February 17, 1996 Biak, Irian Jaya tsunami, and the February 27, 1996 Peru tsunami were eight major devastating geophysical events that caused severe property damage and killed an estimated 2000 people. Field observations raised new questions about the suitability of the standard paradigm of a tsunami model, i.e. a solitary wave attacking a plane beach. For one, most of the eyewitness reported waves which caused the shorelines to recede first before advancing; these waves were studied by Tadepalli and Synolakis and they are now called leading-elevation N-waves (Tadepalli and Synolakis, 1994). Then, practically all field-measured

¹Research associate, School of Engineering, University of Southern California, Department of Civil Engineering, University Park, Los Angeles, California 90089-2531, USA.

²Professor, School of Engineering, University of Southern California, Department of Civil Engineering, University Park, Los Angeles, California 90089-2531, USA.

runup distribution showed three-dimensional effects which had been counter-intuitive. For example, during the 12/12/92 Flores Island tsunami, 263 people were killed and two fishing villages completely annihilated on Babi Island, a small volcanic islet off Flores; all damage concentrated on the tsunami wise and wind-wave wise lee side of the island. During the 9/2/92 Nicaraguan tsunami, the runup varied by a factor of 4 between locations distant less than a mile from each other, suggesting that even though the tsunamis are long waves, local bathymetric features of much smaller length scale did influence the wave runup. A recent increase in tsunami incidence and an abundance of new observations of coastal effects added urgency to the resolution of the question to determine a priori how a given topography will affect the wave evolution.

Besides tsunamis, the long wave theory presented here can be used for the calculation of the runup and evolution of certain wind generated waves particularly in the infragravity spectral band. The numerical solution of the nonlinear shallow-water wave equation were used to calculate the runup of wind swell (Raubenheimer *et al.*, 1995). Also, it has long been known that the runup predicted by the nonlinear shallow-water wave equation is mathematically the same of that predicted by the linear shallow-water wave equation for the one slope beach case (Carrier, 1966; Synolakis, 1987).

FORMULATION OF THE PROBLEM

We will describe a new general method that will provide a closed form analytical solution to determine the relationship between the amplification factor and the incident wave amplitude for the two-dimensional topographies. Given that any physically realistic topography is unlikely to consist entirely of a single-sloping beach or a single constant-depth segment, and to allow the use of analytical (non-numerical) solutions, it is incumbent to be able to break down the physical propagation problem into a series of linear problems which can then be solved with standard method analytically. The proposed method of solution consists of representing a given topography by a series of constant-depth and linearly-varying depth segments.

We will use the linear shallow-water wave equation to solve the propagation problem over linear topographies; this equation is

$$\eta_{tt} - (\eta_x h)_x = 0. \quad (1)$$

We introduce dimensionless variables using a reference undisturbed offshore water depth d as the characteristic length scale, and $\sqrt{d/g}$ as the characteristic time scale. With time harmonic dependence of the form $\eta(x, t) = \zeta(x) e^{-i\omega t}$, for the wave evolution over the dimensionless constant-depth $h(x) = h_c$, equation

(1) becomes,

$$h_c \frac{d^2 \zeta(x)}{dx^2} + \omega^2 \zeta(x) = 0. \quad (2)$$

The general solution is

$$\eta(x, t) = \{A_1 e^{-\frac{i\omega x}{\sqrt{h_c}}} + B_1 e^{\frac{i\omega x}{\sqrt{h_c}}}\} e^{-i\omega t}, \quad (3)$$

where A_1 and B_1 are arbitrary constants. If the depth is linearly-varying and defined by $h(x) = mx + n$ with $m \neq 0$ and n constant, the field equation is

$$(mx + n) \frac{d^2 \zeta(x)}{dx^2} + m \frac{d\zeta(x)}{dx} + \omega^2 \zeta(x) = 0. \quad (4)$$

The eigenfunctions of the field equation are two zeroth-order linearly independent solutions of Bessel's equation, e.g. J_0 and Y_0 . Then the solution for evolution over variable depth is

$$\eta(x, t) = \{A_2 J_0(2\omega\sqrt{\xi}) + B_2 Y_0(2\omega\sqrt{\xi})\} e^{-i\omega t}, \quad (5)$$

with $\xi = \sqrt{(x + n/m)/m}$, where A_2 and B_2 are arbitrary constants.

From the solutions (3) and (5), the appropriate form of η is chosen for each segment. Continuity of the surface elevation and of the mass flux provides two equations at each transition point between the adjacent segments and the unknowns such as A_1 , B_1 , A_2 , B_2 can be calculated from these interface matching conditions.

In general, an m -segment topography involves m -sets of (3) and (5) type eigenfunction expansions, each with 2 unknown coefficients. Given that the incoming wave height is known, $(2m - 1)$ coefficients have to be determined, requiring $(2m - 1)$ equations for closure. To this end, continuity of the surface elevation and of the mass flux boundary conditions must be considered at each transition point between the adjacent segments. These boundary conditions provide $(2m - 2)$ equations. The conditions of transmission at the segment, or the condition of bounded solution at the coastline or perfect reflection off a wall provide one additional equation. Adding a new segment introduces two more unknown coefficients, but at the same time also allows to write two new boundary conditions. This extends the order of the system of equations by two. Thus the wave evolution over any topography composed of any number of piecewise linear segments can be calculated.

Our method consists of establishing basic topography segments, i.e. a constant-depth segment, a linearly-varying depth segment. Each segment has a (2×2) matrix that incorporates its topographic feature. We associate each constant-depth segment of depth h_r with a segment matrix,

Figure 1. Definition sketch of the Revere Beach topography (not to scale).

$$K_{pr} = \begin{pmatrix} e^{-\frac{i\omega x_p}{\sqrt{h_r}}} & e^{\frac{i\omega x_p}{\sqrt{h_r}}} \\ i e^{-\frac{i\omega x_p}{\sqrt{h_r}}} & -i e^{\frac{i\omega x_p}{\sqrt{h_r}}} \end{pmatrix}. \quad (6)$$

We associate each linearly-varying depth segment with $h_r(x) = m_r x + n$ with $m_r \neq 0$ and n constant with the segment matrix,

$$S_{pr} = \begin{pmatrix} J_0(2\omega\sqrt{\xi_{pr}}) & Y_0(2\omega\sqrt{\xi_{pr}}) \\ J_1(2\omega\sqrt{\xi_{pr}}) & Y_1(2\omega\sqrt{\xi_{pr}}) \end{pmatrix}, \quad (7)$$

with $\xi_{pr} = \sqrt{(x_p + n/m_r)/m_r}$. The subscripts p and r identify the transition point and the segment number increasing from the seaward to the shoreward.

Using these topographic-feature matrices, it is possible to write a matrix equation between the unknowns of the eigenfunction expansion. We will provide a specific example for application of this general method.

REVERE BEACH

A physical model of the Revere Beach—located approximately 6 miles northeast of Boston City of Revere, Massachusetts—was constructed at Waterways Experiment Station (WES), US Army Corps of Engineers Coastal Engineering Research Center (CERC), by Ward who investigated the beach erosion and flooding problems (Ward, 1995). Moreover it presented a unique opportunity to evaluate the predictions of the general method presented here. The model of the Revere Beach consisted of three piecewise linear, 1 : 13,

1 : 150 and 1 : 53 slopes from seaward to shoreward respectively, with a vertical wall at the landward end of the compound slope and it is shown in figure 1.

Analytical Solution

Alternative to the conventional method of solution –try to solve $(2m - 1)$ equation numerically– using the general methodology presented here boundary conditions for each transition point can be written as a matrix equation;

$$S_w A_1 = V_1, \quad (8)$$

$$S_{11} V_1 = S_{12} V_2, \quad (9)$$

$$S_{22} V_2 = S_{23} V_3, \quad (10)$$

$$S_{33} V_3 = K_{34} V_4, \quad (11)$$

and finally

$$S_w A_1 = S_{11}^{-1} S_{12} S_{22}^{-1} S_{23} S_{33}^{-1} K_{34} V_4. \quad (12)$$

Here V_1, V_2, V_3 and V_4 are column unknown vectors for each segment. Using the naming style presented for the topographic–feature matrices,

$$\begin{pmatrix} 1 \\ -J_1\left(\frac{2\omega\sqrt{h_w}}{m_1}\right)/Y_1\left(\frac{2\omega\sqrt{h_w}}{m_1}\right) \end{pmatrix} A_1 = \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) & Y_0\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) \\ J_1\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) & Y_1\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) \end{pmatrix}^{-1} \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) & Y_0\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) \\ J_1\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) & Y_1\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) \end{pmatrix} \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) & Y_0\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) \\ J_1\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) & Y_1\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) \end{pmatrix}^{-1} \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_2}}{m_3}\right) & Y_0\left(\frac{2\omega\sqrt{h_2}}{m_3}\right) \\ J_1\left(\frac{2\omega\sqrt{h_2}}{m_3}\right) & Y_1\left(\frac{2\omega\sqrt{h_2}}{m_3}\right) \end{pmatrix} \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_3}}{m_3}\right) & Y_0\left(\frac{2\omega\sqrt{h_3}}{m_3}\right) \\ J_1\left(\frac{2\omega\sqrt{h_3}}{m_3}\right) & Y_1\left(\frac{2\omega\sqrt{h_3}}{m_3}\right) \end{pmatrix}^{-1} \begin{pmatrix} e^{-\frac{i\omega x_3}{\sqrt{h_4}}} & e^{\frac{i\omega x_3}{\sqrt{h_4}}} \\ i e^{-\frac{i\omega x_3}{\sqrt{h_4}}} & -i e^{\frac{i\omega x_3}{\sqrt{h_4}}} \end{pmatrix} \begin{pmatrix} A_i \\ A_r \end{pmatrix}. \quad (13)$$

Notice that first the matrix equation (8) represents perfect reflection boundary condition, $\partial\eta/\partial x = 0$, since the topography has finite depth (h_w) at the shoreline ($x = 0$). We evaluate the following integral to find time histories of surface elevation at any given location;

$$\eta_j(x, t) = \int_{-\infty}^{+\infty} \Phi(\omega) \{A_j J_0\left(\frac{2\omega\sqrt{h_j(x)}}{m_j}\right) + B_j Y_0\left(\frac{2\omega\sqrt{h_j(x)}}{m_j}\right)\} e^{-i\omega t} d\omega, \quad (14)$$

where $j = 1, 3$ represents the segment number. The unknowns of the eigenfunction expansion can be determined equations (8) through (12). Here $\Phi(\omega)$

is the Fourier transform of the initial solitary wave profile located at $x = x_s$ and given by $(2/3)\omega \operatorname{cosech}(\alpha\omega) e^{i\omega x_s}$ with $\alpha = \pi/2\gamma$ and $\gamma = \sqrt{3H/4}$ (Synolakis, 1986). H is the dimensionless incoming waveheight.

We evaluated the integral (14) at the shoreline ($x = 0$) using the contour integration technique to find an analytical expression for the maximum runup (Kânoğlu, 1997). With asymptotic analysis, we found that the maximum runup for the Revere Beach can be given by

$$R = 2 h_w^{-1/4} H; \quad (15)$$

the maximum runup depends only on the incoming waveheight H and on the depth at the wall h_w .

Experimental Results

We performed the experiments 23.2m-long, 45cm-wide glass-walled flume. The wave maker was located 23.22m away from the wall. Ten wave gages were located to record time histories of free surface displacements as shown in figure 1. Gage 4 was moved to a half-wavelength away from the toe of the 1 : 53 slope. This gage was used to define the waveheight of the incoming wave and its location, ensured that all waves propagated the same relative distance of a half wavelength ($L/2 = (1/\gamma)\operatorname{arccosh}\sqrt{20}$) between the reference location and the toe of the beach. This localization is the standard method for referencing the heights of solitary waves climbing up a sloping beach (Synolakis, 1986 and 1987). Experiments were carried out at two different water depths, 18.8cm and 21.8cm. The experiments are described elsewhere in detail (Briggs *et al.*, 1997; Kânoğlu, 1997).

Figure 2. Comparison of the maximum runup between the analytical solution and the laboratory data for two different depth $d = 18.8\text{cm}$ and $d = 21.8\text{cm}$.

Figure 3. Comparison of the time histories of surface elevations between the analytical solution (evaluation of the integral 14) and the laboratory data for $d = 21.8\text{cm}$ and $H = 0.0378$ case at three gages. Dotted lines represent the laboratory results.

A comparison of theory predictions with laboratory data is presented here. We compared the maximum runup heights and the time series of surface elevations predicted by the general method with the laboratory data in figure 2 and figure 3 respectively.

THE CONTINENTAL SHELF AND SLOPE

Our objective is to obtain the amplification factor \mathcal{A} in the first segment and the reflection coefficient A_r in the third segment in terms of the incident wave amplitude A_i . We use general methodology to write a matrix equation to obtain analytical solution;

$$S_{11} \mathcal{A} = S_{12} V_2, \tag{16}$$

$$S_{22} V_2 = K_{23} V_3, \tag{17}$$

Combining the two matrix equations, it is possible to write the following matrix equation;

$$S_{11} \mathcal{A} = S_{12} S_{22}^{-1} K_{23} V_3. \tag{18}$$

Using the naming style for the topographic-feature matrices,

Figure 4. Definition sketch for the continental shelf and slope topography.

$$\begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) \\ J_1\left(\frac{2\omega\sqrt{h_1}}{m_1}\right) \end{pmatrix} \mathcal{A} = \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) & Y_0\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) \\ J_1\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) & Y_1\left(\frac{2\omega\sqrt{h_1}}{m_2}\right) \end{pmatrix} \begin{pmatrix} J_0\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) & Y_0\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) \\ J_1\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) & Y_1\left(\frac{2\omega\sqrt{h_2}}{m_2}\right) \end{pmatrix}^{-1} \begin{pmatrix} e^{-\frac{i\omega x_2}{\sqrt{h_3}}} & e^{\frac{i\omega x_2}{\sqrt{h_3}}} \\ i e^{-\frac{i\omega x_2}{\sqrt{h_3}}} & -i e^{\frac{i\omega x_2}{\sqrt{h_3}}} \end{pmatrix} \begin{pmatrix} A_i \\ A_r \end{pmatrix}. \tag{19}$$

Here \mathcal{A} is the unknown scalar – To ensure a bounded solution at the coastline, as in the single beach case, the unknown coefficient in the eigenfunction equation for Y_0 must be set equal to zero. This gives a scalar unknown for this segment.– for the first segment and V_2 and V_3 are the column unknown vectors for the second and third segments respectively.

The transmitted wave to the beach is given by

$$\eta_1(x, t) = \int_{-\infty}^{+\infty} \Phi(\omega) \mathcal{A} J_0\left(\frac{2\omega\sqrt{h_1(x)}}{m_1}\right) e^{-i\omega t} d\omega. \tag{20}$$

Again here $\Phi(\omega)$ associated with initial solitary wave profile. Amplification factor \mathcal{A} can be determined from equation (19). Using the asymptotic analysis, the maximum runup can be given by

$$R = 2.831 \sqrt{1/m_1} H^{5/4}. \tag{21}$$

This is the same analytical expression that Synolakis (1986) found for the single sloping beach case, implying that at least for long waves the runup only depends on the beach slope closest to the shoreline. To better understand these results, different hypothetical topographies of the continental shelf and slope will be investigated next, by changing the transition point and the wave height H the effects of the slopes on the maximum runup are analyzed. Maximum runup calculations are based on the evaluation of the maximum of the integral (20). Maximum runup calculations are shown in figure 5 for the different ranges of parameters; i.e. H , h_1 , m_1 and m_2 . It is clear from the figure that the most dominant parameter on the maximum runup is the slope of beach closest to the shoreline; i.e. m_1 . More parametric analysis can be found elsewhere (Kânoğlu, 1997).

Figure 5. The effect of the parameters m_2 , h_1 and H on the maximum runup for the continental shelf and slope with $m_1 = 1/20$ - $h_1 = 0$ means topography only with m_2 slope and $h_1 = 1$ means topography only with m_1 slope-.

Figure 6. Island slope in a stepwise fashion.

CONICAL ISLAND

The overall good agreement between the analytic results and the laboratory data for the two-dimensional topography of the Revere Beach suggested the implementation of a similar methodology, i.e. usage of piecewise linear topographies for the three-dimensional topographies.

Analytical Solution

Here we will use linear shallow-water wave equation in polar coordinates. Given the singularity of the equation of motion in the case of the conical island $h(r) = m(r - a) - m$ and a are the slope and the waterline radius of the conical island, respectively— one method of removing it is to approximate the surface of cone with cylindrical boxes—Henceforth a cylindrical box will be referred to as a sill— in a stepwise fashion as in figure 6. For example in the segments, the basic solutions are

$$\eta_j = \sum_{n=-\infty}^{+\infty} e^{i(n\theta - \omega t)} \begin{cases} \{A_{n,i} e^{-\frac{i n \pi}{2}} J_n(kr) + A_{n,r} H_n^{(1)}(kr)\} & r \geq b, \\ \{A_n J_n(kr) + B_n Y_n(kr)\} & r_j \leq r \leq r_{j+1}, \end{cases} \quad (22)$$

where b is the radius of the conical island at the toe, $k = \omega/\sqrt{h_j}$ and j represents the segment number. Given that the solution is known for evolution over a sill, the dividing the solution over the conical surface involves matching solutions at the interface of steps on segments. At the edge of each sill, in other words at a discontinuity in h , it will be required that the surface elevation and the normal component of the mass flux are continuous. At the shoreline ($r = a$); the later matching condition requires that $\partial\eta/\partial r|_{r=a} = 0$. Again here instead of trying to solve the system of equations which can be set up from the matching conditions, we will use (2×2) matrices to get solutions as described two-dimensional case. Details of the analytical study are described by Kânoğlu (Kânoğlu, 1997).

Figure 7. Definition sketch of the basin (not to scale).

Experimental Study

We performed a series of large scale laboratory experiment –in a 30m wide and 25m long basin– at CERC for a conical island. Conical island –60cm high, 7.2m toe diameter and 2.2m crest diameter and 1 : 4 slope– was located in the middle of the basin as shown in figure 7. We varied the water depth, the solitary wave height, the horizontal length of the source and the eccentricities. We recorded the time histories of surface elevation at 27 locations and we measured maximum runup heights at 24 locations around the island. The experiments are described elsewhere in detail (Liu *et al.*, 1995; Briggs *et al.*, 1994; Kânoğlu, 1997). In most cases, the maximum runup heights are the largest at the front of the island and it decreases gradually toward the lee side of the island. Because of the collision of the two trapped waves, there is a drastic increase in the maximum runup height at the lee side of the island. Furthermore, in some cases as in figure 8, the maximum runup heights at the lee side of the island are larger than that of the front side.

We compared the maximum runup heights and the time series of surface elevations predicted by the general method with the laboratory data. Comparisons for the maximum runup and time histories of surface elevation are shown in figure 8 and 9 respectively.

Figure 8. Comparison between analytical solution and experimental results for maximum runup for two different waveheights H .

CONCLUSIONS

Comparisons between the analytical and experimental results are in good agreement for the maximum runup and the time series of surface elevation in both cases, i.e. the Revere Beach and the conical island experiments. For the conical island, we observe that the maximum runup height is largest in the front of the island and it decreases gradually toward the lee side of the island. Because of the collision of the two trapped waves, there is a drastic increase in the maximum runup height at the lee side. As suggested by Yeh (Yeh *et al.*, 1994), our results also confirm the mechanism of catastrophe around Babi island.

CHAPTER 114

OFFSHORE TSUNAMI PROFILES OBSERVED AT THE COASTAL WAVE STATIONS

Toshihiko NAGAI¹, Noriaki HASHIMOTO²,
Kazuyoshi SHIMIZU³, and Fujio KITAMURA⁴

ABSTRACT

This paper presents offshore tsunami profiles observed by NOWPHAS (Nationwide Ocean Wave Information Network for Ports and Harbours) wave-measuring instruments installed at various coastal wave stations and tide stations in Japan. Included are wave profiles of damage-inflicting tsunamis generated by the 1993 Hokkaido-Southwest Earthquake, the 1994 Hokkaido-Eastoff Earthquake, the 1996 Iri-Anjaya Earthquake, and other smaller recently occurring tsunamis. Also presented are characteristics and phenomena of interest clarified through various analyses performed on observational data.

Introduction

Analysis of observed offshore tsunami profiles provides valuable information for clarifying their characteristics, which is essential for preventing disastrous consequences. Here, we present profiles of several damage-inflicting tsunamis which recently struck Japan, i.e., tsunamis generated by the 1993 Hokkaido-Southwest Earthquake on Jul. 12, 1993, the 1994 Hokkaido-Eastoff Earthquake on Oct. 4, 1994, the 1995 Hyogo-South Earthquake on Jan. 17, 1995, and the 1996 Irianjaya Earthquake on Feb. 17, 1996. Wave data was measured by NOWPHAS (Nationwide Ocean Wave Information Network for Ports and Harbours) wave-measuring instruments installed at various coastal wave stations and tide stations in Japan. Also presented are characteristics and phenomena of interest clarified through various analyses performed on observational data.

Wave-Measuring Instrumentation

Figure 1 shows the NOWPHAS wave observation network in Japan (Nagai et al., 1996, 1994a) which is operated under the auspices of the Ports and Harbours Bureau of the Ministry of Transport (MOT) and its associated agencies including the Port and Harbour Research Institute (PHRI). This nationwide network of wave-measuring instrumentation is the product of long-term intensive efforts directed at obtaining more precise and reliable coastal wave information for disaster prevention purposes and the planning, design, and construction of ports and other coastal structures.

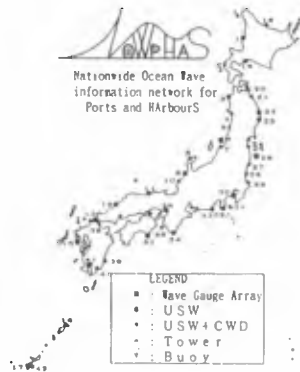

Figure. 1 NOWPHAS Wave Observation Network

Figure 2 shows three types of wave-measuring instruments employed in the NOWPHAS network: (1) The ultrasonic wave (USW) gauge, a widely employed instrument (jointly developed by the Kaijo Co. and PHRI in the 1960s) which precisely determines wave surface elevation by measuring the time for an ultrasonic wave to travel between the seabed and water surface, (2) The current wave directional (CWD) gauge, a widely employed instrument (developed in the 1970s) which determines wave direction by measuring wave-induced horizontal current fluctuations along the seabed, and (3) The Doppler wave directional meter (DWDM), a newly employed instrument (jointly developed by the Kaijo Co., Marine Surveyors Association, and PHRI in 1995) which uses a single sensor to determine with sufficient accuracy the height, period, and directional spectra of waves. DWDMs have been installed at four coastal stations (Fig.1) (Takayama et al., 1995), and in the future are expected to be the main wave-measuring instrument employed under NOWPHAS.

Figure. 2 USW, CWD, and DWDM Wave Gauges

Hokkaido-Southwest Earthquake OffshoreTsunami Profile

Figure 3 shows 20 min of offshore wave records observed at coastal station No.8 Wajima (Sta.8) before arrival of the 1993 Hokkaido-Southwest Earthquake tsunami. Shown are water surface elevation, horizontal current at the seabed in vector form, and the corresponding vector components of water velocity U (m/s) and water direction θ . A USW installed at 50 m measures η and a CWD installed at 27 m measures U and θ . Figure 4 shows corresponding records observed just after the arrival of the tsunami (Nagai et al., 1993, 1994b, 1995a), where it can be seen from the center line determined by low-pass filtering that distinct, long-period oscillations are generated in η . The wave current is also clearly affected as indicated by the long-period oscillations in the horizontal current vectors numerically determined using a triangular low-pass filter of 10s in length.

Figure. 3 Offshre Wave Gauge Data before the Tsunami Attack

Shown in Figure 5 are pair values of USW-measured filtered η and CWD-measured differential change in seabed pressure p observed at Sta.4 Akita before (left) and after (right) tsunami arrival; where for each case, 20 min of data are plotted at a sampling interval of 0.5s. Before arrival, most values are concentrated around the origin ($\eta = p = 0$) indicating no long-period oscillations in η or seabed current. In contrast, however, after the tsunami arrives they are concentrated along the line $\eta = p$; thereby indicating long-period oscillations occur as expected under linear long wave theory. Taken together, these results confirm the reliability of the observed.

Under linear progressive long wave theory, the following relationship should hold:

$$U_{max} = (\eta / 2)(g/h)^{-1/2} \tag{1}$$

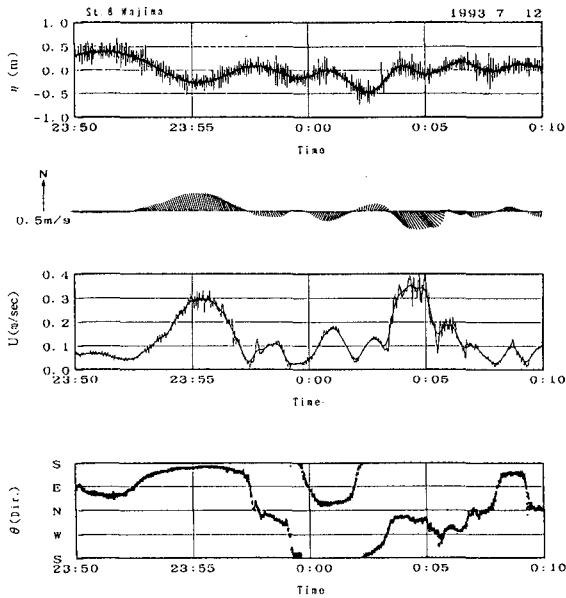

Figure. 4 Offshore Wave Gauge Data after the Tsunami Attack

Figure. 5 Comparison of η and p

where U_{max} is the maximum horizontal water velocity at the seabed, $\eta/2$ the amplitude of water surface elevation $(\eta_{max} - \eta_{min})/2$, g the acceleration of gravity, and h the water depth. These parameters are respectively plotted as pair values in Figure 6 for various wave stations over a 20-min period following the arrival of the tsunami. If eq. (1) is satisfied, then the plotted values should fall on the indicated 45 degree line. For standing waves, $\eta=0$ at the nodes (y-axis) and $U=0$ at the antinodes (x-axis). Considering the results, it appears that the observed tsunami is not completely progressive, but rather exhibits characteristics of standing waves due to the effect of wave reflection.

Integration of current velocity over time gives the motion of water particles at the seabed, being shown in Figure 7 for 20 min before and after the tsunami's arrival at Sta. 8 with and without tide corrections. Motion is shown in the horizontal plane in which the x- and y-axis indicate directions East(+) and West(-) and North(+) and South(-). The effect of the tsunami is quite apparent, especially when considering tide effects. Note that the direction of the constant-velocity tidal current is shown before arrival, and that after correction it is

Figure. 6 Comparison of η and U

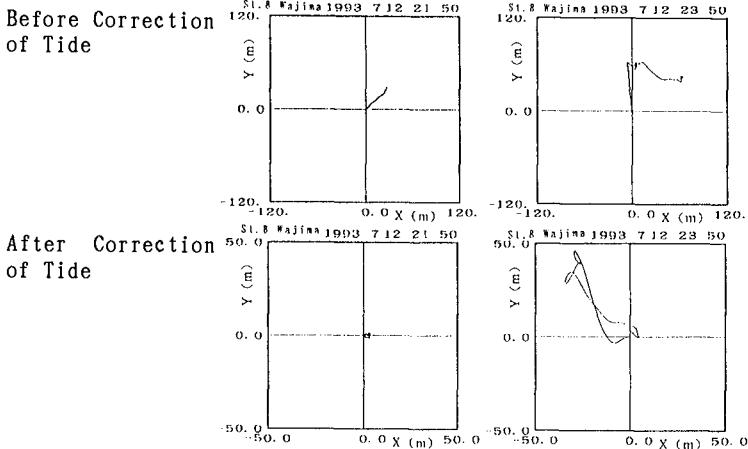

Figure. 7 Seabed Water Particle Movement

properly accounted for. The amplitude of seabed particle motion due to the tsunami is shown to be about 50m, i.e., a distance much greater than can be explained by even the strongest wind-wave conditions.

Figure 8 shows the low-pass filtered offshore wave profile η and tide record Z , before and until more than 6 hours after tsunami arrival as measured at Sta.8 (3km offshore), and the Wajima Port tide station, respectively. Upon tsunami arrival just after 0:00LT, both records show a large peak which cannot be accounted for by the effects of wind or tidal motions. In addition, short-period oscillations less than 10 min, i.e., such as those clearly shown in η , cannot be observed in tide records due to the occurrence of low-pass-filter effects in the measuring instrument's seawater drain tube; thereby demonstrating the

necessity for deploying offshore wave-measuring instrumentation.

Figure. 8 Comparison of Offshore Wave Profile and Tide Record

Hokkaido-Eastoff Earthquake Offshore Tsunami Profile

Figure 9 summarizes the heights and periods of the tsunami generated by the 1994 Hokkaido-Eastoff Earthquake as observed along Japan's Pacific Ocean coast by NOWPHAS wave-measuring instrumentation (Nagai et al., 1995b, 1995c). Individual tsunami waves were defined by the zero-up-cross method. A "*" denotes wave station data while all other data is from tide stations. Note that individual tsunami waves show a long period of about 40 min.

Figure. 9 Tsunami Heights and Periods of the 1994.10 Earthquake

Figure 10 shows a continuous offshore profile η of the tsunami as observed at Sta.19 off Tomakomai Port at a water depth of 18.5 m. This data was obtained as part of a continuous offshore long wave observation project conducted in Oct.1994 by the Tomakomai Port Construction Office of the Hokkaido Development Agency in order to investigate a port resonance problem caused by long waves. Although η is low-pass filtered, clearly distinguishing the tsunami from wind waves and tides is difficult due to the presence of waves with significant wave heights of more than 2 m and a large range of tidal motion. Nevertheless, when these observations are considered in conjunction with those in Figure 10, this confirms the presence of tsunami-generated waves with very long periods of 30 to 80 min.

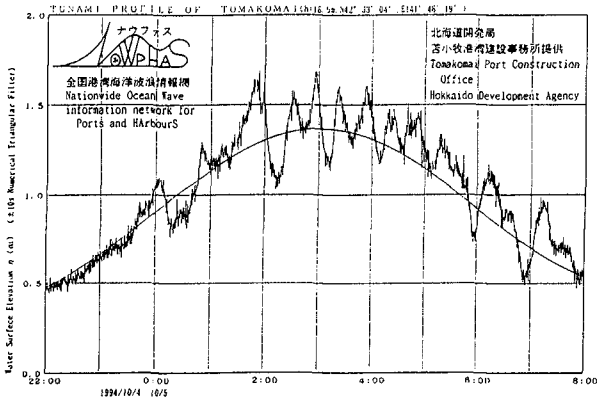

Figure. 10 Tsunami Profile of the No.7 Tomakomai Port

Figure 11 also shows continuous tsunami wave data observed by tide and offshore wave stations at Sta.20 Mutsu-Ogawara for the tsunamis generated by the Hokkaido-Eastoff and 1994 Sanriku-Faroff (Dec.28,1994) Earthquakes. Also shown are the predicted tides, as well as seabed horizontal current vectors for the Hokkaido-Eastoff tsunami.

The results of applying frequential spectral analysis to the data in Figure 11 are presented in Figure 12, which shows corresponding power spectra and the response functions of the wave and tide gauges for each tsunami. Note that both tsunami show the same correlation between their wave and tide spectra; thereby indicating accurate and reliable measurements even under transient, unstable conditions caused by a tsunami.

Figure 13 shows the results of a spectral correlation analysis between η and Z power spectra determined from observation data of the Hokkaido-Eastoff tsunami. Coherence and phase values indicate high stability for measurements at frequencies less than 10^{-8} Hz, which includes the frequency range where dominant tsunami energy exists.

Shown in Figure 14 are corresponding results for spectral correlation analysis between η and the two vector components of seabed horizontal current velocity u and v , where u is the east-west (on-off shore) direction and v the north-south (longshore) direction.

Evaluation of the respective coherence and phase values indicates consistent results with those shown in Figure 13.

Figure. 11 Tsunami Profile of the No. 20 Mutsu-Ogawara Port

Figure. 12 Frequential Spectra of the No. 20 Mutsu-Ogawara Port

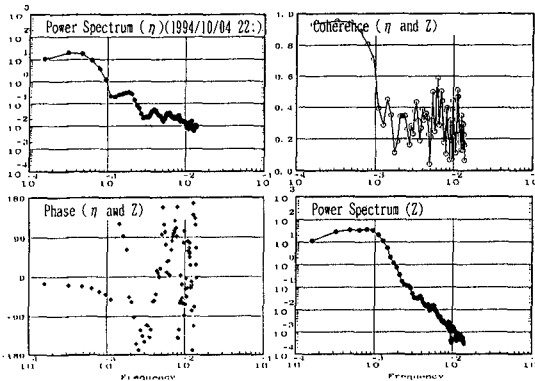

Figure. 13 Spectra Correlation between η and Z

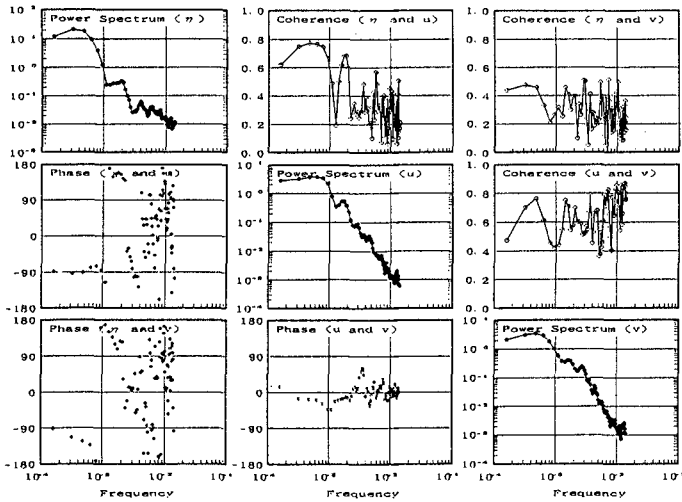

Figure. 14 Spectra Correlation among η , u and v

Figure 15 shows pair values of u and η (g/h)^{-1/2} plotted over three 15-min periods in which the first-arriving individual Hokkaido-Eastoff tsunami wave was observed by Sta.20, where the values should fall on the straight line passing through the origin under linear progressive wave theory. In this case, the difference between the observation depth of the USW (50m) and CWD (28m) gauges is accounted for. A comparison of observed values indicates the presence of standing wave characteristics at the early stage of observation due to wave reflections off the coast.

Figure. 15 Relation between η and U for the First Tsunami Wave

Continuous-observed offshore wave profiles provide a good benchmark from which to evaluate numerical models for simulating tsunami characteristics. Figure 16 compares observed wave/tide station η/Z and u of the Hokkaido-Eastoff tsunami obtained at Sta.20 with those calculated by a numerical simulation model of 3 km grid based on linear long wave propagation characteristics(Aida,1962), and the initial seabed movement determined by the DCRC-3b model (Table 1) developed at the University of Tohoku. Good agreement is present for all three measured parameters, possibly being due to employing a grid size that is relative

-ly small compared to tsunami wave length with a 40-min period.

Table. 1 The 1994 Tsunami Model (DCRC-3b Model by Univ. of Tohoku)

Origin of Fault	43.210°N, 146.120°E
Length	140km
Width	70km
Strike	52°
Dip Angle	77°
Slip Angle	128°
Depth	30km
Dislocation	7.62m

Figure. 16 Comparizon of the Observed and Calculated Tsunami Profile

Hyogo-South Earthquake Tsunami Profile

The city of Kobe and its surrounding region suffered tremendous damage and loss of life when the 1995 Hyogo-South Earthquake struck during the early morning hours (05:47). Figure 17 shows USW-measured off-shore wave profile before and immediately after striking as observed by Sta. 36 Kobe, where amplitudes of several centimeters and periods of 1 or 2 min are indicated by the low-pass-filtered line, i.e., most of the earthquake's energy was expended on land areas such that its effect generated only slight movement of the seabed.

Figure. 17 The 1995 Hygo-South-Earthquake Tsunami Profile

Irianjaya Earthquake Tsunami Profile

Figure 18 shows the wave profile of the tsunami generated by the 1996 Irianjaya-Earthquake as observed by Sta. 31 Habu (USW, 50 m) and PHR1 (USW and tide station) at the entrance to Tokyo Bay 50 km distant. The tsunami arrived at the bay entrance 20 to 30 min after initial observation at Sta. 31, which indicates that continuous observation and monitoring of offshore waves at this offshore station would allow predicting the strike time and provide an early warning for the Tokyo area. Note that the maximum wave heights are about 10 and 70 cm, respectively, with this amplification in height being due to topographical resonance effects.

Figure. 18 The 1996 Irianjaya-Earthquake Tsunami Profile

The results of applying frequential spectral analysis to the data in Figure 18 are presented in Figure 19, where a distinct resonance peak is apparent and indicates that amplification occurs in the frequency band of $0.9 \cdot 10^{-3}$ and $1.5 \cdot 10^{-3}$ Hz ($T = 18.5$ and 11 min).

Figure. 19 Frequential Spectra of the 1996 Irianjaya-Earthquake Tsunami

Summary

We have analyzed selected wave profiles and associated data of large, recently striking tsunami as observed by NOWPHAS offshore wave-measuring instruments and harbor tide stations throughout Japan. As a result of our analysis, several tsunami characteristics and phenomena of interest have been clarified, and through our better understand we can expect to improve observation capability. To fully understand the characteristics of tsunamis and long waves, however, the data acquisition system of NOWPHAS must be reconfigured to a more continuous observation scheme as wave observations are at the present time only performed for 20min every 2h. Efforts to realize such an observation system are now in progress (Nagai et al., 1995d).

Acknowledgments

For their outstanding cooperation, sincere gratitude is extended to all personnel involved with NOWPHAS, with a special thank you to those from the Ports and Harbours Bureau, District Port Construction Bureaus of MOT, Hokkaido and Okinawa Development Agencies, and PHRI.

CHAPTER 115

A REALISTIC MODEL FOR THE 1992-96 TIDAL WAVES

Srinivas Tadepalli†

Costas Emmanuel Synolakis‡

ASCE, Associate Member

I. ABSTRACT

Tidal waves or tsunamis are long water waves of small steepness generated by impulsive geophysical events of the seafloor or by coastal landslides. Whereas their coastal evolution is now well-understood, their generation is not. Until recently (Tadepalli and Synolakis 1994a, 1996), numerous anecdotal records of historic tsunamis where shorelines significantly retreated before the tidal waves advanced up the coastline have been disregarded; the prevailing paradigm for tsunami studies is the modeling of the evolution and runup of a single-hump leading-elevation waves which offshore have solitary-wave profiles. We propose a model for the leading-wave of tsunamis to explain why the coastal manifestation of most tsunamis suggests a leading-depression N-wave, a waveform which causes the shoreline to recede before advancing up the beach. Farfield, we use the Korteweg-De-Vries equation, and we find that N-waves of geophysical scales do not fission over transoceanic propagation distances and no leading solitary waves emerge. Nearshore, we use shallow water theory to calculate the evolution and runup of emerging non-breaking waves, and we observe that they evolve according to Greens' law (Green, 1837, Lamb, 1945, Synolakis, 1991). We discuss the effects of certain ground deformation parameters and provide one application of our theory by modeling the Nicaraguan tsunami of September 1, 1992.

II. INTRODUCTION

The study of the generation, evolution and coastal effects of tidal waves is one of the classic problems in coastal engineering. Tsunamis are generated by impulsive geophysical events such as submarine earthquakes, volcanoes and landslides. The understanding of their coastal effects has progressed considerably in the last four years, both due to detailed field observations of tsunami inundation (Satake et al, 1993, Yeh et al, 1993, Synolakis et al, 1994, Imamura et al, 1995) and due to the availability of large scale laboratory data (Briggs et al, 1994 and 1995), all of which have helped validate inundation calculations in hydrodynamic models. Yet, the process of tsunami generation is less-understood,

† Environmental Fluid Mechanics Laboratory, Department of Civil Engg., Stanford Univ., Stanford, CA 94305-4020.

‡ Associate Professor, School of Engg., Univ. of Southern California, Los Angeles, CA 90089-2531.

and only very recently there has been an effort to understand the effects of seismic parameters on the leading-wave evolution at generation (Geist and Yoshioka, 1996). In fact as Tadepalli and Synolakis (1994) showed, the sign of the leading-wave which is a reflection of the direction of ground motion is of paramount importance in the determination of coastal effects.

Several recent earthquakes in Nicaragua [Sept. 1, 1993], Flores, Indonesia [Dec. 12, 1992], Okushiri, Japan [July. 7, 1993], East Java, Indonesia [Jun. 6, 1994], Kuril Islands, Russia [Oct. 4, 1994], and Mindoro, Philippines [Nov. 14, 1994] have produced tsunami waves which caused nearby shorelines to first recede before advancing. These observations have challenged further the prevailing paradigm for studying the coastal effects of tsunamis, i.e., the canonical model of a Boussinesq solitary wave profile propagating over constant depth and then climbing up a sloping beach (Liu et al, 1991). To quantify the persistent field observations and tsunami folklore, a class of water waves referred to as N-waves have been proposed (Tadepalli and Synolakis, 1994a) for nearshore-generated tsunamis, and it was observed that at least for three different types of N-waves, leading-depression N-waves climb up higher on sloping beaches than leading-elevation N-waves with the same leading-wave amplitude. They also derived asymptotic relationships referred to as runup laws, whose utility was recently demonstrated (Geist and Yoshioka, 1996) to supplement numerical computations for a Cascadia Subduction Zone giant earthquake. However, unresolved questions persist as to the long-distance hydrodynamic stability of these waves. Also, given the uncertainty associated with inferring the seafloor displacement from distant strong-motion records (Yamashita and Shato, 1974) there is little understanding as to the relative effects of the vertical deformation, of the deformed or of the relative magnitudes of subsidence and uplift, forcing laboratory modelers to work exclusively with solitary waves or periodic long waves, and numerical modelers to routinely introduce arbitrary large "amplification" factors to fit their results to runup field observations. We will attempt to address these questions here, by first deriving an initial sea-surface profile for the leading wave of a tsunami from a specification of the sea-bottom deformation and by demonstrating that this profile encompasses as special cases all N-wave like and solitary wave like profiles used in earlier studies (Synolakis, 1987, Tadepalli and Synolakis 1994a, Carrier, 1993). We then will discuss their stability with respect to fission in far field evolution, and we derive nearshore evolution relationships. We will then obtain asymptotic estimates of the relative effects of some generation parameters on the runup of non-breaking waves.

We therefore propose as a model for the leading wave of tidal waves the following normalized waveform,

$$\eta(x) = (\mathcal{E}_g \mathcal{H}) \cdot (x - X_2) \operatorname{sech}^2[\gamma(x - \theta)]|_{t=0} \quad (2.1)$$

where $\gamma = \sqrt{3\mathcal{H}p_0}/4$, $\theta = X_1 + ct$, $L = X_1 - X_2$, $c = 1$ and p_0 is a steepness parameter. We have nondimensionalized all variables with the offshore depth d , and in this normalization, $c = 1$. $\mathcal{E}_g < 1$ is a scaling parameter defining the crest amplitude introduced only for reference to ensure that the wave height (2.1) is \mathcal{H} ; \mathcal{E}_g can be chosen to fit desired field-inferred surface profiles. \mathcal{H} and the wavelength of the profile inferred from (2.1) are vertical and horizontal measures of the ground deformation respectively.

When the crest of the wave at generation is ahead of the trough, we will refer to this wave as a leading-elevation N-wave (LEN); when the trough starts propagating ahead of the crest, we will refer to these waves as leading-depression

N-waves. As suggested by Carrier (1993), multi-lobe waves similar to (2.1) can be described by combinations of Gaussian profiles; we prefer (2.1) because it allows direct derivation of asymptotic results. Here, for brevity, we will refer to all multilobe waveforms as N-waves. We will also use the qualifier non-breaking to refer to waves which do not break in the specific evolution problem, and we note that the same leading wave which evolves to its maximum penetration without breaking on a steep beach may break on a gentle beach; in the steepness range of geophysical interest the leading waves of most tsunamis do not break on most natural beaches[†], but they may break when advancing up rivers, during overland flow, or when focused on headlands.

III. TIDAL WAVE GENERATION

To motivate the generation of N-waves and our particular choice of the initial profile, consider the normalized linearized shallow-water equation (LSW) for propagation over constant depth, long believed as the physically realistic generation approximation (Tuck, 1972, Carrier, 1966) i.e.,

$$\eta_{tt} - \eta_{xx} = h_{0,tt} \quad (3.1)$$

and we consider the following seafloor motion,

$$h_0 = -\frac{2\mathcal{E}_g\mathcal{H}}{\gamma}\tanh[\gamma(x - \theta)] \quad (3.2)$$

where $h_0(x, t)$ is the ground motion, measured from a horizontal datum. Most submarine earthquakes are bipolar, and $h_0(x, t)$ is a motion with both a sudden uplift and subsidence such as would occur with a normal or oblique thrust fault. In nature, the ground deformation would stop quickly after the rupture and the deformation would not propagate indefinitely as the definition of h_0 suggests. Nonetheless, since our objective is only to determine an initial profile valid only for short times, the above ground deformation is adequate. It can be verified directly that (2.1) is an exact solution of the equation (3.1) with ground deformation given by (3.2). The ground deformation that generates a leading depression N-wave is shown in figure 1. Other ground motions (Tuck, 1972, Carrier, 1966) would also produce multi-lobe waves, but not of the same mathematical form; the advantage of the ground deformation h_0 in (3.2) is that it allows for the explicit evaluation of the nearfield and farfield effects in terms

[†] Since quite often tsunamis/tidal waves are reported in the press as giant walls of breaking water, we quote from the Proceedings of the 1979 NSF Workshop on Tsunamis, reported by E.O. Tuck and P. L.-F. Liu who wrote, "of course the physical mechanism has nothing to do with astronomical tides, but the common term "tidal waves" surely arose because most tsunamis are quite satisfactorily described as giving the appearance of a 'fast-rising' tides . . . we should be pleased that it (the term tidal wave) provides a correct picture of what actually happens . . . A near vertical moving wall of water as in movies like the Poseidon Adventure is unlikely to occur in the open ocean and it is the exception rather than the rule for coastal impact of tsunamis." Therefore we will resurrect the term tidal wave and use it interchangeably with the term tsunami.

of simple and intuitive asymptotic formulae.

To appreciate the range of surface profiles that (2.1) describes, figure 2(a) compares a classical Boussinesq solitary-wave profile with the surface profile obtained by (2.1), and for reference, with an isosceles[‡] leading-elevation (LEN) wave with the same leading wave steepness $p_0 = 1$ and a Gaussian profile suggested by Carrier (1993). Figure 2(b) shows leading-depression (LDN) profiles generated by equation (2.1) for a fixed \mathcal{H} and different values of L and, for reference, an isosceles LDN and a combination of Gaussian profiles (Carrier, 1993).

As an initial condition we will use the N-wave of (2.1), and then we will solve the Korteweg-De-Vries equation to calculate transoceanic propagation over constant depth. Once the wave arrives nearshore, we will use the LSW equation (Liu, 1991); it is well-established that for the non-breaking waves we are considering here, dispersive effects do not have sufficient time to manifest over the relatively short propagation distances on a sloping beach. We will show that both LDNs and LENs evolve according to a relationship equivalent to Greens' law (1837). Finally, we will provide results for the maximum runup and we will discuss the relative importance of certain generation parameters.

IV. PROPAGATION DISTANCE FOR SOLITARY WAVE EVOLUTION

Since, we are most interested in the effective propagation distance over which the leading solitary waves emerge, we propagated LDN waves by solving the KDV equation numerically (Synolakis, 1990). The prevailing paradigm would suggest that leading solitary waves should emerge rapidly, and therefore the leading tidal wave attacking nearby coastlines would be a solitary wave. LDN waves with geophysically-realistic initial height-to-depth ratio of 0.001 were practically unchanged after a transoceanic propagating distance of 2000 depths (see figure 3 (a)), indicating the hydrodynamic stability of N-waves and explaining anecdotal reports of LDN waves striking Hawaii after the Chilean 1960 event. No distinct solitary waves emerge even when LDN waves with initial height-to-depth ratio of 0.01 (much larger amplitude than a possible transoceanic tsunami) are propagated through twice the typical transoceanic distances, of about 4000 depths (see figure 3 (b)).

V. COASTAL EVOLUTION OF N-WAVES

We will now solve the propagation problem described by linearized shallow water equations (LSW) for variable depth $h_0(x)$, i.e.,

$$\eta_{tt} - (\eta_x h_0)_x = 0 \tag{5.1}$$

normalized with the offshore depth d as the characteristic length scale, and

[‡] Isosceles N-wave is a wave with equal peak and trough heights.

$\sqrt{g/d}$ as the time scale, $h_0(x) = x/\cot\beta$, when $x \leq \cot\beta$ and $h_0(x) = 1$ otherwise. It is widely believed that these equations describe the essential physics of the coastal tsunami evolution problem well (Liu et al, 1991). When the incident wave from infinity is of the form $\int_{-\infty}^{\infty} \Phi(\omega)e^{-i\omega t}d\omega$, then the transmitted wave to the beach is given by :

$$\eta(x, t) = 2 \int_{-\infty}^{\infty} \frac{\Phi(\omega)J_0(2\omega\sqrt{x\cot\beta})e^{-i\omega(\cot\beta+ct)}}{J_0(2\omega\cot\beta) - iJ_1(2\omega\cot\beta)}d\omega, \tag{5.2}$$

where $\Phi(\omega)$ is the transform function of the incoming wave. When $x = 0$, $R(t) = \eta(0, t)$ and its maximum value R is the maximum runup i.e., the elevation above the shoreline at the point of maximum penetration of the wave. Carrier (1966) and Synolakis (1987) have proved the runup invariance between linear and non-linear theory, and it has been repeatedly (Synolakis, 1991, 1993) shown that linear theory describes well the evolution of the maximum height of long waves which offshore had a Boussinesq solitary-wave profile. Therefore, without loss of generality, we will use linear theory for non-breaking waves we are considering here, to calculate the evolution of the wave height and the maximum runup.

The transform $\Phi(\omega)$ of (2.1) is obtained through contour integration (Tadepalli and Synolakis, 1994a) along a semi-circular contour in the upper half plane and is given by :

$$\Phi = \frac{2\mathcal{E}_g}{3p_0} \text{csh}\left(\frac{\pi\omega}{2\gamma}\right) \left[L\omega - i\left[1 - \frac{\pi\omega}{2\gamma} \text{coth}\left(\frac{\pi\omega}{2\gamma}\right)\right] \right] e^{i\omega X_1} \tag{5.3}$$

The evolution of this wave is obtained by substituting equation (5.3) into equation (5.2). We write $\eta(x, t) = F_1(x, t) + F_2(x, t) + F_3(x, t)$ and introduce $\theta = X_1 - X_0 - ct$. Then,

$$F_1(x, t) = \frac{4\mathcal{E}_g}{3p_0} L \int_{-\infty}^{\infty} \frac{\omega \text{csh}\left(\frac{\pi\omega}{2\gamma}\right) J_0(2\omega\sqrt{xX_0}) e^{i\omega\theta}}{J_0(2\omega X_0) - iJ_1(2\omega X_0)} d\omega. \tag{5.4}$$

Noting that $J_0(z) - iJ_1(z)$ is entire in the upper half-plane (Synolakis 1988, Tadepalli and Synolakis, 1994b), we use contour integration and compute the Laurent expansion to obtain :

$$F_1(x, t) = \frac{32}{3} \mathcal{E}_g \gamma_s^2 L \sum_{n=1}^{\infty} \frac{(-1)^{n+1} n I_0(4n\gamma\sqrt{xX_0}) e^{-2n\gamma\theta}}{I_0(4n\gamma X_0) + I_1(4n\gamma X_0)}, \tag{5.5}$$

where $\gamma_s = \sqrt{3\mathcal{H}/4}$. Using the asymptotic expansions for the modified Bessel functions (Abramowitz, 1970), we approximate F_1 by

$$F_1 = \frac{16}{3} \mathcal{E}_g L \frac{\gamma_s^2}{h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} n e^{-2n\gamma\phi'}, \tag{5.6}$$

where $\phi' = X_1 + X_0 - ct - 2\sqrt{xX_0}$. Similarly we find that,

$$F_2(x, t) = -\frac{8\mathcal{E}_g \gamma_s}{3\sqrt{p_0} h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} e^{-2n\gamma\phi'}, \tag{5.7}$$

and

$$F_3(x, t) = -\frac{4\pi^2 \mathcal{E}_g}{3\gamma_s p_0^{\frac{3}{2}}} \sum_{n=1}^{\infty} a_n \tag{5.8}$$

where,

$$a_n = \lim_{\omega \rightarrow 2n\gamma_i} (\omega - 2n\gamma_i)^2 f(\omega) e^{i\omega\theta} \times \frac{\cosh(\frac{\pi\omega}{2\gamma})}{\sinh^2(\frac{\pi\omega}{2\gamma})} \left\{ 1 + i\omega\theta + \frac{\omega f'(\omega)}{f(\omega)} \right\}, \tag{5.9}$$

with,

$$f(\omega) = \frac{J_0(2\omega\sqrt{xX_0})}{J_0(2\omega X_0) - iJ_1(2\omega X_0)}. \tag{5.10}$$

On further simplifying we find that

$$a_n = \frac{2(-1)^n \gamma_s^2 p_0}{\pi^2 h^{1/4}} \left\{ \frac{3}{2} - 2n\gamma\phi' \right\} e^{-2n\gamma\phi'}, \tag{5.11}$$

and therefore,

$$F_3(x, t) = \frac{8\mathcal{E}_g \gamma_s}{3\sqrt{p_0} h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} \left\{ \frac{3}{2} - 2n\gamma\phi' \right\} e^{-2n\gamma\phi'}. \tag{5.12}$$

where $\gamma_s = \sqrt{3\mathcal{H}/4}$. Using the asymptotic expansions for the modified Bessel functions (Abramowitz, 1970), we approximate F_1 by

$$F_1 = \frac{16}{3} \mathcal{E}_g L \frac{\gamma_s^2}{h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} n e^{-2n\gamma\phi'}, \tag{5.13}$$

where $\phi' = X_1 + X_0 - ct - 2\sqrt{xX_0}$. Similarly we find that,

$$F_2(x, t) = -\frac{8\mathcal{E}_g \gamma_s}{3\sqrt{p_0} h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} e^{-2n\gamma\phi'}, \tag{5.14}$$

and

$$F_3(x, t) = -\frac{4\pi^2 \mathcal{E}_g}{3\gamma_s p_0^{\frac{3}{2}}} \sum_{n=1}^{\infty} a_n \tag{5.15}$$

where,

$$a_n = \lim_{\omega \rightarrow 2n\gamma_i} (\omega - 2n\gamma_i)^2 f(\omega) e^{i\omega\theta} \times \frac{\cosh(\frac{\pi\omega}{2\gamma})}{\sinh^2(\frac{\pi\omega}{2\gamma})} \left\{ 1 + i\omega\theta + \frac{\omega f'(\omega)}{f(\omega)} \right\}, \tag{5.16}$$

with,

$$f(\omega) = \frac{J_0(2\omega\sqrt{xX_0})}{J_0(2\omega X_0) - iJ_1(2\omega X_0)}. \tag{5.17}$$

On further simplifying we find that

$$a_n = \frac{2(-1)^n \gamma_s^2 p_0}{\pi^2 h^{1/4}} \left\{ \frac{3}{2} - 2n\gamma\phi' \right\} e^{-2n\gamma\phi'}, \tag{5.18}$$

and therefore,

$$F_3(x, t) = \frac{8\mathcal{E}_g \gamma_s}{3\sqrt{p_0} h^{1/4}} \sum_{n=1}^{\infty} (-1)^{n+1} \left\{ \frac{3}{2} - 2n\gamma\phi' \right\} e^{-2n\gamma\phi'}. \tag{5.19}$$

Summing (5.13), (5.14) and (5.19) and evaluating the series expansions, we obtain

$$\eta(x, t) = \eta_0 \left[\gamma d_0 \operatorname{sech}^2(\gamma\phi') + \frac{1}{2} e^{-\gamma\phi'} \operatorname{sech}(\gamma\phi') \right] \tag{5.20}$$

where $\eta_0 = 4\mathcal{E}_g \gamma_s / (3\sqrt{p_0} h^{1/4})$, $\gamma_s = \sqrt{3\mathcal{H}/4}$, $\phi = X_1 + \cot\beta - ct$, $\phi' = \phi - 2\sqrt{x \cot\beta}$ and $d_0 = L - \phi'$. Note that only η_0 depends on the local depth h . Solving $\partial\eta/\partial\phi' = 0$, the extremum η_{ext} for any location x , we obtain

$$\left| \frac{\eta_{\text{ext}}(x)}{\mathcal{H}} \right| = \frac{F(\gamma, \phi'_m)}{h^{1/4}} \tag{5.21}$$

where ϕ'_m is the phase corresponding to η_{ext} . Therefore for any given initial LEN or LDN wave, η_{ext} is independent of L and depends only on the local depth h . N-waves are therefore seen to evolve far from the shoreline in a manner similar to what is referred to as Greens' law (Green, 1837, Lamb 1945, Synolakis, 1991) whether a leading-depression or leading-elevation wave.

VI. RUNUP OF N-WAVES

To calculate the maximum runup, the maximum of equation (5.2) at $x = 0$ has to be evaluated; proceeding as in the previous section, we find that

$$\eta(0, t) = R_0 \sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{1}{2}} \left\{ 2n\gamma(L - \phi) + \frac{1}{2} \right\} e^{-2n\gamma\phi}, \tag{6.1}$$

where $R_0 = \frac{16}{3} \mathcal{E}_g \gamma_s^3 / 2(2\pi \cot\beta)^{\frac{1}{2}} / p_0^{\frac{1}{4}}$. Here, we compute the maximum runup of a N-wave (2.1) explicitly; in Tadepalli and Synolakis (1994a), only an upper limit had been calculated. We first note that the phase ϕ_m at the extremum runup satisfies

$$-\frac{4\gamma}{3} (L - \phi_m) = \frac{\sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{3}{2}} e^{-2n\gamma\phi_m}}{\sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{5}{2}} e^{-2n\gamma\phi_m}}. \tag{6.2}$$

Denoting

$$S(\phi_m) = \sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{3}{2}} e^{-2n\gamma\phi_m}, \quad (6.3)$$

we rewrite the equation for ϕ_m as

$$\frac{dS(\phi_m)}{d\phi_m} = \frac{3S(\phi_m)}{2(L - \phi_m)} \quad (6.4)$$

Solving for $S(\phi_m)$ for LDN ($L - \phi_m > 0$), we find that $S(\phi_m) = S_o(L - \phi_m)^{-\frac{3}{2}}$. We then note that

$$-2\gamma \int S(\phi_m) d\phi_m = \sum_{n=1}^{\infty} (-1)^{n+1} n^{\frac{1}{2}} e^{-2n\gamma\phi_m} \quad (6.5)$$

and obtain the maximum runup of a non-breaking leading-depression N-wave,

$$\mathbf{R} = 3.3\mathcal{E}_g p_0^{\frac{1}{4}} Q(L, \gamma) \mathbf{R}_{\text{sol}}. \quad (6.6)$$

Here \mathbf{R}_{sol} is the runup of a Boussinesq solitary wave of the same \mathcal{H} , and (6.6) is asymptotically close to runup law for solitary waves given by Synolakis (1987). This is reassuring; as figure 2(a) shows in the asymptotic limit LEN profiles describe solitary waves, for example when $L = 30$, $\mathcal{E}_g = 0.032$, $Q \approx 10$ and $p_0 = 1$.

This relationship (6.6) referred to as the N-wave runup law is valid when $4\gamma\cot\beta \gg 1$ for non-breaking LDN waves. The limiting wave amplitude for the validity of the above runup law can be obtained from the non-linear shallow water theory using Carrier and Greenspan hodographic transformation (Carrier, 1958) and is the same amplitude as outlined in Tadepalli and Synolakis (1994a) for $p_0 = 1$. $Q(L, \gamma)$ has to be determined numerically, but to the same order of approximation as (6.6) and over a wide range, Q varies linearly with L .

As examples, figures 4(a) and 4(b) show the variation of maximum runup with L and \mathcal{H} respectively. Clearly in the region of physical interest the runup increases almost linearly with \mathcal{H} .

Figure 5 shows the maximum runup variation with the crest-to-trough heights ratio; this parameter is uniquely determined from (2.1) through \mathcal{H} , L and p_0 . Notice that the maximum runup decreases from the isosceles N-wave limit to the solitary wave limit as the crest-to-trough ratio increases, consistent with the earlier observation that LDNs and LENs climb further than the equivalent solitary waves of the same \mathcal{H} and steepness.

VII. DISCUSSION

We have presented a model for the leading wave of tsunamis, encompassing as special cases waves similar to the Boussinesq solitary wave profiles, N-waves, and the certain combinations of Gaussian profiles (Carrier, 1993). The function can be fully described by specifying the crest amplitude \mathcal{H} , the steepness

parameter p_0 and L , and it includes the individual classes of N-waves outlined earlier by Tadepalli and Synolakis (1994a).

Our conjecture is that tsunamigenic faulting generates multi-lobe waves, and that the leading wave of the tsunami is important for estimating coastal effects, at least along open coastlines. Most physically realistic tsunamis retain their overall N-wave character even after transoceanic propagation. Nearshore-generated tsunamis do not have sufficient propagation distance to fully evolve, and their nearshore manifestation is almost invariably N-wave like. We found that the maximum runup decreases as the ratio of trough height-to-crest height decreases, confirming that the dip angle is an important parameter for tsunami characterization, as suggested by Yamashita and Shato (1974) and Geist and Yashioka (1996).

The two-dimensional character of the generation region limits the application of our proposed model, even though the canonical model itself is two-dimensional. We do note, however, that two-dimensional SW propagation models are still used extensively by oceanographers for calculating wave evolution and runup of wind-generated swell (Raubenheimer et al 1995, Raubenheimer and Guza, 1996), a wave motion presumably much shorter than tsunamis.

Nonetheless, we are reluctant to draw excessive physical conclusions other than claim that our initial profile provides a conceptual framework for analysis and for explaining certain field observations qualitatively, or even certain local numerical calculations as demonstrated by Geist and Yashioka (1996). Yet, we did perform simple calculations using our model in one of the recent tsunami catastrophes, where the coastal topography allowed it. One segment of the pacific coastline of Nicaragua is a 73km long with almost uniform plane beach slope ($\cot\beta = 33.18$), fronted by a continental shelf. This simplicity has allowed the use of two-dimensional numerical shoreline models coupled with three-dimensional offshore propagation models to calculate the runup and inundation. Figure 6 shows a comparison between the numerically generated surface profile for the Nicaraguan tsunami with that of equation (2.1), at the time when the wave reaches the toe of the beach (Titov and Synolakis, 1993, Satake, 1995). The measured and numerically computed maximum runup values were $6\text{m} \pm 2\text{m}$, while the runup law (6.6) predicts 3.5m .

We envision our model being applied for first-order estimates of tsunami or tidal wave inundation, as the realistic alternative to the solitary wave model. Given an approximate seafloor deformation area and an average seafloor displacement and the known dip angle of a fault, the parameters $\mathcal{E}_g, \gamma, \mathcal{H}$ can be estimated, and our N-wave model can provide an initial condition for numerical computations. It can also provide an estimate of the runup through the runup law (6.6), when the coastline is fronted by a fairly uniform beach. The runup of a real tsunami may vary substantially in the longshore direction due to local topographic features, yet the model will provide representative values for preliminary design purposes.

ACKNOWLEDGMENTS

We are grateful for the generous support of the National Science Foundation (Program Director, Dr. Cliff Astill, CMS 9201326). We would like to thank Professor J.B. Keller, Dr. Eric L. Geist for several useful discussions and Vassili V. Titov for providing the Nicaraguan profile.

CHAPTER 116

LONG-PERIOD OSCILLATIONS IN A HARBOUR CAUSED BY TYPHOON

Wataru Kioka¹

ABSTRACT

A nonlinear model for predicting the resonant oscillations in a harbour due to typhoon is developed and its validity is evaluated through the comparisons with filed measurements obtained in Yui Fishery Harbour facing Suruga Bay in Japan. The numerical model is based on a time domain solution of Boussinesq equations proposed by Nwogu(1993) with an additional Forchheimer resistance term in the momentum equation to take account of the reflection characteristics of permeable seawalls in the field. It is shown that the numerical model predicts well the low-frequency oscillations inside the harbour exited by incident wave groups.

1. INTRODUCTION

Excessive long-period oscillations are often observed in relatively small harbours along sea coasts when typhoons or atmospheric low pressures pass over sea area. Such oscillations often lead to the breaking of mooring lines and the flooding on the wharf. Recent filed observations reveal that locked or bound long waves accompanied by incident wave groups have relevance to large oscillations in a harbour (e.g., Okihiro *et al.*, 1993). The resonance phenomena due to such infragravity forcing are essentially nonlinear as the locked long waves exist under wave groups through nonlinearity. In this study, a nonlinear model for predicting the low-frequency oscillations inside a harbour due to the typhoon is developed using the Boussinesq equations. The validity of the model is evaluated through the comparisons with field measurements obtained during Typhoon in Yui Fishery Harbour facing Suruga Bay in Japan.

2. MATHEMATICAL MODEL

¹ Professor, Dept. of Civil Eng., Nagoya Institute of Technology, Nagoya, 466 Japan.

Fig. 1 Sketch of numerical model

2.1 Model Equations

The numerical model is based on a time domain solution of Boussinesq equations proposed by Nwogu (1993) with an additional absorbing term in the momentum equation and a source generation term in the continuity equation (Borsen and Larsen, 1987) :

$$\zeta_t + \nabla \cdot [(\zeta + h)\mathbf{u}] + \nabla \cdot \left[\left(\frac{1}{2} z_\alpha^2 - \frac{1}{6} h^2 \right) h \nabla (\nabla \cdot \mathbf{u}) + \left(z_\alpha + \frac{1}{2} h \right) h \nabla \{ \nabla \cdot (h\mathbf{u}) \} \right] - U^* = 0 \quad (1)$$

$$\mathbf{u}_t + (\mathbf{u} \cdot \nabla) \mathbf{u} + g \nabla \zeta + \left[\frac{1}{2} z_\alpha^2 \nabla (\nabla \cdot \mathbf{u}_t) + z_\alpha \nabla \{ \nabla \cdot (h\mathbf{u}_t) \} \right] + f_s \left[\mathbf{u} + \left[\frac{1}{2} z_\alpha^2 \nabla \cdot (\nabla \cdot \mathbf{u}) + z_\alpha \nabla \{ \nabla \cdot (h\mathbf{u}) \} \right] \right] = 0 \quad (2)$$

where $\zeta(x, y)$ is the water surface elevation, $\mathbf{u}(x, y, t)$ is the velocity at an arbitrary elevation $z = z_\alpha(x, y)$, U^* is the vertical source distribution extending from the bottom to free surface, and $f_s(x, y)$ is the distribution function for the sponge layer. The instantaneous horizontal volume flux of the source distribution is included only in the continuity equation, provided that the weak nonlinearity represented by the ratio of wave amplitude to water depth, $\varepsilon = a_0/h_0$, is in the same order of magnitude as the frequency dispersion represented by the square of the ratio of the water depth to wavelength, $\mu^2 = (h_0/l_0)^2$. The distance z_α is determined using an error-minimizing criterion for the dispersion relation. Following Nwogu (1993), the elevation z_α is set

Fig. 2 Definition sketch of porous structure model

to be $-0.53h$. On the upwave control boundary and sides of the computational domain, all outgoing waves are absorbed by using sponge layers and applying the Sommerfeld radiation condition at the outer boundaries of the sponge region (see Fig. 1). The radiation condition is prescribed from the linear long wave theory. The function $f_s(x, y)$ varies linearly over the sponge region, i.e. increases linearly with the distance from fluid boundary lines, so that local disturbances due to the sponge layers are kept to a minimum. A harbour with fully reflective boundaries is treated as the solid walls.

2.2 Modeling Porous Structures

For the cases of partially reflective boundaries, the Boussinesq equations (1) and (2) are further modified to account for the reflection characteristics of permeable seawalls, assuming Forchheimer resistance law for the fluid motion in porous structures, as in the forms (Kioka et al., 1996)

$$\zeta_t + \nabla \cdot [(\zeta + h)\mathbf{u}_p] + \nabla \cdot \left[\left(\frac{1}{2} z_\alpha^2 - \frac{1}{6} h^2 \right) h \nabla (\nabla \cdot \mathbf{u}_p) + \left(z_\alpha + \frac{1}{2} h \right) h \nabla \{ \nabla \cdot (h \mathbf{u}_p) \} \right] = 0 \quad (3)$$

$$\frac{\tau}{\lambda} \mathbf{u}_{p,t} + \frac{1}{\lambda^2} \frac{1}{2} \nabla (\mathbf{u}_p^2) + g \nabla \zeta + \frac{\tau}{\lambda} \left[\frac{1}{2} z_\alpha^2 \nabla (\nabla \cdot \mathbf{u}_{p,t}) + z_\alpha \nabla \{ \nabla \cdot (h \mathbf{u}_{p,t}) \} \right] + \alpha \left[\mathbf{u}_p + \left[\frac{1}{2} z_\alpha^2 \nabla (\nabla \cdot \mathbf{u}_p) + z_\alpha \nabla \{ \nabla \cdot (h \mathbf{u}_p) \} \right] \right] + \beta |\mathbf{u}_p| \mathbf{u}_p = 0 \quad (4)$$

where \mathbf{u}_p is the discharge velocity vector at the distance z_α in porous structures, λ is the porosity, τ is the inertial coefficient given as $\tau = 1 + \kappa(1 - \lambda)$ with κ being the added mass coefficient, α and β are the linear and nonlinear damping coefficients in the unsteady Forchheimer equation, respectively. The flow in the porous domain is

Fig. 3 Reflection coefficients ($h = 4.0$ m)

assumed irrotational. The damping coefficients α and β are respectively given after van Gent (1995) as

$$\alpha = 1000 \frac{(1-\lambda)^2}{\lambda^3} \frac{\nu}{D^2} \quad (5)$$

$$\beta = 1.1 \left(1 + \frac{7.5}{KC} \right) \frac{(1-\lambda)}{\lambda^3} \frac{1}{D} \quad (6)$$

where ν is the kinematic viscosity coefficient, D is the mean grain size of the material of the porous media, and KC is the Keulegan-Carpenter number. The contribution of the added mass to the total inertial resistance is assumed to be disregarded ($\tau = 1$).

The damping coefficients of porous structures cannot be exactly determined from the field measurements, as methods for evaluating these coefficients of large blocks are, at present, not fully established. In the numerical analysis, the porosity λ is adjusted to suit the observed reflection coefficients while the damping coefficients α , β are held fixed. Fig. 3 shows the computed reflection coefficients K_R as a function of the ratio of the thickness of porous body B to the deepwater wavelength L_0 , using sinusoidal waves in the constant water depth of $h = 4.0$ m. The coefficients K_R are simply given as the ratio of the maximum wave height measured in front of the porous structure to the incident wave height. For example, in the case of wave period $T = 9.5$ s and $B = 20$ m, the porosity $\lambda = 0.4$ approximately gives $K_R = 0.4$, according to Fig. 3. The energy dissipation of the incident waves due to the porous

the porous structure, however, decreases with the increase of the water depth. In the case of $h = 6.0$ m, K_R nearly equals 1.0 in the range of $\lambda > 0.4$ and $B/L_0 < 0.2$. For porous structures in relatively deep water depths, the reflection coefficients are underestimated even when using an unrealistic value of the porosity λ . In the deeper water depth, the thickness of the porous structure B is then taken longer than the actual width of the wave-dissipating blocks in the field. The wider porous body leads to better agreements with the observed reflection coefficients, but yields slightly different reflection characteristics of the short waves.

2.3 Numerical Scheme

The equations (1)-(4) are numerically solved using a finite difference scheme. The spatial derivatives in one direction are approximated using 5grid-point centered differences with fourth-order accuracy, leading to a truncation error that is small relative to all retained terms in the equations. Although the finite difference approximations of the xy -, xyx - and yyx -derivatives can be respectively approximated with fourth-order accuracy using 3grid-point centered differences per a direction, 5grid-point approximations are adopted here in order to avoid numerical instabilities. For the temporal integral, an iterative scheme based on the 3rd-order Adams-Bashforth-Moulton method is employed. The water surface elevation ζ can be obtained explicitly. As the velocity component in the x -direction u is solved by calculating matrices, the derivatives of the component in the y -direction v can be treated explicitly for the sake of efficient calculations.

The directional spreading of incident wave energy has a significant influence on the long-period oscillations, and thus must be taken into account for the quantitative prediction. The wave condition at the upwave boundary is then specified in terms of a directional wave spectrum. The single direction per frequency method is used to describe the first-order water surface elevations with the parametric cosine power function for the directional distribution. Since the contribution of second-order waves, especially sub-harmonic waves, is important for the quantitative prediction, i.e., for preventing the generation of spurious free waves at the incident boundary, all the sub-harmonics and super-harmonics in directional wave fields are included in the incident waves through the quadratic transfer function. The characteristics of the groupiness of individual waves and the associated long-period waves are influenced by the initial phase angles of the different frequency components. In the numerical analysis hereafter, the computations are carried out three times for each set of the initial phases. The effective duration of each run is about 1200s.

3. FIELD OBSERVATIONS

Yui Fishery Harbour is a relatively small harbour facing Suruga Bay in Japan (see Fig. 4). Two breakwaters are constructed at the eastern and western side of the harbour entrance, and the offshore breakwater (under construction) is located about 70 m away from the tip of the western breakwater. These breakwaters and the

Fig. 4 Layout of Yui Fishery Harbour

revetments facing open sea are covered with wave dissipating blocks. The field measurements of the water surface elevations have been carried out for two months from August to October in 1994, at station about 300 m offshore from the southern offshore breakwater, station at the harbour entrance and 4 stations inside the harbour basin, as shown in Fig. 4. The time series of surface elevation with the significant wave height $H_{1/3} = 3.7$ m and period $T_{1/3} = 9.5$ s have been obtained at the offshore station due to Typhoon 26, September 29-30 in 1994. The wave heights of the short-wave components were significantly reduced inside the harbour. The low-frequency waves in the range from 0.0025 Hz to 0.013 Hz were, however, amplified to a certain degree due to resonant oscillations inside the harbour.

4. NUMERICAL CONDITIONS AND RESULTS

4.1 Numerical Conditions

The directional spectra have not been observed at the offshore station. The measured time series of the surface displacements cannot be directly used for the incident waves in the numerical calculations. The incident short-wave components are given from the Bretschneider-Mitsuyasu spectrum assuming the Mitsuyasu-type directional function for the directional distributions. The water depth at the offshore station is 25.0 m. The significant wave height $H_{1/3} = 3.7$ m and the period $T_{1/3} = 9.5$ s observed during Typhoon 26, 1994 are used for the numerical simulations. The parameter S_{\max} indicating the degree of directional spreading was not directly measured but estimated from the measured wave steepness using the procedure proposed by Goda and Suzuki (1975). Their estimation method gives $S_{\max} = 40$ at

Fig. 5 Snapshot of free-surface displacements

the offshore station. The frequency bands of $0.4 \sim 2.0$ times the peak frequency are decomposed into 100 first-order wave components. The directional spread of $\pm 50^\circ$ from the principal wave direction is modeled using 20 components. The wave directions are selected in a random order within each frequency band. The set-down wave components defined as low-frequency waves below the bands of short-waves are calculated through the quadratic transfer function, and are added to the short-waves at the incident boundary. The super-harmonic wave components are also included, but with no effect on the long-period oscillations in the harbour. Since the inclusion of all second-order waves requires a large computational effort, only the contribution of the sub-harmonic components may be considered for the second-order waves. The numerical simulation is carried out using a time interval $\Delta t = 0.1$ s, and spatial grid sizes $\Delta x = 5$ m, $\Delta y = 5$ m.

The water depths at each grid-points are counted, referring to the mean water level observed at the offshore station. The 1:6 constant slope slipway is located at the end of harbour basin. The short-wave components are expected to break on the slope. The wave heights are, however, very small inside the basin, so that the influence of long-period free waves caused by the wave breaking on the slope of the slipway may be disregarded for predicting the harbour oscillations. The slipway inside the harbour is then assumed to be an upright porous structure similar to the other partially reflective boundaries.

4.2 Numerical results

Fig. 5 shows the snapshot of the free-surface displacements in the vicinity of Yui Fishery Harbour due to Typhoon 26, 1994. The offshore breakwater, being under

construction, is not effective in reducing the transmitted waves on the leeward side. The incoming short-waves considerably attenuate inside the harbour basin primarily by the breakwaters and the wave absorbing works.

The comparisons of the time series between the numerical results and the observations are shown in Fig. 6. In the case of offshore station, the temporal profiles of the long-period components are exaggerated by multiplying by 5. The set-down waves generated by the short-waves crossing at small angle tend to be underestimated in the region of relatively deep water depth. This may result in the slightly smaller long-period components as compared with the observations at the offshore station. At the station D inside the basin the low-frequency oscillations near 0.013 Hz are clearly reproduced, but their amplitudes are slightly smaller than the measured ones. The computed short-wave components inside the basin appear to be calmer than the measurements. The wave dissipation inside the harbour is possibly overestimated from the porous structure model.

The computed spectra at the stations C and D inside the harbour are compared with the measurements in Fig. 7. The numerical model predicts well the amplification in the low-frequency range. It should be noted the secondary peak near 0.013 Hz is slightly larger than the first peak near 0.0025 Hz. The linear model gives much smaller amplification for the secondary peak.

The spatial profiles of the long-period components are plotted in Fig. 8. The long-period components of near the peak frequencies $f = 0.0025$ Hz, 0.0090 Hz and 0.013 Hz are extracted from the computed spectra inside the harbour. The long-period oscillations are seen to be not multi-directional, but quite uni-directional in the y -direction (in the direction of the longer side of the basin). Near the first peak ($f = 0.0025$ Hz), the surface elevations within the harbour rise more or less in unison. At the second and third peaks (0.0090 Hz, 0.013 Hz), the long-period waves behave as a standing wave, respectively corresponding to two and three anti-nodes in the y -direction.

5. CONCLUDING REMARKS

A nonlinear model, which takes account of the multi-directional features of the incoming waves as well as the partially reflecting boundaries, is developed for predicting the resonant oscillations in a harbour due to typhoon. The spectra observed in Yui Fishery Harbour are well reproduced in the low-frequency range of interest by the present numerical model. Possible countermeasures against the resonant oscillations observed in a small harbour like Yui Fishery Harbour are currently under investigation using the present model.

ACKNOWLEDGEMENTS

The research has been funded by the Grand-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan. The author would like to thank Dr. M. Tanaka of Shimz Corp. and Yui Fisheries Co-operative Organization for

CHAPTER 117

ESTIMATION OF WAVE GROUPS PARAMETER FROM WAVE CLIMATE STATISTICS

Satoshi Nakamura¹

Abstract

Field measurement of sea surface elevation for analysis of wave groups have been carried out at the 4 wave observation points around Japan about for 6 months. As the result of analysis of coefficient variation of wave group parameter, that a record length of wave data needs more than 60 minutes for the reliable statistics of wave groups. Using the wave record of the enough length for wave groups analysis, the empirical relationship between wave group statistics and wave climate statistics is estimated.

Introduction

We have well known that wave groups cause hydraulic problems near the surf-zone, for example harbor tranquillity due to long period oscillations taken by wave groups, abrupt beach erosion due to the infragravity waves generated by breaking of wave groups, a sliding of breakwaters by continuous high waves, and fluctuations of over-topping volume on sea-walls. In spite that the grouping waves are the origin force of hydraulic problems, the research on the statistics of the wave groups which incident to beaches and harbor has not been carried out sufficiently yet. For indicating the degree of wave grouping, a lot of parameters have been proposed. For example, Goda(1970) proposed the peakedness parameter of spectral distribution, Q_p , Funke-Mansard(1979) proposed the groupiness factor, GF , Kimura(1980) shows theoretically relationship between

¹ Senior research engineer, Marine Environment Division
Port and Harbour Research Institute, MOT
3-1-1 Nagase, Yokosuka 239, JAPAN

the run length, j , and the correlation coefficient with succeeding waves, γ_{HH} , and Battjes(1984) proposed the correlation coefficient of wave envelop curve, κ . It is no problem to use whichever parameter for the statistics of wave groups, because they have an adequate correlation each other. The statistical variability of the parameters with record length of the data is rather more important for the analysis.

This study is to discuss on the statistical variability of a wave group parameter for reliable information of wave groups and to propose the empirical formula to estimate the wave groups parameter from wave climate statistics in case of no information on the wave groups.

Field Observation

There are many wave observation stations to observe waves and to get wave climate statistics around Japan. Figure 1 shows the location of wave gages connected to the nationwide ocean wave information network(Nowphas)

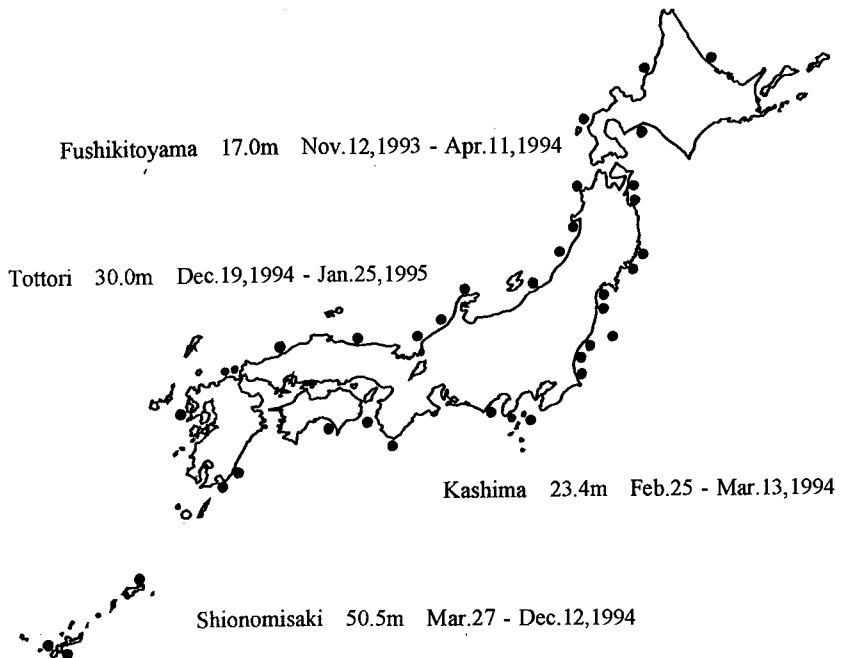

Figure 1 Location, water depth of wave gages, and observation terms

and some of the independent wave gages. This network consist of the wave gages near the big harbors. The data of this network is generally collected about 100 waves every 2 hours and sent to the Port and Harbour Research Institute. The representative value of the wave such as mean wave height and period and the significant wave height and period are computed. The data of un-networked wave gages is similarly processed at each station. This record length is enough for analysis of the representative value of the individual waves distribution, but for analysis of wave groups, it is too short to get the reliable results. Therefor, the special recordings of continuous 119 minutes every 2 hours for about 6 months of sea surface elevation are done at the 4 wave stations (Toyama, Kashima, Tottori and Shionomisaki) which are selected with a basis of the different sea condition. The locations, the establishment water depths and the observation periods of the stations are shown in the figure 1. The sea surface data divided every 2 hours is A/D transformed with a sampling interval 2 Hz and stored in MO disk. After whole data recorded, the data which has some noise was removed and the data was deducted in the tide level change. Table 1 shows the value of skewness and kurtosis of sea surface elevation each observation

Table 1 Skewness and kurtosis of surface elevation

	Skewness	Kurtosis
Fushikitoyama	0.068 ± 0.054	3.0 ± 0.079
Kashima	0.086 ± 0.041	3.0 ± 0.069
Shionomisaki	0.059 ± 0.036	3.0 ± 0.086
Tottori	0.086 ± 0.036	3.0 ± 0.081

points and their standard deviation. At the each points, the skewness almost equals to zero and the kurtosis equals to 3. These value indicate that the distribution of surface elevation is not affected of wave breaking and wave shoring.

Parameter to Identify Wave Groups

There are several parameter of wave groups. The groupiness factor GF is calculated in the value of coefficient variation of smoothed instantaneous wave energy history(SIWEH). The run length j is calculated in how many time the wave height which is higher than the standard height such as $H_{1/3}$ or H_{mean} happens continuously after defining the lines of individual wave heights. The γ_{HH} is by the correlation coefficient of consecutive wave heights. The spectral peakedness Q_p is the moment of spectral distribution. The envelope correlation κ is the correlation coefficient of wave

Figure 2 Relationship between γ_{HH} and others

envelop curve. The each correlation of these parameters are adequate. Among these parameters, the parameter γ_{HH} are used following analysis. Because it is easy to calculate in a series of analysing wave climate statistics based on the individual wave analysis and it is possible to change from the γ_{HH} into the others using the relationships which was gotten from field observation. Figure 2 show the relationship between γ_{HH} and other parameters. In the upper left graph, solid lines are theoretically given by Kimura. The relation in each graphs can be approximated with the simple functions. Suzuki and Kawai et al.(1994) also showed the relationships among them by numerical simulations.

Statistics Variability of Wave Groups Parameter γ_{HH}

In order to estimate statistical variability of the parameter γ_{HH} which is related to the record length, the value of coefficient variation, C.V., of the standardized parameter $\gamma_{HH}(t)/\gamma_{HH}(119)$ is used, where $\gamma_{HH}(t)$ is calculated with the record length of variable t minutes and $\gamma_{HH}(119)$ is the value with 119 minutes of data length. Figure 3 shows the change of statistical variability γ_{HH} with the record length t minutes. The solid line is the mean value of the 372 various conditions of wave groups. As the record length becomes

Figure 3 Change of statistical variability of γ_{HH} with the record length

long, the variability of γ_{HH} becomes small rapidly until 30 minutes and decrease of it tend to stable longer than 30 minutes. The value of γ_{HH} is reliable with a record length of 60 minutes although there is some variability in the value of γ_{HH} . As considering the sea condition change of itself, for example, the change due to the movement of the low atmosphere pressure, it is necessary for wave groups analysis to observe among from 60 minutes to 120 minutes. In this paper, the record length of 119 minutes is used for further analysis. Figure 4 show the relative frequency of the parameter γ_{HH} at the 4 observation points. In each figure, The symbol N shows total number of records. There is a difference in the occurring frequency of the large value of γ_{HH} , because the total number is not equal.

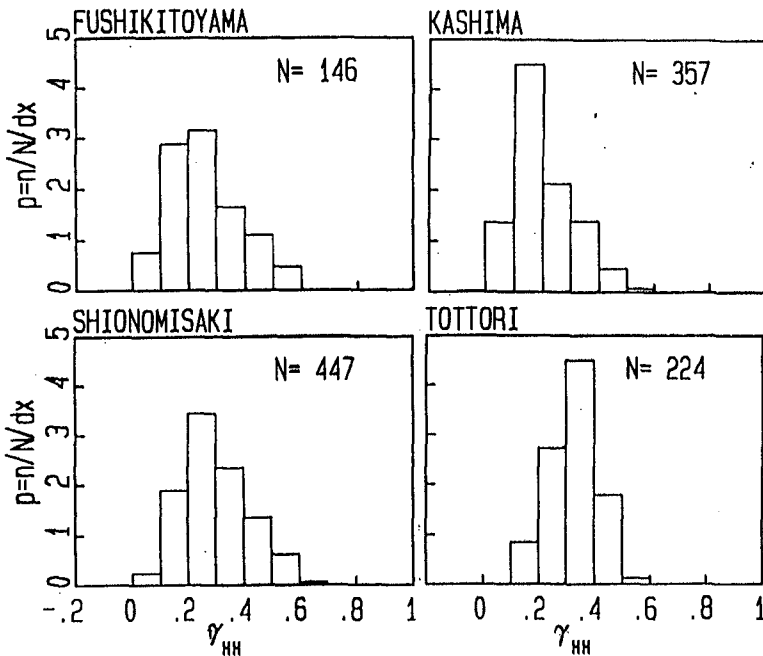

Figure 4 Relative frequency of γ_{HH}

Relationship between Wave Group Statistics and Wave Climate Statistics

It is necessary to record as a lot of waves as possible from now, to study on wave groups structure, and to process statistics of the wave group characteristics. As for getting a statistical value of it, however, the long terms are needed by getting a reliable value because strong wave groups happens rarely. Then, for information of wave groups, it is necessary to show the degrees of the wave group using the characteristics of wave climate such as $(H_{1/3}, T_{1/3})$ and (H_{mean}, T_{mean}) which is obtained enough at many ports. As for the study on the statistics of the wave characteristics, a principal objective is placed in the height of the waves. For example, above-mentioned $T_{1/3}$ is average period with higher 1/3 rank wave height and also the peak period T_p obtained by spectral analysis is the period with highest spectral density. In case of analysis of the wave group, the analysis to have paid attention to the period must be done. Figure 5a and 5b

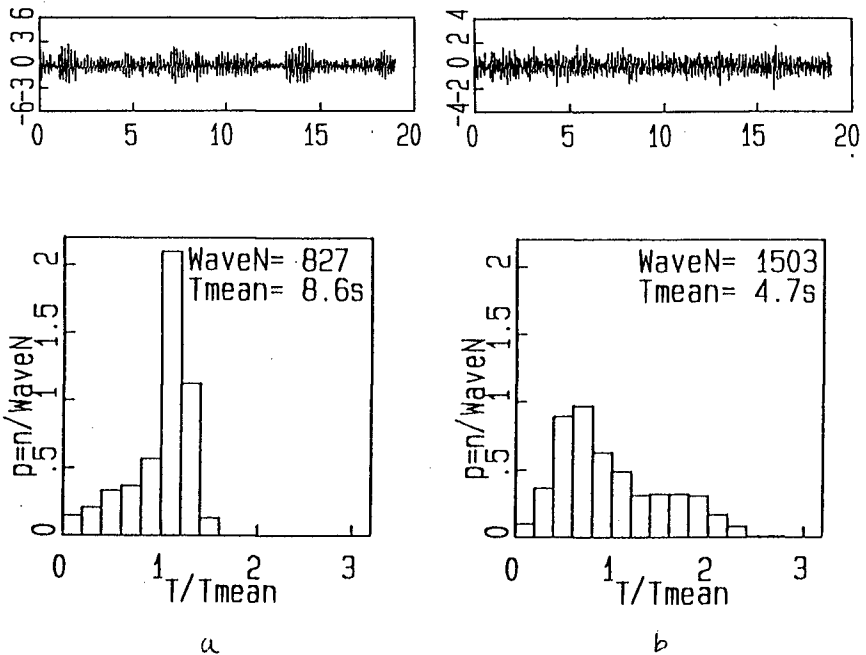

Figure 5 Time series of surface elevation and its period distributions

are the time series of surface elevation and the its non-dimensional periods distribution obtained different wave groups condition. When the wave grouping appears strongly in the time series(5a), the non-dimensional distribution of periods has a peak towards long period side. The other hand, when the wave grouping does not appear clearly(5b), the distribution has a peak towards short period side. This fact indicates that the skewness of periods distribution is related with the wave group parameter γ_{HH} . The skewness can be easily measured with the quartile skewness, QS , with the definition of the following:

$$QS = \frac{(T_{75} - T_{50}) - (T_{50} - T_{25})}{T_{75} - T_{25}} \quad \dots (1)$$

where the quartile value of periods, T_{xx} , is selected in ascending order of wave period until the subscript xx percentage of the total number of waves is reached. When the peak leans to the large percentage with the condition of the distribution has a one peak, the value of the index QS is negative. When the peak leans to small side, the QS is positive. Figure 6 shows the

Figure 6 Relationship between γ_{HH} and QS

relationship between QS and γ_{HH} . Their coefficient of correlation is 80%. We find that the wave groups influence strongly in the distribution of periods. In our field wave climate observation, however, a standard procedure is not to define representative wave period such a T_{xx} , depend on the distribution of wave periods. Therefor, I use the combination parameter wave height ratio and the period ratio, which is calculate the characteristics of wave such a (H_{max}, T_{max}) , $(H_{1/3}, T_{1/3})$, and (H_{mean}, T_{mean}) depend on the wave height, instead of the distribution representative period T_{xx} . For estimating the value of γ_{HH} from the value of wave heights and periods, the combination parameter $\chi^n \tau^m$, which composed of wave periods ratio $\tau = T_{1/3} / T_{mean}$ and wave height ratio $\chi = H_{1/3} / H_{mean}$ is used as the parameter QS . The powers of this parameter are defined on condition that the parameter has high correlation with γ_{HH} . Figure 7 shows the correlation coefficient between γ_{HH} and $\chi^n \tau^m$ with value of n and m . The combination parameter $\chi^n \tau^m$ has

Figure 7 Correlation coefficient between γ_{HH} and $\chi^n \tau^m$

high correlation with the ratio of n and m on 5 to -2. This ratio of n and m is same at this 4 observation points. The value of $n=2.5$ and $m=-1$ are chose because the combination parameter has positive correlation coefficient and the relationship between γ_{HH} and this parameter is almost linear. The γ_{HH} is approximated with a first order function of $\chi^{2.5} \tau^{-1}$ as follows:

$$\gamma_{HH} = a \chi^{2.5} \tau^{-1} + b \quad \dots(2)$$

and determined the constant a and b using the least squares method. Table 2 shows the pair of coefficients a and b at each observation points. These pair of coefficients are approximately same value at the 4 observation points in spite of different sea condition

Table 2 Pair of coefficients a and b

	a	b
Fushikitoyama	0.74	-1.69
Kashima	0.69	-1.50
Shionomisaki	0.69	-1.52
Tottori	0.72	-1.57

of wave energy and direction. This result shows that the degree of wave groupiness is independent to the location of wave gages. On all seashore, the grouping waves come. Figure 8 shows a comparison of the observed γ_{HH} with the estimated one at the Shionomisaki observation point. There is a close agreement between them. The empirical formula to estimate the wave groups parameter from wave climate statistics is proposed.

Figure 8 Comparison of observed γ_{HH} and estimated one

Conclusions

To identify wave groups, the correlation coefficient of consecutive wave heights, γ_{HH} , is easy to add in a series of analysing wave climate statistics based on the individual wave analysis. It is possible to change from the γ_{HH} into the other parameter proposed by many researchers using the relationships obtained from field observation.

The value of wave group parameter γ_{HH} is corresponded to the data record length. The reliability of γ_{HH} increases rapidly until 30 minutes of data length and increase of it tend to stable longer than 30 minutes. The value of γ_{HH} is reliable with a record length of 60 minutes although there is some variability in the value of γ_{HH} . Using the enough record length of sea surface elevation data, the relative frequency of the parameter

γ_{HH} based on the 6 months observation at 4 points are shown.

The degree of wave grouping appears on the skewness of distribution of periods strongly. The relationship between quartile skewness of distribution of periods, QS and γ_{HH} has 80% coefficient of correlation. In case that the distribution of wave periods is not calculated, standard wave climate procedure don't define representative wave period such a T_{xx} , the combination parameter, $\chi^{2.5}\tau^{-1}$, composed of wave climate statistics ($H_{1/3}, T_{1/3}$) and (H_{mean}, T_{mean}) have an adequate correlation with wave groupiness.

Empirical formula of the wave groupiness to estimate from wave climate (equation 2) is proposed. The coefficients are constant regardless of the observation points.

CHAPTER 118

REFLECTION COEFFICIENTS OF THE STEP-SHAPED SLIT CAISSON ON THE RUBBLE MOUND

Sung Mo. Ahn,¹ Ryuichi Fujiwara², Hiroshi Matsunaga³,
Katsuhiko Kurata⁴, Shohachi Kakuno⁵

ABSTRACT

The characteristics of the reflection coefficients of a step-shaped slit caisson on the rubble mound are examined by experimental data. A numerical analysis which combines the method of matched asymptotic expansions with a boundary element method has been applied for the calculation of the reflection coefficients of the caisson on the rubble mound. Numerical results are compared with experimental data to show the validity. Dimensions of the preferable cross-section of the step-shaped slit caisson on the rubble mound are discussed and obtained through the numerical results.

1. INTRODUCTION

Many kinds of perforated breakwaters, seawalls, and quay-walls have been constructed in Japan. A large number of studies about the hydraulic characteristics of this type of breakwaters have been performed since Jarlan's original work (1961). Reflection coefficients of the structures of this type depend strongly on the relative wave chamber width, the ratio of the wave chamber width to the wave length, and low reflection coefficient can be expected only in a narrow band of wave frequency. From this reason, a new type of breakwater with a step-shaped slit wall, whose cross section is shown schematically in **Fig. 3**, has been developed recently and some very fascinating

Osaka, Japan

results have been found. It was found that this breakwater has low reflection in a wider range of wave frequency compared to conventional slit-type breakwaters. Although a numerical analysis which combines the method of matched asymptotic expansions with a boundary element method (BEM) has successfully been applied for calculation of the reflection coefficients of this structure (Kakuno et al., 1989), the previous analysis was on the condition of non rubble mound. It is essential to verify the effect of rubble mound and to discuss the preferable shape of the *step-shaped slit caisson* (SSC) on the rubble mound for the objective of the construction of this breakwater in the field.

The main objective of the present study is to present the preferable shape and dimensions of the SSC on the rubble mound from the viewpoint of the reflection coefficient. Wave flume experiments were carried out for this objective and the results were compared with those of a modified numerical model which was modified to take the effect of the rubble mound into consideration.

2 NUMERICAL ANALYSIS

2-1 Assumptions and the Boundary Conditions

We consider two-dimensional problem as shown in Fig.1. Assuming non-viscous and incompressible fluid except the region of the vicinity of the slits, we may have the velocity potential for the fluid motion in the whole fluid domain Ω . The velocity potential $\phi(x, z)$, which excludes the time term $\exp(-i\sigma t)$ satisfies the governing equation and the boundary conditions as follows :

$$\nabla^2 \phi = 0 \quad ; \text{in } \Omega \quad (1)$$

$$\partial \phi / \partial y - v \phi = 0 \quad ; \text{on } y = 0 \quad (2)$$

$$\partial \phi / \partial y = 0 \quad ; \text{on } y = -h \quad (3)$$

$$\partial \phi / \partial n = 0 \quad ; \text{on } S_U \quad (4)$$

$$\partial \phi / \partial x = 0 \quad ; \text{on } x = l \quad (5)$$

$$\lim_{|x| \rightarrow \infty} (\partial \phi_{sc} / \partial |x| - ik \phi_{sc}) = 0 \quad ; x \rightarrow -\infty \quad (6)$$

Radiation condition, Eq.(6), can be rewritten for this problem with a complex reflection coefficient ρ as follows:

$$\phi(x, y) \Big|_{x \rightarrow -\infty} \rightarrow (e^{ikx} + \rho e^{-ikx}) \cosh k(y+h) / \cosh kh \quad (7)$$

Figure 1. Definition sketch

2-2 A Method of Matched Asymptotic Expansions

(1) Far-field Solutions

The flow domain is divided into two fields; one is the region 1 and the other the region 2 as shown in Fig. 1. Applying Green's theorem to the governing equation in each region, far-field solutions having no local influence by slit walls are derived as follows:

$$\begin{aligned} \phi_1(\xi, \eta) = & \int_{-h_m}^0 \left[\frac{\partial \phi_1}{\partial x}(0_+, y) G_1(0_+, y; \xi, \eta) - \phi_1(0_+, y) \frac{\partial G_1}{\partial x}(0_+, y; \xi, \eta) \right] dy \\ & + \int_{-h_m}^0 \phi_1(l, y) \frac{\partial G_1}{\partial x}(l, y; \xi, \eta) dy \end{aligned} \tag{8}$$

$$\begin{aligned} \phi_2(\xi, \eta) = & \phi_0(\xi, \eta) \\ & + \int_{-h_m}^0 \left[\phi_2(0_-, y) \frac{\partial G_2}{\partial x}(0_-, y; \xi, \eta) - \frac{\partial \phi_2}{\partial x}(0_-, y) G_2(0_-, y; \xi, \eta) \right] dy \\ & + \int_{-d}^0 \phi_2(x, -h_m) \frac{\partial G_2}{\partial y}(x, -h_m; \xi, \eta) dx + \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; \xi, \eta) ds \end{aligned} \tag{9}$$

where G_1 and G_2 are Green's functions, (ξ, η) is a coordinates in the fluid domain, (x, y) is a coordinates on the pass of integration, Γ is the pass of integration on the slope of the rubble mound, $\phi_2(x, y)$ is the velocity potential on the Γ , and $\phi_2(x, -h_m)$ is the velocity potential on the flat top of the rubble mound. $\phi_0(\xi, \eta)$ is the velocity potential of the incident waves which may be written as:

$$\phi_0(\xi, \eta) = \exp(ik\xi) \cosh k(\eta + h) / \cosh kh \quad (10)$$

(2) Near-field Solutions

The near-field solutions which must satisfy the boundary condition on the surfaces of cylinders may be taken as an oscillating flow through the slits between cylinders with a velocity amplitude $U(\eta)$

$$\phi(\xi, \eta) = (\xi \pm C(\eta))U(\eta) + C'_0(\eta) \quad (11)$$

where the positive and negative signs correspond to region 1 and region 2, respectively, $C'_0(\eta)$ is a complex constant, and $C(\eta)$ is a complex blockage coefficient (Kakuno et al., 1993) whose real part corresponds to the coefficient of the inertia resistance and imaginary part to the coefficient of energy dissipation due to the separation at slits.

(3) Matching and reflection coefficient of the SSC

In order to match the inner expansions of the far-field solutions and the outer expansions of the near-field solutions, we have to obtain the limit form for $\xi \rightarrow \pm 0$ in Eq.(8) and Eq.(9):

$$\begin{aligned} \phi_1(0_+, \eta) &= 2 \int_{-h_m}^0 \frac{\partial \phi_1}{\partial x}(0_+, y) G_1(0_+, y; 0_+, \eta) dy \\ &\quad + 2 \int_{-h_m}^0 \phi_1(l, y) \frac{\partial G_1}{\partial x}(l, y; 0_+, \eta) dy \end{aligned} \quad (12)$$

$$\begin{aligned} \phi_2(0_-, \eta) &= 2\phi_0(0_-, \eta) - 2 \int_{-h_m}^0 \frac{\partial \phi_2}{\partial x}(0_-, y) G_2(0_-, y; 0_-, \eta) dy \\ &\quad + 2 \int_{-d}^0 \phi_2(x_1, -h_m) \frac{\partial G_2}{\partial y}(x, -h_m; 0_-, \eta) dx \\ &\quad + 2 \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; 0_-, \eta) ds \end{aligned} \quad (13)$$

Equation (12) and (13) may be matched with Eq.(11) to yield unknown parameters, $U(\eta)$, $\phi(x, y)$ and $\phi_2(x, y)$ and we may have:

$$\begin{aligned} C(\eta)U(\eta) + \phi_0(0_-, \eta) &= \int_{-h_m}^0 U(y) \cdot [G_1(0_+, y; 0_+, \eta) + G_2(0_-, y; 0_-, \eta)] dy \\ &\quad + \int_{-h_m}^0 \phi_1(l, y) \frac{\partial G_1}{\partial x}(l, y; 0_+, \eta) ds - \int_{-d}^0 \phi_2(x, -h_m) \frac{\partial G_2}{\partial y}(x, -h_m; 0_-, \eta) dx \\ &\quad - \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; 0_-, \eta) ds \end{aligned} \quad (14)$$

Also we may derive three equations as the limit form of Eqs. (8) and (9) making (ξ, η) approach impermeable surfaces:

$$\phi_1(l, \eta) = 2 \int_{-h_m}^0 \left[\frac{\partial \phi}{\partial x}(0+, y) G_1(0+, y; l, \eta) - \phi_1(0+, y) \frac{\partial G_1}{\partial x}(0+, y; l, \eta) \right] dy \quad (15)$$

$$\begin{aligned} \phi_2(\xi, -h_m) - \int_{-d}^0 \phi_2(x, -h_m) \frac{\partial G_2}{\partial y}(x, -h_m; \xi, -h_m) dx &= \phi_0(\xi, -h_m) \\ + \int_{-h_m}^0 \left[\phi_2(0-, y) \frac{\partial G_2}{\partial x}(0-, y; \xi, -h_m) - \frac{\partial \phi_2}{\partial x}(0-, y) G_2(0-, y; \xi, -h_m) \right] dy \\ + \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; \xi, -h_m) ds & \quad (16) \end{aligned}$$

$$\begin{aligned} \phi_2(\xi, \eta) - \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; \xi, \eta) ds &= \phi_0(\xi, \eta) \\ + \int_{-h_m}^0 \left[\phi_2(0-, y) \frac{\partial G_2}{\partial x}(0-, y; \xi, \eta) - \frac{\partial \phi_2}{\partial x}(0-, y) G_2(0-, y; \xi, \eta) \right] dy \\ + \int_{-d}^0 \phi_2(x, -h_m) \frac{\partial G_2}{\partial y}(x, -h_m; \xi, \eta) dx + \int_{\Gamma} \phi_2(x, y) \frac{\partial G_2}{\partial n}(x, y; \xi, \eta) ds & \quad (17) \end{aligned}$$

Obtaining $U(\eta)$, $\phi_1(l, y)$, $\phi_2(x, -h_m)$, $\phi_2(x, y)$ from Eqs.(14) through (17), we may calculate limit values for Eq.(8) and (9). Comparing these limit values with Eq.(7), the reflection coefficient can be obtained. The numerical method for the type of those equations has been discussed in detail, for example, by Macaskill(1979).

3 EXPERIMENTS

A wave flume in which model tests were conducted is 40m long, 1.0m wide and 2.0m deep, and is shown in Fig. 2. The slope of the foreshore was uniform with 1:100. The cross section of the breakerwater model is shown in Fig.3, where the water depth on the horizontal bottom was kept constant: $h = 50\text{cm}$. To examine the characteristics of the reflection coefficient and to verify the validity of the calculation, we used 12 types of model caissons with 2 types of rubble mound. The test conditions are shown in Table 1. From measured wave profiles in front of the caisson, the reflected wave height and

the reflection coefficients were estimated by using Goda's method (Goda et al., 1976).

4 DISCUSSION

4-1 Results of Experiments

In Fig. 4, the variation of the reflection coefficients as a function of the

relative wave chamber width, l/L , is presented with a parameter h_s/h_m , where h_s is the height of the lower part of the slit wall and h_m the depth of the top of the rubble mound. From Fig. 4, it is observed that the reflection coefficients K_R become slightly smaller at larger period as h_s/h_m becomes large, that is, the height of the lower part of the slit wall (h_s) increases. Fig. 5 shows the variation of the reflection coefficients as functions of the relative wave chamber width and a parameter h_c/h_m , where h_c is the height of the bottom of the wave chamber. From the figure, it is obvious that the reflection coefficients K_R become smaller at longer period as the height of the bottom of the wave chamber becomes large. However, in the shorter period the reflection coefficients become large with increasing h_c/h_m . Also, the value of l/L where the reflection coefficient attains minimum value becomes small. These results implies wave energy must be dissipated effectively by raising the bottom of the wave chamber; that is, the flow through the gaps of the lower part of slit wall is directed upward and is merged with the flow through the gap of the upper part of slit wall. Therefore, the flow through the gap of slit wall is accelerated and more energy loss due to eddy-formation and flow separation may be expected. From these results, lower part of the slit wall and raised bottom of the wave chamber may be effective for the reduction of the reflection coefficient. Fig. 6 and Fig. 7 show the reflection coefficients as functions of the relative wave chamber length and h_r/h (Fig.6), where h_r is the height of the rubble mound, or the wave steepness, H/L (Fig.7). From these figures, as h_r/h increases from 0.14 to 0.33, or as the wave steepness increases, the reflection coefficients K_R become small.

Figure 6. Effect of the height of rubble mound

Figure 7. Effect of the wave steepness

4-2 Comparison of Numerical and Experimental Results

In Fig. 8, an example of the comparison of numerical results and experimental data for the reflection coefficients is shown. From Fig. 8, it is obvious that the numerical results of the reflection coefficients agree well with the experimental ones and the validity of the present numerical scheme is shown.

Figure 8. Comparison of numerical and experimental reflection coefficient

4-3 Preferable Shape and Dimension of the SSC on the Rubble Mound

The preferable shape and dimensions of the SSC are discussed on the basis of the criteria as follows:

- 1) *for short-period waves, the value of the reflection coefficient is almost the same as one of the conventional slit-type caisson.*
- 2) *for long-period waves, the value of the reflection coefficient is smaller than the conventional slit-caisson in a wider range of wave period.*

Fig.9 shows the relation between the reflection coefficients K_R and the relative wave chamber width, l/L , with a parameter h_s/h_m , of the SSC on the rubble mound and the conventional slit-type caisson. As the height of the lower part of the slit wall increases, the minimum value of K_R shifts to longer period slightly. In order to decide the preferable dimension of the SSC, the criteria as mentioned above was applied in the range of the relative wave chamber width where the reflection coefficients become smaller than 0.5. Table 2 shows the range of the relative wave chamber width for $K_R \leq 0.5$ read from Fig. 9. From Table 2, the preferable height of lower part of the slit wall, h_s , should be taken as 0.6 times the depth of the top of the rubble mound, h_m . The same routine may be performed for the preferable depth of the wave chamber, and the results of that are shown in Fig.10 and Table 3. From Table 3, the preferable height of the raised bottom of the wave chamber, h_c , may be judged to be 0.4 times the depth of the top of the rubble mound, h_m . Therefore, dimensions of the most preferable cross-section of the SSC is a combination of, $h_s = 0.6h_m$ and $h_c = 0.4h_m$. Now, as readily expected, the gap-ratio $2a/D$, where $2a$ is the gap, or slit, width and D is the distance between adjacent cylinders, is very effective parameter on the reflection coefficients of this type of structure. Fig. 11 shows the effect of the gap-ratio $2a/D$ for the cross

section of the SSC with $h_s = 0.6h_m$ and $h_c = 0.4h_m$. Table 4 shows that the most preferable gap-ratio $2a/D$ of the SSC is 0.25.

CONCLUSION

The main conclusions obtained from this study can be summarized as follows:

- 1) Lower part of the slit wall and raised bottom of the wave chamber are effective for reduction of the reflection coefficient. The reflection coefficient of the *SSC* becomes low in a wider range of wave frequency than the conventional slit type caisson .
- 2) The numerical analysis which combines the method of the matched asymptotic expansion with BEM is supported and verified by the results of experiments on the reflection coefficients of the *SSC* on the rubble mound for regular waves.
- 3) Dimensions of the most preferable cross-section of the *SSC* is a combination of, the lower part of slit wall whose height is 60% of the water depth of the top of the rubble mound and, the raised bottom of the wave chamber whose height is 40% of the water depth of the top of the rubble mound, and the gap-ratio is 25%.

The next step we should take is to examine the stability of the *SSC*, for the purpose of the construction of the *SSC* in deeper seas.

CHAPTER 119

BERM BREAKWATER TRUNK EXPOSED TO OBLIQUE WAVES

A. Alikhani¹, G. R. Tomasicchio² and J. Juhl³

ABSTRACT

Comprehensive three-dimensional model tests with a berm breakwater round-head and the adjacent trunk section were carried out at the Danish Hydraulic Institute (DHI) and at the Hydraulic & Coastal Engineering Laboratory of Aalborg University (AAU). This paper describes the influence of wave obliquity on the profile shape, on the initiation of longshore transport and on the longshore transport rate at the trunk section both during and after the profile reshaping, whereas the roundhead stability is described in Juhl et al (1996). Furthermore, tests were made for studying the influence of storm duration and of short crested waves. Equations for calculation of profile development and longshore transport rate under oblique wave attack are introduced.

keywords: berm breakwaters, reshaping, threshold values, longshore transport.

1. INTRODUCTION

A berm breakwater exposed to head-on waves can hardly be destroyed unless it is overtopped, whereas for oblique waves the stones can move along the breakwater. Burcharth and Frigaard (1987) made the first systematic study of oblique wave attack on reshaping breakwaters by testing with angles of wave attack of 15° and 30°. As guideline they recommend $H_o < 4.5$ for a trunk exposed to steep oblique waves, $H_o < 3.5$ for a trunk exposed to long oblique waves and $H_o < 3$ for a roundhead, where

$$H_o = \frac{H_s}{\Delta D_{n50}} \quad (1)$$

is the stability number, Δ is the relative density, D_{n50} is the equivalent cube side length and H_s is the significant wave height. Dependency on wave obliqueness was not described. Burcharth and Frigaard (1988) mentioned that H_o is insufficient to describe the phenomena as it among other things does not contain the effect of wave length and the effect of the duration of the sea storm.

¹Ph.D. student., Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

²Ph.D. Assoc. Prof., Università degli Studi di Perugia, S. Lucia, I-06125 Perugia, Italy

³Senior Eng., Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark

They concluded that the erosion in oblique waves has a non-linear dependency of the sea state.

Van der Meer (1988) introduced the product of dimensionless wave height and wave period parameters for the design of a reshaping breakwater:

$$H_o T_{op} = \frac{H_s}{\Delta D_{n50}} T_p \sqrt{g/D_{n50}} \quad (2)$$

where T_p is the peak period and g is acceleration due to gravity.

Vrijling and Swart (1991) used data from tests of Burcharth and Frigaard (1988) and data from Delft Hydraulics to fit a formula for the transport of stones along the trunk of a breakwater under oblique wave attack. The formula gives the along-structure transport measured as the number of stones per wave, S :

$$S = 4.8 * 10^{-5} (H_o T_{op} - 100)^2 \quad (3)$$

The effect of obliquity of the incident waves is not included in Eq. (3). In average the onset of transport corresponds to $H_o T_{op} = 100$. van der Meer and Veldman (1992) presented Eq. (3) in a slightly different form. They concluded that the longshore transport for larger angles of wave attack such as 50° is much smaller than for 15° and 30° ; their formula is:

$$S = 5.0 * 10^{-5} (H_o T_{op} - 105)^2 \quad (4)$$

The influence of angle of wave attack for shingle beaches was studied by Van Hijum and Pilarczyk (1982) who proposed Eq. (5) for the along-structure volume transport rate under different angles of wave attack. The formula is only valid for shingle beaches, $H_o = 12 - 27$, and can thus not be applied for berm breakwaters.

$$\frac{S_V}{g D_{90}^2 T_s} = 7.12 * 10^{-4} \frac{H_{so} \sqrt{\cos \psi}}{D_{90}} \left(\frac{H_{so} \sqrt{\cos \psi}}{D_{90}} - 8.3 \right) \frac{\sin \psi}{\tanh kh} \quad (5)$$

where ψ is the incident wave angle, H_{so} is the deep water significant wave height, T_s is the 15% excess value of wave period, D_{90} is the sieve diameter for which 90% of the stones (by weight) are smaller, k is the wave number at the structure toe, h is the water depth at the structure toe, g is the acceleration of gravity and S_V is the bulk volume transport rate. With regard to the geometry of a reshaped breakwater Van Hijum and Pilarczyk (1982) concluded that profile parameters should be reduced by $\sqrt{\cos \psi}$. However, van der Meer (1988) re-analysed the data and came to a reduction factor of $\cos \psi$. The analysis was done only for 30° of wave attack and for finer material ($12 < H_o < 27$).

In the Shore Protection Manual (CERC, 1984) a longshore transport formula is given by the following relationship which is valid for H_o larger than 50 (i.e. for sand beaches):

$$S_V = 0.12 * 10^{-4} \pi H_s^2 c_{op} \sin 2\psi \quad (6)$$

where c_{op} is the wave celerity associated to the peak wave period. The formula includes the effect of the wave angle, but does not consider the grain size.

Tomasicchio et al. (1994) and Lamberti and Tomasicchio (1996) on the basis of flume tests, proposed a conceptual model relating longshore transport due to oblique wave attack to stone mobility. The transport model assumes that stones move during up-rush and down-rush in the direction of incident and reflected waves and that movement statistics is affected by obliquity through a modified stability number:

$$N_s^{**} = \frac{H_k}{C_k \Delta D_{n50}} \left(\frac{s_{mo}}{s_{mk}} \right)^{-1/5} (\cos \psi)^{2/5} \quad (7)$$

where H_k is a characteristic wave height for the phenomena under study. For stone movements at a berm breakwater $H_k = H_{1/50}$ is assumed; C_k is the ratio between the characteristic and significant wave height and has a value 1.55 if a Rayleighian wave height distribution is valid. The second factor in Eq. (7) is such that $N_s^{**} = H_o$ for $\psi = 0$ if $s_{mo} = s_{mk}$, where s_{mo} is the wave steepness in deep water based on the mean wave period and s_{mk} was assumed to be 0.03. Tomasicchio et al. (1994) defined the longshore transport, S , as the number of stones moved per wave to be related to the displacement length, l_d , a standard measure for damage, N_{od} , and to the incident wave angle, ψ . The damage index N_{od} was found to

$$N_{od} = 2.05 N_s^{**} (N_s^{**} - 2.0)^{2.2} \quad (8)$$

and for $N_s^{**} > 2.0$, S is given by:

$$\frac{S}{\sin \psi} = \frac{l_d}{D_{n50}} \frac{N_{od}}{1000} \quad (9)$$

In the following, the analysis of the effect of incident wave angle will be presented but also some other important parameters will be discussed.

2. EXPERIMENTS AND TEST PROGRAM AT DHI

2-1. Model set-up

An experimental investigation has been carried out at DHI in a 23 x 30 m wave basin in order to study the stability of a berm breakwater roundhead and the adjacent trunk section under the exposure of oblique waves. Fig. 1 shows a plan of the model basin including the various positions of the two 5.5 m wide wave generators capable of generating irregular long crested waves. Fig. 2 shows the initial profile at the trunk section, and the roundhead was made by rotating the profile around the centreline.

2-2. Stone characteristics

The berm breakwater was constructed of two stone classes, i.e. one for the core and the scour protection and one for the berm, the crest and the rear side protection. The core material had a nominal diameter of $D_{n50} = 0.010m$. A relative wide stone gradation was used for the berm, $\frac{D_{n85}}{D_{n15}} = 1.8$, with an equivalent cube length of $D_{n50} = 0.023m$. The density of the stone material was $\rho_s = 2.68t/m^3$.

Figure 1: Plan view of the experimental set-up at DHI showing different positions of the wave paddle.

Figure 2: Initial profile for tests at DHI.

2-3. Test program

A total of six test series with irregular long crested waves were carried out in order to consider five angles of incident waves with a wave steepness of 0.05 (-30° , 0° , 15° , 30° , and 45° ; 0° is perpendicular to the trunk, see Fig. 1) and two wave steepnesses for the angle of incidence of -30° ($s_m = 0.03$ and 0.05). Each test series consisted of five tests ($H_0 = 2.0, 2.5, 3.0, 3.5,$ and 4.0) with a duration corresponding to 2,000 waves for initial reshaping of the berm breakwater followed by four tests with a duration of 1,000 waves for studying the stone movements on the reshaped profile ($H_0 = 2.5, 3.0, 3.5,$ and 4.0). All waves were generated on the basis of a Pierson Moskowitz spectrum.

2-4. Measurements

The waves were measured at 14 positions in the wave basin by the use of resistance type wave gauges. The wave conditions were checked by five reference wave gauges placed in a way to minimise the effect of reflection from the berm breakwater. Spectral analysis and zero-crossing analysis were carried out.

A total of 38 profiles along the 8.5 m long breakwater were measured after its construction (initial profile) and after each test run. The profiling was made with a laser running on a beam across the breakwater trunk. The horizontal position of the laser along the beam was measured by another laser, whereas the location along the breakwater axis was fixed manually. The profiles were measured for each 0.5 m along the trunk and for each 0.1 m at the roundhead. Assessment of the stone movements was made based on visual observations, photos taken after each test run and video recordings. Observations were made both during the reshaping process involving a large number of stone movements and after the reshaping. In order to facilitate observations of the threshold conditions for longshore transport and the longshore transport rate, all the armour stones in a one meter wide section of the trunk were painted (immersed in paint) before the reshaping phase and the surface was painted again before the stone movement tests.

3. EXPERIMENTS AND TEST PROGRAM AT AAU

3-1. Model set-up

A model test program for studying the effect of directionality of the waves and the effect of the number of waves on the behaviour of a berm breakwater trunk section exposed to oblique waves has been carried out in a 8.5 x 15.7 m directional wave basin at Aalborg Hydraulic & Coastal Engineering Laboratory. Fig. 3 shows the layout of the model basin and the cross section of the structure. The waves were generated by 9 paddles each 0.9 m wide.

Figure 3: Lay-out of model basin and breakwater cross-section used for the directional wave tests at Aalborg University.

3-2. Stone characteristics

The berm breakwater was constructed with only one stone class having a nominal diameter of $D_{n50} = 0.0152m$ and $\frac{D_{n85}}{D_{n15}} = 1.44$. The density of the stone material was measured to $\rho_s = 2.70t/m^3$.

3-3. Test program

A total of 20 tests with irregular waves were carried out. The reshaping phase considered 5 wave attacks ($H_o = 2.2, 2.7, 3.3, 3.8,$ and 4.1) with long crested oblique waves. The tests were made with an angle of incidence of 60° with respect to the breakwater and a duration of 2,000 waves. The reshaping phase was followed by 4 tests with long crested oblique waves (60°) for studying the stone movements on the reshaped profile ($H_o = 2.9, 3.2, 3.5,$ and 4.0); each test with a duration corresponding to 1,000 waves.

After these stages, long duration tests with a total duration corresponding to 11,000 waves were carried out (11 tests with $H_o = 4.0$). Two of the tests were made with directional waves having an angle of incidence of 60° and a cosine spreading function of $s = 10$. All waves were generated on the basis of a JON-SWAP type spectrum with peakedness parameter $\gamma = 3.3$, width parameters $\sigma = 0.10$ for $f \leq f_p$ and $\sigma = 0.50$ for $f > f_p$.

3-4. Measurements

Prior to the initiation of the model tests, the directional waves were calibrated with a very gentle stone absorber in order to minimise wave reflection. The waves were measured at 6 positions in the wave basin by the use of resistance type wave gauges. The wave conditions have been checked by five reference wave gauges placed in positions with minimum effect of reflection from the berm breakwater. For the long crested waves the incident wave height was calculated using the method of Funke and Mansard (for separation of incident and reflected waves) and for the directional waves the calibrated target waves were used.

A total of 3 manual profile measurement were made: the initial profile, the profile after reshaping of the trunk and the profile after the long duration test with $H_o = 4.0$. Assessment of the stone movement was made based on visual observations and photos taken after each test. Observations were made both during the reshaping process involving a large number of stone movements and on the reshaped profile. In order to facilitate observations of the threshold conditions for the longshore transport and of the longshore transport rate, all the berm stones in a 0.6 m wide section of the trunk were painted (immersed in paint).

4. DISCUSSION

Three effects will be discussed in the following:

1. effect of wave obliquity on threshold of movement;
2. effect of wave obliquity on profile shape and sorting of the stones;
3. effect of wave obliquity on longshore transport.

4-1. Threshold of stone movement

For smaller angles of incidence the unstable stones will first start rocking and/or rolling and will not move in the longshore direction as long as the longshore

component of the energy flux is not big enough to move them. Table 1 shows the longshore transport (stones per wave) on the reshaped profile as a function of $H_o T_{op}$ for different angles of wave attack.

$H_o T_{op}$	15°	30°	45°
40	0.000	0.000	0.000
55	0.000	0.000	0.000
80	0.002	0.003	0.005
100	0.008	0.014	0.015
131	0.021	0.05	0.07
161	0.2	-	-

Table 1: Longshore transport after reshaping (tests made at DHI).

In general, the largest transport distance occur for $\psi = 45^\circ$ with a decreasing tendency for smaller and larger angles of wave attack. Now the threshold values are described as:

$$H_o T_{op} > \frac{50}{\sqrt{\sin 2\psi}} \quad (10)$$

during the reshaping phase, and

$$H_o T_{op} > \frac{75}{\sqrt{\sin 2\psi}} \quad (11)$$

after the reshaping phase

4-2. Sorting and profile shape

With regard to the tests made at DHI, Fig. 4 shows the as built structure stone distribution as well as the stone distribution around the water level and in the lower steep part of the reshaped breakwater after exposure to head-on waves with $H_o = 4.0$. w_{50} around the water level is found to be half the w_{50} in the lower

Figure 4: Stone distribution after exposure to 2,000 head-on waves with $H_o = 4.0$ (DHI tests).

steep part, where w_{50} is defined as the stone weight for which 50% of the stone are smaller. However, for more narrow stone gradations the differences will be less pronounced showing that the stone distribution might be an important parameter. The result of the tests at AAU with larger angle of wave attack and narrower stone gradation indicate less sorting of the stones. The major part of the resorting happens in the first 1000 waves. Due to the less sorting of stones for larger ψ and narrower stone gradation, a modification should be applied to the D_{n50} value. This modification might be dependent on the incident wave angle as well as on the value of $\frac{D_{85}}{D_{15}}$. From Fig. 5 it is seen that in long duration tests the lower part of the profile is not changing but the upper part is developing as a function of duration. The reason for this continued recession is lack of nourishment from the upstream of the breakwater. In the test of Van Hijum and

Figure 5: AAU tests, initial and reshaped profile at trunk section ($\psi = 60^\circ$).

Pilarczyk (1982) some of the structural parameters are neither fitting to $\sqrt{\cos \psi}$ nor to $\cos \psi$ as re-analysed by van der Meer (1988), e.g for the crest width the reduction factor is even bigger than unity. The fact is that the reduction factor for the upper part of the profile under oblique waves is more dependent on the storm duration, while for head-on waves this is not the case. Therefore, due to the longer duration sea state the recession of the berm under oblique waves can exceed the value for head-on waves for fixed equivalent wave parameters. Thus, a reduction factor for the upper part of the profile is meaningless under a long duration sea storm.

Equations were developed to calculate the reshaped profile under head-on and oblique wave attack. For reshaped profiles there is always a point, below SWL, which indicates the change of the curvature of the profile, see Fig. 6. This step point, h_s , can be described by

$$h_s = \frac{H_o T_{op} D_{n50} N^{0.07} \sqrt{\cos \psi}}{40} \quad (12)$$

where N , is the number of waves. From this point, depending on the water depth, wave parameters, stone weight, incident wave angle, initial shape of the profile, and repose angle of the stones, two power functions can represent the reshaped

profile namely upper part and lower part. The lower part can be described as:

$$Y = -hm_1\left(\frac{X}{h}\right)^{1.7} + h - h_s \quad (13)$$

where X and Y are the length and height of the reshaped profile counted from the center line of the breakwater, h is the water depth at the toe of the breakwater and coefficient m_1 is given by

$$m_1 = \frac{1.7e^{(-0.013H_oT_{op})}}{\cos \psi} \quad (14)$$

Figure 6: Initial, predicted and measured reshaped profiles for $H_oT_{op} = 161$.

Tests result at DHI show that the part of the profile below the transition point h_t follows the repose angle of the stones under water, where h_t is given by

$$h_t = H_s \cos \psi + h_s \quad (15)$$

The upper part can be described as:

$$Y = hm_2\left(\frac{X}{h}\right)^{1.7} + h - h_s \quad (16)$$

where

$$m_2 = \frac{1.7e^{(-0.01H_oT_{op})}}{\cos \psi} \quad (17)$$

The upper part above still water line is more depending on the initial shape of the profile. Tests result at DHI show that the part of the profile above the berm is following the initial profile shape.

A computer program "RESHAPED" is developed for calculating the profiles, see examples in Fig. 6. The profiles are drawn from an arbitrary point say from the center line of the breakwater and then by the use of an iterative procedure shifted along still-water line until the mass balance is fulfilled. In the case, where enough nourishment is not supplied from upstream, additional erosion due to longshore transport must be considered. For this purpose the longshore transport rate described in Eq. 18 can be used. RESHAPED is calibrated for a breakwater with core material and a relatively wide stone gradation. Comparison was made with some of the tests at AAU with a structure without core material and narrower gradation, showing more resistance of the breakwater compared to the tests at DHI. Calculations of the profile developments for the tests at DHI were also made using BREAKWAT, see van der Meer (1992), showing an overestimation of the structure response.

4-3. Longshore transport

Eq. 4 seems to be adaptable for berm breakwaters, but no influence of the wave angle is included, i.e the formula does not consider any difference between the effect of head-on waves and of oblique waves on the longshore transport.

One of the most important parameters influencing longshore transport is the longshore component of the incident wave energy. Therefore it is rational to relate the longshore transport to this parameter and consequently Eq. 4 is modified as:

$$S = 0.8 * 10^{-6} \sqrt{\cos \psi (H_o T_{op} \sqrt{\sin 2\psi} - 75)^2} \quad (18)$$

The formula is calibrated to give the maximum longshore transport for $\psi = 45^\circ$ and zero transport for head-on waves and waves propagating parallel to the breakwater axis. As the test conditions at laboratories were different (e.g water depth, nearshore slope, stones characteristics, initial profiles, wave generation and calibration procedures, and analysis of incident and reflected waves), each set of laboratory data will be discussed separately. Eq. 18 is shown in Fig. 7 together with data from DHI tests after reshaping. The test results and Eq. 18 show comparable relationships of the wave conditions and angle of wave attack. Fig. 8 shows Eq. 18 together with longshore transport data from the tests by Burcharth and Frigaard (1987). The tests for studying the influence of the wave angle were all made with a breakwater constructed with a profile as will develop after exposure to head-on waves, as they assumed the profile to be almost independent of the wave angle. Three points may concern here:

Figure 7: Longshore transport, in form of stone per wave, S , as function of $H_o T_{op}$.

- 1) The structure was not compacted during a reshaping process and redistribution of the stones did not take place. By constructing a breakwater in this manner, the additional stability due to the natural armouring that occurs as a result of stone motion induced by wave attack will not develop. This can have more influence on the tests with 15° than on the tests with 30° .
- 2) Results have shown that the profile reshaping is larger for head-on waves than for oblique waves. Running tests with oblique waves on a more reshaped profile will result in more energy dissipation and thus reduced longshore transport, which could be the reason for the small difference in longshore transport rate between 15° and 30° .
- 3) In some of the tests with increasing wave parameters the longshore transport was not increased; which can be due to the breakwater becoming more consolidated during exposure to more and more waves.

Figure 8: Longshore transport for data of Burcharth and Frigaard (1987).

Fig. 9 shows the longshore transport after reshaping based on data from van der Meer and Veldman (1992).

Figure 9: Longshore transport for data of van der Meer and Veldman (1992).

This figure confirms that other important parameters are the directionality of waves and the number of waves. Test results from AAU for directional waves have shown that the longshore transport is much lower than for long crested waves. For example for $s = 10$, where s is a parameter that controls the angular distribution in the cosine power spreading function, the longshore transport was 1/4 of the case for long crested waves for $H_o = 4.0$. More tests with different s values are necessary in order to formulate the directionality effects. Fig. 10 shows a plot of the data of the tests of van der Meer and Veldman (1992), where the directionality has been taken into account applying a reduction factor of 4.

Figure 10: Longshore transport for data of van der Meer and Veldman (1992), with a reduction factor of 4 for directional waves.

For an angle of wave attack of 25° the data fit very well, but for 50° there must be some other reason which is not explainable.

In order to show the effect of the storm duration, long duration tests were carried out with a total of 11,000 waves. The number of moved stones was counted after each 1,000 waves. The longshore transport rate was decreasing with increasing number of waves, see results presented in Fig. 11. Experimental data fit in with an exponential function:

$$S = \frac{ae^{-bN}}{1000} \quad (19)$$

For tests at AAU with $\psi = 60^\circ$ and $H_o = 4.0$, a was found to be equal to 350.

Figure 11: Long duration tests at Aalborg University $H_o = 4.0$, $\psi = 60^\circ$.

5. CONCLUSIONS

Three-dimensional experiments both at DHI and Aalborg University shown that the threshold value of the stone movement, the shape of the profile and the rate of longshore transport are dependent on both the angle of wave attack and the wave energy.

Laboratory investigations shown that due to the wave induced sorting of the stones, D_{n50} does not remain constant during the reshaping process at certain locations on the cross section. The sorting is a function of the hydrodynamic vector in front of the structure and will change as a function of the incident wave energy and the wave direction.

An equation for calculation of the longshore transport rate on a reshaped berm breakwater is established, see Eq. 18. Criteria for initiation of stone movements both during and after reshaping are given, see Eq 10. and 11. Moreover, laboratory investigations from Aalborg University shown that directional waves reduce the longshore transport rates (a specific test with a wave angle of 60° showed a reduction of 4) and that the longshore transport is reduced by an exponential function when increasing the number of waves.

The presented longshore transport formula can not necessarily fit all the data because it does not consider the effects of the stone gradation, the shape of the stones, the permeability, the armour layer thickness, the spreading function and the number of waves considered for each test at different laboratories. Further analysis are required to study the influence of especially stone gradation and directional waves.

The profile of a reshaped profile can be described by two equations, one for the part above a defined step point and one below this point, see Eq. 13 and 16. It was found that the angle of wave attack can be included by a reduction factor of $\cos \psi$.

ACKNOWLEDGEMENTS

The present study was carried out as part of the research project on Berm Breakwater Structures and was co-sponsored by the European Commission as part of the research and development program in the field of Marine Science and Technology (MAST) through contract MAS2-CT94-0087.

CHAPTER 120

INTERACTION BETWEEN MAIN ARMOUR AND TOE BERM DAMAGE

by P. Aminti¹ and A. Lamberti²

ABSTRACT

Wave flume tests were carried out aiming to describe and quantify the interaction between main armour and toe-berm damage up to failure. Experiments are described in brief, as well as the qualitative combined damaging process. An interaction scheme is formulated; data and formulae are provided for the quantification of the risk implied in the combined failure.

1. INTRODUCTION

The toe berm of a breakwater is primarily supposed to provide static support to main armour layer, avoiding that its lower units might roll down on the sloping lower surface.

Regarding the effects on the armour layer, if, on one hand, the whole toe-berm upper surface is eroded and erosion undermines the lowest units of the armour layer, the armour units may slide down producing relevant damage of the main armour layer. On the other hand, if the berm is wide enough and almost horizontal, units which are removed from the overlaying armour layer can be retained on the berm itself, reducing the effective slope of the layer and possibly increasing armour resistance to waves. Secondarily and proportionally to its width, the toe berm acts on the water flow, modifying for instance the wave breaking process and the boundary layer evolution at the breakwater surface.

In the case the armour layer is damaged when the berm still shows a significant retaining capacity, armour stones held on the berm can hinder its further erosion.

Some information regarding rubble mound toe protection stability in front of an impermeable vertical wall may be found in the Shore Protection Manual referring to Brebner & Donnelly (1962). Similar information drawn from Japanese experience can be found in Tanimoto & al. (1982) or Goda (1985).

Regarding toe berm stability at a rubble mound breakwater van der Meer (1992) presented a first design formula for depth limited wave conditions desumed from model tests of seven breakwaters with alternatives, whereas Gerding (1993) performed several tests for the specific purpose and derived a verification and design formula valid also for deep water conditions.

No precise information could be found in literature about damaging interaction,

¹ Professor, DIC, University of Florence, via Santa Marta 3, 50129 Firenze, Italy

² Professor, DISTART, University of Bologna, viale del Risorgimento 2, 40136 Bologna, Italy

and only an indirect and qualitative statement, van der Meer (1992), that berm damage greater than 3-10% may cause the berm to lose its functionality and should therefore be considered not acceptable.

In order to quantify the outlined interaction between toe-berm and armour layer a set of laboratory experiments was performed aiming:

- to identify the effect of a stable berm on main armour damage;
- to analyse the damaging process of the berm in a wide set of structure and wave conditions;
- to identify the berm damage level which forces the downsliding failure of the armour layer.

Analysing the wide set of experimental data obtained from our tests we have finally

- compared results from our tests and Gerding tests
- derived revised damage formulae for the berm including the effect of factors not variables in Gerding data set or not represented by Gerding formula;
- derived a relation between the berm width and the critical damage level causing main armour failure;
- analysed the statistical errors of Gerding and our revised formulae.

2. PERFORMED TESTS

Tests were performed in Florence. The wave channel used has a 0.8x0.8 m² section, is 40 m long and is equipped with a wave paddle of the absorbing type; water depth at the wave paddle is 0.5 m. A 1:100 bed slope reduces water depth to 0.34 or 0.20 m in front of the tested structure. The maximum significant wave height that could be produced in the test section is 0.15 m.

The test section was divided into three parts 0.265 m wide where structures were built with an identical profile, but with stone of different size in the berm. This enabled to test contemporary three berm conditions, but forced also to use a smaller scale than usual. The absence of scale effects was checked reproducing tests T23, T25 and T27 of Gerding (1993) in 1:2 scale. All the geometrical dimensions of the breakwater were accurately reproduced as well as the testing procedure used by Gerding at DH De Voorst: in these tests (only in these) no settling wave attack was run before the nominal ones and berm was rebuilt after each wave attack. Only the foreshore slope, which was yet prepared with a slope 1:100 in our channel, while it was 1:20 in DH experiments, is different. . The milder foreshore slope caused in our tests a reduced wave height at breaking and a slight distortion of the wave height distribution which was accounted for by assuming as characteristic wave height for stone mobility $H_{2\%}$; no significant scale effects could be observed with this assumption.

Several test structures were designed keeping fixed some parameters and others variable. Fixed were: armour stones (weight 32 g, density 2.6 g/cm³, equant shape) breakwater crest elevation (15 cm, irrelevant overtopping), berm base depth (25 cm in deep water, fig 1, and 15 cm in shallow water), shape and grading of berm stones (equant, very well sorted) and, approximately, the wave height likely to produce structure failure ($H_{s\sigma}=8$ cm). Variable were: water depth at structure toe, armour

slope, toe berm depth and width (the mentioned parameters define a structure shape) as well as wave steepness and toe berm stone size.

The criterion for the choice of variable parameters characterising each test series was to select combinations of reasonably extreme parameters. Each structure shape is identified by four parameters and denoted by four letters specifying in the order:

- water depth at structure toe h_m : D (deep) $\Leftrightarrow h_m=34$ cm, S (shallow) $\Leftrightarrow h_m=20$ cm; in the first case wave are not depth limited, whereas in the second case extreme waves are depth limited;
- berm depth h_f : H (high berm) $\Leftrightarrow h_f=H_{sd}$; L (low berm) $\Leftrightarrow h_f=1.6H_{sd}$; in the first case berm stones almost as great as armour stone are requested, in the second case almost as great as the underlayer ones;
- berm width b_f : F (no berm) $\Leftrightarrow b_f=0$, the berm depth marks a reduction in armour size; N (narrow) $\Leftrightarrow b_f=3D_{n50td}$; W (wide) $\Leftrightarrow b_f=10D_{n50td}$; D_{n50td} is our conventional design size of berm stones, i.e. the size satisfying Gerding berm stability formula () with damage $N_{odt}=b_f D_{n50t}$ (1 in the case of no berm)
- armour slope: S (steep) $\Leftrightarrow \cot\alpha=1.5$; M (mild) $\Leftrightarrow \cot\alpha=2.5$; it was supposed that milder slopes could hinder armour sliding even in the case of severe berm erosion.

Fig. 1 Section of the tested structure DLWS

Figure 1 shows the DLWS structure.

Different berm stone size were tested corresponding to more and less stable berms than provided by the design criterion. The actual number of stones in the berm width can be significantly different from one of the nominal values (0,3,10), ranging actually from 0 to 25.

Each structure was attacked with waves of increasing intensity up to failure. Wave conditions were drawn from a fixed wave signal set providing a wave height increase around 10-12% per step. For each test series the wave spectrum shape was kept constant and in all cases each wave attack lasted 3000 waves. Two combinations of wave steepness and spectral shape were used: a PM spectrum giving $H_s/L_{om}=0.05$ (short waves, identified by a 5th letter S in test series code) and a JONSWAP spectrum with $\gamma=5$ and $H_s/L_{om}=0.02$ (long waves, L).

12 structure shapes (8 in deep water and only 4 in shallow water conditions, since low berm are unrealistic in this case) and 73 test series, i.e. combinations of structure shape, wave steepness and berm stability conditions, were tested systematically.

Waves were generated using the same signals and target wave conditions were preliminarily measured at structure toe in the absence of any structure. Measurements

were repeated during tests for control purposes but target values were used for analysis.

Damage to the armour layer and to the berm was measured:

- by profiling the structure with a rod array after each wave attack and deriving erosion area (A_e) from profiles (erosion damage $S \equiv A_e/D_{n50}^2$) and
- by counting over a certain observation area (the relevant part of the structure times an observation width B_o) the number of stones (N_d) displaced from the armour layer or removed from the berm ($N_{od} \equiv N_d/(D_{n50} \cdot B_o)$).

3. QUALITATIVE RESULTS AND CLASSIFICATION OF FAILURE PROCESS

Figure 2 shows some typical results of one test series.

Fig. 2 Structure DHNS at start of test and after the 3rd and last wave attacks. Remark in the central photo how a moderate berm damage in the left structure (dark-coloured stones removed) does not induce any incremental damage on main armour compared to the central structure, whereas the right photo shows how a relevant berm damage forces the armour down sliding in the left structure and a significant incremental damage in the central structure, where the narrow flattened berm is unable to stop falling units, compared to the right structure.

Since every stone moved on the armour layer is displaced downwards and almost certainly removed from it, erosion and displacement damage of the armour are strictly linked and represent a single damaging process.

This is not the case for the berm when the armour layer is damaged, see fig. 3, since profiles do not distinguish armour from berm stones, whereas the distinction was natural while counting removed stones. Berm apparent erosion usually decreased when the armour layer was severely damaged, whereas the number of stones displaced from it is regularly increasing with wave height. As index of damage to the berm the displacement damage is therefore used in principle. A qualitative description of the damaging process must however accompany the damage quantification in order to

avoid ambiguities.

Referring to failure conditions the following classification was used:

1. stable and wide berm: the berm maintains its initial shape up to armour layer failure, most of falling armour stones are stopped by the berm causing a reduced damage increase with wave intensity;
2. stable but narrow berm: the berm maintains its initial shape but most of the armour stones fall below it;
3. wide berm less stable than the armour layer but effective in retaining falling units;
4. berm less stable than the armour layer and ineffective in retaining falling units;
5. severely unstable berm: the armour layer fails due to lack of support provided by the berm.

Fig. 3 Damage progress for a typical structure: DHNS, long waves, $D_{n50t} = 2.04 \text{ cm}$

By decreasing berm stability wide berm structures move from type 1 to 3 ending at 5; narrow berm structures normally follow the sequence 2, 4 and 5.

Figure 4 shows schematically the damage progress in berm and main armour for a non effective (left) or effective (right) berm. The three progress lines represent in left to right order a stable berm, a moderately unstable and a severely unstable one. The right figure shows also how a stable and wide berm retards the damaging of the main armour, the effect being cancelled in a weak berm, and how, hypothetically, main armour damage can retard the berm damage causing armour down sliding.

Since the damage causing main armour failure is well documented in literature

Fig. 4 Damage progress in a non effective berm case (left side) and in an effective berm case (right)

($S_a = 8 \div 12$ depending on slope, van der Meer 1988), the main aspects requiring quantification are:

- the benefit of a stable berm if any,
- the berm damage threshold causing armour down sliding
- a reliable relation providing berm damage (in the stable armour case at least).

Figure 5 shows the comparison of main armour damage over berm of different stability. In the presented cases the sudden damage increase due to berm flattening is evident. A curve is shown representing van der Meer formula, i.e. the usual increase of damage with increasing incident wave height. Erosion damage is converted to displacement damage dividing by 2.0.

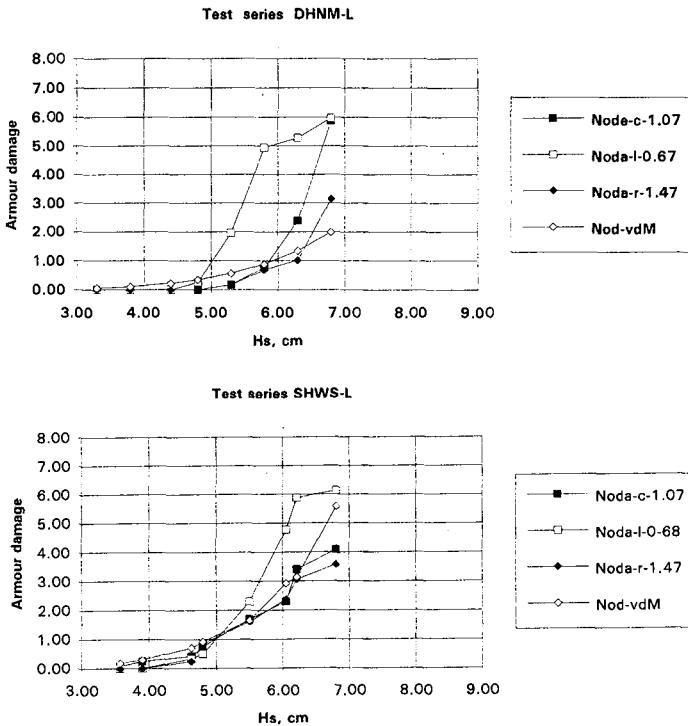

Fig. 5 The effect of berm stability on main armour damage in two tested structures

4. POSITIVE EFFECTS OF A STABLE BERM ON THE ARMOUR LAYER

The positive effect of a stable berm can be desumed from the comparison of observed armour damages over a certainly stable berm with damage estimates obtained from van der Meer (1988) formulae. This formula is actually deduced mostly from experiments on slopes, i.e. in the absence of any berm; the comparison with the formula is quantified by evaluating the average ratio of observed and

Fig. 6 Comparison among experimental displacement damages due to long waves in deep water acting on steep armour slopes over berms of varying width and depth

correlated: we have observed $S_a = 2.5 \cdot N_{oda} \pm 0.8$; but, while the first is subject to the evaluation error due to the limited number of profiles and includes structure settlement, the second is not subject of any measurement error, since counting is exact and displaced stones are clearly recognizable. Displacement damage was therefore preferred. Figure 6 shows the comparison of armour damages due to long waves on steep armour slopes in deep water. The compared results are derived from cases where the berm was very stable and show the effect of berm width and height. Every existing formula, as e.g. Van der Meer's formula, returns equal damages for the four structures. The effect is comparable to discrepancy observed between data in extreme conditions and van der Meer formula were observed also by Mase & al. (1995). The effect is in this case out of discussion: both the height and width of the berm have evident and positive effects. The effect is similar but smaller for mild armour slope and/or in shallow water, supporting the interpretation that the positive effect is due to

Fig. 7 Typical ratio of observed damage to the damage derived from van der Meer eq.. Structure DHWS with long waves (most effective berm among tested ones)

computed damages presented in table 1. Since formulae include the effects of wave and of armour layer parameters (wave height and period, armour slope, stone size and density) the ratio even if not constant is less variable than the damage itself and can characterize the damage relation below the threshold.

Armour damage was measured both as erosion and as displacement damage. The two damage estimates are well correlated: we have observed $S_a = 2.5 \cdot N_{oda} \pm 0.8$; but, while the first is subject to the evaluation error due to the limited number of profiles and includes structure settlement, the second is not subject of any measurement error, since counting is exact and displaced stones are clearly recognizable. Displacement damage was therefore preferred. Figure 6 shows the comparison of armour damages due to long waves on steep armour slopes in deep water. The compared results are derived from cases where the berm was very stable and show the effect of berm width and height. Every existing formula, as e.g. Van der Meer's formula, returns equal damages for the four structures. The effect is comparable to discrepancy observed between data in extreme conditions and van der Meer formula were observed also by Mase & al. (1995). The effect is in this case out of discussion: both the height and width of the berm have evident and positive effects. The effect is similar but smaller for mild armour slope and/or in shallow water, supporting the interpretation that the positive effect is due to reshaping of the armour layer sustained by the berm in the most severely attacked zone.

Figure 7 presents a typical behaviour of the ratio between observed damage and the damage estimated by van der Meer formulae.

Table 1 shows the average ratio between the observed damage and the damage foreseen by the formula. Due to the recognized inaccuracy of the

formula (6-7% on H_s) and due to the recognized lack of reproducibility of armour strength ($\approx 30\%$ on damage) only discrepancies greater than 40% are singularly evident.

Table 1. Average reduction factor to be applied to van der Meer equation below the negative effect threshold

	Long waves						Short waves					
	FS	NS	WS	FM	NM	WM	FS	NS	WS	FM	NM	WM
DH	---	0.4	0.2	---	0.8	0.4	---	0.5	0.4	---	0.9	0.6
DL	1.0	---	0.5	1.6	---	1.0	0.5	---	0.7	---	---	0.8
SH	1.2	0.9	0.8	---	---	0.8	0.8	1.1	0.6	---	---	0.6

Some conclusions may be drawn:

- positive effects are evident only in deep water;
- the effect normally increases with berm height and width;
- the effect is greater for steep armour slopes;
- strong positive effects are possible only when the berm can retain displaced stones from falling to a depth where they would be of no use for the portion of the profile that is attacked by waves.

5. NEGATIVE EFFECTS OF AN UNSTABLE BERM ON THE ARMOUR LAYER

In most cases armour damage increased quite abruptly as a consequence of berm flattening, see fig. 5. In a few others it raised more gradually. The damage increase shows always some irregularity due to the limited number of armour stones in the test area, and this makes the identification of small deviations questionable.

As long as the berm damage is significantly below the critical threshold no evident correlation between armour and berm damage could be observed.

Actually the erosion and flattening of the berm is supposed to cancel progressively the beneficial effect of the stable berm, but this is covered by the "noise" in most cases.

On the other side, when the armour is severely damaged and armour stones cover the berm, the conditions for experimental evaluation of the berm damage are the worst and only the order of magnitude of the damage can be assessed. Visual inspection showed also that armour stones were never covering with sufficient and uniform density the berm, so that a compensation between the shelter effect of a dense armour stone cover and the erosive effect of isolated stones is likely to occur.

When eventually erosion undermines the armour layer, a rather sudden incremental damage $\Delta N_{od} = 3 \div 4$ takes place.

Since the flattened berm has an almost constant shape (slope 1:4÷5), the corresponding berm damage level measured either as erosion or as displacement damage should depend only on the nodimensional berm width: berm damage, represented by either the erosion area A_e (volume of erosion per unit length) or by the number of displaced stones N_{dt} (proportional to the length where removed stone are

Fig. 8 Empirical relation between the critical berm erosion and the relative berm width

counted), should depend only on berm width B_t and stone size D_{n50t} , the nondimensional version of this relation is a relation between N_{odt} or S_t and B_t/D_{n50t} .

Figure 8 shows the two average empirical relations. For each substructure the critical damage was assessed (either as a value, when sliding was observed, or as a bound, when sliding was not observed) and statistics were evaluated for berm-width classes. Figure 8 shows the

average values and the 2 standard deviation range.

The two lines represent relations fitted to the average raw values; from these a unique corrected relation for the damage can be derived (following paragraph describes the correction):

$$S_t^c \cong 2.0 \cdot N_{odt}^c = 3 + 0.7 \cdot (B_t/D_{n50t})^{5/4} \quad (1)$$

The final interaction scheme is:

- if the berm damage is below critical threshold, the effect on the armour is normally weak; it can be:
 - disregarded (traditional approach, using e.g. van der Meer formulae) increasing parallelly the estimate error;
 - pointed out by some new method (e.g. Mase & al., 1995) or derived from tests; in this case the benefit should be reduced progressively to zero with increasing berm damage up to the critical value;
- if the berm damage reaches the critical value the upper layer of the armour will slide down causing a considerable increase of damage and reaching, for any reasonably safe design, armour failure ($N_{oda} \cong 4$).

6. RELIABILITY OF OUR DAMAGE ESTIMATES

For several reasons raw estimates of the berm damage S_t and N_{odt} are only moderately correlated and show an average ratio far greater than 2.0. If every removed stone causing erosion is counted in N_d and if no other mechanism but erosion causes profile modification, then the relation between the two variables would be

$$S \cdot (1 - n) = N_{od} \quad , \quad (2)$$

where n is the void fraction near the surface ($\cong 0.5$), expressing in non dimensional form the fact the eroded part of the initial profile was occupied by stones and by

interstitial void.

But actually settlement do occur, particularly for the berm since it was reconstructed after each test series, and some error in counting the removed stones could not be avoided. Berm stones were made recognisable by colouring the top layer, and removed stones were counted only when they were removed outside the berm including its face. Some berm stones were removed from the berm and not counted, because maybe they were hidden by fallen armour stones or among armour stones (particularly when in order to obtain a very unstable berm berm stones were smaller than those in the underlayer), some more eroded by the second layer were not counted because they were uncolored and confused with stones of the lower layers, some others were not counted because they moved within the berm.

The best experimental relation between the two variables in our experimental set-up and procedure was

$$S_t = 5.2 \cdot N_{odt} + \frac{0.5 \cdot B_t}{D_{n50t}^2} \quad \text{c.det.} = 0.76$$

It can be interpreted as:

- the average structure show a berm settlement of approximately 0.5 cm;
- on the average only 38% of berm stones contributing to erosion are positively counted as removed.

The first assumption corresponds to observations. The second was controlled in some final tests series where the upper first three layer of the berm where coloured differently from the front face, eliminating the second and partly the third cause of counting errors. It was observed that stones of the upper first layer transported out of the berm were on the average 45% of those that were counted as moved, i.e. that were moved outside they colour area. The difference (45-38%) can be easily explained by the remainin error causes.

The above empirical relation was used to correct raw berm damage estimates and combine them into "true" berm erosion and displacement damage indexes

$$S_t^* \equiv 2.0 \cdot N_{odt}^* \equiv \text{avg} \left(S_t - \frac{0.5 \cdot B_t}{D_{n50t}^2}, 5.2 \cdot N_{odt} \right)$$

The relation compensates for some systematic errors performed in the evaluation but shows also the errors present in the raw estimates.

Likely errors of compensated values are about 40% (less or more depending on the number of original raw estimates available: in some cases counting was impossible, in some others berm stones erosion area could not be assessed).

7. REVISION OF TOE BERM DAMAGE FORMULAE

Tests were programmed making use in a predictive sense of Gerding formula,

$$\frac{H_s}{\Delta_t D_{n50t}} = \left(1.6 + 0.24 \cdot \frac{h_t}{D_{n50t}} \right) \cdot N_{odt}^{0.15} \quad (3)$$

The results of the tests substantially confirm the formula.

Comparing the two sets of experimental results and or the derived formulae a few differences must be remarked. Formula (3) is based on a series of tests expressly designed for the evaluation of berm damage under a fixed armour layer, whereas our tests were primarily focused on the influence on armour damage and were therefore carried in a more complex and difficult experimental environment. The berm in Gerding's tests was reconstructed every time and damage are the damages of the wave attack, whereas in our tests the berm was reconstructed at the beginning of the test series and the observed damage is the cumulated effect of all the wave attacks in the current progression. Foreshore slope was different in the two experiments, as mentioned before. Armour slope in Gerding test was fixed: 1:1.5. Wave steepness in Gerding tests varied in {0.02, 0.03, 0.05} with preference with the central steepness, i.e. varied significantly less than in our experiments.

The main differences we observed are:

- the average exponent of displacement damage was higher: 0.2;
- the average sensitivity to berm depth was lower 0.15;
- a systematic effect of wave steepness (or wave period) was evident as in Benoit & Donnars (1996).

A formula similar to (3) that fits our results is:

$$\frac{H_s}{\Delta_t D_{n50t}} = \left(1.1 + 33 \cdot s_m + 0.15 \cdot \frac{h_t}{D_{n50t}} \right) \cdot N_{odt}^{0.20} \quad (4)$$

We have also reanalysed berm damage data with a more free approach since some aspects of formulae (3) and (4) did not convince us.

Let $u_c \equiv \sqrt{g \cdot H_s}$ be the conventional reference velocity (the velocity scale in the breaker area), let u_t be the maximum velocity at the toe-berm i.e. the real cause of damage, and let $v_t \equiv u_t/u_c$ be the non dimensional velocity at the berm. The erosion of toe berm stones depends on the ratio between the hydrodynamic force on the stones and their submerged weight

$$N_{odt}^* = \text{funct} \left(\frac{H_s}{\Delta_t D_{n50t}} \cdot v_t^2 \right) \quad (5)$$

where 1) *funct* should be a monotonic increasing function with no upper bound, and 2) v_t should depend only on what influences the flow field and not on Δ_t .

The non dimensional velocity at the berm should depend on:

- a location parameter specifying where the berm is located with special refence to breakers: h_t/H_s ;
- a roughness ratio, ratio between the flow field dimension and the surface roughness: h_t/D_{n50t} ;
- wave period and armour slope, determining wave penetration into depth, reflection, run down: s_m and $tg\alpha$
- berm width: B_t/D_{n50t} .

Formulae (3) and (4) conform to the above scheme but represent the influence of the roughness ratio which seems of secondary importance compared to the location parameter. Making use of the fact that Δ_t was practically constant in Gerding tests,

formula (3), for instance, can be easily transformed into an equivalent relation involving the location parameter:

$$\frac{H_s}{\Delta_t D_{n50t}} = \left(1.6 + 0.4 \cdot \frac{h_t}{H_s} \cdot \frac{H_s}{\Delta_t D_{n50t}} \right) \cdot N_{odt}^{0.15} \tag{6}$$

This relation however shows an upper limit in the damage $\left(\frac{H_s}{0.4 \cdot h_t} \right)^{1/0.15}$ which was almost reached in some of our experiments.

We have therefore interpreted also our data according to a power regression equation returning toe berm damage as function of the independent variables described above. The relation is fitted on our data and checked with Gerding's results.

The best representation is obtained with different equations fitting for h_t/H_s greater and smaller than 1.35; the separation value is empirical but not far from the condition that berm emerge at extreme run down; in the tested conditions the average run-down according to van der Meer (1992) is $R_{d2\%}/H_s = 0.75$.

All the independent variables were initially included in the regression; the less influent were progressively discarded until the loss of of determination (percentage of explained variance) became greater than 0.01. The final regression are:

- for $h_t/H_s < 1.35$

$$N_{odt}^* = 3 \cdot 10^{-6} \cdot \left(\frac{H_s}{\Delta_t D_{n50t}} \right)^{4.0} \cdot \left(\frac{H_s}{L_{om}} \right)^{-3.1} \cdot \left(\frac{B_t}{D_{n50t}} \right)^{-0.4} \tag{7}$$

on our data the coeff. of determination is 0.75 and r.m.s. log deviation is 0.48; on Gerding data r.m.s. log deviation is 0.85;

- for $1.35 < h_t/H_s$

$$N_{odt}^* = 9 \cdot 10^{-6} \cdot \left(\frac{H_s}{\Delta_t D_{n50t}} \right)^{3.5} \cdot \left(\frac{H_s}{h_t} \right)^{1.9} \cdot \left(\frac{H_s}{L_{om}} \right)^{-3.0} \cdot (tghkh_m)^{4.8} \cdot \left(\frac{B_t}{D_{n50t}} \right)^{-0.3} \tag{8}$$

on our data the coeff. of determination is 0.73 and r.m.s. log deviation 0.71; r.m.s. log deviation is 1.43 on Gerding data. As a comparison the r.m.s. log deviation of N_{odt} in Gerding's relation is 1.50 on our data, and 0.75 on Gerding's data.

Figure 9 gives an impression of data fitting to equation (7).

8. CONCLUSIONS

An effective berm (high, wide and stable) can reduce significantly the damage progress of a steep armour layer, particularly in deep water conditions;

The effect is significantly greater than the error range usually attributed to design formulae, particularly to van der Meer's one, which is quoted as providing estimates with a 6-7% error on H_s . The effect may be as great as 40 % on H_s at start of damage level ($N_{oda} = 1$) and is in several tested cases above 20%.

A berm damage above a critical threshold causes the rapid regressive erosion of a one stone layer (sliding) and the failure of the armour layer for every tested conditions ($tga \geq 1 / 2.5$). The threshold damage value increases with berm width; a graph representing the critical damage is provided.

Fig. 9. Comparison of our experimental data with damage relation (7)

The armouring process of an unstable berm by displaced armour units, visually observed, does not produce evident effects in our tests, mainly because the surface armouring layer never was so dense everywhere to induce an effective protection of the underlying berm stones.

The test showed that wave steepness has an evident effect on berm damage. The berm depth influence is secondary if the berm is struck by breakers ($h_t/H_s < 1.35$ in our tests or berm above run-down level in a more general case), whereas it becomes predominant if the berm is deeper.

Secondary effects of berm width and of depth at structure toe are recognizable.

A formula for toe-berm damage is provided representing principal and secondary effects. In all tested conditions Gerding's formula gives however reasonable results. Correction terms in Gerding formula are provided in order to represent all the principal effects.

The design criterion "failure of the main armour (i.e. filter visible) and of the berm (i.e. erosion undermining armour units) for the same wave conditions" provides a balanced design. The criterion used for programming the tests, "failure of the main armour for wave conditions that, according to Gerding formula, cause as many displaced stones in the berm as they are in the top layer", lead to failure types 2 or 3 and can also be considered a balanced criterion, showing only minor unrepresented effects of wave steepness and berm width.

CHAPTER 121

Stability of artificial roughness elements and run-up reduction

M. Klein Breteler¹ and K. W. Pilarczyk²

Abstract

Smooth concrete slope protection structures are an interesting alternative to rip-rap slopes for areas with a mild wave climate (up to $H_s = 3$ m), especially where the accessibility and the aesthetic appearance of the slope is of great importance. The smooth surface makes the water line accessible to bathers and fishermen and it also enables an integrated design in the scenery.

Unfortunately the smooth surface gives a much higher wave run-up, leading to a higher structure. To tackle this problem one can use a smooth surface with artificial roughness elements.

The present research leads to the conclusion that relatively small roughness elements reduce wave run-up considerable, but don't effect the stability of the cover layer.

Figure 1, Cross section and plan view of smooth slope with artificial roughness

Introduction

Smooth concrete slope protection structures are used throughout the world, especially in areas where the accessibility and the aesthetic appearance of the slope is of great importance. The smooth surface allows recreation and makes the water line accessible to bathers and fishermen but it also enables an integrated design in the scenery.

On the other hand there are important disadvantages that cannot easily be overcome. For example, the smooth surface gives a much higher wave run-up. Consequently, the height of the structure must be much larger than that for an alternative structure with e.g. rip-rap. This leads not only to higher construction costs, but it is also undesirable in areas where the view over the sea should not be hindered by coastal structures.

To illustrate the problem an example has been presented in Figure 2. It shows the necessary height of the structure with slope of 1:3 for a wave attack of 2 m high waves with wave period of 5 s. The crest of the smooth slope with height of 2.85 m will have the same amount of wave overtopping as the rip-rap slope of 1.70 m height.

Figure 2, example of crest height for a smooth structure and a rip-rap structure

These problems can be tackled by using a smooth surface with artificial roughness elements. Walking across a slope, on which 5 to 15% of the surface is covered with block-shaped roughness elements with a height of less than 20 cm, is almost as easy as on a smooth slope. It is even easier when the slope is a bit slippery.

As a covered slope decreases the wave run-up, one can expect larger hydraulic forces on the structure. The influence of these extra hydraulic forces on the stability of the cover layer is investigated by way of large-scale model tests.

The tests have also resulted in new wave run-up data, which are compared to earlier small-scale test results.

The research was commissioned by the Rijkswaterstaat of the Dutch Ministry of Transport and Public Works (Road and Hydraulic Engineering division) and was performed by Delft Hydraulics in co-operation with Delft Geotechnics.

Reduction of wave run-up

The influence of artificial roughness elements has first been studied in a small-scale model with wave heights ranging from $H_s = 0.11$ up to 0.25 m. Various types of elements were used, resulting in reduction factors depending on the type of element and the relative spacing and dimensions of the roughness element. These results were described briefly by De Waal and Van Der Meer (1992).

The spacing and dimensions of the roughness elements in the small scale model is shown in Figure 3. All tests have been performed on a slope with steepness of 1:3, which is a common steepness for Dutch dikes.

The amount of roughness elements is expressed in a percentage: the total area of the roughness elements compared to the total area of the slope. In this way the first configuration in Figure 3 has 4% roughness.

schematised cross section

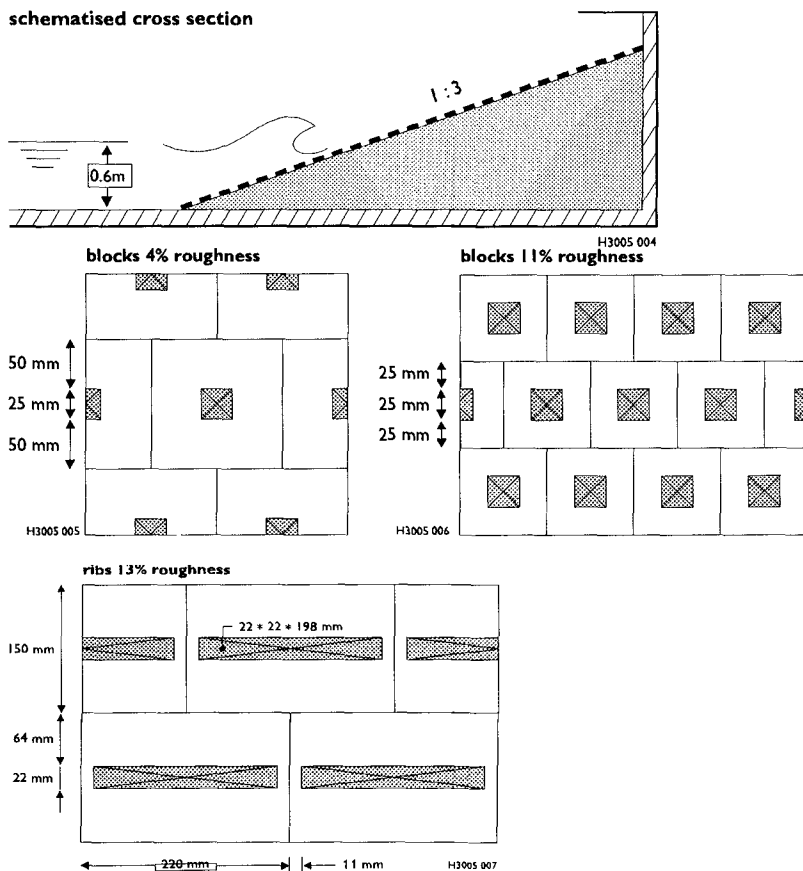

Figure 3, Small scale model of smooth slope with roughness elements.

An important parameter for designing the height of a structure is the wave run-up level which is seldom exceeded. For practical reasons $R_{u2\%}$ has been chosen, which is the run-up level relative to the still water level with exceedence frequency of 2%. The exceedence frequency is defined as the number of run-ups exceeding the $R_{u2\%}$ level divided by the number of incoming waves.

The test results are plotted in a dimensionless form in Figure 4. In the Figure one can see that the tests on a very smooth slope (plastic) and the tests on a smooth concrete slope give the same results. These test results can be summarised with the following formula (De Waal and Van der Meer, 1992):

- if $\xi_{op} \leq 2$:
$$\frac{R_{u2\%}}{H_s} = 1.5 \cdot \xi_{op} \quad (1)$$

- if $\xi_{op} \geq 2$:
$$\frac{R_{u2\%}}{H_s} = 3 \quad (2)$$

with: $R_{u2\%}$ = level of run-up which is exceeded by 2% of the incoming waves, relative to the still water level (m)

H_s = significant wave height of the incoming waves at the toe of the structure (m)

ξ_{op} = breaker parameter (-)
 $= \tan\alpha / \sqrt{(H_s/L_{op})}$

α = slope angle ($^\circ$)

L_{op} = wave length at deep water (m)
 $= gT_p^2 / (2\pi)$

T_p = wave period at the peak of the spectrum (s)

Figure 4, results of small scale run-up tests.

The tests with the roughness elements show a considerable lower wave run-up than the tests with a smooth slope. The following reduction factor is introduced:

$$f = \frac{[R_{u2\%}]_{rough}}{[R_{u2\%}]_{smooth}} \tag{3}$$

with: $[R_{u2\%}]_{rough}$ = wave run-up on a slope with roughness elements (m)
 $[R_{u2\%}]_{smooth}$ = wave run-up on a smooth slope without roughness elements (m)
 f = run-up reduction factor (-)

The smaller the reduction factor, the more the wave run-up is reduced. The range of the reduction factors is as follows:

- blocks with 4% roughness: $f = 0.61$ to 0.73 (average: 0.66)
- blocks with 11% roughness: $f = 0.58$ to 0.68 (average: 0.62)
- ribs with 13% roughness: $f = 0.46$ to 0.65 (average: 0.55)

The smallest reduction factors are measured with the ribs on the slope. The largest factors are found for the slope with 4% roughness, but the differences are only small. It means that with only a small amount of roughness elements, such as only 4% of the surface, one can obtain a considerable run-up reduction.

These results have been checked in the Deltaflume of Delft Hydraulics. In this large scale flume we can make waves up to 2 m high. For the present study a slope with steepness of 1:4 was installed with 4% roughness elements. A roughness element of $0.10 \times 0.10 \text{ m}^2$ and 0.088 m high was placed on each area of $0.5 \times 0.5 \text{ m}^2$, resulting in a 4 times larger model than during the small scale tests. The significant wave height was varied between 0.41 m and 0.82 m at a water depth of 5 m .

Figure 5, Results of large scale tests in comparison with small scale tests

In Figure 5 the results of the large scale model tests on a 1:4 slope in the Deltaflume are presented together with the small scale tests on the 1:3 slope and results of large scale tests performed in the Large Wave Channel in Germany

(Führböter et al '89). The German tests were performed on a slope with steepness of 1:6 and 4% roughness elements. The size of the roughness elements were $0.16 \times 0.16 \text{ m}^2$ and 0.14 m high. The wave height was varied between 0.75 m and 1.25 m with relatively large wave period (small wave steepness).

From the results with a smooth slope we can conclude that the large scale model also matches the formula (1) and (2) very well.

The results with roughness elements, however, show a difference. The large scale tests in the Deltaflume and from Germany both give an average reduction factor of 0.78, which is considerably higher than the small scale tests (0.66). This difference can not be explained with the difference in the slope angle, because the Deltaflume tests (slope of 1:4) and the German tests (slope 1:6) give the same result.

Probably there is a scale effect that can not be neglected. The influence of the Reynolds number may be of influence. Therefore we should be cautious when using the reduction factors from small scale tests. For now we estimate the run-up reduction for a slope with 4% roughness to be $f = 0.75$ to 0.80.

Stability of block revetments without roughness elements

The smooth surface of a block revetment and its nice interaction between the blocks leaves only one possible damage mechanism under wave attack: the uplift of blocks due to a pressure difference over the cover layer.

This damage mechanism is explained with Figure 6.

Figure 6, Damage mechanism of block revetment

Figure 6 shows the most important moment during wave attack. The previous wave has resulted in maximum wave run-down and the next wave is going to plunge on the slope. At this moment, which lasts for approximately $0.15T_p$ to $0.25T_p$, there is a region with a large pressure on the slope (under the oncoming wave) and a region with a low pressure on the slope (almost dry region above wave run-down level). The high pressure is transmitted through the filter, which is filled with water to at

least the still water level and probably even higher. The transmitted pressure leads to an upward pressure difference in the region with low pressure on the slope.

The wave impact itself lasts very short (less than a $0.1T_p$) and therefore can not be responsible for lifting a heavy block: The inertia dominates the motion.

The pressure transmission and resulting uplift pressure is influenced by the ratio of permeability's of cover layer and filter layer and the thickness of the cover layer and filter layer. Based on the assumption that each infinitesimal segment of filter cannot store water, a differential equation can be derived (Klein Breteler et al 1991), which can be used to quantify the uplift pressure. The uplift pressure turns out to be influenced only by the leakage length:

$$\frac{\Lambda}{D} = \sqrt{\frac{kb}{k'D}} \quad (4)$$

with: Λ = leakage length (m)
 D = thickness of cover layer (m)
 b = thickness of filter layer (m)
 k = permeability of filter layer (linearized) (m/s)
 k' = permeability of cover layer (linearized) (m/s)

A large leakage length will lead to a large pressure difference over the cover layer and a small stability. A small leakage length can be achieved by applying an open cover layer with large permeability of the cover layer (relative to the filter layer). An open cover layer will easily relief the high pressure in the filter, without resulting in an uplift force on the blocks.

The stability calculation of a block revetment follows several steps:

1. calculation of the decisive pressure on the slope for the given wave conditions.
 2. calculation of the permeability of filter and cover layer and calculation of leakage length.
 3. calculation of pressure difference over the cover layer (load on the blocks)
 4. calculation of weight of the blocks, friction between blocks and other aspects of the strength of the cover layer.
 5. comparing the load and strength leads to a conclusion about the stability.
- All of these aspects are dealt with by Klein Breteler (1995).

Stability of slope protection with artificial roughness elements

The stability of a smooth block revetment under wave attack is hardly affected by the water motion along the surface, because the hydraulic forces have no grip on the surface. This apparent advantage, compared to a rip-rap slope for example, does no longer hold when large artificial roughness elements are applied. If, however, the dimensions of the roughness elements are small compared to the thickness of the cover layer, it is possible to minimise the influence on the stability and still provide a large reduction in wave run-up.

This concept has been tested in the Delta flume of Delft Hydraulics with regular waves ranging from $H_i = 0.3$ m up to 1.0 m. The sand slope of the dike in the flume was protected against wave attack with a geotextile, a granular filter of 0.15 m thick and a cover layer of rectangular blocks of 0.5×0.5 m². The thickness of the cover layer was 0.15 m, but the roughness of the cover layer was created by replacing 25% of the blocks by thicker blocks. Most of these so called 'roughness blocks' were 0.238 m thick, giving a roughness height of 0.088 m.

To study the influence of the roughness height on the stability also blocks without extra thickness were used (no roughness), 0.200 m thick blocks (roughness height of 0.05 m) and 0.300 m thick blocks (roughness height of 0.15 m).

The test set up is given in Figure 7.

Figure 7, Model set up in Deltaflume for stability tests.

The objective of the study was to compare the uplift pressures on the cover layer with roughness elements and on a smooth cover layer. Regular waves were used as they were sufficient for the experiments.

The stability of a smooth cover layer can be jeopardised by the uplift pressure as is described in the previous chapter. For a rough surface one should anticipate on other forces as well. Führbötter (1986) described serious damage to the bottom protection of the Eider Barrage in Germany. This bottom protection was constructed with blocks with various thicknesses on a filter layer, comparable to the structure presently studied. The structure was seriously damaged after a period with large flow velocities. Supported by scale model tests he found that the stability was influenced by the flow that causes a high pressure against the roughness elements, see Figure 8.

The high flow pressure against the side of a roughness element is transmitted to the filter, contributing to an uplift pressure. At the Eider Barrage the blocks could also move aside by the flow pressure and rotate out of the bottom protection. The latter mechanism is not possible on our slope protection.

Figure 8, Flow pressure against roughness element is transmitted to filter

The two major causes of forces on the blocks on a slope protection:

1. The large pressure gradient on the slope during maximum wave run-down, just before the wave impact, leads to transmission of pressure through the filter to the blocks in the low pressure region. This results in an uplift force on the blocks near the wave run-down level.
2. The flow over the slope causes a flow pressure against the roughness elements, leading to a horizontal force on the blocks. But it is also transmitted to the filter contributing to an uplift force. The largest forces can be found at locations with largest velocities along the slope: near the level of wave impact.

Since it could not be foreseen which mechanism would give the largest uplift pressure on the slope with roughness elements, the model lay-out anticipated on four different levels of maximum wave forces, relative to the still water level.

At each level several blocks were equipped with pressure gauges and instruments to measure the displacement of blocks. The instrumentation was such that hydraulic loads on the roughness element itself and on adjacent blocks could be measured (see figure 7).

The levels of the roughness elements equipped with pressure gauges and displacement devices ranged from SWL-H_i up to SWL.

In addition, two water velocity meters were installed to measure the velocity parallel along the slope in front of roughness elements. These devices were installed to support the derivation of (theoretically based) formulas to quantify the influence of the roughness elements on the stability.

Typical test results are presented in Figure 9.

The measured uplift pressure in Figure 9 is drawn with the solid line. It should be compared to the weight of the blocks, which is drawn with the dotted line. With increasing height of the roughness elements we see an increasing uplift pressure, but since the weight of the roughness elements is larger as well, the stability does not decrease.

Figure 9, Pressure difference over the cover layer ($H_i = 0.80$ m and $T = 3.3$ s).

Also the uplift pressure over an adjacent block in the same row, in one row lower and in one row higher is measured. The influence of the roughness elements on the uplift of these adjacent blocks was negligible.

Figure 10, Forces acting on a roughness block.

A theoretical analysis of the relation between the water velocity on the slope, the pressure against the roughness elements and the uplift pressure on the cover layer was performed to see if the results of the measurements are applicable to all kinds of revetment and roughness geometry's. Figure 10 shows the pressures and forces acting on a roughness element. By considering the balance of forces and momentum it was possible to distinguish two damage mechanisms, each relevant for a certain type of roughness elements:

1. Wide blocks (width measured perpendicular to the water line) with relatively small roughness height: $f_h/B \ll 0.5$. The influence of the horizontal forces is small. The uplift pressure is the most important force and the block will slide out of the revetment during instability. Instability will not occur at a lower wave height than for a slope without roughness elements
2. Small blocks (width measured perpendicular to the water line) with relatively high roughness height: $f_h/B \gg 0.5$. The influence of the horizontal forces is large. The uplift pressure and forces along the slope result in a rotating motion if the blocks have open joints (such as at the bottom protection of the Eider Barrage, see Führbötter 1986). Instability may occur at a lower wave height than for a slope without roughness elements.

The exact criteria to distinguish these types have not yet been established. The preliminary advice is to make roughness elements smaller than 1/3 of the width of the blocks:

$$f_h/B < 0.33$$

with: f_h = height of the roughness element (m)
 B = width of the block, measured perpendicular to the water line (m)

In that case the roughness elements will not decrease the stability.

Conclusions

For areas with a mild wave climate (up to $H_s = 3$ m) a smooth concrete slope protection structure is an interesting alternative to rip-rap slopes. The smooth surface makes the water line accessible to bathers and fishermen and it also enables an integrated design in the scenery.

Unfortunately the smooth surface gives a much higher wave run-up, leading to a higher structure. This extra construction height can be kept within acceptable limits if artificial roughness elements on the smooth surface are used.

Small scale tests are performed to find the wave run-up reduction f , defined as a multiplication factor. The smaller the reduction factor, the more the wave run-up is reduced. The range of the reduction factors from small scale tests is as follows:

- blocks with 4% roughness: $f = 0.61$ to 0.73 (average: 0.66)
- blocks with 11% roughness: $f = 0.58$ to 0.68 (average: 0.62)
- ribs with 13% roughness: $f = 0.46$ to 0.65 (average: 0.55)

The first type of structure (4% roughness) is also tested on a large scale, with waves up to 1.2 m high. The large scale tests in the Deltaflume and from Germany both give an average reduction factor of 0.78, which is considerably higher than the small scale tests (0.66).

Probably there is a scale effect that can not be neglected. The influence of the Reynolds number may be of influence. Therefore we should be cautious when using the reduction factors from small scale tests. For now we estimate the run-up reduction for a slope with 4% roughness to be $f = 0.75$ to 0.80 .

The present conclusion for the reduction factor means the following for the example structure given in Figure 2:

- crest height for smooth surface: +2.85 m
- crest height for surface with 4% roughness elements: +2.20 m
- crest height for rip rap structure: +1.70 m

We see that with only 4% roughness the crest height can be reduced considerable and is now not that much higher than the rip rap structure.

From a theoretical analysis of the water motion and loads following two major causes of forces on the blocks on a slope protection has been identified:

1. The large pressure gradient on the slope during maximum wave run-down, just before the wave impact, leads to transmission to transmission of pressure through the filter to the blocks in the low pressure region. This results in an uplift force on the blocks near the wave run-down level.
2. The flow over the slope causes a flow pressure against the roughness elements, leading to a horizontal force on the blocks. But it is also transmitted to the filter contributing to a uplift force. The largest forces can be found at locations with largest velocities along the slope: near the level of wave impact.

The forces on the blocks were measured in the Delta flume of Delft Hydraulics with regular waves ranging from $H_i = 0.3$ m up to 1.0 m. Based on these measurements and on a theoretical analysis of the balance of forces on the blocks it was concluded that stability is not decreased by roughness elements when these are small compared to the width of the blocks (measured perpendicular to the water line): $f_i/B < 0.33$.

CHAPTER 122

WAVE INDUCED VELOCITIES AT A RUBBLE MOUND BREAKWATER

Bruno Brunone¹, member ASCE, and Giuseppe R. Tomasicchio¹

Abstract

An experimental study has been carried out concerning horizontal velocities induced by a regular wave acting on a rough permeable steep slope. Time-histories of vertical distributions of the horizontal component of local velocity observed for all the considered wave conditions have been compared with results from 1st and 2nd order wave theories. Further analysis has concerned water surface elevation, depth-averaged velocity and uniformity level of velocity profiles. For both local and global characteristics of velocity field, results from wave theories expected to apply are not in good agreement with experimental data. 1st order theory appears satisfactory for the shorter waves but departs significantly from data as the Ursell number increases.

INTRODUCTION

Despite their importance in design of rubble mound breakwaters, kinematics of waves propagating along a steep slope has received little experimental attention (Tørum and Gudmestad 1990). On the contrary, a large amount of experimental data is available for the case of a wave propagating over a horizontal impermeable smooth bottom (e.g. Ragone 1983) or over a gentle slope (e.g. Iwagaki et al. 1974; Stive 1980). Due to the lack of data, no comparison between theoretical and experimental vertical distributions of velocity on a steep slope is available. In the last decade, interest for systematic experimental investigations has grown up due to the

¹ University of Perugia, Institute of Hydraulics, Località S. Lucia, 06125, Perugia - Italy.
e-mail: brunone@unipg.it; tomas@unipg.it

development of 1-D numerical models simulating the wave induced kinematic field along and inside a rubble mound breakwater (Kobayashi and Wurjanto 1990; van Gent 1993). Comparisons between 1-D model provisions and experimental values have been carried out for the case of regular waves spilling on a rough, impermeable mild (1:35) slope (Cox et al. 1995) while with regard to steep slopes, only not consistent comparisons between computed depth-averaged velocity, U , and experimentally observed values of the mean local velocity, u , are available (e.g. Tørum and van Gent 1992). Moreover, 1-D numerical models have been extended to the formulation of a vertically 2-D shallow-water model (Bradley et al. 1996) and even to the reshaping simulation of a berm breakwater (Norton and Holmes 1992; van Gent 1995). The purpose of this paper is to present and discuss results from an experimental investigation concerning regular waves acting on a rough permeable steep slope. Data from this study are discussed from two complementary points of view. The first of them relates vertical distributions of the horizontal component of local velocity; the second one concentrates on the characteristics of some selected global quantities of the wave induced flow field which are provided by 1-D numerical models. In both cases comparisons are provided with wave theories which are expected to apply.

EXPERIMENTS

Laboratory tests were carried out in a wave flume 35 m long and 0.75 m wide equipped with a piston-type wave maker generating regular waves. The water depth, constant along the flume, was equal to 0.50 m. The breakwater, with a 1:2 uniform slope, was composed of an armour layer $2D'_{n50}$ thick, with nominal diameter $D'_{n50} = 0.027$ m, a filter layer $6D''_{n50}$ thick, with $D''_{n50} = 0.015$ m, and an impermeable core (Fig. 1).

Wave conditions were selected in order to produce no damage or overtopping of the structure and breaking waves of surging type. Table I shows the considered wave conditions at the structure toe with T and H' being the wave period and the wave height (incident + reflected), respectively.

Water surface elevation, η , was contemporary measured by standard conductivity-type gauges at the structure toe and at the section where velocity measurements were taken. Time-histories of the vertical distribution of the horizontal component of the mean local velocity, u , at four sections along the slope ($x = 0.0, 0.3, 0.4$ and 0.5 m) were obtained placing a single micro-propeller at different depths.

Figure 1 - Geometry of the tested structure and co-ordinate system.

The deepest point for velocity measurement was at 3.5 cm from the surface of the mound. Due to the use of a single micro-propeller, velocity measurements along the vertical were synchronised by superimposing measurements of free surface elevation at the considered section; synchronisation of velocity measurements at different sections was reached by superimposing measurements of η at the structure toe. Velocity signals presented noise which was removed by a Butterworth lowpass digital filter. Finally, according to observations by Tørum and van Gent (1992) and Cox et al. (1994), a phase averaging was made in order to reduce the remaining small irregularities in the velocity time series.

EXPERIMENTAL OBSERVATIONS AND THEORETICAL RESULTS

Local Characteristics of the Velocity Field

Time-histories of the vertical distributions of the horizontal component of local velocity were obtained for all the five wave conditions at the four considered sections. All velocity distributions present values of u with the same sign along the vertical. A time shift can be observed between the extreme values of the free surface elevation η and those of u . Absolute values of u at the passage of the wave through result systematically larger than the corresponding ones at the wave crest. Finally, the non-uniformity of the velocity profile depends on the wave characteristics; in particular, non uniformity increases for decreasing wave period.

Before introducing comparisons between experimental and theoretical velocity distributions, a selection of wave theories to consider was made, even if in a somewhat arbitrary and merely qualitative way, by evaluating the following dimensionless parameters (Le Méhauté 1976): relative water depth, h/gT^2 , and relative wave height, H/gT^2 , where H = wave height, h = water depth, and g = acceleration due to gravity. Ursell number, $U_R = HL^2/h^3$, with L = wave length, related to the ratio of the convective inertia term to the local inertia one, was also considered. Table II reports the values of the three above mentioned dimensionless parameters for the considered experimental conditions.

TABLE II. Wave dimensionless parameters

wave condition no.	1	2	3	4	5	
h/gT^2	$x = 0.0$ m	0.0796	0.0226	0.0226	0.0176	0.0326
	$x = 0.3$ m	0.0557	0.0158	0.0158	0.0123	0.0228
	$x = 0.4$ m	0.0478	0.0136	0.0136	0.0105	0.0195
	$x = 0.5$ m	0.0398	0.0113	0.0113	0.0088	0.0163
H/gT^2	$x = 0.0$ m	0.0056	0.0023	0.0025	0.0026	0.0020
	$x = 0.3$ m	0.0072	0.0023	0.0018	0.0020	0.0032
	$x = 0.4$ m	0.0059	0.0021	0.0015	0.0017	0.0033
	$x = 0.5$ m	0.0057	0.0016	0.0013	0.0013	0.0031
U_R	$x = 0.0$ m	0.2823	4.3470	4.8407	8.5617	1.4858
	$x = 0.3$ m	1.0551	9.4812	7.2463	13.6100	6.1511
	$x = 0.4$ m	1.3674	11.294	8.3772	15.3138	8.5275
	$x = 0.5$ m	2.2798	13.0164	10.3179	17.1729	11.5205

The range of experimental conditions include relative depths, h/gT^2 , from 0.0398 to 0.0796 for wave condition no. 1 and from 0.0088 to 0.0326 for wave

conditions no. 2 to 5; relative wave height, H/gT^2 , from 0.0056 to 0.0072 for wave condition no. 1 and from 0.0013 to 0.0033 for wave conditions no. 2 to 5; Ursell number, U_R , from 0.2823 to 2.2798 for wave condition no. 1 and from 1.4858 to 17.1729 for wave conditions no. 2 to 5. Thus, values of the three dimensionless parameters for wave condition no. 1 are significantly different from those attained in conditions no. 2 to 5. Specifically, wave motion no. 1 appears to be characterised by quasi-deep water conditions and by very small values of the Ursell number with respect to the other cases. On the basis of Fig. 2 (Le Méhauté 1976), for wave condition no.1, 2nd order and only marginally 3rd order theories apply; for the case of wave conditions no. 2 to 5, 2nd order theory should be taken into account. As a term of reference, also 1st order theory was considered in calculations.

Figure 2 - Regions of validity for various wave theories and experimental conditions from the present study (modified from Le Méhauté 1976).

Comparisons have been carried out between observed and calculated velocity

distributions at some selected times counted in terms of $t^* = t/T$, with $t^* = 0$ corresponding to $\eta = \eta_{\max}$ at the considered section. Figs. 3a and 3b refer to section $x = 0.3$ m and to wave conditions no. 2 to 5; in plots, z is the vertical co-ordinate, positive upward with $z = 0$ at the armour surface. Fig. 3a shows the comparison between experimental and 2nd order theory velocity profiles, while in Fig. 3b 1st order theory results are considered. It is noted from these figures that nor the 2nd nor the 1st order theory is valid and that only small differences between them arise. Analogous results (not shown) are found at the other sections for wave conditions no. 2 to 5. On the contrary, with regard to wave condition no. 1, values from the 2nd and 1st order theories are practically indistinguishable and therefore in Fig. 4 only results from the 1st order theory are reported. A rather good agreement is found at section $x = 0.0$ m; further landward it gets slightly worse but it can be noticed that the 1st order theory well approximates the velocity profiles of wave condition no. 1.

As a preliminary result, it can be stated that the 1st order theory well simulates experimental velocity profiles characterised by a noticeable disuniformity and corresponding to a short period wave. Moreover, in accordance with the results of Le Méhauté et al. (1968) for a horizontal bottom, also for the case of a steep slope, the selection of the appropriate wave theory to describe the velocity field on the basis of relative water depth, h/gT^2 , and relative wave height, H/gT^2 , appears to be not completely reliable.

With regard to the wave kinematics field on a steep slope, more precise indications on the wave theory selection can be obtained by evaluating the influence of different terms like local inertia, convective inertia, wave reflection, energy dissipation due to surface roughness and flow in the mound. For wave condition no. 1, where U_R ranges from 0.2823 to 2.2798, accordance between the 1st order theory and the experimental velocity profiles suggests the predominance of the local inertia term with respect to the others. This is probably due to the small wave period which determines a so rapid change in the kinematic characteristics in one section that the effect of different conditions in the adjacent sections can be considered negligible. For the case of wave conditions no. 2 to 5, where U_R ranges from 1.4858 to 17.1729, other terms become more important than the local inertia one and there is no agreement with 1st and 2nd order theories. In other words, when in a given section the wave field characteristics vary very rapidly due to the small wave period, there is a minor influence of the contemporary changes in the adjacent sections.

The not large number of the examined experimental conditions and the lack of velocity measurements at the surface and close to the bottom give no possibility to

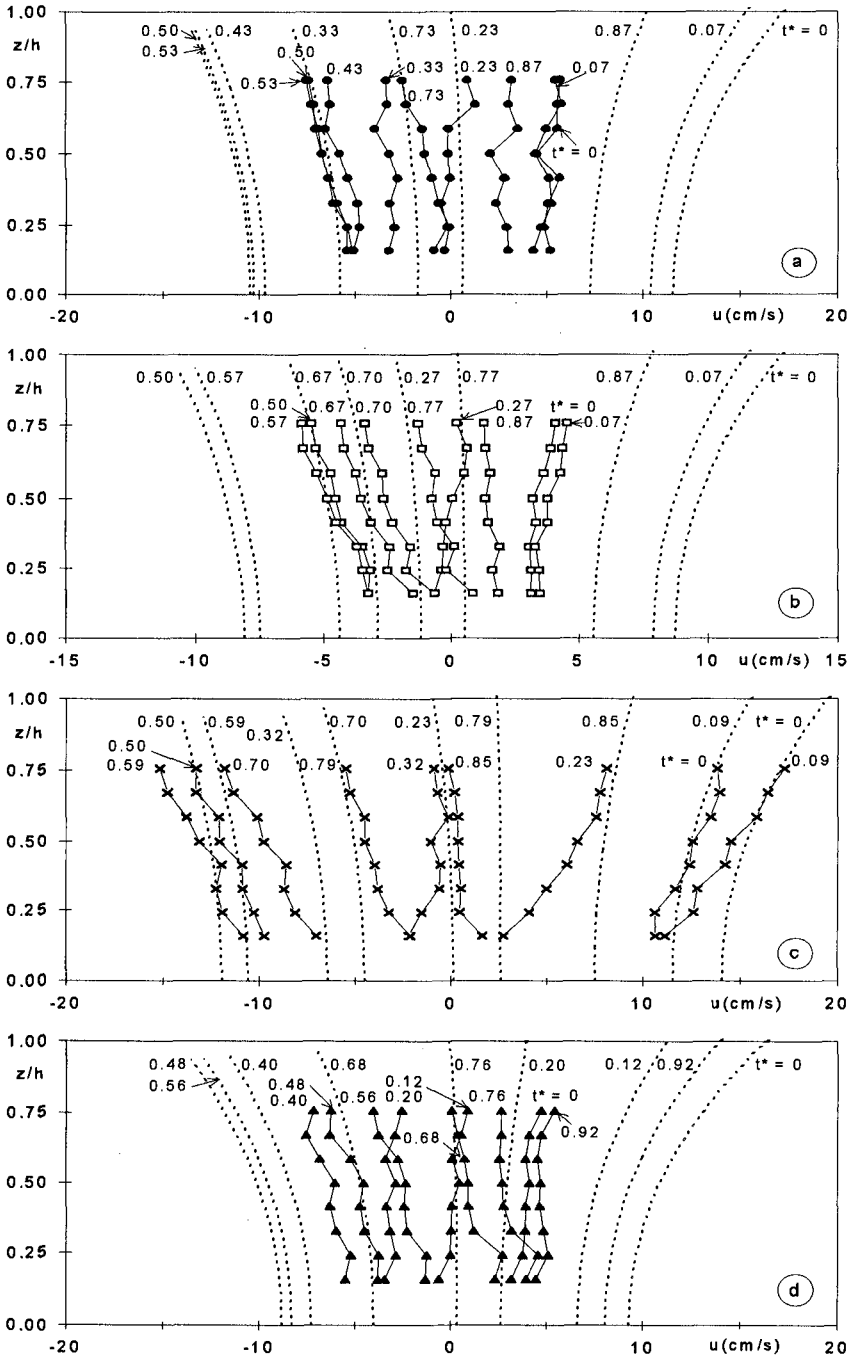

Figure 3a - Vertical distributions of the horizontal component of mean local velocity at section $x = 0.3$ m for wave condition: a) no. 2, b) no. 3, c) no. 4, d) no. 5 (dotted lines: 2nd order theory).

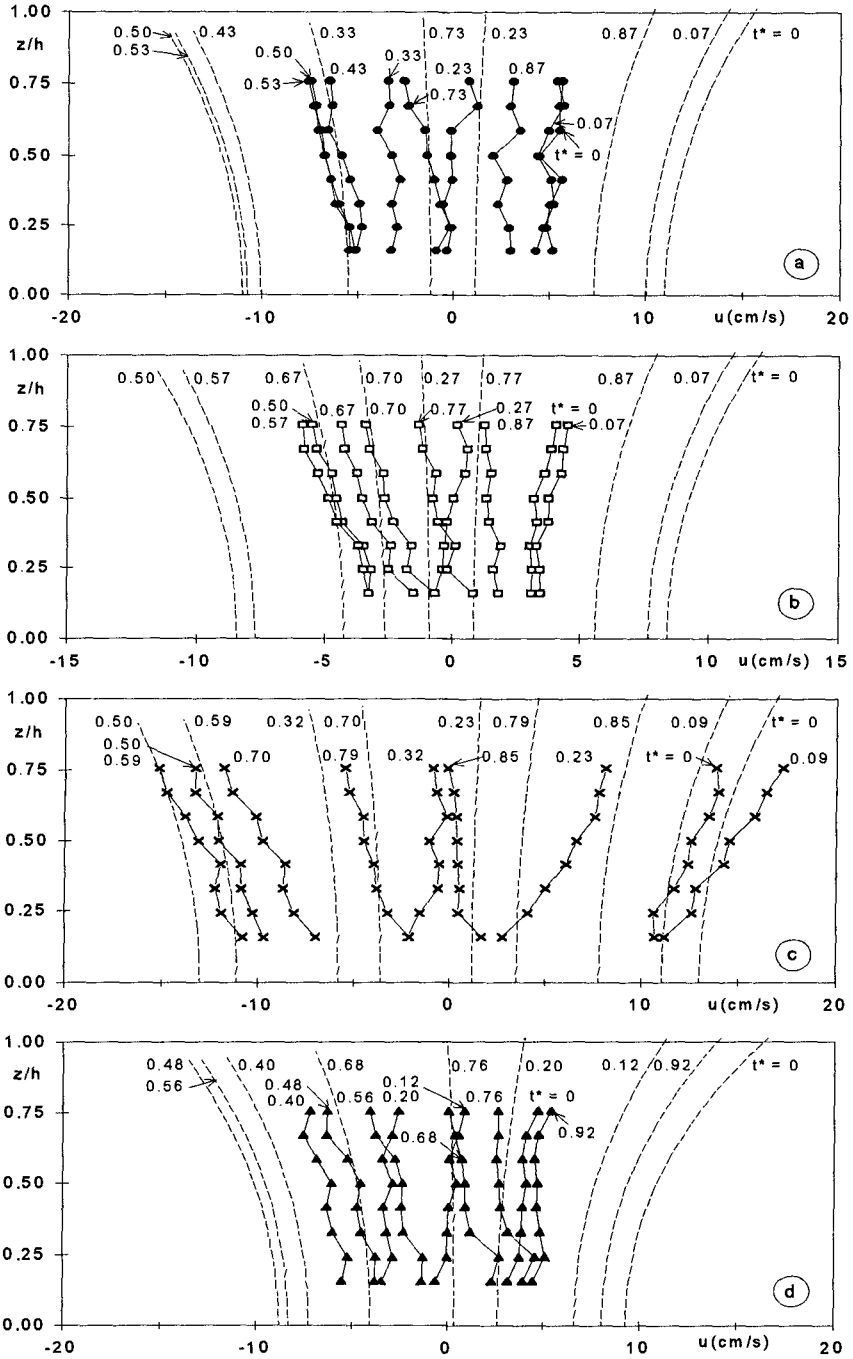

Figure 3b - Vertical distributions of the horizontal component of mean local velocity at section $x = 0.3$ m for wave condition: a) no. 2, b) no. 3, c) no. 4, d) no. 5 (broken lines: 1st order theory).

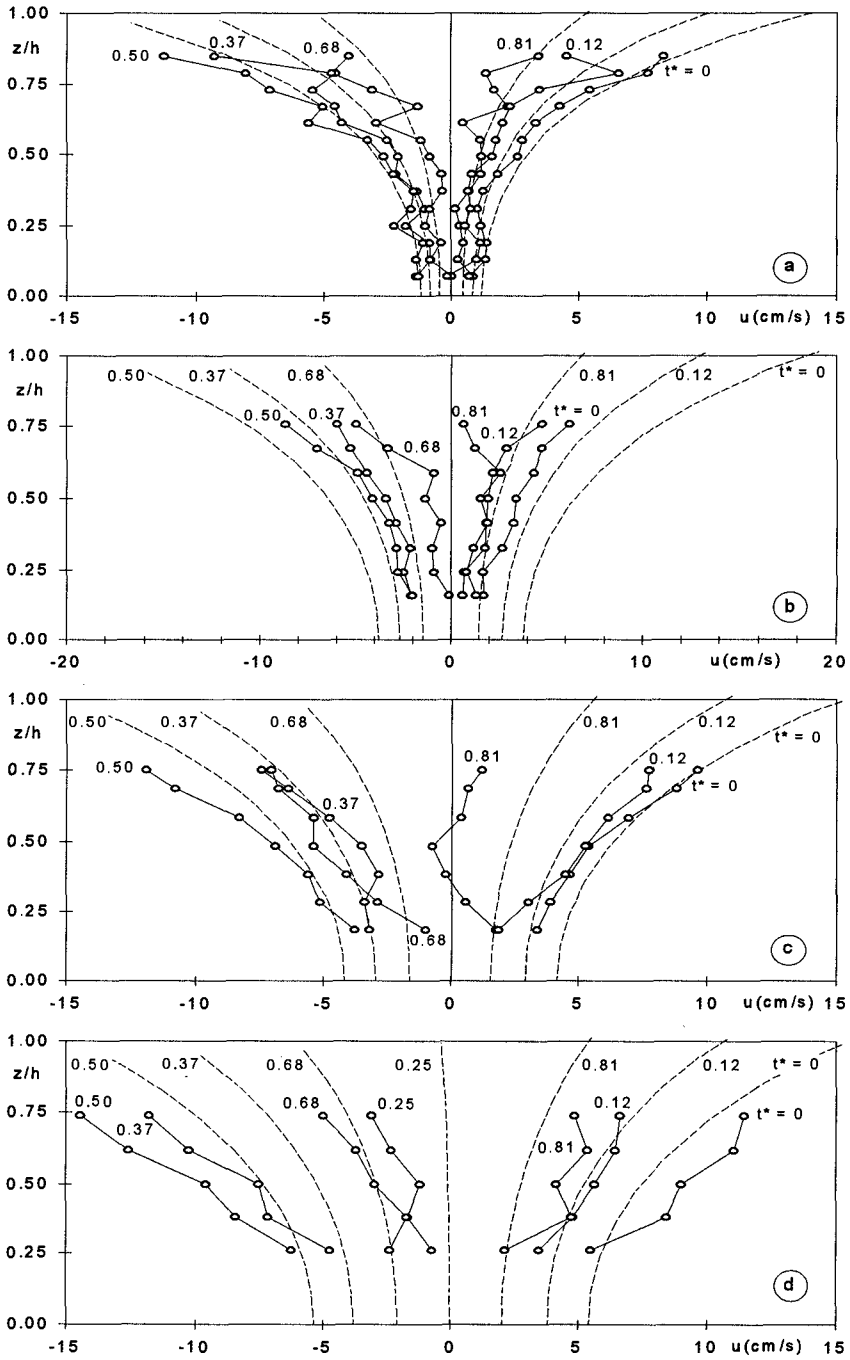

Figure 4 - Vertical distributions of the horizontal component of mean local velocity for wave condition no. 1 at section: a) $x = 0.0$ m, b) $x = 0.3$ m, c) $x = 0.4$ m, d) $x = 0.5$ m (broken lines: 1st order theory).

discuss further in terms of velocity profiles and makes not convenient to consider higher-order wave theories.

Global Characteristics of the Flow Field

In the present section the discussion refers to global quantities of the flow field, provided by 1-D numerical models, such as water surface elevation, η , and depth-averaged velocity, U , defined as:

$$U = \frac{\sum_{i=1}^{n'} u_i \Delta z_i}{h + \eta} \quad (1)$$

where $n' = n + 2$, with n being the number of the velocity measurement points along the vertical at the considered section. The extension of the experimental velocity profiles to the bottom and to the surface has been obtained by extrapolation. Because the momentum flux correction coefficient, β , is not defined when U is close to zero, the variance, σ^2 (Brunone and Tomasicchio 1996) defined as:

$$\sigma^2 = \frac{\sum_{i=1}^{n'} (u_i - U)^2}{n' - 1} \quad (2)$$

must be introduced. It allows to describe the uniformity level of velocity profiles and to evaluate 1-D approximations during the whole wave period.

With regard to η , for all the considered cases, in agreement with Le Méhauté et al. (1968), also when a steep slope is considered, differences between experiments and theory are not as great as that for local velocities since the most significant feature, the wave height, is imposed by experiments. For wave condition no. 1, Fig. 5 presents the experimental and calculated (1st order theory) time-histories of η , U and σ^2 through the wave period at the four different sections. Small differences and a moderate phase shift are observed between the experimental and calculated values of U . Maximum and minimum values of U happen at the same time of the corresponding extreme values of η . In agreement with the experimental observations (Brunone and Tomasicchio 1996), the calculated time-history of variance σ^2 presents a bimodality with two relative maximum (minimum) values. At section $x = 0.0$ m, calculated variance of velocity profiles simulates rather well the experimental data; further landward, differences increase and approximation is not satisfactory even if the

Figure 5 - Time-history of water surface elevation, depth-averaged velocity and variance of velocity profiles for wave condition no. 1 at section: a) $x = 0.0$ m, b) $x = 0.3$ m, c) $x = 0.4$ m, d) $x = 0.5$ m (broken lines: 1st order theory).

Figure 6 - Time-history of water surface elevation, depth-averaged velocity and variance of velocity profiles at section $x = 0.3$ m for wave condition: a) no. 2, b) no. 3, c) no. 4, d) no. 5 (broken lines: 1st order theory).

behaviour of the experimental values of the variance is certainly captured. Fig. 6 presents time behaviour of η , U and σ^2 at section $x = 0.3$ m for wave conditions no. 2 to 5. Still the experimental and calculated values of η are almost identical. This is not the case for the values of the depth-averaged velocity, for which differences are large and only a certain similarity in the shape can be found. Calculated time-histories of the variance present values much larger than the experimental ones and a very different shape.

CONCLUSIONS

Water surface elevation and horizontal velocity profiles at some sections along a rough permeable steep slope were observed for different wave conditions. Two different groups of wave conditions were identified by evaluating relative water depth, relative wave height and Ursell number. For wave condition no.1, 2nd order and only marginally 3rd order theories are expected to apply; for the case of wave conditions no. 2 to 5, 2nd order theory should be considered. As a term of reference, also 1st order theory was taken into account in calculations. Accordance between experimental and calculated values of water surface elevation was found for all the cases. Only for wave condition no. 1, where U_R ranges from 0.2823 to 2.2798, experimental and 2nd order theory velocity profiles show a satisfactory agreement and accordance is noticed also when 1st order theory is considered. Analogous considerations are valid for global characteristics of flow field such as depth-averaged velocity U and variance of velocity profiles σ^2 . For the case of a rough permeable steep slope, as a preliminary result of the study, it can be stated that wave kinematics is not correctly described by wave theories which are expected to apply considering only the values of relative water depth and relative wave height. Phenomena like wave reflection, energy dissipation due to slope roughness and flow in the permeable layer should be necessarily taken into account in description of wave induced kinematics on a steep slope.

CHAPTER 123

Natural Periods of Armor Stones

Fred E. Camfield¹, Fellow, ASCE

Abstract

Results of a laboratory investigation were analyzed to determine the response of quarystone armor units to particular wave periods. Results indicate that individual stones appear to respond to particular wave periods depending on the stone's mass, shape, and placement in the structure's armor layer. Results also indicate that the wave period critical for design may not be the longest wave period in the incident waves, and investigations must be carefully conducted to determine the critical design conditions.

Introduction

Variables affecting stability of armor stones include wave height, wave period, water depth at the structure, foreslope of the shoreline, structure slope, structure porosity, and armor stone variables. Armor stone variables include stone density, mass, stone shape, orientation of the stone in the structure, contact with adjoining stones, and location of the stone in the armor layer with respect to the still water line (SWL).

Structures, in general, have natural frequencies and can be excited into motion by impulses applied at that frequency. Likewise, individual armor units on a coastal structure will have a natural frequency dependent on the mass, shape, and orientation of the armor unit in the structure. For concrete armor units, with a fixed mass and shape and uniform interlocking, this should be a

¹Research Hydraulic Engineer, Coastal and Hydraulics Laboratory, U.S. Army Engineer Waterways Experiment Station, Vicksburg, MS 39180-6199

single frequency. For armor stones, with variations in mass, shape, and orientation, there would be a range of natural frequencies due to the variations in the units.

Results of laboratory investigations were analyzed to compare motion of armor stones with various incident wave periods for different cases where the foreslope, water depth, structure slope, structure porosity, and stone density were held constant. Both monochromatic and spectral waves were used for the investigations. Separate investigations were carried out for three revetment slopes and one breakwater cross-section.

Laboratory Investigations

Investigations were carried out as part of a research effort to study the stability of selectively placed armor stones. Field practice is to place quarystone armor units to provide the best fit obtainable for particular site conditions. The selective placement of quarystones, i.e., the selection and placement of armor stones one at a time to achieve the best fit (often call Standard Placement), is known to provide better stability. The tighter fit of armor stones using this placement method may also allow the use of a single layer of armor stones which will result in significant construction cost savings when compared to the traditional use of two armor layers. Guidelines for selective placement specifications are given by the Coastal Engineering Research Center (1995).

Laboratory tests were conducted at the U.S. Army Engineer Waterways Experiment Station's Coastal and Hydraulics Laboratory in a two-foot wide wave flume. The flume is equipped with a programmable wave generator capable of producing both spectral and monochromatic waves. A long, two percent (1:50) foreslope was constructed in front of the model structures to produce breaking waves on the structure.

Tests were for model revetments having slopes of 1:1.5, 1:2, and 1:3, and for a breakwater cross-section with a 1:1.5 structure slope. The model revetments were constructed to be "impermeable" with a dense sand core overlaid with filter cloth. Layers of smaller bedding stone were used under the model armor stone. This bedding stone conformed to the present guidance in the Shore Protection Manual (1984), i.e., w50/10 for a first underlayer and w50/200 for a second underlayer. The tests on the breakwater cross section used the second underlayer stone as the structure core.

Tests were conducted for single layers of armor stones. Revetment tests were conducted using model armor

stones with a median weight of 0.47 lbs, and a range from 0.31 - 0.70 lbs (0.66 w50 - 1.49 w50). Breakwater tests were conducted using stones with a median weight of 0.43 lbs, with a range from 0.33 - 0.66 lbs (0.77 w50 - 1.53 w50).

Tests were conducted with waves breaking on the model structures. A total of 11 model revetments and five model breakwaters were tested. The water depth was varied to produce breaking waves of different heights. Tests were conducted using both monochromatic waves and spectral waves with periods (peak spectral periods) ranging from 1.3 to 3.0 seconds in the model. Waves were analyzed using a three-gage array (Hughes, 1993). Visual observations were made of armor stone movement for the various test conditions.

Repetitive tests were conducted to determine the stability of the armor stones. Initial tests were conducted using spectral waves with varying peak periods until rocking motion was detected in the armor stones. These tests were followed by tests using monochromatic waves with various periods that were embedded in the spectral waves. Tests continued until the structure failed, i.e., several stones rolled out of the armor layer, after which the revetment structure was reconstructed and retested.

Observations of Armor stone Movement

Observations indicated that different wave periods often affected different armor stones. Stone movement generally occurred at or somewhat above the still water line. With other variables, including water depth, held constant, breaking waves were generated with variations in wave period. If waves having a particular period caused motion, i.e., rocking of an armor stone, waves were then generated at periods slightly higher and/or lower than the initial period. It was found that moderate changes in wave period could cause changes in which stones exhibited motion, i.e., a stone which appeared stable at one wave period would be set in motion by a slightly different wave period, while a stone that initially had exhibited motion would become stable when the wave period changed. Examples of observations for three test set-ups are shown in Table 1. For each set-up shown, the only variables were the wave period and wave height, all other parameters being held constant.

Placement of the individual stones played a role in stone movement but did not appear to be the controlling factor. Stones that appeared to be less well placed (fewer points of contact) often remained stable while

stones with seemingly better placement moved when subjected to particular wave periods.

TABLE 1. Stone Movement vs. Wave Period

14 Mar 96 Run No. 3	1.7	18.3	Breaking waves, movement in same stone plus one additional stone
14 Mar 96 Run No. 12	2.0	19.0	Breaking waves, movement in second stone, other not moving
14 Mar 96 Run No. 18	2.5	19.2	Surging breakers, stone near SWL (not previously moving) came out

Consideration needs to be given to the different equations used for armor stone stability. The Hudson equation (Shore Protection Manual, 1984) does not include wave period, and bases stability on stone movement at whatever period may cause motion. This approach would appear to be correct if testing is conducted at a full range of wave periods. The stability equation proposed by van der Meer (1987, 1988) incorporates wave period which could be incorrect as it assumes a significant effect at all wave periods and lower stability at longer wave periods. The present tests showed that shorter wave periods often caused motion in stones and structural failure while longer wave periods, at similar wave heights, did not cause instability. Tests by others (Mansard, et al., 1996) also show that the longest wave period may not be the critical period for design. Previous tests by

McCartney and Ahrens (1975) for a concrete revetment unit also showed lower stability at a shorter wave period.

Investigations comparing wave spectra with monochromatic waves showed that wave spectra sometimes caused movement in armor stones while monochromatic waves having a period equal to the peak spectral period did not cause stone movement. This has also been observed by Kamphuis (1996). As noted above, minor variations in wave period can cause major changes in the response of the armor stones. As a wave spectrum contains waves at many periods, it is possible that an armor stone may respond to a period other than the peak spectral period. As an example, one test set-up for a breakwater cross-section (8 Jul 96) exhibited stronger motion of armor stones when subjected to a wave spectrum with a peak spectral period of 2.0 seconds than when the test section was subjected to 2.0 second monochromatic waves, even though the monochromatic waves had a higher wave height. Lowering the wave period of the monochromatic waves to 1.8 seconds produced stronger motion and one stone was displaced from the structure. It should be noted that comparisons between spectral and monochromatic waves were not consistent. In some cases wave spectra did not cause stone motion and monochromatic waves caused motion, and in other cases both the wave spectra and the monochromatic waves caused movement of the armor stones.

Conclusions

While this paper presents a concept for consideration, additional testing is needed to more completely investigate the natural periods of armor stone. The scalability of natural periods has not been established, and tests at different scales are needed. Finally, a practical method of applying the knowledge gained from this research to field use must be determined.

Acknowledgments

A field office working group was formed to provide input to the Waterways Experiment Station on field practice and experience in the placement of quarystone armor units on Corps structures. Members of this working group who participated in meetings at the Waterways Experiment Station were Messrs. Douglas Pirie, Bradd Schwichtenberg, Thomas J. Bender, Jeff Wiggan, George Young, and Jack McKellar. Messrs. Raymond Reed and John Williams, civil engineering technicians, Mr. David Daily, electronics technician, Mr. Bryan Johnston, contract student, and Ms. Dynisha Hayes, science and engineering apprentice, assisted in the testing. This paper was prepared under the Coastal Structures Evaluation and

Design Research Program of the U.S. Army Corps of Engineers Civil Works Research Program at the U.S. Army Engineer Waterways Experiment Station, Coastal and Hydraulics Laboratory. A draft of the material presented in this paper was technically reviewed by Messrs. C. Eugene Chatham, Jr., D. D. Davidson, and Donald L. Ward. Permission of the Chief of Engineers to publish this paper is appreciated.

CHAPTER 124

Reliability based optimal design of vertical breakwaters modelled as a series system of failure

E. Christiani ¹ H.F. Burcharth ² J. Dalsgaard Sørensen ³

Abstract

Reliability based design of monolithic vertical breakwaters is considered. Probabilistic models of important failure modes such as sliding and rupture failure in the rubble mound and the subsoil are described. Characterisation of the relevant stochastic parameters are presented, and relevant design variables are identified and an optimal system reliability formulation is presented. An illustrative example is given.

Keywords: Vertical wall breakwaters, sliding failure, rupture failure, design optimisation, reliability

Introduction

A number of breakwater failures have been reported during the last 20 years for rubble mound breakwaters as well as for vertical breakwaters e.g. Sines (Portugal), Arzew (Alger), Mutsu-Ogawara Port (Japan), Gela (Italy) and Algeciras Port (Spain). This has resulted in new ways of approaching the design problems related to breakwaters. Probabilistic methods have been introduced to solve breakwater design problems in the early stage of planning. Reliability based design of breakwaters has been discussed by Nielsen et. al. (1983), Burcharth (1991), (1992a), (1992b), Burcharth et al. (1994) and (1995) and by Takayama (1994).

In the following a caisson vertical breakwater is analysed with respect to probability of failure for single failure modes. Emphasis is put on the foundation failure modes and their relative importance.

Identification of the failure modes

Sliding and rupture failure in the rubble mound foundation and in the subsoil are usually the most critical failure modes for vertical breakwaters. Other failure modes exist e.g. settlement of the caisson, seaward sliding, scour at the toe (subsoil and/or rubble mound), instability of the armour stones in the foundation, and structural failure of the caisson.

²Prof. dr.techn., Hydraulics and Coastal Eng. Lab., Dept. of Civil Eng., Aalborg University

³Assoc. Prof. Ph.D., Dept. of Building Technology and Structural Engineering, Aalborg University

Nine foundation failure mechanisms including sliding are identified cf. Figure 1. Overturning is a relevant failure mode only in the cases of monolithic structures placed on very strong foundation soils or rock. The designs considered cover vertical breakwaters placed on low or high rubble mounds and sand or clay subsoils.

Figure 1: *Nine foundation rupture failure mechanisms*

Sliding

Sliding, i.e. horizontal displacement of the caisson, can occur as a slip either at the interface between the caisson concrete base plate and the rubble material, or entirely in the rubble material.

Corresponding to the first mentioned case stability against sliding exists when the ratio of the resultant horizontal force, F_H , to the resultant vertical force is equal to or less than $\tan \mu$, i.e.

$$F_H \leq (F_G - F_V) \tan \mu \tag{1}$$

where F_G is the weight of the caisson reduced for buoyancy, F_U is the wave induced uplift force on the base plate, and μ is the angle of friction between the concrete base plate and the rubble mound or the bedding layer. Reference is given to Takayama (1992) for values of $\tan \mu$.

If the sliding failure takes place entirely in the rubble material, e.g. in the bedding layer, then μ must be substituted by the effective angle of friction φ' of the material. The most critical of the two cases should be considered in the design.

F_H and F_U are in this paper calculated by using the wave load formulation by Goda et al. (1972) and (1974) extended to include impulsive pressure, Takahashi (1994). The design wave height is adjusted in the surf zone as described by Goda (1975).

The resultant of the forces F_H , F_G and F_U is indicated in Figure 2 as F_R .

Rupture failure in rubble, sand and clay subsoil - cases 1 - 9

To evaluate the stability of the foundation, consisting of the rubble mound, sand or clay subsoil, the upper bound theorem of general plasticity theory is used. This theorem can also be applied in a probabilistic approach of design.

Application of the upper bound theorem requires that the normality condition is fulfilled. Experience shows that good estimates of the bearing capacity can be obtained by introduction of a reduced effective angle of friction φ_d , Hansen (1979) defined by

$$\tan \varphi_d = \frac{\sin \varphi' \cos \psi}{1 - \sin \varphi' \sin \psi} \quad (2)$$

Both φ' and ψ are dependent on the stress level for which reason either reasonable mean values must be used, or calculations must be performed on increments.

Three dimensional effects are not included in the derivation of the zone rupture mechanism. The plane failure mode corresponding to case 8 is shown in Figure 2, where the line AB is approximately assumed to be a straight line. Note that it is assumed that tensile stresses cannot occur under the caisson base plate. Also note that because the caisson is a stiff body, the failure mechanism shown is not fully kinematic admissible. Actually, the intersection point A should be at the corner of the caisson, and the slip surface A-B is not necessarily a straight line. However, the rupture configuration is a close approximation as to the exact rupture mode can be demonstrated by comparison with results of finite element analyses.

Since the derivation of the mathematical formulation of the rupture failure modes 1 - 9 is rather lengthy, only rupture failure mode 8 will be discussed. Reference is given to Christiani (1996) for the rest of the failure modes.

Foundation in rubble and clay (rotation mechanism)

Case 8 in Figure 1 is considered.

The slip line AB is theoretically a logarithmic spiral. The areas, 1 and 2 move as stiff zones and interact with the clay subsoil, where a circular rupture zone evolves. The kinematic admissible rupture figure is described by a rotation mechanism about point D.

Figure 2: Rupture in the rubble mound and clay subsoil.

The geometrical lengths and the radius for the kinematically admissible rupture figure are cf. Figure 2.

$$l_{BC} = B_z + B_{rm} + 2h_{II} - \frac{h_{II}}{\tan(\varphi_{d1} + \theta_2)} \tag{3}$$

As noted above, the slip line AB is approximated by a straight line. The radius R_2 then becomes

$$R_2 = \frac{1}{2} l_{BC} / \sin \theta_2 \tag{4}$$

Further l_{AD} becomes

$$l_{AD} = \frac{h_{II}}{\tan(\varphi_{d1} + \theta_2)} + \frac{1}{2} l_{BC} \tag{5}$$

The centre of gravity for zone 1 and 2 is defined by the length l_G , cf. Figure 2

$$l_G = \frac{(l_{AD} - \frac{1}{2} l_{BC})(\frac{1}{3} l_{AD} + \frac{5}{6} l_{BC} - h_{II}) + \frac{1}{2} (l_{BC} - 2h_{II}) l_{BC} + \frac{2}{3} h_{II}^2}{\frac{1}{2} l_{AD} + \frac{3}{4} l_{BC} - h_{II}} \tag{6}$$

External work done

The external work W_E done by the wave loads, the pore pressure along the rupture boundary line and the weight of the vertical breakwater is for an infinitesimal rotation δ around point D

$$W_E = \delta M_o \tag{7}$$

where M_o is the moment around D of the wave loads, the pore pressure and the weight of the caisson.

The work done due to the weight of zones 1 and 2 is a rotation around D

$$W_{1,2} = \delta(\gamma_s - \gamma_w)(l_{AD} - l_G)(\Omega_1 + \Omega_2) \tag{8}$$

where Ω_1 and Ω_2 are the areas of zone 1 and 2, and $l_{AD} - l_G$ is the perpendicular length between the point of rotation and the center of gravity for zone 1 and 2.

The work done by the weight of zone 3 is zero as the resultant displacement of the centre of gravity is horizontal.

The internal work done in zone 3 along the rim of the rupture boundary BC is

$$W_3 = \delta R_2^2 \int_0^{2\theta_2} c_u(\theta) d\theta \tag{9}$$

where c_u is the undrained shear strength of the clay.

The limit state equation for the rupture mechanism in Figure 2 is then:

$$W_3 - W_{1,2} - W_E = 0 \tag{10}$$

θ_2 is the unknown angle to be determined by minimising the ratio between the stabilising work and driving work.

System model of failure modes for rupture failure and overturning

In design of vertical breakwaters, the main concern is sliding, overturning, and rupture failures in the rubble mound and in the subsoil. These failure modes can be modelled by a series systems cf. Figure 3.

a) Rubble mound and sand subsoil

b) Rubble mound and clay subsoil

Figure 3: Series system of failure modes for rupture failure of the sand and clay subsoil.

Characterisation of the stochastic variables

All variables are in principle stochastic variables in a limit state formulation. Some parameters e.g. geometrical parameters have small coefficient of variation and might be regarded as deterministic variables. The parameters which have a significant degree of uncertainty in breakwater design will be discussed in the following. It is assumed that all stochastic variables are independent, unless otherwise stated in the text.

The wave induced horizontal force and the uplift force can be calculated from equations given by Goda et. al. (1974) and Takahashi (1994). The model uncertainty related to the *Goda wave load* is modelled by a normal distribution. This has been clarified by Bruining (1994) who compared a number of laboratory tests results with the Goda formula in order to evaluate the uncertainty related to the horizontal wave load, the wave induced uplift force, the horizontal moment and the wave induced uplift moment. The model uncertainties are represented by variables $U_{F_H}, U_{F_U}, U_{M_H}$ and U_{M_U} . Expected values (bias) and standard deviations are given in Table 2.

The *deep water wave climate* characterised by the significant wave height H_{so} is assumed to follow a Weibull distribution. The distribution function of the maximum significant wave height within T years is given by

$$F_{H_{so}^T}(H_{so}) = \left[1 - \exp \left(- \left(\frac{H_{so} - B_w}{A} \right)^k \right) \right]^{\lambda T} \tag{11}$$

where λ is the average number of H_{so} data values per year. $B_w = 2.69$ is usually regarded as a deterministic parameter.

Due to the limited number of data A and k are subject to statistical uncertainty. A and k values are modelled as normal distributed stochastic variables with a variance based on the maximum likelihood estimates. The expected value and the standard deviation of A and k are presented in Table 1.

	mean	standard deviation, σ
k	μ_k	$\simeq \sqrt{\frac{1}{N}}$ (approximation)
A	μ_A	$\left[\frac{\mu_A^2}{N} \left(\frac{\Gamma(1 + 2/\mu_k)}{\Gamma^2(1 + 1/\mu_k)} - 1 \right) \right]^{0.5} \simeq \mu_A \left(\frac{0.3}{N} \right)^{0.5}$

Table 1: Mean and standard deviation of A and k values in the Weibull distribution.

In Table 1 N is the number of available H_{so} -values and Γ is the gamma function. $\mu_A = 0.58$ and $\mu_k = 1.14$ and $N = 30$ will be used in the illustrative example, cf. Table 2.

As the water depth decreases from deep water to shallow water, wave transformation will result in refraction (when waves are not head on), shoaling and finally wave breaking. Therefore the uncertainty of the breaker heights should be considered in design in depth limited cases.

The *design wave height* $H_{design} = H_{1/250}$ to be applied in the Goda formula is in case of no surf zone in front of the structure taken as $1.8 \cdot H_{so}$.

i	X_i	Definition	Mean μ_{X_i}	Standard deviation σ_{X_i}	$\frac{\sigma_{X_i}}{\mu_{X_i}}$	Distribution	Reference

Table 2: Stochastic model of the stochastic variables

In case of a surf zone in front of the structure the breaker height is taken as (Goda, 1994)

$$H_b = L_0 0.17 \left(1 - \exp \left(-1.5 \frac{\pi h_b}{L_0} \left(1 + 15 \tan^{4/3} \theta \right) \right) \right) \quad (12)$$

where h_b is the water depth at a distance $5H_s$ seaward of the structure, and $L_0 = H_{so}/0.035$ is the deepwater wavelength. Consequently, $H_{design} = \min[H_{so}, H_b]$.

Tidal elevation ζ is assumed to follow a cosine distribution function, see Takayama (1992).

$$F_\zeta(\zeta) = -\frac{1}{\pi} \arccos \left(\frac{\zeta}{\zeta_a} - 1 \right) - 1 \quad (13)$$

where ζ varies between $\pm \zeta_a = 0.75 \text{ m}$.

Storm surge η_s should be considered when the structure is in shallow water, due to possible change in breaker wave heights and buoyancy of the structure. For simplicity the storm surge is not taken into account.

The total water depth in front the structure is $h_{tot} = h_s + \zeta$, where h_s is the mean sea water level at the foot of the structure, without influence from the storm surge or tidal level.

The average mass density of a conventional vertical breakwater including sand ballast, reinforced concrete walls and concrete cap can be assumed to be normal distributed with a mean value in the range $\rho_c = 2.15 - 2.3 \text{ t/m}^3$ and a coefficient of variation of 5%, Burcharth (1992).

It is generally accepted that the variability of the effective friction angle of a well known soil sample is small, but authors such as Nadim et al. (1994) and Cherubini (1992) have encountered variation coefficients in the range 3% to 15%. It is assumed in this paper that the angle of dilation and effective friction angle have a variation coefficient corresponding to 10 %.

The friction coefficient between the base plate and rubble is assumed normal distributed with a mean value $\tan \mu = 0.636$ and a coefficient of variation of 15 %, Takayama (1992).

Even homogeneous soil layers exhibit change in strength from point to point. The undrained shear strength of clay is an example where spatial variability exists. It is assumed to be modelled by a log-Gaussian stochastic field $\{c_u(x, z)\}$ where x is the horizontal coordinate and z the vertical coordinate, see e.g. Andersen et al. (1992). The mean value function and covariance function are in this paper assumed to be

$$E[c_u(x, z)] = \mu_{c_u} + az \quad (14)$$

$$Cov[c_u(x_1, z_1), c_u(x_2, z_2)] = \quad (15)$$

$$\sigma_{c_u}^2 \exp\left(-\left|\frac{z_1 - z_2}{3.0}\right|\right) \exp\left(-\left(\frac{x_1 - x_2}{30.0}\right)^2\right)$$

where c_u is in kPa and x, z are taken in metres with origo $(x, z) = (0, 0)$ equal to point B, see cf. Figure 2, μ_{c_u} is the expected value of the undrained shear strength, σ_{c_u} is the standard deviation of the undrained shear strength and $a = 3 \text{ kPa/m}$ is a constant signifying the linear increase of the undrained shear strength of the clay subsoil.

Method of reliability analysis

The uncertainties (physical, statistical and model) related to the above failure modes cf. Figure 1 are modelled as stochastic variables, and limit state functions for the failure modes are formulated as described above. The wave loads are estimated using the Goda formula, (including impulsive pressure modification) with model uncertainty included. For the foundation failure modes the strength of the clay subsoil is modelled as a stochastic field and a probabilistic limit state function is then formulated using kinematically admissible failure mechanisms, Christiani (1996).

The probability of failure of the failure modes are estimated using First Order Reliability Methods. System failure is modelled by a series system and the system probability of failure can be evaluated on the basis of the FORM analysis of the single failure modes, see Madsen et al. (1986) and Burcharth (1992).

Limit state functions

Sliding failure.

Failure corresponding to sliding can be modelled by the limit state function, cf eq. (1):

$$g_{sliding} = (F_G - F_U) \tan \varphi' - F_H \quad \begin{cases} < 0 & \text{failure} \\ = 0 & \text{limit state} \\ > 0 & \text{no failure} \end{cases} \quad (16)$$

Foundation failure in the rubble and clay subsoil

As mentioned above the undrained shear strength of the clay is modelled as a log-Gaussian stochastic field $\{c_u(x, z)\}$. The correlation lengths for $\{c_u(x, z)\}$ are small compared to the integration intervals and it follows from the central limit theorem that the total internal work in the clay subsoil can be approximated by a normal distributed stochastic variable W_3 with mean value μ_{W_3} and standard deviation σ_{W_3} . The limit state function is written, see eq. (10)

$$g_{clay} = E[W_3] + u_W \sigma_{W_3} - W_{1,2} - W_E \quad (17)$$

where u_W is a realization of a normal distributed stochastic variable U_W with mean 0 and unit standard deviation.

The expected value of W_3 is

$$E[W_3] = \delta R_2^2 \int_0^{2\theta_2} E[c_u(\theta)] d\theta \quad (18)$$

where $E[c_u(\theta)]$ is the expected value of c_u at the position described by the angle θ along the circular rupture line BC.

The variance of W_3 is

$$Var[W_3] = \sigma_{W_3}^2 = \delta^2 R_2^4 \int_0^{2\theta_2} \int_0^{2\theta_2} Cov[c_u(\theta), c_u(\theta_1)] d\theta_1 d\theta \quad (19)$$

where $Cov[c_u(\theta), c_u(\theta_1)]$ is the covariance function of c_u at the positions corresponding to θ and θ_1 .

Systems reliability of the series systems involving sand and clay subsoils

The single failure modes in Figure 1 are regarded as m failure components. It is clear from a deterministic design of a monolithic structure that if one of the failure components fail then the system fails, i.e. the breakwater has no load carrying capacity after the failure of one component. The system probability of failure P_f^s can be written as a probability of unions.

$$P_f^s = P \left(\bigcup_{i=1}^m g_i(\mathbf{x}) \leq 0 \right) = \int_{\bigcup_{i=1}^m g_i(\mathbf{x} \leq 0)} f_{\mathbf{x}}(\mathbf{x}) d\mathbf{x} \quad (20)$$

where $g_i(\mathbf{x})$ is the failure function corresponding to components $i = 1, 2, \dots, m$. The FORM approximation of the generalised systems reliability index β^s can be estimated as:

$$\beta^s = -\Phi^{-1}(1 - \Phi_m(\boldsymbol{\beta}^c, \boldsymbol{\rho})), \quad \text{or} \quad P_f^s = 1 - \Phi_m(\boldsymbol{\beta}^c, \boldsymbol{\rho}) \quad (21)$$

where Φ_m is the m -dimensional standardised normal distribution function, $\boldsymbol{\beta}^c$ is the vector of the reliability indices of the individual failure modes $\boldsymbol{\beta}^c = (\beta_1^c, \beta_2^c, \dots, \beta_m^c)$ and $\boldsymbol{\rho}$ is the correlation coefficient.

If the failure modes are fully correlated then $P_f^s = \max_{i=1}^m P_i$, where $P_i = \Phi(\beta_i^c)$ is the probability of failure for component i . If only failure modes involving foundation failure are considered the correlation coefficients are fairly close to 1. Taking $P_f^s = \max_{i=1}^m P_i$ is then a good approximation, although it is on the unsafe side.

Reliability based optimisation

In design of breakwaters the main objectives are usually to obtain an inexpensive structure and to have a satisfactory structural reliability.

Cost optimal design of a breakwater for construction or rehabilitation is always of interest to the design engineer. An example is presented in the following where the minimum reliability index is fixed and the decision variables are the geometrical values from a cross section of a vertical breakwater cf. Figure 4.

The design (decision) variables are denoted $\mathbf{b} = (b_1, \dots, b_N)$, i.e. the number of design variables is N .

Figure 4: Definition of the design variables for optimal reliability design.

If the objective function is chosen as the total expected costs C_T of the structure during the lifetime, the optimal design can be found as the solution to the optimisation problem

$$\min_{\mathbf{b}} \quad C_T(\mathbf{b}) = C_I(\mathbf{b}) + C_F P_f(\mathbf{b}) \tag{22}$$

$$b_i^l \leq b_i \leq b_i^u \quad , \quad i = 1, \dots, N \tag{23}$$

where b_i^l and b_i^u are lower and upper bounds to b_i . C_I is the initial/construction costs, C_F is the costs of failure, and P_f is the probability of failure during the expected lifetime of the breakwater.

Alternatively an element reliability-index based optimisation problem can be formulated

$$\min_{\mathbf{b}} \quad C_I(\mathbf{b}) \tag{24}$$

$$s.t. \quad \beta_i(\mathbf{b}) \geq \beta_i^{min} \quad , \quad i = 1, \dots, m \tag{25}$$

$$b_i^l \leq b_i \leq b_i^u \quad , \quad i = 1, \dots, N \tag{26}$$

where β_i is the reliability index for failure mode i and β_i^{min} is the corresponding lower bound on the reliability index. Equivalent solutions from (22)-(23) and (24)-(25) can be obtained by suitable choices of β_i^{min} $i = 1, \dots, m$. The above optimisation problems are usually non-linear and non-convex. The optimisation problems can be solved effectively using non-linear optimisation algorithms and FORM.

The reliability indices in (25) are determined on the basis of limit state functions written as $g_i(\mathbf{x}(\mathbf{b}), \mathbf{b}) = 0$, $i = 1, \dots, m$. In a traditional deterministic design the design (optimisation) problem the constraint (25) is exchanged by the deterministic constraint

$$B_i(\mathbf{b}) = g_i(\mathbf{x}^D(\mathbf{b}, \boldsymbol{\gamma}), \mathbf{b}) \geq 0 \quad , \quad i = 1, \dots, m \tag{27}$$

where x^D are design values calculated using the statistical parameters for the stochastic variables X and γ are partial safety factors.

Evaluation of the failure modes

Reliability analysis of an engineering example is performed to show the significance of the failure modes in two series systems involving sand and clay subsoils.

The deterministic design of the vertical breakwater is designed according to Goda's pressure formulation (1974), considering recommended Japanese design guidelines for sliding (safety factor 1.2), overturning (safety factor 1.2) and max heel pressure ($400 - 600 \text{ kN/m}^2$), the tidal elevation $\zeta = 0$ and friction coefficient between base plate and rubble is taken as 0.6 cf. Figure 5.

Figure 5: Illustration of a monolithic vertical breakwater.

The sensitivity of the caisson width on the probability of failure considering shoaling and breaker heights in the surf zone is shown in Figure 6

Figure 6: Effect of the width B of the caisson on the probability of failure P_i within 50 year structure lifetime, considering shoaling and breaker heights.

Numbers in the graphs refer to type of foundation failure mechanisms cf. Figure 1. From Figure 6 it is seen that the failure modes (4) and (2) are the most critical failure modes. It is also seen that the probability of failures for the deterministically determined caisson width of 11.2 m are very high.

Optimal design

Optimal design of the example cf. Figure 5 is determined on the basis of the formulation in equations (24) - (26) i.e. the cost of failure is neglected. The initial costs are divided into weight contributions from the rubble mound and the caisson. As design (decision) variables the width (B) and the height (h_{II}) of the rubble mound are chosen.

$$C_I(B, h_{II}) = C_{I_1} \cdot W_{caisson}(B) + C_{I_2} \cdot W_{rubble}(h_{II}) \quad (28)$$

where $W_{caisson}$ is the weight of the caisson and W_{rubble} is the corresponding weight of the rubble. The difference in price per unit weight between the weight of the rubble and caisson is chosen as $\frac{C_{I_1}}{C_{I_2}} = 2$. The cost of construction is minimised with upper bounds on the probability of failure of the significant failure modes.

Optimal designs for different levels of the acceptable probability of failure P_f without considering wave height reduction in the surf zone is presented in Table 3:

Applying Japanese design guidelines	P_f	B (sand & clay), h_{II}	B (sand & clay), h_{II}
$H_s^{50} = 5.56m, B = 17.8m, h_{II} = 6m$	0.1	24.7 (m), 5.0 (m)	26.5 (m), 6.0 (m)
waterdepth at the toe $h_s = 14m$	0.2	20.6 (m), 5.0 (m)	21.6 (m), 6.0 (m)
waterdepth, foot of the caisson $d = 8m$	0.3	18.2 (m), 5.0 (m)	19.0 (m), 6.0 (m)

Table 3: Optimal design for different levels of acceptable probability without considering shoaling and breaker heights in the surf zone.

Conclusions

Foundation failure modes for vertical breakwaters are formulated such that reliability analyses can be performed. The failure modes include sliding failure and failure modes involving sand and clay subsoils. Stochastic models for uncertain parameters are described using the information from experimental tests and from the literature. Further it is mentioned that foundation failure modes can be modelled as components in a series system.

Reliability based optimisation formulations for rational design of vertical wall breakwaters are given. Finally an illustrative example is presented, where the reliability of a breakwater on a high rubble mound is investigated and optimal designs are determined.

CHAPTER 125

OVERALL SLOPE STABILITY ANALYSIS OF RUBBLE MOUND BREAKWATERS

Julien DE ROUCK¹, member ASCE
Luc VAN DAMME²

ABSTRACT

In this paper a “semi-dynamic approach for the slope stability analysis of rubble mound breakwaters” is presented. The principles of the method are described. Tide and wave action are taken into account in the slope stability analysis of deep slip-surfaces. For these slip-surfaces the moment of maximum wave run-up is most critical.

Pore water pressure variations at the seabottom are also measured below the seabottom but attenuated and approximately up to the so called influence depth h_{IP} . The fact that the pore pressure variation is attenuated leads to “overpressures” at the moment of low water and below the wave trough. The attenuation depends mainly on the wave period T and soil characteristics k (permeability) and E_{oed} (oedometric compression modulus).

INTRODUCTION

The design of a rubble mound breakwater normally starts with the determination of the overall geometry: crest level, crest width and slope angles of both seaward and rear slope. Once the overall geometry is fixed most attention is paid to the design of the armour layer: choice of the type of armour unit (rock or concrete block and in the latter the type of block: cube, tetrapod, dolos, ACCROPOD[®], HARO[®], ...) and the weight of the armour unit.

On behalf of the design of the armour layer, several design rules are available. These rules are based on extensive research: theoretical but mainly scale model tests in hydraulic laboratories. The main loading for the armour layer is the wave attack. Furthermore it is common use to carry out scale model tests on behalf of the design of (important) rubble mound breakwaters.

With regard to the overall slope stability of the slopes of a breakwater, distinction has to be made between the seaward slope and the rear slope. For the rear slope, which is normally not subjected to wave attack, one can apply calculation methods normally used for banks of a river, a canal, ... The seaward slope however is subjected to wave attack. Considering the seaward slope, designers and researchers were used to pay too little attention to the hydrodynamic effect of wave attack.

2) Ministry of Flemish Community, Coastal Division, Vrijhavenstraat 3, B-8400 Ostend, Belgium.

Frequently the experience gained on land is applied (Quinn, 1972 ; Fisher et al., 1975 ; Toppler, 1982 ; Chew, 1990 ; Murray et al, 1990 ; Koutitas, 1992). Only Barends takes into account the effect of waves. But he focuses on slip surfaces inside the breakwater core (Barends, 1983, 1985). Only in his paper of 1985 he presents some results with regard to the influence of (partial) liquefaction of the foundation layer due to wave attack.

During the design of the Zeebrugge breakwaters, extensive studies, research, testing and investigation into the geotechnical stability of rubble mound breakwaters have been carried out. One of the results is the proposed calculation method which takes into account the dynamic impact of waves and tides. The method is focusing on deep slip-circle stability analysis. As the dynamic effect of waves and tides is taken into account, we call it **“a semi-dynamic approach for the slope stability analysis of rubble mound breakwaters”**.

DESCRIPTION OF THE PROPOSED METHOD

Principles

The slope stability analysis can be carried out by using different methods: Fellenius, Bishop ... for circular slip surfaces and Nonveiller, Janbu, Morgenstern and Price, ... for non circular slip surfaces. In the analysis the friction angle ϕ' and the cohesion c' based on the effective stresses, are used. For the results shown in this paper, the Bishop formula has been applied. However the principles described further can be used for any other analysis method.

A sensitivity analysis has been carried out in order to learn which parameters are really influencing the overall stability of the seaward slope of a rubble mound breakwater. The following characteristics influencing the geotechnical safety factor F are considered: overall geometry, external forces, geotechnical characteristics (ρ , c' , ϕ') of both the material (mainly the breakwater core) and the subsoil, and pore water pressures. The sensitivity analysis showed the paramount importance of the pore water pressures along a potential slip surface: they are as important or even more important than the shear resistance characteristics.

Figure 1 shows a simplified cross-section of a rubble mound breakwater with a possible slip surface DEFA. All forces acting on the volume ABCDEFA are considered: weight of the volume, external forces acting on the faces AB, BC, DE, EFA. In that way the water pressures influence the overall geotechnical stability:

- water mass in front of the breakwater (AB);
- pressure on the breakwater slope (BC);
- pore pressure within the mound, influencing shear resistance along DE;
- pore pressure within the foundation layers, influencing the shear resistance along EFA.

To find the most critical load situation, two load conditions called A and B are considered: **tide action (A)** and **tide combined with wave action (B)**.

The first case, only tide action without considering any wave action, occurs at the rear slope of a breakwater. In that case low tide is the most critical situation.

Figure 1. Simplified cross-section of a rubble mound breakwater (max. wave run up)

In the second case tide and wave action are acting together. The determining situation is the maximum wave run-up (wave crest) combined with the most critical moment in the tide cycle. A thorough investigation has shown that for a breakwater constructed in shallow water the most critical situation exists at high tide at the moment of maximum wave run-up, in fact immediately after maximum wave run-up. At that moment the wave action is changing from “pushing on the slope” into seepage forces, in fact “pulling on the mass CDEB”. For a breakwater in transitional water depths the most critical situation will occur at maximum wave run-up at either low water (L.W.), mean water or high water (H.W.). This is in clear contradiction with the widespread idea that the moment of maximum wave run-down, with the wave through in front of the breakwater is the most critical. The latter is only valid for slip surfaces which fully develop in the breakwater core.

Weight of the volume ABCDEFA

The weight of the considered volume (partially of the breakwater and partially of the foundation layer) can easily be calculated based on the geometry and the unit mass of the breakwater material and subsoil.

Watermass in front of the breakwater: forces acting on surface AB

We can easily take into account the water mass in front of the breakwater by suggesting that the slip surface reaches the water surface, calculating with following water characteristics: $\rho_w = 1 \text{ t/m}^3$; $c' = 0$; $\phi' = 0$ (De Beer, 1959). This is only valid for a horizontal water surface in rest, e.g. case A, because the water level is varying with a great period, so very slowly. Combining tide and wave action the sea level is going up and down and the surface isn't horizontal any more, the water pressure won't be hydrostatic: the so called Still Water Level (S.W.L.) is varying between low

and high tide and the waves are characterised by a wave height H , a wave period T and wave length L .

Several wave theories describe the water surface, determined by those parameters: Airy (linear wave theory), non linear wave theory, cnoidal waves ... As breakwaters are normally constructed in shallow water the cnoidal wave theory has to be applied, although the cnoidal theory is very complicated. Grace showed that for both cnoidal and Airy theory correction coefficients have to be used (Grace, 1978). So pressures on the surface AB can be calculated with sufficient accuracy using the Airy theory but taking into account the correction coefficients proposed by Grace.

Water pressure on the slope surface: forces acting on surface BC

In the case of not overtopped breakwaters the pressure on the slope surface of the breakwater is directly influenced by the shape of the incident wave. Based on results published by Brandtzaeg (Brandtzaeg, 1962 ; Brandtzaeg et al, 1966, 1969) and based on the measurements taken during the scale model tests for the Zeebrugge breakwaters, we recommend to registrate the wave form in front of the slope up to one wave length. Having determined the wave form at the time of maximum wave run-up allows to calculate forces on the slope. Essential in this method is the determination of maximum wave run-up. The run-up height R_u is defined as the vertical distance between S.W.L. and the highest point to which water from an incident wave will run up the slope of a structure. The value of R_u/H depends on the wave characteristics (H , T , L) and slope characteristics (slope angle, roughness, porosity, ...).

Pore pressure within the mound: forces acting on surface DE

On surface DE shear forces are acting. These shear forces depend on the shear strength characteristics of the material and on the effective stress. The latter depends on the pore pressures.

Involving water pressures in the mound, a distinction is made between tide action (case A) and tide and wave action (case B). In case A we can adopt a hydrostatic pressure for the water pressures along the slip surface.

Wave action (case B) on the seaward slope results in a water level set up inside the core. This is due to the fact that the inflow surface during wave run-up is greater than the outflow surface during run-down. In addition the mean flow path for inflow is shorter than that for outflow. This set up leads to higher mean pore pressures. Due to wave action pore pressures are varying within one wave period, depending on the location and on the attenuation through the armour layer, filter layer and core (Troch P. et al, 1996a and b).

Pore pressures within the foundation layers: forces acting on surface EFA

As for surface DE, on surface EFA shear forces are acting which depend on the pore pressures. The sensitivity analysis has shown the predominant importance of the pore pressures along EFA.

If these pressures are hydrostatic with regard to the seawaterlevel, they can be defined easily. But the question has to be put whether they are hydrostatic or not. The

sea waterlevel is continuously changing: slowly (tide with a period = 12h25min) or fast (waves: with periods between 6, ..., 20 s).

Figure 2. Definition sketch of attenuation of tide

Figure 2 shows the principle of wave attenuation in the subsoil. This attenuation results in an “overpressure” in the pores at the moment of L.W. or below the wave through. For tides the overpressure can be written as:

$$\begin{aligned} \Delta u &= \rho_w g \Delta h \\ &= \rho_w g (1 - \alpha_{Pi}) \frac{H_{sea}}{2} \end{aligned} \quad (1)$$

with	Δu	:	overpressure at low tide (in kPa)
	ρ_w	:	unit mass of seawater (t/m ³)
	Δh	:	overpressure at low tide (in m seawater)
	α_{Pi}	:	attenuation coefficient of piezometer Pi (-)
	H_{sea}	:	tidal range H.W. - L.W. (m)

This overpressure highly influences the overall slope stability.

ON SITE MEASUREMENT OF TIDE AND WAVE ATTENUATION IN THE SUBSOIL

Test set-up

In order to investigate the attenuation of varying water pressures (at the seabottom) in the subsoil four measurement campaigns have been carried out on behalf of the design of the Zeebrugge breakwaters. In this paper we will focus on the 4th campaign, taking into account both tides and waves.

In general this 4th campaign has the following characteristics:

- The seabottom is located at ca. Z-5,50.
- From the seabottom the following layers are found:
 - up to -14,00 : coarse sand with shells
 - up to -15,50 : a clayey sand layer
 - a stiff clay layer (Tertiary, Bartonian clay) up to much greater depths.
- In the harbour area M.L.W.S. is situated at the level Z+0,32 and M.H.W.S. at the level Z+4,62, i.e. waterdepths of about 5,80 m to about 10,10 m at the location of the multiple piezometer probe. The design wave height for the main breakwaters amounts 6,20 m, at design waterlevel Z+6,76.

A general view of the measuring system is given in fig. 3. The pore pressures in the seabottom are measured by electrical pressure transducers, mounted at seven levels in a multiple piezometer probe which was jacked into the seabottom. The pressure transducers are connected by a cable bundle to a measuring platform installed on top of a steel tube pile in the vicinity of the probe. The measuring platform contains the conditioning for the piezometer probe, a transmitter and all the related equipment. The measured values are sent by the transmitter to the coast by an UHF link. At the coast, the measured values are caught by a receiver and sent to a computer by telephone link where they are stored on disk and subsequently analysed.

Figure 3. Lay-out of the measuring system for the 4th campaign

The multiple piezometer probe consists of six steel pipes linked together by stainless steel nipples containing the pressure transducers. Below each nipple a decrease in diameter was chosen to prevent direct contact between the different piezometer levels along the mantle of the probe. The diameters of the elements of the probe were kept as small as possible in order to keep the penetration forces within acceptable limits and to minimize soil disturbances. The pressure transducers are of the semi-conductor strain gauge type with very fast response and suitable electric output signal; they have a very small volume displacement, no moving parts and a low energy consumption.

More details about the lay-out of the system and the multiple piezometer probe, even about the measuring platform and equipment, data acquisition system and installation procedure are given in De Wolf et al. (1983) and De Rouck (1991).

Results

The tide is transmitted up to the tip of the probe at 13,00 m below the seabottom: within the sand layer only slightly attenuated but strongly attenuated in the clay layer.

Even wave action is registered up to the tip of the probe: the amplitude of the waves decreases very quickly from the seabottom to a depth of about 2,00 m underneath the seabottom, with further attenuation for greater depths.

THEORETICAL MODEL OF WATER PRESSURE PROPAGATION IN THE SUBSOIL

Out of the results of the measuring campaign it can be concluded that the water pressure in the subsoil is not hydrostatic due to the continuously changing seawaterlevel. The amplitude of the pressure variation is attenuated.

The differential equation governing the pore water pressure change during one tide (and one wave) has been written based on the Darcy equation and the continuity equation.

Consider an elementary volume $dx \cdot dy \cdot l$ and the effect of tides (fig. 4).

Figure 4. Tide: pore water flow in the subsoil due to seawater lowering

The equation of Darcy:

$$w = -\frac{k}{\rho_w g} \frac{\partial u}{\partial z} \quad (2)$$

with: w : flow velocity in z-direction
 u : pore water pressure
 k : permeability coefficient of the soil
 ρ_w : specific mass of seawater

The continuity equation takes into account following phenomena:

- if the seawater level drops from high tide to low tide, the pore water pressure decreases; the pore water expands, so some water is pressed out of the considered volume;
- at the same time the total effective stress decreases (both the vertical and horizontal stress decrease): the grain skeleton expands, so some water is sucked.

The continuity principle leads to:

$$\frac{\partial w}{\partial z} = -\left(\frac{1}{E_{oed}} + \frac{n}{K_w}\right) \frac{\partial u}{\partial t} \quad (3)$$

with E_{oed} : oedometric compression modulus of the soil
 n : porosity of the soil
 K_w : compression modulus of seawater

As all soil layers are situated below the seabottom it has been assumed that they are fully saturated.

Combining the equation of Darcy and the continuity equation leads to the differential equation for pressure response in the soil underneath the seabottom:

$$\frac{\partial^2 u}{\partial z^2} = \frac{\rho_w g}{k} \left(\frac{1}{E_{oed}} + \frac{n}{K_w}\right) \frac{\partial u}{\partial t} \quad (4)$$

- via $\frac{1}{E_{oed}}$ the compressibility of the grain skeleton is taken into account
- via $\frac{n}{K_w}$ the compressibility of seawater is taken into account

Comparing the order of magnitude of both terms for clay and sand learns that $\frac{n}{K_w}$ is

clearly smaller than $\frac{1}{E_{oed}}$, so $\frac{n}{K_w}$ can be neglected. Equation (4) can be simplified to

$$\frac{\partial^2 u}{\partial z^2} = \frac{\rho_w g}{k E_{oed}} \frac{\partial u}{\partial t} \quad (5)$$

In a similar way the general equation for water flow in the subsoil due to wave action can be written as:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial z^2} = \frac{\rho_w g}{k} \left(\frac{1}{E_{oed}} + \frac{n}{K_w} \right) \frac{\partial u}{\partial t} \quad (6)$$

As for tides the term $\frac{n}{K_w}$ can be neglected, leading to:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial z^2} = \frac{\rho_w g}{k E_{oed}} \frac{\partial u}{\partial t} \quad (7)$$

Comparison of the order of magnitude of $\frac{\partial^2 u}{\partial x^2}$ and $\frac{\rho_w g}{k E_{oed}} \frac{\partial u}{\partial t}$ for normal waves (e.g.

as measured during the 4th campaign) and for both clay and sand shows that $\frac{\partial^2 u}{\partial x^2}$ is

clearly smaller than $\frac{\rho_w g}{k E_{oed}} \frac{\partial u}{\partial t}$. So $\frac{\partial^2 u}{\partial x^2}$ can be neglected.

Equation (7) can be simplified to:

$$\frac{\partial^2 u}{\partial z^2} = \frac{\rho_w g}{k E_{oed}} \frac{\partial u}{\partial t} \quad (8)$$

Equation (5) and (8) are identical.

Solving this differential equation is done taking into account the following boundary conditions:

a) at the sea bottom (z = 0)

$$u(0,t) = u_o \cos \left(\frac{2\pi x}{L} - \frac{2\pi t}{T} \right) \quad (9)$$

Or, for a fixed spot, take x = 0

$$u(0,t) = u_o \cos \frac{2\pi t}{T} \quad (10)$$

with u_o - for tides $u_o = \rho_w g H_{sea}$

with H_{sea} : tidal range H.W. - L.W.

$$\text{- for waves } u_o = \frac{\rho_w g}{n} \frac{H}{2 \cosh \frac{2\pi d}{L}}$$

with H: wave height

L: wave length

d: water depth

n: correction coefficient of Grace

b) at great depth ($z = \infty$)

$$\lim_{z \rightarrow \infty} u(z,t) = 0 \tag{11}$$

This leads to the following solution:

$$u(z,t) = u_o e^{-Az} \cos\left(\frac{2\pi x}{L} + \frac{2\pi t}{T} - Az\right) \tag{12}$$

with:

$$A = \sqrt{\frac{\rho_w g \pi}{k E_{oed} T}} \left[\frac{1}{m} \right] \tag{13}$$

- with L : wave length
- T : wave period
- k : permeability coefficient of the soil
- E_{oed} : oedometric compression modulus of the soil

Figure 5 shows the pore water pressure variation in a soil layer due to tide or wave action. Curve 1 is valid for $x = 0$, $t = T/2$ and $A = 0,3$, while curve 2 is the envelope. Approximatively curve 1 can be replaced by the straight line AB. The distance OB is the so called "influence depth". This influence depth has proven to be a very handsome tool to introduce the variation of the pore water pressure in the subsoil into the slope stability analysis.

Figure 5. Pore water pressure variation in a soil layer due to tide or wave action

The attenuation decreases when the influence depth h_D increases, i.e. when A decreases. A decreases when the product $k \cdot E_{\text{sed}} \cdot T$ increases: a more permeable and less compressible soil combined with longer wave period (and subsequent longer wave length).

Comparison of on site measurement results with the theoretical model

It is investigated how the results of the on site measurements fit with the theoretical model. On the one hand the results for tides for respectively the stiff Bartonian clay and all sand layers (in which pore water pressure measurements have been carried out) and on the other hand the results of the 4th campaign for waves for the sand layer are considered.

For both tides and waves the attenuation coefficient is "measured on site" (i.e. determined based on the measurements on site). The attenuation coefficient is also "calculated" (i.e. by introducing soil characteristics in equation (13)). It is found that "measured" and "calculated" values coincide quite well (De Rouck, (1991)).

APPLICATION OF THE PROPOSED METHOD FOR SLOPE STABILITY ANALYSIS

The proposed method for analysing the overall slope stability has been applied at numerous occasions. Within this paper an example for Zeebrugge (Belgium) and Antifer (France) will be given.

Zeebrugge inner harbour breakwater

Figure 6 shows the most critical slip circle for a Zeebrugge inner harbour breakwater when considering the design water level $Z+6,76$. The crest of the breakwater is situated at $Z+10,30$. Maximum run-up will not fully occur as the considered extreme wave will pass over the crest (overtopping). The safety factor $F_{\text{min}} = 1,42$, which is rather high.

Figure 6. Zeebrugge breakwater slope stability analysis

Antifer main breakwater

Based on the geometry as given in Feuillet et al. (1987) the slope stability analysis is carried out. As no exact geometric data and hydraulic data (tide, waves) and no exact characteristics of the materials were available, approximative geometry and wave loading and approximative but realistic values for the characteristics of all layers (breakwater and subsoil) have been introduced in the slope stability analysis. Regarding these circumstances the result has to be considered as approximative as well. The analysis has been carried out for high tide and low tide. Low tide is clearly more critical. So fig. 7 shows the result for max. wave run-up at low tide: $F_{\min} = 1,13$. For the design of the Zeebrugge breakwaters for the case B (tide combined with wave attack) an $F_{\min} \geq 1,10$ has been required.

Figure 7. Antifer main breakwater slope stability analysis

FURTHER USE OF RESULTS

Knowledge of the water pressures in the soil layers below the seabottom, resp. below the bottom of a river subjected to tides, allows to explain unexpected behaviour of structures. Two examples are given.

An intake of water, constructed on a sand layer on top of a 12 m thick clay layer subsides at high tide and rises at low tide. This is completely unexpected regarding the higher submerged part at high tide. The phenomenon can be explained by taking into account the water pressures in the clay layer (De Rouck, 1991).

The crest of a quaywall subjected to tides, constructed on a claylayer or on a sandlayer on top of a claylayer may move towards the river at high tide and return at low tide. This will be the case if the effect of compression of the claylayer at high tide is dominant compared with the effect of the higher stabilising forces at high tide.

CONCLUSIONS

Within this paper a method for slope stability analysis of the seaward slope of a rubble mound breakwater has been described. The dynamic effect of both tides and waves has been taken into account.

The main conclusions are:

- Slope stability analysis of the slopes of the breakwater, especially the seaward slope, deserves as much attention as the design of the armour layer.
- The slope stability can be carried out by considering a volume ABCDEFA (fig. 1) which reaches into the soil layer underneath the seabottom.
- Pore water pressure variation (due to waves and tides) at the seabottom are also measured below the seabottom but attenuated and approximatively up to the so called influence depth h_{ID} . The fact that the pore pressure variation is attenuated leads to "overpressures" at the moment of low water and below the wave trough (for both L.W. and H.W.)
- The attenuation decreases with increasing influence depth h_{ID} , i.e. with decreasing factor A. The factor A on his turn decreases when the product $k.E_{oed}.T$ increases.

CHAPTER 126

INTERACTIONS IN THE STABILITY OF TOE-BERM AND MAIN-ARMOUR FOR RUBBLE-MOUND BREAKWATERS : AN EXPERIMENTAL STUDY

Philippe DONNARS ¹ and Michel BENOIT ¹

Abstract

This experimental study is concerned with one particular aspect of possible failure modes for a rubble-mound breakwater : the interactions between the toe-berm and the main-armour of the breakwater. Through a series of laboratory tests in a wave basin under long-crested and short-crested waves, we investigate the mutual influence of both these component parts of the breakwater on its general stability. The effects of several wave parameters are examined for four sizes of toe-berm stones. For the trunk section, experimental results are found to compare quite satisfactorily with existing design formulas both for the main-armour and the toe-berm. As a general trend from the tests results, the interaction processes appear to have only moderate effect. Their major feature is an increase of damage to the armour when the toe-berm is unstable. On the opposite, minor effects of main-armour on toe-berm stability were observed. In particular, the "toe-berm armouring process" (by units falling from the armour) appears to occur only marginally and under precise conditions.

1. INTRODUCTION - SCOPE OF WORK

The common practice for designing a breakwater is usually to use existing design formulas and rules for each individual part of the breakwater (main armour, rear armour, crest,...). This design approach is quite well documented in the scientific literature, in particular for the main armour (e.g. Van der Meer, 1992). In a following step, the whole breakwater profile has to be further tested and optimized through model tests in wave flume or basin, to obtain a reliable and safe structure.

The overall stability of the breakwater is however not only a function of the stability of each individual component part of the breakwater, but also of the interaction mechanisms between these parts. Present knowledge on the latter point is quite limited and it is not straightforward to find in the literature precise and quantitative descriptions of these possible interaction effects. Improving this knowledge was the main objective of the European Research Project "Rubble-Mound Breakwater Failure Modes (RMBFM)" of MAST-2. The study presented in this paper is concerned with one particular aspect of these possible failure modes : the interactions between the toe-berm and the main-armour of a breakwater.

¹ Research Engineer — Maritime Group
EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 CHATOU, FRANCE

This experimental study continues previous tests performed in a wave flume at the University of Bologna (UB) in Italy (Lamberti and Aminti, 1994) within the same RMBFM project. In particular, Lamberti (1994) emitted the idea that, for sufficiently wide toe-berms, the main feature of this interaction process could be a phenomenon of "toe-armouring" by stones falling down from the damaged armour. If these stones remain on the toe-berm, they may increase its stability (lower damage to the toe-berm). Still addressing these possible interactions, we focus here more closely on three-dimensional effects, by considering the following aspects :

- wave obliquity (effect of angle of wave incidence)
- wave directionality (effect of angular spreading of wave energy)
- behaviour on the trunk section and at round-heads. Within the frame of this paper, attention will be mainly paid to the trunk section. Additional results for the round-head section may be found in Benoit and Donnars (1996).

In the present study, these effects are investigated through a series of laboratory experiments in a multidirectional wave basin. The experimental conditions and procedure are described in Section 2. Results for the main-armour and the toe-berm are presented and compared with other experimental results and existing design formulas in Section 3 and 4 respectively. The effects of the interaction processes are discussed in Section 5. The conclusion of Section 6 summarizes the main findings of this study and gives some recommendations for practical design.

2. EXPERIMENTAL SET-UP AND TEST CONDITIONS

2.1 Brief description of the wave basin used for laboratory tests.

The tests have been conducted in the multidirectional wave basin of Laboratoire National d'Hydraulique (LNH) in Chatou (France) (Figure 1). This experimental facility is dedicated to physical modelling applied to maritime and coastal studies. The overall dimensions of the basin are 54 m x 31 m x 1.3 m (maximum water depth for operational use : 0.80 m). This basin is fitted out with a multidirectional piston-type wave-maker composed of 56 paddles (segment width : 0.40 m).

Figure 1 : General lay-out of experimental set-up in LNH wave basin.

The total length of the wave-maker thus reaches 22.4 m. It can operate in the frequency range [0.2 ; 2.0 Hz]. During the experiments, vertical side-walls (of 2 m in length) were set up at each side of the wave-maker in order to increase the work area by making use of "corner-reflection" method (Funke and Miles, 1987).

2.2 Breakwater lay-out and cross-sections.

The present tests were aimed to continue previous tests, performed within the same research project in a wave flume at the University of Bologna (UB) in Italy (Lamberti and Aminti, 1994). So, we started from the same breakwater characteristics, except that the geometric scale was multiplied by a factor of 1.32 with respect to UB tests in order to adapt to the characteristics of LNH wave basin.

The main features of breakwater cross-sections (Figure 2 for the slope of 1:1.5) are summarized below :

- tests are performed with a flat bottom at a water depth of $d=0.45$ m.
- the ratio of water depth above toe-berm h_t to design wave height H_{sd} is about 1 ($h_t/H_{sd} \approx 1$)
- the width of toe-berm B_t is constant over the whole test programme and is taken to be three times the diameter of design toe-berm stones $D_{n50t(\text{design})}$
- the thickness of the toe-berm is constant and is taken to be that of two layers of design toe-berm stones $D_{n50t(\text{design})}$.
- two armour slopes are considered : 1:1.5 ($\cotg \alpha = 3/2 = 1.5$) and 1:2.5.

The breakwater is not parallel to the wave-maker, but there is an angle of 15 degrees between them (Figure 1). This orientation has been chosen in order to ensure a sufficiently high frequency limit for generated waves even for oblique incidences. In the paper, we only make use the direction of incidence as referred to the breakwater (for instance, a 0° direction corresponds to normal wave attack).

Figure 2 : Cross-section of breakwater (slope 1:1.5).

The breakwater used for the experiments consists in two half-breakwaters, each of them being composed of a trunk section and a round-head section (Figure 3). Each half-breakwater has the same armour units, but different toe-berm stones. A 1 m long test section is considered on each trunk section. The round-head sections are divided in 6 angular sectors of 36 degrees (Figure 3). By this way, it is possible to test simultaneously 4 sections (2 trunks and 2 round-heads) under normal waves and 3 sections under oblique waves (2 trunks, 1 round-head).

Figure 3 : Test sections on the breakwater and wave directions.

2.3 Choice of governing parameters and test programme.

The choice of varying governing parameters for the experimental tests is based on the analysis performed by Gerding (1993) and Lamberti (1994) :

- the **nominal diameter of the toe-berm stones** [4 values]. The first value corresponds to the "design" value as determined by a conventional design approach, whereas the other ones lead to "unstable" berms (see § 2.5).
- the **slope of the main-armour** [2 values : 1:1.5 and 1:2.5] (see § 2.2).
- the **wave steepness** [2 values : $s_{om} = 2\%$ and $s_{om} = 5\%$]
The wave steepness is defined as : $s_{om} = H_s/L_{0m} = H_s/1.56T_m^2$. As "longer" waves ($s_{om} = 2\%$) are thought to be more severe for the stability of the breakwater than "shorter" waves ($s_{om} = 5\%$), most of tests are performed with the 2 % steepness for incident waves.
- the **angle of wave incidence** [2 values : $\beta = 0^\circ$ and $\beta = 30^\circ$]. One test has also been conducted under a $\beta = 10^\circ$ angle of wave incidence to check whether such a value could lead to higher damage, as shown by Galland (1994) for toe-berm stability at concrete armoured structures or by Juhl and Sloth (1994) for wave overtopping.
- the **angular spreading of energy** [2 values : $s = \infty$ (unidirectional waves) and $s = 15$]. The spreading index s corresponds to the exponent in the model of directional spreading function used for generating drive signals for the wave-maker $D(\theta) = 1/\Delta \cos^{2 \cdot s}(\theta)$. The short-crested case ($s = 15$) produces a directional sea-state with moderate angular spreading (directional width of about 10 degrees).

The test programme is based on the above choice of governing parameters. Due to this rather large number of parameters, it was not possible to test all the combinations between all parameters, which would have resulted in $4 \times 2 \times 2 \times 2 \times 2 = 64$ tests. This number has been reduced to 30 by considering only some of the above combinations (Benoit and Donnars, 1996). Because two half-breakwaters are tested simultaneously, the overall number of tests is finally equal to 15. Due to the fact that only three sections are tested under oblique wave, the total number of sections (trunk + round-head) examined during the experiments is equal to 52.

2.4 Review of incident wave conditions.

A JONSWAP-type spectrum is used for the distribution of wave energy over frequencies with a value of the peak enhancement factor $\gamma = 5$ for the tests at steepness $s_{om} = 0.05$ and a value of $\gamma = 1$ for the tests at steepness $s_{om} = 0.02$.

For a given test, the wave steepness is constant and the target wave height is increased by successive steps : each step corresponds to a run. A test is thus composed of 7 runs. The target wave characteristics for the experiments (in terms of significant wave height H_s and mean period T_m) are summarized in Table 1.

Each run has a duration of about 2000 waves of target mean period T_m .

run n°	$s_{om} = 0.05$ ($\gamma = 5$)		$s_{om} = 0.02$ ($\gamma = 1$)	
	H_s (m)	T_m (s)	H_s (m)	T_m (s)
1	0.060	0.88	0.045	1.20
2	0.071	0.95	0.053	1.30
3	0.082	1.02	0.061	1.40
4	0.093	1.09	0.069	1.49
5	0.104	1.15	0.077	1.57
6	0.115	1.21	0.085	1.65
7	0.126	1.27	0.093	1.73

Table 1: Target wave characteristics for model experiments (H_s , T_m).

2.5 Review of incident wave conditions.

• **Armour stones** : The following characteristics were obtained for the stones of the main armour (two layers) : Density=2.55 ; Nominal diameter $D_{n50a} = 2.91$ cm ; Nominal weight $W_{n50a} = 63$ g ; $\Delta.D_{n50a} = 4.51$). Same stones are used for the armour-layer both at the trunk sections and at the round-heads.

• **Toe-berm stones** : The "design" value of toe-berm stones for trunk section (labelled T1) was determined according to the design formula of Gerding (1993), leading to the following characteristics : Density=2.72 ; Nominal diameter $D_{n50t} = 2.58$ cm ; Nominal weight $W_{n50t} = 47$ g ; $\Delta.D_{n50t} = 4.44$)

From the design value of toe-berm stones, the three other values (termed T2 to T4) are computed from the relationship proposed by Lamberti (1994) :

$$W_{n50t}(T_j) = \frac{W_{n50t}(T_1)}{2^{K_j}} \quad \alpha \quad K_j = \ln_2 \left(\frac{W_{n50t}(T_1)}{W_{n50t}(T_j)} \right)$$

The values of K_j are chosen to be :

- toe-berm stones T2 : $K_2 = 1.2$ $W_{n50t}(T2) = W_{n50t}(T1) / 2.3 \approx 20$ gr
- toe-berm stones T3 : $K_3 = 2.5$ $W_{n50t}(T3) = W_{n50t}(T1) / 5.66 \approx 7.5$ gr
- toe-berm stones T4 : $K_4 = 4.5$ $W_{n50t}(T4) = W_{n50t}(T1) / 22.6 \approx 2.2$ gr

The weight of toe-berm stones at the round-head are increased by about 25 % from the above values determined for the trunk section.

The sorting index D_{85} / D_{15} for the various toe-berm stones lies in the range [2 ; 2.5]. It must be emphasised that this sorting index is much larger (but also more representative of natural conditions) than the value of 1.1 used during the flume experiments at UB (Lamberti, 1994).

2.6 Measurement and analysis of damage.

There is no rebuilding of the breakwater between consecutive steps of a test : cumulative damage is observed and reported during the experiments.

Damage is first evaluated by counting the number of units displaced from the armour-layer and the toe-berm. This is the standard method for measuring damage during the tests. For the trunk section, the damage index is given by the number N_{od} of units displaced within a strip of width equal to one D_{n50} :

$$N_{od} = N_d \frac{D_{n50}}{l} \quad \text{where } l \text{ is the width of the trunk section.}$$

An optical sensor has also been used for several tests in order to get information on the changes in the profile of the breakwater and to estimate the eroded area A_e in the breakwater profile. The damage level is then defined as : $S = A_e / D_{n50}^2$.

By combining present experimental results and previous observations (Van der Meer, 1992 ; Burcharth, 1993), the relationship : $S \approx 2 \cdot N_{od}$ is obtained and will be used further in the analysis of test results.

3. STABILITY OF THE MAIN-ARMOUR FOR THE TRUNK SECTION

3.1 Descriptive analysis of the stability of the main-armour of the trunk

We only report here the main observations from the tests. A more complete description and analysis of results may be found in Benoit and Donnars (1996).

3.1.1 Influence of wave direction and directionality (angular spreading)

Examples of test results for the stability of the main-armour are plotted on Figure 4 for four wave conditions and the four toe-berm stone sizes (armour-slope 1:2.5 only). In the range of tested values, the wave direction does not appear to have a significant effect on the stability of the main-armour as long as the toe-berm is stable (toe-berms T1 and T2). When the toe-berm is unstable, damage levels are higher on the armour layer and the normal direction seems to be more severe than an oblique (30°) direction.

Damage on the main-armour is higher under short-crested waves (only one tested value of angular spreading) than under long-crested waves for the same incident wave height. This is a clear observation from present experiments, which appears to be in some contradiction with other experimental test results. For instance, Thunbo Christensen *et al.* (1984) found from model tests on a breakwater armoured with quarry stones that uni-directional waves result in 30-40 % more damage to the breakwater when compared to short-crested waves. Canel and De Graauw (1992) also concluded that short-crested waves result in an increase of the stability number (from 0 to 60 %) for rock for the 1 % damage level. Although no definite conclusion may be drawn from the rather low number of present experiments, this increase of damage under short-crested waves appears quite clearly. It is assumed to be due to a rather low angular spreading of wave energy.

This increase of damage under short-crested waves is clearly observed for the normal attack, but seems to be quite feeble for the 30° direction.

3.1.2 Influence of wave steepness (long-crested waves ; armour slope 1:2.5)

The effect was examined for toe-berms T1 and T2 only. For the same wave height, it is observed that the "longer" waves ($s_{om} = 2$ %) clearly result in more damage to the armour-layer than the "shorter" waves ($s_{om} = 5$ %).

3.1.3 Influence of toe-berm stones weight (long-crested waves only)

For the normal wave attack, a clear increase of damage to the main-armour with decreasing toe-berm stone weight is observable. For toe-berm stones T1 and T2, damage to the armour remains at an acceptable and comparable level. But for lighter stones (toe-berm stones T3 and T4), the main-armour is significantly more damaged. Severe damage occurs for the lightest toe-berm stones T4.

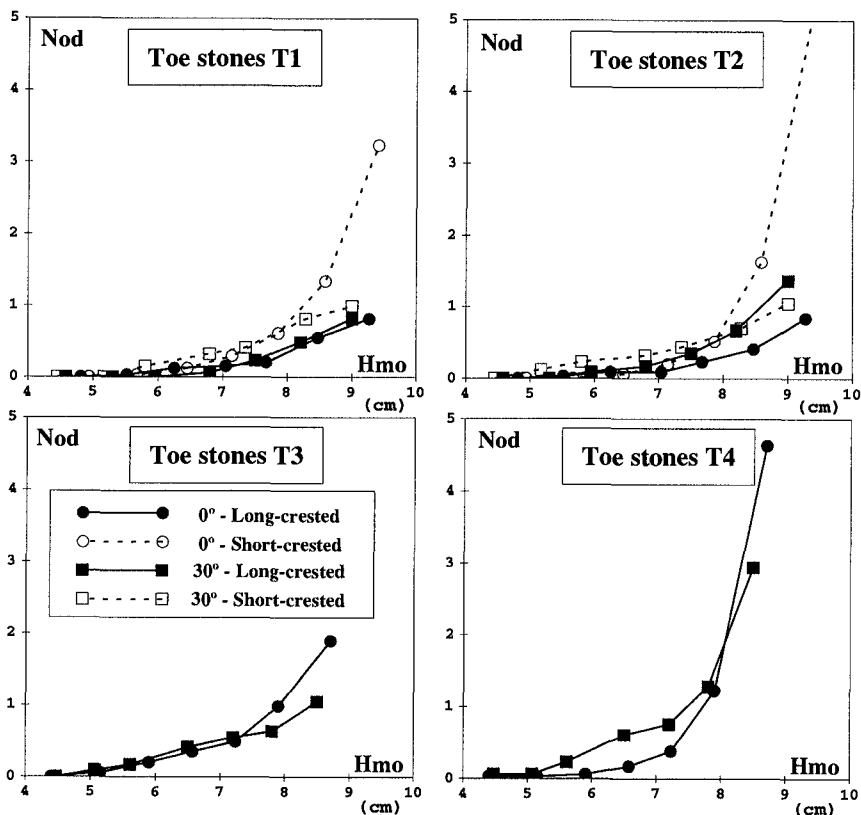

Figure 4 : Evolution of observed damage to the main-armour for four wave conditions (armour-slope 1:2.5 only).

3.2 Synthetic analysis of the stability of the main-armour of the trunk

In order to compare our test results to existing design formulas, we consider the Van der Meer design formulas (Van der Meer, 1988) for the armour layer :

$$\text{Plunging waves } (\xi_m < \xi_{mc}) : \frac{H_s}{\Delta \cdot D_{n50a}} = 6.2 \frac{P^{0.18}}{\sqrt{\xi_m}} \left(\frac{S}{\sqrt{N}} \right)^{0.2}$$

$$\text{Surging waves } (\xi_m > \xi_{mc}) : \frac{H_s}{\Delta \cdot D_{n50a}} = 1.0 P^{-0.13} \left(\frac{S}{\sqrt{N}} \right)^{0.2} \sqrt{\cotg \alpha} \xi_m^P$$

where N is the number of waves in a storm or in the test (N=2000), S is the damage index defined from the eroded area A_c (here, S is computed from N_{od} by : $S = 2 \cdot N_{od}$; see § 2.6), ξ_m is the surf-similarity parameter defined from the mean wave period T_m , P is the notional permeability factor (taken to be 0.4 as suggested by Van der Meer (1988) for a permeable core with a filter and an armour composed of two layers of natural rocks). ξ_{mc} is the critical value of surf-similarity parameter ξ_m , determining the transition from plunging waves to surging waves :

$$\xi_{mc} = \left[6.2 P^{0.31} \sqrt{\tan \alpha} \right]_{P+0.5}^{-1}$$

The values surf-similarity parameter ξ_m depend on both the steepness (two possible values) and the slope of the armour (two possible values). From these

values, it appears that tests performed for the 1:1.5 slope are of "surging" type whereas they are of "plunging type" for the 1:2.5 slope (and 2 values of steepness).

The tests results are plotted and compared to Van der Meer stability formulas on Figure 5.a (plunging waves) and 5.b (surging waves). Experimental points from Van der Meer (1988), Galland (1994) and Lamberti (1994) are also superimposed.

— Analysis of the "plunging waves" tests (figure 5.a) :

An acceptable agreement is found between experimental points and the formula. However, one can observe that the lower values of damage are overpredicted by the formula, whereas the higher values seem to be underpredicted. This is in particular quite clear for the tests with 5 % steepness, which may indicate that the effect of steepness is not perfectly resolved in the Van der Meer formula for plunging waves. If we consider the experimental points from Van der Meer (1988) for permeable core, we again note that most of points lie above the design curve.

— Analysis of the "surging waves" tests (figure 5.b) :

Based on present experiments, the general trend of the formula is to overpredict the observed damage levels. The use of Van der Meer formula on these experiments thus seems to lead to a conservative design of the armour. Test results from Lamberti (1994) also confirm this trend in spite of a rather high scatter. However, one should also note that Van der Meer formula appears to be a good fit to the Van der Meer (1988) test results obtained with a permeable core. Additional analysis and comparisons should be performed in order to check this point. In particular, it was observed that the permeability factor P may play a significant role in the formula and the precise determination of P for an existing breakwater is not straightforward.

Figure 5 : Comparison of present test results with Van der Meer (1988) formula for the stability of the main armour (tests under normal wave attack).

4. STABILITY OF THE TOE-BERM FOR THE TRUNK SECTION

4.1 Descriptive analysis of the stability of the toe-berm of the trunk

4.1.1 Influence of wave direction and directionality (angular spreading)

Examples of test results are plotted on Figure 6 for four wave conditions and the four toe-berm stone sizes (armour-slope 1:2.5 only). From the tests, we observe that the normal direction seems to be usually more severe than the 30° direction.

Damage to the toe-berm is higher under short-crested waves than under long-crested waves only for the normal attack, whereas long-crested waves produce more damage for the 30° direction.

The toe-berms are less stable for the slope 1:2.5 slope of armour than the same ones associated with the 1:1.5 slope. This may be related to slight different hydrodynamical conditions of wave breaking and run-down, resulting in stronger action to the toe-berm.

4.1.2 Influence of wave steepness (long-crested waves ; armour slope 1:2.5)

The longer waves ($s_{om} = 2\%$) create more damage to the toe-berm than shorter waves ($s_{om} = 2\%$), but this trend is stronger than for the damage to the main-armour (see § 3.12). This indicates that the toe-berm is more sensitive to the steepness of incident waves than the main-armour.

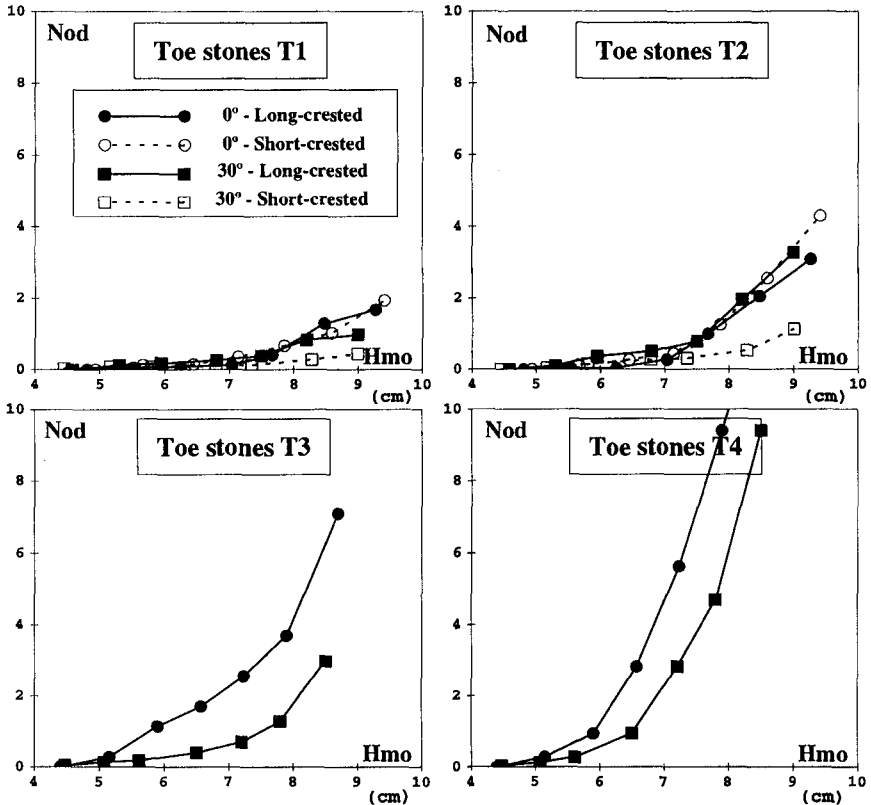

Figure 6 : Evolution of observed damage to the toe-berms for four wave conditions (armour-slope 1:2.5 only).

4.1.3 Influence of toe-berm stones weight (long-crested waves only)

For the normal wave attack, damage to the toe-berm increases with decreasing toe-berm stone weight. The effect of the toe-berm stone size is clearly more sensitive on the damage to the toe-berm itself than on the damage to the main-armour. However, one may distinguish two different behaviour : toe-berms T1 and T2 are quite stable with low damage levels, whereas toe-berms T3 and T4 are clearly unstable with higher damage levels.

4.2 Synthetic analysis of the stability of the toe-berm of the trunk

In this section, we consider the formula established by Gerding (1993) for the stability of the toe-berm of a rubble-mound breakwater :

$$\frac{H_s}{\Delta \cdot D_{n50t}} = \left(0.24 \frac{h_t}{D_{n50t}} + 1.6 \right) N_{od}^{0.15}$$

where Δ is the relative buoyant density of toe-berm stones ($\Delta = \rho_r / \rho_w - 1$), D_{n50t} is the nominal diameter of stones composing the toe-berm, h_t is the depth of toe-berm below the Mean Water Level and N_{od} is the damage index to the toe-berm.

The damage level is classified as : $N_{od} = 0.5$: hardly any damage ; $N_{od} = 2$: acceptable damage (design criteria) and $N_{od} = 4$: unacceptable damage.

On Figure 7, the experimental data points plotted on the graph are composed of all the present experiments conducted with normal wave attack and long-crested waves (including 2 slopes of main-armour, 4 toe-berm stone sizes and 2 values of wave steepness). On this figure, an acceptable agreement between present experiments and the formula from Gerding (1993) is obtained. However, one must note that the effects of mound-slope and wave-steepness are not included in Gerding's formula. Although these effects do not appear as dominant on experimental points, it is possible to distinguish on Figure 7 the data points for the 1:1.5 slope (triangles) and for the 1:2.5 slope (circles). The effect of steepness is more sensitive (compare crosses and circles for toe-berm stones T1 and T2), indicating that damage to the toe-berm appears to be lower for the "shorter" waves than for the "longer" waves. The inclusion of these effects in an extended formula appears as an interesting research item.

Figure 7 : Comparison of present test results with Gerding (1993) formula for the stability of the toe-berm (tests under normal wave attack only).

5. DISCUSSION OF THE INTERACTION PROCESSES

During the experiments, the following points have been observed :

- For most of tests, as the wave height increases between each run, damage first appears on the toe-berm and then on the main-armor. This is not really surprising, as the main-armor is made of stones whose weight is determined from "standard" design value whereas the toe-berm stones weight are equal (toe-berm stones T1) or lower than the design value (toe-berm stones T2 to T4). It is thus quite a "normal" behaviour that toe-berms are damaged first.
- The stability of the toe-berm continuously decreases as the weight of toe-berm stones decreases. The stability of the main-armor is also decreasing with the size of toe-berm stones (in particular for toe stones T3 and T4).
- Damage to the main-armor for the trunk section is mainly located between the toe (- 0.10 m referred to MWL) and about + 0.05 m referred to MWL.

In order to describe the interaction processes between the main-armor and the toe-berm, we start from the classification of evolution mechanisms proposed by Lamberti (1994). We further tentatively propose a correlation diagram between damage to toe-berm and damage to main-armor where the evolution processes (A, a, B, b, c) from Lamberti (1994) are schematically summarized (figure 8).

Figure 8 : Tentative analysis of correlation between damage to armour and damage to toe-berm after a classification of mechanisms from Lamberti (1994)

Based on the data from our experiments, it is possible to build such plots for the four toe stones used and for different wave conditions (Figure 9). On these plots, we can directly compare the synthetic evolution of the observed interaction process to the classification of evolution processes of figure 8. The main comments raising from this analysis are summarized below :

• **Toe-berm stones T1 and T2 : evolution process : a**

The toe-berm is rather narrow, but quite stable for the various wave conditions. Damage appears approximately at the same time on the main-armour and the toe-berm. There is no significant effect of toe-armouring process. As the toe-berm is quite narrow, the stones falling down from the armour do not stop on the toe-berm.

• **Toe-berm stones T3 : evolution process : b**

The toe-berm is less stable than the armour layer and is damaged first. It thus becomes narrower and is then not very effective in retaining armour units when damage further appears on the main armour.

• **Toe-berm stones T4 : evolution process : c**

The toe-berm is severely unstable and the static support of the armour layer fails when the toe-berm is fully damaged. The armour layer may then slide down abruptly, exposing the underlayer.

In particular, the evolution process B (stones falling down from the armour layer stop on the toe-berm and enhance its stability : toe-armouring process) only rarely occurred and then exhibited quite feeble effect on the stability of the toe-berm. Most

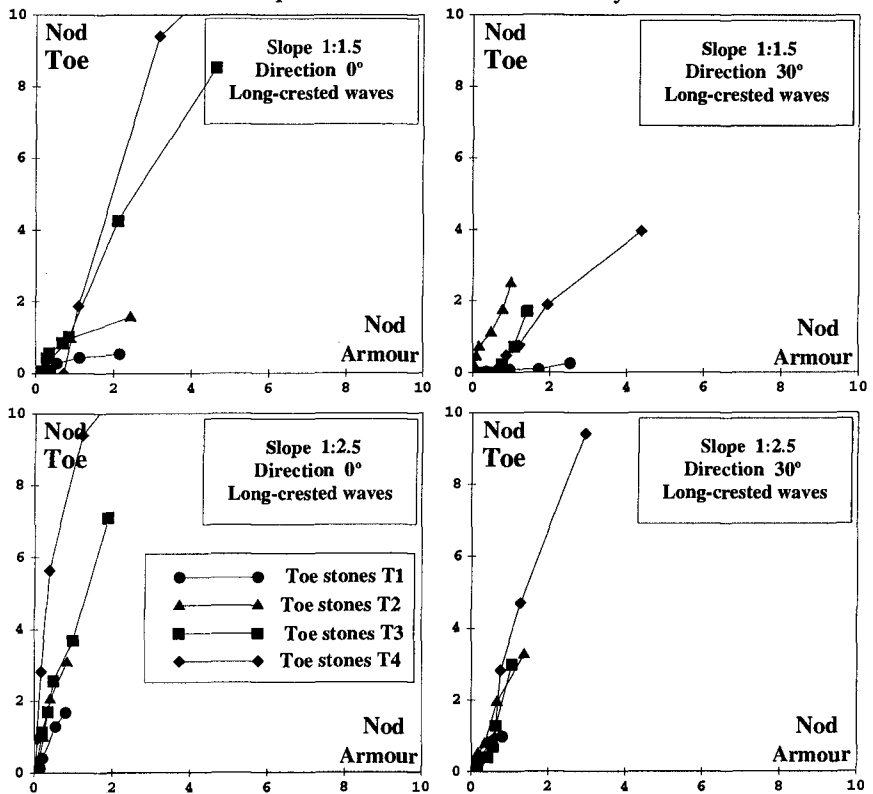

Figure 9 : Correlation diagrams based on present experiments for various conditions

of stones falling from the armour went directly to the floor of basin either because the berm was too narrow (toe-berm stones T1 and T2) or because it was already significantly damaged when damage started on the main-armour (toe-berm stones T3 and T4). For the breakwater profiles tested in the present study, there thus appears to be only a weak coupling in the stability of the main-armour and the toe-berm for the trunk section. It is suspected that the considered toe-berms were either too unstable or too narrow for the occurrence of the "toe-armouring" process. Such a process could maybe be observed with a wider and still quite stable toe-berm, but tests in this direction remain to be performed.

6. CONCLUSIONS

The major observations and conclusions raising from present experiments are **very briefly** summarized below for the trunk section of the breakwater :

- Effect of wave incoming direction : No definite effect emerges from the tests results for the main-armour. For the toe-berm however, the normal direction seems more severe than the 30° direction, at least for long-crested waves.
- Effect of wave directionality : More damage to the main-armour and to the toe-berm is observed under short-crested waves, in particular for normal wave attack. This point is rather in contradiction with previous experiments (Thunbo Christensen *et al.*, 1984 ; Canel and De Graauw, 1992), but is rather clear from present tests. It is supposed to be related to a quite low angular spreading of energy, which could be more severe for the stability. This point has however to be addressed by additional tests.
- Effect of wave steepness : Among the two tested values of steepness (2 % and 5%), the one corresponding to "longer" waves results in more damage both to the armour-layer and to the toe-berm. However, the toe-berm appears to be more sensitive to the steepness of incident waves than the main-armour.
- Effect of toe-berm stones size : when the toe-berm is "stable" (T1 or T2), the stability of the armour is not significantly affected by the stability of toe-berm. However, when the toe-berm is unstable (T3 or T4), higher damage is observed on the main-armour, leading sometimes to its failure. As expected, damage to the toe-berm increases as the toe-berm stone size decreases.

Comparing present results with existing design formulas, acceptable agreement was observed with the Van der Meer formulas for the stability of the main-armour. However some differences were also noted, in particular for the "plunging waves" formula : the lower values of damage to the armour-layer are overpredicted by the formula, whereas the higher values seem to be underpredicted. The Van der Meer formula for "surging waves" appears to lead to a somewhat conservative design. For the toe-berm, the formula from Gerding (1993) lies in acceptable agreement with present results, although the effects of wave steepness and mound-slope (not included in the formula) slightly increase the scatter of experimental points.

As a matter of conclusion, it appears from the present tests that the major feature of the interaction process between main-armour and toe-berm is an increase of damage to the armour when the toe-berm is unstable. This may lead to a total failure of the armour if the toe-berm is sufficiently eroded to fail in providing static support to the armour-layer. On the opposite, minor effect of main-armour on toe-berm stability was observed. In particular the "toe-armouring" process appeared to occur only marginally and under precise conditions. This process is thus regarded as a particular mechanism, which will occur only under specific conditions (precise relative stability of the toe-berm and the armour-layer, wide berm, ...).

As the effects of interaction processes between main-armour and toe-berm appear quite weak (unless toe-berm stones are significantly lighter than their design value), it appears both more natural and safe to use state-of-the-art stability formulas to establish a first design of both the toe-berm and the armour-layer independently. The full breakwater profile should then be tested in a wave flume, or preferably in a wave basin with a correct representation of the actual bathymetry in order to validate its design.

CHAPTER 127

POTENTIAL USES FOR THE RAPIDLY INSTALLED BREAKWATER SYSTEM

Jimmy Fowler¹, Donald Resio², Michael Briggs¹, Cheryl Pollock¹
Members, ASCE

Abstract

Engineers and scientists at the U.S. Army Engineer Waterways Experiment Station (WES) are developing a Rapidly Installed Breakwater (RIB) System specifically designed to address problems associated with the military's efforts to off-load ships during Logistics Over The Shore (LOTS) operations. Problems arise with these operations when seas become energetic and limit capabilities of crane operators and stevedore crews. The RIB System is designed to solve this problem by creating a 'pool' of calmer water where these operations occur so that crews can continue to function. A series of small-scale laboratory experiments conducted in 1995 and 1996 at WES's facilities in Vicksburg, Miss., and at the O. H. Hinsdale Wave Research Laboratory at Oregon State University in Corvallis, laid the groundwork for the RIB System development and yielded an optimum RIB System configuration known as the "Double Delta". Laboratory results, obtained with the Double Delta configuration, showed that wave heights could be reduced by more than 80 percent. During the spring and summer of 1996, a mid-scale RIB System successfully demonstrated its capabilities during a field deployment, with wave height reduction on the order of 75 percent. Based on these results, it is believed that the RIB System will be integrated into the Army's LOTS asset inventory and become a key part of the solution to the military's LOTS problems.

Introduction

For many years, the US Army Engineer Waterways Experiment Station (WES) has been involved with the design and deployment of floating breakwaters, primarily for application within bays or estuaries which are semi-protected from large waves. Such structures typically are intended to attenuate waves with heights not exceeding 4 ft and periods not exceeding 4 sec. Extrapolation to an open ocean environment is at least an order of magnitude greater in difficulty. In an oceanic environment, waves with heights and periods up to 10 ft and 10 seconds respectively, are common during storm conditions. Previous experiments have shown that to be effective, floating breakwaters must have widths on the order of 1/4 of the wavelength being attenuated, and hence, must be very massive to be effective. Such structures are simply not feasible for most temporary and rapidly installed floating breakwater applications, since it would be necessary to transport large volumes of construction materials to the site being sheltered. As described below, this problem was the driving force behind recent floating breakwater developments at the WES.

During energetic seas, the primary problem occurs in key offshore areas (anchorage) where containerships and roll-on/roll-off (RO/RO) vessels discharge cargo and unit equipment onto much smaller vessels, collectively termed lighterage. Hence, WES efforts were directed towards creating sheltered areas in which these anchorages could be located and operated more effectively. A Tactical Auxilliary Crane Ship (TACS) anchorage for offloading containerships offshore is shown in Figure 1 while a Roll On/Roll Off anchorage for offloading rolling stock, such as

Figure 1. Example of Crane Ship (TACS) Anchorage.

Figure 2. Example of Roll On/Roll Off Anchorage.

tracked and wheeled vehicles, is shown in Figure 2. The ability to move vehicles, equipment, and supplies from ship to shore in a rapid manner is considered vital to existing military force deployment operations such as humanitarian relief efforts or supporting a war-fighting effort. Therefore, a key feature of the RIB System is the ability to use existing assets to transport and deploy the system within acceptable time constraints. In light of this, the RIB System will very likely be stockpiled at various pre-positioned locations around the world in fairly large modular components. When exercises or real-world events require its use, the RIB System would then be loaded from the nearest pre-positioned site and transported via sealift to the LOTS site, where it would be assembled with the assistance of either Fast Sealift Ships or TACS in combination with Army and/or Navy tugs.

Operational Requirements of the RIB System.

The main problem to be overcome during these operations is the demonstrated inability to effectively conduct LOTS offloading operations when wave climate conditions exceed what is commonly termed "sea state 2", as given by the Pierson-Moskowitz scale for characterizing energetic seas. The Army uses the period of maximum energy associated with a given significant wave height as found in the Pierson-Moskowitz scale to characterize sea state, which has categories ranging between zero and nine. Figure 3 is provided to demonstrate the relationship between sea state, significant wave height, and period as found in the Pierson-Moskowitz scale. The problematic condition described above is commonly known as the "sea

state 3 problem" and exists when significant wave height is between 3 to 5 feet and periods range from about 3 to 7 seconds. The military considers the sea state 3 problem to be critical since these conditions exist a significant percent of the time worldwide, and in fact is considered to be a potential "war stopper" for present force projection plans and technology.

Figure 3. Relationship Between Sea State, Significant Wave Height and Period.

In light of the above, for the RIB System to be effective, it should be deployable during sea state 3 conditions and should reduce incident waves to create a "pool" of calmer water in the immediate vicinity of these anchorages which is below the sea state 3 threshold. With this scenario, crane operators and stevedore crews could continue to function during sea state 3 and even greater, since existing lighters can operate effectively in sea state 3, once safely loaded. An efficiently performing RIB System would cause the limiting sea state condition to be determined by capabilities of the various lighterage and equipment being used during the LOTS operation.

WES-Developed Rapidly Installed Breakwater System.

The RIB System is presently being developed and evaluated by research coastal engineers at WES. The RIB System consists of a V-shaped structure in plan view, with vertical barrier curtains extending from the surface of the water toward the bottom for a distance sufficient to preclude excessive wave energy from penetrating beneath the structure (see Figure 4). The RIB system concept was initially developed to address specific problems encountered by military personnel during LOTS operations, primarily those affected by sea state conditions characterized by relatively short period waves.

Figure 4. Double Delta Version of the RIB System

When deployed, the tip of the V-shape is oriented into approaching waves and spreads wave fronts apart based on geometric spreading and coupled deflections of wave motion. Ships and lighterage are moored in the lee of the V-shape for offloading. Depending on the specific location where the RIB System is to be employed, the legs of the "V" will vary, but for maximum effectiveness, each leg should be at least three wavelengths in length. The legs are joined at the front of the RIB System and supported with braces to insure structural stiffness. Wave-related mooring loads are relatively small due to two factors. First, the structure is designed to deflect waves rather than absorb them. Second, since the structure is oriented at an angle and is several wavelengths long, the oscillatory nature of the wave forces associated with the crest are simultaneously reduced by the force associated with the trough, which acts in the opposite direction.

Small Scale Laboratory Model Experiments.

During the early stages of the RIB System development, scale model studies were conducted at WES and Oregon State University (OSU) to test the concept, refine the initial design, and subsequently to test enhancements and various modifications. Results indicated that a significant "offshore" area could be effectively reduced from sea state 3 to sea state 1 by the RIB system. The objective of this effort was to obtain data relating to wave transmission in the lee of the RIB system, by evaluating multidirectional waves with both frequency and directional spreading. Wave heights were recorded at 15 locations throughout the sheltered region to ascertain diffraction effects around the ends of the RIB System. Laboratory experiments evaluating the Double Delta configuration which yielded the favorable results are depicted in Figure 5, with each plotted line representing a different wave period. Results are presented as the ratio of recorded wave height in the lee of the system divided by measured incident wave height approaching the RIB System versus distance from the leading edge of the RIB system. As shown below, it was possible to obtain up to 83 percent attenuation (19 percent transmitted height ratio) for some of the wave conditions, for the Double Delta configuration RIB system arrangement.

Figure 5. Laboratory Results Using Double Delta RIB System.

Figure 6 is a photograph which shows the wave basin setup and wave reduction achieved by the RIB System during one of the Double Delta experiments conducted at the OSU facilities. Based on the successes achieved in laboratory environments, a mid-scale field experiment was designed and subsequently conducted in the Currituck Sound during May 20 - 14 June 1996.

Figure 6. Laboratory Experiment Conducted at OSU Using the Double Delta Version of RIB System with Significant Height = 5 ft, Period = 6 sec..

RIB System Field Experiment

The field study was performed at WES's Field Research Facility, located on the Outer Banks in Duck, North Carolina. Since the model was constructed at a 1 to 4 scale, open ocean deployment was not suitable, and the somewhat milder wave climate of the Currituck Sound was selected. The RIB System deployed at Duck consisted of a combination of welded steel structure and closed cell foam floatation. The model was designed as a modular system capable of being assembled using simple hand tools on the beach at Currituck Sound. The deployment featured two 150-ft long RIB System legs, which were assembled from 30 RIB System modules and a nose buoy which was designed and constructed to expedite connecting the two legs. Each leg was assembled on the beach and subsequently towed into deeper water,

where they were joined to the previously positioned nose buoy as shown in the photo in Figure 7. Following attachment to the nose buoy, the trailing ends of each leg were attached to prepositioned anchors to achieve the desired "V" configuration. Instrumentation to measure wave height and weather conditions along with video recordings were used to document the effectiveness of the model used during the field investigation. During the two

Figure 7. Joining of RIB System Legs.

week period, the RIB System was successfully deployed, and data were collected to document wave reduction capabilities and allow comparison to the laboratory data. The comparison indicated that the mid-scale field deployment performed quite similar to the laboratory version, again reducing incoming wave heights by about 75 percent. Figure 8 is a photograph of the RIB System as it was functioning during the field deployment. Incident waves in the photograph scaled to mid- to upper sea state 3, while the wave climate in the lee of the RIB System scaled to sea state 1.

Figure 8. Aerial View of RIB System During 1996 Field Deployment.

Future Plans.

The next step in the development of the RIB System will be additional laboratory investigations to study deployment options, construction materials, and mooring requirements. These efforts will be followed by the construction, and field deployment of a larger, near full size version in 1997. This will in turn be followed by design, construction and deployment of a full-scale version during an actual LOTS operation exercise in the year 2000.

Conclusions

Based on results such as those obtained in the extensive laboratory studies and observations made during the field study in May-June 1996, the RIB System being developed at WES holds great promise for alleviating the military's ship offloading problems associated with higher sea states during LOTS operations. Additional laboratory investigations oriented towards mooring techniques and methods of deployment are scheduled for 1997. These studies will be designed to optimize present design and examine potential alternative uses for the RIB System. A second field deployment of the RIB System constructed at a 1 to 3 scale, will occur during the summer of 1997, primarily to evaluate mooring and deployment options developed during the laboratory studies. These efforts will be followed by a full-scale demonstration, and by research to evaluate other potential applications of the RIB system, including protection of shore-based offloading sites, protection of nearshore construction/repair sites such as for jettys or breakwaters, and temporary small boat harbors.

Acknowledgements

The authors acknowledge Headquarters, U.S. Army Corps of Engineers, for authorizing preparation and publication of this paper. It was prepared as part of the Military RDT&E Program of the U.S. Army Engineer Waterways Experiment Station's Coastal and Hydraulics Laboratory. The RIB System deployed during the field study was fabricated by Kepner Plastics Fabricators, Inc., Torrance, California. M. J. Plackett & Associates (MJP&A) provided technical assistance and support to WES related to the design, planning, structural analysis and fabrication of the RIB System models used in both the field and laboratory studies. Plackett & Associates, and the staff of the Field Research Facility for their help during this project.

CHAPTER 128

Stability of Reshaping Breakwaters with Special Reference to Stone Durability

P. Frigaard ¹, T. Hald ¹, H.F. Burcharth ¹, Sigurdur Sigurdarson ²,

1 Introduction

Traditionally, conventional rubble mound breakwaters are designed with stable armour units, and consequently, very large stones or even artificial armour units are required. Reshaping breakwater designs allow reshaping of the seaward slope thus involving stone movements. Ultimately, dependent on the degree of safety in the design, this reshaping process might end up in a stable profile where no changes in the cross sections occur even though stone movements are allowed.

Unfortunately, large movements of the protecting stones during the structural lifetime in combination with high stone velocities inherently cause some breakage and abrasion of the individual stones and thereby also reduced stability. In order to avoid excessive abrasion a high stone quality is demanded or larger stones must be applied when constructed. To allow the designer to account for abrasion and armour stone breakage due to the stone motion a description of the overall wave climate during the structural lifetime must be derived involving knowledge of transport rates, movement patterns, stone velocities and stone quality.

The main objective of the paper is to describe a tool enabling calculation of the anticipated armour stone movements. Also tensile stresses occur, as a result of stone against stone impact are discussed in order to make a more close connection between wave climate, stone movements and abrasion/breakage. Finally, a comparison to selected prototype structures is made to compare the armour stone movement model with visual profile observations of existing breakwaters.

2 Longshore Transport Rate

Motion of stones along the active profile occurs when even slightly oblique waves attack the breakwater. This longshore motion has been evaluated in model tests performed by Burcharth and Frigaard (1988) and by van der Meer and Veldman (1992). Longshore transport was measured by observing the movements of stones layed out in coloured bands over the profile. To calculate the steady state transport the number of stones per wave passing a specific cross section at each sea state was divided by the number of waves. This ratio is termed the longshore transport rate S_x .

In Figure 1 the measured longshore transport rate is plotted against the mobility index $H_oT_{op} = \frac{H_a}{\Delta D_{n50}} T_p \sqrt{\frac{g}{D_{n50}}}$. The longshore transport rate seems to be described quite well by a power function as originally proposed by Vrijling (1991). The best fit of the power function to the data is:

$$S_x = 85 \cdot 10^{-6} (H_oT_{op} - 105)^2 \tag{1}$$

Figure 1: Longshore transport rate for reshaping breakwaters.

One might argue if the model in eq. (1) is too simple because of the absence of obliquity. The model can however, easily be adjusted to include the angle of incidence θ as discussed by Alikhani et al. (1996). Though the effect of obliquity is small.

Another aspect of the transport model is the obvious sensitivity to the onset of motion. From the model it is seen that sea states slightly above those corresponding to the onset of motion result in significant transport due the rapid increase of the power function. The latter comparison with prototype breakwaters outlines this sensitivity.

3 Longshore Distribution of Transported Material

To characterize the motion of the individual stones on the breakwater several video recordings from the model tests performed by Burcharth and Frigaard (1988) have

been reanalysed thoroughly.

The main conclusion based on the analysis of the video recordings was a typical zigzag motion pattern as shown in Figure 2. The typical upward motion of the stone follows

Figure 2: Typical pattern for single stone motion.

the wave direction θ whereas the downward motion is more controlled by gravity and an angle of half the angle of incidence seems more appropriate, see Figure 2. From Figure 2 the total travelled longshore distance can be calculated, assuming the upward and downward distances orthogonal to the structure in average are equal

$$l = l_u + l_d = \frac{2x}{3 \sin(\theta)} + \frac{x}{3 \sin(\frac{1}{2}\theta)} \tag{2}$$

To quantify the travelled longshore distance x the longshore distribution of the transported material has been derived from the same tests. The longshore distribution was derived from recordings of the number of stones positioned in 5 cm wide bands over the profile along the entire length of breakwater. From these recordings the number of stones per m, the position of the individual stones and the mean stone movements are calculated. Figure 3 shows an example from a single longshore transport test.

Figure 3: Example of the longshore distribution of transported material.

In Figure 4 the longshore distribution is shown for all 22 tested wave conditions. As abscissa the travelled longshore distance x is normalized by the mean travelled distance \bar{x} and as ordinate the stone distribution along the structure $s(x)$ (unit: stones/m per wave) is normalized by multiplying with $\frac{\bar{x}}{S_x}$.

Figure 4: Longshore distribution of transported material.

From Figure 4 an excellent uniformity of the distribution curves for different wave climates and different angles of incidence is seen. Hence, a general exponential function can be fitted to the entire data set

$$s(x) = 0.6 \exp\left(-0.6 \frac{x}{\bar{x}}\right) \frac{S_x}{\bar{x}} \tag{3}$$

In Figure 5 the mean stone movement is plotted against the mobility index for all 22 tested wave climates.

The mean stone movement is described by

$$\bar{x} = 5.3 \cdot 10^{-3} D_{n50} (H_o T_{op} - 105) \sin^{0.8}(2\theta) \tag{4}$$

or by inserting the longshore transport model eq. (1).

$$\bar{x} = 0.6 D_{n50} \sqrt{S_x} \sin^{0.8}(2\theta) \tag{5}$$

Inserting the mean travelled distance in the expression for l , eq. (3) gives the average distance moved per wave. Knowing the wave height/period scatter diagram describing the storm history for a specific area, it is possible to calculate the accumulated average distance moved by each single storm during the structural lifetime simply based on the easy accessible parameters, H_s , T_p , θ , number of waves and D_{n50} .

Figure 5: Mean stone movement versus the mobility index.

4 Impact Stresses in Armour Stones

A more close description than the stone motion connecting abrasion and breakage is to consider the tension stresses as a result of armour stones impacting armour stones during movements. This impact results in a shock wave propagating through the stone which is reflected at the edge structure resulting in a reverse propagating tensile stress wave. In case the tensile stress is too high the stone may crack depending on the stone quality.

In Figure 6 an idealized static model of a stone impact is sketched where the impacted stone remains at rest after impact. This is modelled by giving the stone infinity mass and zero velocity.

Figure 6: Static model

Applying Hertz' law to the system in Figure 6 results in the following equation

$$\sigma_{max} \propto \left(\frac{V_s^4}{D_{n50}} \right)^{0.2} E \tag{6}$$

where:

- W_s = Stone weight
- V_s = Stone velocity
- D_{n50} = Nominal stone diameter
- E = Young's Modulus

Generally, eq. (6) describes the stresses with reason: a high velocity yields high stresses, a small diameter signifies large curvature and thus larger impact stresses because of the smaller contact area, and finally the elasticity of the stone is described by Young's Modulus. Another aspect is that by simple Froude scaling larger stones gain larger stresses.

From the previously described tests typical stone velocities during both run-up and run-down were investigated by video. A typical stone velocity during run-down equals the wave run-down velocity whereas the typical stone velocity during run-up is approximately 50-70% of the wave run-up velocity.

Several attempts to assess the run-up and run-down velocities have been made showing that the maximum expected velocity can be well described by H_s and $\xi = g(\alpha, H_s, T_p)$. The overall maximum velocity is expected to be in the order of $1.5\sqrt{gH_s}$, e.g. Sawaragi, (1995).

From the above considerations it seems that the impact stresses can be described by the same easy accessible parameters as the movement model. The model still needs verification and calibration to physical model tests as well as prototype measurements. More work has to be done into these subjects.

5 Comparison with Prototype Breakwaters

For prototype comparison four sites are investigated with wave and structural characteristics given in the two tables 1 and 2. The accumulated travelled mean distance have been calculated followingly:

- Calculation of longshore transport rate from eq. (1) for each storm.
- Calculation of mean position moved from eq. (5) for each storm.
- Calculation of total travelled distance from eq. (3) for each storm.
- Summation of total travelled distance during lifetime.

Regarding

1. Caldera, Costa Rica: Estimated stone movements are rather small indicating little stone movements during lifetime. Observations show little profile changes but some broken stones. This might be due to the very poor quality of the stones.
2. St. Paul, Alaska: Vast stone movements are estimated. Total damage of the breakwater was observed.
3. Racine, Wisconsin: Long travelled distance is estimated. Severe breakage and large profile changes were observed.

4. Bolungarvik, Iceland: Little stone motions were estimated. Little profile changes observed.

It seems that the calculated distance corresponds very well to what might have happened. Though, it is clear that actual damage depends on both the travelled distance and the quality of the stones. In all, the comparison indicates that there is reason in relating breakwater damage to the armour stone motion.

6 Conclusions

A model enabling calculation of the accumulated travelled stone distance is given based on the easily accessible parameters such as H_s , T_p , θ , number of waves and D_{n50} . Furthermore, a short discussion focusing on the structural integrity is given. It is argued that the anticipated maximum tensile impact stresses can be evaluated by the same easily accessible parameters, though more work need to be done into this subject.

A comparison with selected prototype structures is presented showing that there is reason in relating breakwater damage to the armour stone motion. The comparison also signifies that only little transport should be allowed in order to avoid severe damage.

In areas where sufficiently large armour stones can be difficult to get, the stone quality is often poor. Even little stone transport or stone motion will in these cases result in breakage and abrasion of the armour stones. In practice it is difficult to avoid the abrasion and breakage of the armour stones and thus little transport should be allowed. The best possible design of the berm breakwater with maximum utilization of the quarry when possible is suggested by Sigurdarson et al. (1995). The aim is to minimize stone movements and make a more or less statically stable structure with little expected movements during the lifetime if suitable quarries are found in the vicinity. Still if stone movements occur on the berm breakwater no abrupt failure occur. By the berm concept up to 100% of the quarry yield can be used. This design approach have been used videly in Iceland with succes, see Sigurdarson and Viggosson (1994).

CHAPTER 129

FIELD INVESTIGATIONS ON WAVE-DISSIPATING CONCRETE BLOCKS COVERING VERTICAL WALL BREAKWATER

Michio Gomyoh¹, Kazuhiko Sakai², Tomotuka Takayama³,
Kojiro Suzuki⁴, Shigeo Takahashi⁵

Abstract

The failures experienced in Japan by wave-dissipating concrete blocks (WDCB) covering vertical wall breakwaters are investigated, and the deformation characteristics such as failure features and factors are examined.

Typical examples for failures are illustrated, and two main types for failures are suggested: (a) scattering of WDCB due to shortage of their weight, (b) settlement of WDCB following deformation of the toe area. These types are analyzed and then the latter is discussed with some preliminary experiments. The results suggested that both stability of WDCB and applicability of the Hudson formula depend on the location and their cross-sectional shape, and that a weakening of sand bed due to wave action, especially wave-induced liquefaction, is an important factor of settlement deformation as well as scouring.

From these results and additional field surveys, finally, two parameters are suggested which can explain the effect of stability of WDCB and toe area on both scattering and settlement behavior, and a classification of resultant failure characteristics and a conceptualized diagram of failure behavior of WDCB are presented.

1. Introduction

Throughout the world, and especially in Japan, the Hudson formula has

been applied in the design process used to evaluate the stability of WDCB which cover the front of large-scale vertical wall breakwaters. However, based on the fact that this design tool was not for WDCB, but originally formulated for evaluating the armor layers of rubble mound breakwaters, WDCB may show different stability properties in the applied fields.

Therefore, firstly, we performed field stability investigations to determine the deformation characteristics and resultant suitability of the Hudson formula in designing Japan's recently built vertical breakwaters covered with such blocks. Secondly, we also carried out some preliminary experiments and field surveys to understand a unique failure characteristics of settlement deformation observed at Miyazaki Port. Finally, in discussion, we classified these complicated failure features and explained them quantitatively, so that the results will be helpful to develop an improved design method.

2. Investigation method

Field investigations were conducted in Japan on major breakwaters located at 16 ports among more than a hundred as shown in Figure 1. Failure

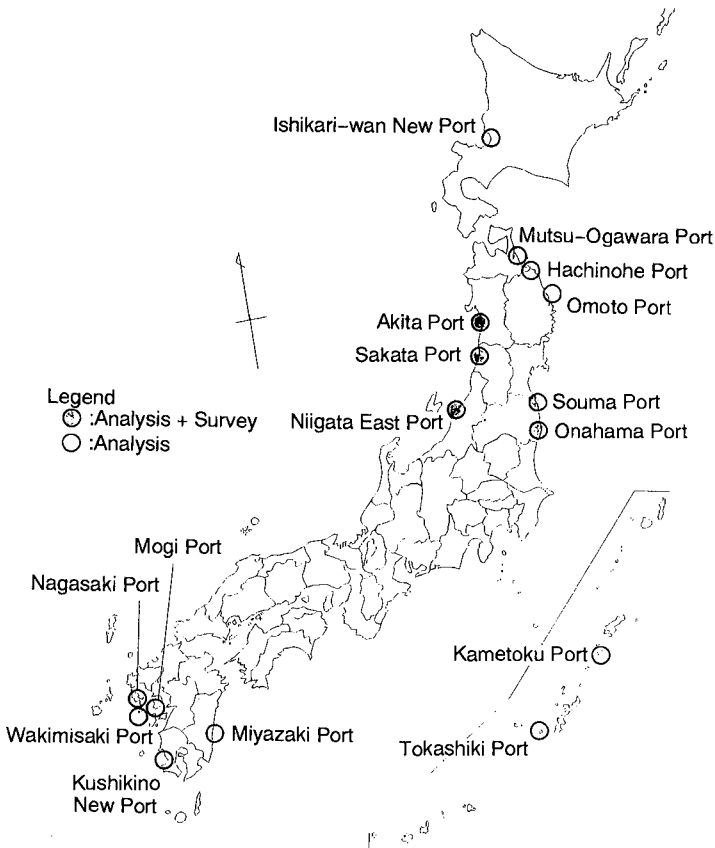

Figure 1. Map of ports investigated in this study

cases investigated in this study are limited to those which recently occurred remarkably and whose data have been accumulated enough to analyze their features and factors. As the result, 27 cases including both damage and no damage were analyzed using pertinent data including wave conditions, damage features (area, type, and weight of blocks), and design conditions. After these analyses some preliminary experiments were done to study a unique failure at Miyazaki port. Furthermore, in order to see not only failure results but also its process going on in site, 6 cases (Case 22 to 27 in Table 1) were surveyed noting the physical conditions before and/or after deformation. All cases are summarized in Table 1.

3. Investigation results

From all the cases in Table. 1, the following specific features of WDCB failures are obtained:

1) Few failure cases of WDCB are reported in spite of the fact that they are used in many sites.

Table 1 (continued)

No.	Block*	Wave conditions**: $H_{1/3}$, T, θ	Failure features of WDCB	Other failure features
1	T:50t, S:50t (1:4/3)	9.6m/ 13.4s/ -7.1°	scattering, settlement	caisson sliding, breakage

* T: Tetrapods, S: Sealock, D: Dolos, H: Hexa-leg-block

** Incident wave conditions calculated by wave hindcasting when the failures occurred

2) Though the predominant disturbances are typhoons in summer and depressions in winter, gradually advancing deformations during about one year are also observed.

3) Tetrapods and its normal slope gradient of 1:4/3 are used for more breakwaters, however, gentler slope of 1:1.5 is locally adopted at the ports facing to the Sea of Japan where scouring at the toe area of composite type breakwater is remarkable.

4) Occurrence of the breakage of blocks is less than that of scattering and settlement which seem to be typical failure features.

5) Other two failure features, caisson sliding and breakage, and scouring at the toe area, are observed at the breakwater head/sectional end and breakwater trunk, respectively.

In the following paragraphs, the investigation results on scattering and settlement of WDCB will be indicated.

3.1 Scattering failures of WDCB

Typical examples

Figure 2 shows the scattering of WDCB, 40 t Tetrapods, and the damage of caissons of No.2 breakwater at Hachinohe Port (Case 6,7). The important point to note in these cases is that the scattering of WDCB was found to be severe at the breakwater head/sectional end, A-A line, and that it was very mild at the trunk section, B-B line, in spite of neighboring the damaged area. The predominant reason responsible for the former is the action of severe wave force at the sectional end as pointed out by Takahashi et. al.(1993). A nesting process of the scattering of WDCB and the caisson sliding due to increase of wave force acting on the caisson wall lead to the larger scattering. Similar failure features like this are observed at east breakwater in Mutu-Ogawara Port (Case1,2,3), No.1 breakwater in Hachinohe Port (Case 4,5), Nagasaki Port (Case9,10,11), and Wakimisaki Port (Case12,13).

Figure 2. Scattering of WDCB at breakwater trunk section and head sectional end (Hachinohe Port)

Figure 3. Scattering of WDCB covering a reef (Kametoku Port)

Figure 4. Relationship between degree of scattering and safety factor

Figure 5. Effect of steepness on stability number as determined by three formulas and observed failure cases

Figure 3 shows the scattering of WDCB, 50t Dolos, covering the reef at Kametoku Port (Case18). Here, the south breakwater is located on the natural reef around the Tokunosima island, and its head on the edge of reef whose bottom slope is steep. This scattering occurred due to both waves breaking there suddenly and resultant severe currents.

Relationship between degree of scattering and safety factor

Judging from the above, the degree of scattering of WDCB seems to depend on its location and cross-sectional shape. Figure 4 shows the relationship between the degree of scattering of WDCB and the safety factor, where $\Delta A/A$ is the ratio of the cross-sectional damaged area to design area, and SF shows the ratio of the actual weight to the calculated weight when failure occurred. It is clear that WDCB at the trunk section remains stable at a safety factor as low as 0.5, and in contrast, the scattering of WDCB at the breakwater head/sectional end occurs severely even though the safety factor is as high as 1.7. Consequently, it is indicated that the applicability of the Hudson formula is adequate at the breakwater trunk section and marginal at the head/sectional end.

Applicability of stability formulas for WDCB

Corresponding analyses are also performed using the design formulas by van der Meer(1988) and Kajima(1994) as well as the Hudson formula. Figure 5 shows the effect of steepness on the stability number by comparing the no

damaged cases at trunk section to the results calculated by three formulas in such conditions that relative damage level in van der Meer(1988), $N_o=0.2$; deformation level in Kajima(1994); $S=1.2$, and wave number; $N=1000$. It is found that they show similar applicability when considering limited amount of field data though the effects of steepness varies among them. In other words, there is almost no difference among them in a practical wave steepness ranging from 0.01 to 0.05.

3.2 Settlement failure of WDCB

Typical examples

Of particular interest, the failure at Miyazaki Port is a typical one caused by long-term, gradual settlement of blocks, being a sometimes hard-to-recognize type of damage that frequently occurs in areas where sand transport is significant. Figure 6 shows that the cross-sectional change such as settlement of WDCB, 64t Tetrapods and armor blocks. Although the nesting process of blocks and/or scouring at the toe area have generally been considered to be the main cause, block settlement may instead be due to various wave actions weakening the sand bed to such an extent that the blocks literally sink into it. Figure 7 shows a photograph supporting this possibility, i.e., the entire body of blocks appears to have moved toward and down during settling. This characteristic feature is also observed at Kushikino Port.

Reproduction of settlement behavior at Miyazaki Port

In order to discuss this type of settlement behavior in detail, wave flume experiments designed to reproduce the breakwater deformation at Miyazaki Port were conducted with reduced scale of 1:55. It was found that block scattering did not occur, even when attacked by waves exceeding the design wave height, and scouring was produced at the toe area, though the use of gravel mats prevented subsequent deformation of the block section.

Figure 6. Cross-sectional change of south breakwater at Miyazaki port

Figure 7. Settlement deformation of WDCB at Miyazaki Port

Then, to clarify whether weakened strength of the sand bed is responsible for settlement of blocks, we liquefied it by supplying pore water from bottom of the bed. Figure 8 shows a photograph of the results. The important point to note is that the settlement of the block section is quite definitive, i.e., the blocks at the toe area have sunk into the sand bed and the entire body of blocks has moved forward and down (Figure 8(b), (c)), being a similar behavior to that actually observed (Figure 7) and quite different from the not-liquefied case (Figure 8(a)). These results indicate that weakening of the bed caused such settlement deformation, and that as wave loadings most likely lead to bed weakening, the phenomenon of wave-induced liquefaction may play a key role.

Figure 8. Block settlement deformation due to weakening the sand bed by liquefaction

3.3 Surveys of settlement deformation

During Dec. 1995 to Mar. 1996, field surveys were carried out at 5 ports as shown in Table 1, to examine whether a similar settlement deformation like Miyazaki Port is observed or not. The results indicate that there are two patterns of settlement, excluding the initial settlement due to compaction by wave attack after construction. These are 1) settlement of the top of WDCB due to scattering, a pattern which looks like true settlement, and 2) settlement of an entire body of WDCB following the deformation of a toe area. Furthermore, it is reasonable to think that these features are possible to occur either alone or together.

4. Discussions

The discussions were made below towards a better understanding of the scattering and settlement behavior of WDCB.

Classification of predominant failure characteristics of WDCB

The following classification and identification of failures can be obtained from the investigated failure cases:

- 1) Failure features
 - Direct and independent:
 - Scattering
 - Breakage
 - Others
 - Indirect and complex:
 - Scattering with caisson sliding
 - Settlement following deformation of toe area
 - Others
- 2) Failure factors except for waves exceeding the design condition
 - Major factors for scattering
 - Sea bottom topography: reef and steep slope
 - Location: breakwater head
 - Cross-sectional shape: sectional end
 - Major factors for settlement
 - Soil condition: sand
 - Toe structure

In the following discussions, the scattering and settlement at the breakwater trunk will be discussed in particular.

Structural Parameterization

Considering the settlement feature and its process, it seems reasonable to suppose that both material and dimension of the toe area are important factors to prevent settlement deformation of blocks. Therefore, the structures including WDCB in front of a vertical wall are represented with dimensionless parameters as shown in Figure 9. In this figure, x and z indicate the distance measured from the vertical wall and sea bottom, and h and L show the water depth and wave length in design, respectively. Furthermore, the following abbreviations are used: AB (armor block), AS (armor stone), FPB (foot protection block), FPS (foot protection stone), G (gabion), GM (gravel mat), M

(asphalt mat or scour protection mat), RF (rubble foundation).

As illustrated in this figure, the structures for toe area have a certain range from the thick and wide to the thin and narrow. Consequently, we parameterized the structure for toe area by its thickness; t and width; s as shown in the top right, where st shows an index of cross-sectional area of toe structure.

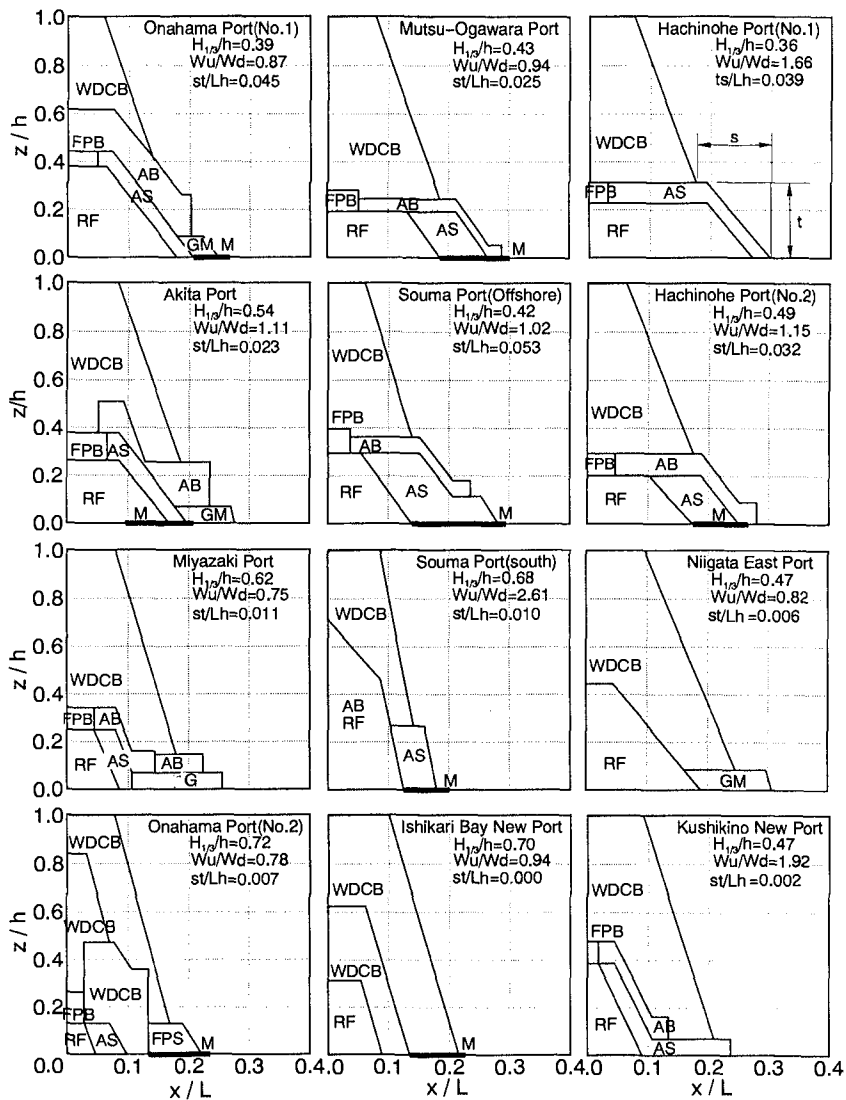

Figure 9. Structure parameterization

Effects of stability of WDCB and toe area on scattering and settlement behavior

To discuss both effect of stability of WDCB and toe area on scattering and settlement behavior, two parameters are suggested: $st/LH_{1/3}$ which indicates the stability of toe area being non-dimensional parameter with st , design significant wave height; $H_{1/3}$ and wave length; L , and W_u/W_d which indicates the stability of WDCB by using actual weight; W_u and design weight; W_d . Figure 10 shows the relationship between two parameters and the degree of deformation at trunk section. As shown in this figure, deformation becomes larger when $st/LH_{1/3}$ is smaller than 0.04 and the failures can be divided into four regions in this figure: no failure, settlement, settlement and scattering, and scattering.

Furthermore, each failure case can be explained reasonably and estimated. For example, the following consideration is possible:

1) Both Miyazaki Port and Kushikino Port are unstable for settlement and indicate similar failure feature, however, if severe waves exceeding the design wave condition attack, they will show different failure features, with scattering or no scattering, because of the difference in the stability of WDCB.

2) The failure case observed at Souma Port (south) shows the severe deformation against the wave attack slightly exceeding the design wave condition although the weight of WDCB is enough to keep itself stable under such a wave condition. This case can be explained as typical one caused by settlement deformation.

3) The case at Onahama Port (No.2), where the blocks less than design weight were used, the value of $st/LH_{1/3}$ is 0.01, and the exceedance of wave design condition was experienced, seems to indicate a complex failure feature which both settlement and scattering occurred at the same time.

Figure 10. Influence of stability of toe area and WDCB on scattering and settlement behavior (values in parentheses indicate $\Delta A/A$)

Figure 11. A diagrammatic representation of Figure 10

Conceptualization of failure behavior of WDCB

Based on the above discussion and Figure 10, the failure behavior can be conceptualized as shown in Figure 11. This diagram shows a summary representation of the effects of stability of toe area and WDCB on failure behavior of WDCB.

5. Conclusion

The following main conclusions can be drawn from these investigations:

- 1) Few failure cases of WDCB covering vertical breakwaters are reported in spite of the fact that they have been used in many sites.
- 2) WDCB designed by using the Hudson formula are very stable at the breakwater trunk. On the other hand, those at the breakwater head/sectional end are less stable and have experienced the typical scattering failures consequently.
- 3) Of the failures which have been considered as scattering failures, not a few failures due to settlement are observed like Miyazaki Port and Kushikino Port.
- 4) Not only scouring at the toe area but also liquefaction due to waves may play a key role on the settlement failure, and to clarify its cause, further research is necessary.
- 5) However, a suggestion is possible as a countermeasure for the settlement failure that one adopts a large value of the parameter st , that is, makes a toe structure wider and thicker.

ABSTRACT

A new stability formula for wave-dissipating concrete blocks covering horizontally composite breakwaters is proposed after reviewing the existing stability formulae and verified using experimental data. A method for estimating the expected value of the accumulated damage to wave-dissipating concrete blocks within their lifetime using the Monte Carlo simulation follows thereafter and the practicability of this method for reliability based design of wave-dissipating concrete blocks is shown.

1. INTRODUCTION

Horizontally composite breakwaters (Fig. 1), covered with wave-dissipating concrete blocks, are widely employed in Japan (Takahashi, 1996) due to their proven effectiveness in reducing (i) wave forces acting on caissons, (ii) reflected waves and (iii) overtopping.

The design process used in Japan for horizontally composite breakwaters has strongly relied on the Hudson formula (Hudson, 1959) to provide the design weight of these blocks. Van der Meer (1987, 1988) developed stability formulae for rock/stone and armor unit breakwaters, both of which include parameters not considered by Hudson, i.e., damage level, wave steepness, and wave number.

The formula for armor units, however, is based on a two-layer type rubble-mound breakwater with a high crest level. This results in characteristics such as permeability and run-up/run-down features which are quite different from the case in horizontally composite breakwaters. The stability of wave-dissipating concrete blocks has been investigated by many researchers. For example, Kajima (1994) proposed a stability formula applicable to Tetrapods, as used in the protective covering of vertical seawalls. This formula, however, can not determine a specific design value to correspond to the assurance of no damage.

The above considerations have led to the present study and a new design formula specifically formulated to analyze the stability of wave-dissipating concrete blocks covering horizontally composite breakwaters is proposed herein.

In recent years reliability based design has been introduced to port and coastal structures. Takayama et al. (1994) developed a probabilistic design for caissons in composite breakwaters in order to estimate the probability of slide and overturn of caissons. As for probabilistic design for wave-dissipating concrete blocks, the total damage level accumulated within the life time of these structures proves very important as well as the probability of occurrence of damage. The authors in this study demonstrate a method for probabilistic design for wave-dissipating concrete blocks by Monte Carlo simulation with a new stability formula.

2. NEW STABILITY FORMULA

2.1 Example of Experimental Data

Various kinds of experimental research for wave-dissipating concrete blocks has been carried out in Japan. The several available data sources shown in Table 1 were carefully examined in this study. The type of structure is a typical horizontally composite breakwater.

Table 1 Example of experimental data

(Figures in Model)

No.	Port Name	Water Depth (cm)	Sea Bed Slope	$T_{1/3}$ (sec)	$H_{1/3}$ (cm)	Wave Steepness	Mass of Tetrapod (gf)
1	General. Tanimoto (1979)	39.0~48.0	1/100	2.5	16.2~25.9	0.017~0.027	743.3
2	General. Tanimoto (1985)	39.7	1/50	2.46	12.0~23.0	0.013~0.024	296.0, 596.4
3	S	25.0~31.3	1/15	1.95	8.0~15.0	0.013~0.025	91.7, 128.6
4	Mu	29.3	1/50	1.95	11.4~17.1	0.019~0.029	171.7
5	K	24.3	1/50	1.91	12.9~18.6	0.023~0.033	235.0
6	A	37.5~42.0	1/100	1.74~2.37	13.0~20.0	0.015~0.040	449.2
7	Mi	27.2	1/50	1.94	16.8	0.029	297.4

The Tetrapod was applied as it is a typical example of a wave-dissipating concrete block. The scales of the experiments vary from 1/40 to 1/80. The water depth ranges from 25 to 50cm in the model (14 to 20m in the prototype), the seabed slope is from 1/15 to 1/100, and the mass of the blocks is from 90 to 700gf in the model (32 to 80 tf in the prototype). All experiments were carried out under irregular waves of wave height 6.5 to 12m and wave period 11 to 17s in the prototype, and wave steepness 0.013 to 0.04.

2.2 Review of Existing Formulae

(1) Hudson's formula

Hudson (1959) carried out an experimental study on 2-layer type armor units under regular waves and proposed his stability formula to calculate a mass of units as shown below.

$$W = \frac{\rho_r H^3}{Ns^3(Sr - 1)^3} \quad (1)$$

where W is the mass of the armor unit, Ns the stability number, $Sr = \rho_r / \rho$, ρ_r the mass density of the unit, ρ the mass density of water, H the wave height.

Then Hudson obtained expression of Ns as a function of the slope angle α and the stability coefficient K_D as shown below.

$$Ns^3 = K_D \cot \alpha \quad (2)$$

Figure 2 shows the relation between the damage D(%) and K_D for the data from Table 1. D(%) denotes the ratio of the number of displaced units to the total number of units. K_D was calculated by Eqs.(1) and (2) using $H_{1/3}$ as H corresponding to the damage D(%). The data is scattered in a wide range and it is difficult to find any certain trend. The reason behind the data scatter is that the damage D(%) is affected by the size of the structure and the duration of wave attack is not considered in the Hudson's formula.

Figure 2 Relation between K_D and damage D(%)

(2) Van der Meer's Expression of Stability Number

Van der Meer (1988) proposed the following expression of stability number for 2-layer Tetrapod armoring on a rubble slope of 1 on 1.5.

$$Ns \approx H_{1/3}/(\Delta Dn) = \left(3.75N_0^{0.5}/N^{0.25} + 0.85\right) Sz^{-0.2} \tag{3}$$

where Δ is Sr-1, Dn the nominal diameter of the unit ($=V^{1/3}$), V the volume of the unit, N_0 the relative damage level defined by van der Meer (1988) as the actual number of displaced units related to the width (along the breakwater alignment) of one nominal diameter Dn , N the number of waves, Sz the wave steepness ($=2\pi H_{1/3}/gTs^2$) and, Ts the wave period.

Figure 3 shows the results from Eq. (3) with the model test data employed. The abscissa is calculated using the right side of Eq.(3) with N_0 , N and Sz , and the ordinate is calculated using the left side with $H_{1/3}$, Δ and Dn .

The difference between the model test data and those calculated is not acceptable, even when the slope difference between 1:4/3 of the model data in Table 1 and 1:1.5 of Eq. (3) by van der Meer is considered. This result shows that Eq. (3) derived for the 2-layer type can not be directly used on wave-dissipating concrete blocks covering horizontally composite breakwaters. The reason behind this is considered to be mainly from the difference of permeability as van der Meer (1987, 1988) incorporated permeability into his stability formula for the armor stones.

Figure 3 Comparison of van der Meer's formula with model test data

(3) Kajima's Expression of Stability Number

Kajima (1994) proposed the following expression of stability number applicable to Tetrapods for horizontally composite breakwaters.

$$Ns = H_{1/3}/(\Delta Dn) = 8.5(S/N^{0.5})^{0.16} \xi^{-0.5} \tag{4}$$

where S is the deformation level defined by van der Meer (1987) for rubble mound breakwaters as A/Dn^2 , A the sectional area of erosion, ξ the surf similarity parameter ($=\tan\alpha/(H_{1/3}/L_0)^{0.5}$, L_0 the offshore wave length).

Kajima et. al. (1993) showed that the deformation parameter S is related to the damage D' (%) corresponding to the 2-layers as follows.

$$S = 0.6 D' \tag{5}$$

Figure 4 shows the relation between $H_{1/3}/(\Delta Dn)\xi^{0.5}$ and $S/N^{0.5}$.

Figure 4 Relation between $H_{1/3}/(\Delta Dn)\xi^{0.5}$ and $S/N^{0.5}$

The solid line indicates the relation derived from Eq.(4). In the model test data, S was calculated from damage D' based on Eq.(5). Eq.(4) was verified by model test data from Kajima et. al. (1993). Eq.(4) however does not agree well with the model test data employed from Table 1.

One of the reasons for this disagreement is considered to be that Eq.(4) is formulated so as to cover a range of relatively high damage level which is usually not seen in the ordinary design of port structures. Also, the water depth of the structure Kajima investigated was greater than those in Table 1 resulting in a bigger cross section. This is considered to affect parameter S calculated through D' from our data.

2.3 Basis of Formulation

To establish a new stability formula, the above mentioned three formulae, i.e. Hudson, van der Meer, and Kajima were comparatively evaluated and various main parameters in the formulae were investigated. These subsequently led to the determination of the basis of a new formula as summarized below:

- 1) *Type of Formula*: The type of formula desired is for use to obtain the stability number $N_s = H_{1/3}/(\Delta D_n)$ by parameters of damage and number of waves.
- 2) *Damage*: Damage to wave-dissipating concrete blocks is expressed as N_0 following van der Meer. According to the preliminary investigation for a typical horizontally composite breakwater, the relation between N_0 and D(%) is considered as $N_0 = 0.2$ to $0.3 D$.
- 3) *Duration of Wave Attack*: Damage to blocks is considered to be proportional to the root of the duration of wave attack (van der Meer, 1988 and Kajima, 1994). So the number of waves N is incorporated into the formula as the form $N_0 N^{0.5}$.
- 4) *Wave Steepness*: This parameter is treated somewhat differently among the formulae, with Fig. 5 showing how it respectively varies with respect to wave steepness. Note that the relationship derived by van der Meer and Kajima show opposite behaviors, i.e., increasing wave steepness either decreases (van der Meer) or increases (Kajima) stability. The stability itself however is relatively similar at wave steepness values from 0.02 to 0.04, and this is the normal design condition. In accordance to this discussion, wave steepness is neglected as a parameter.

Figure 5 Comparative formula evaluation on the effect of wave steepness on stability

5) *Design for No Damage*: The formula was constructed so as to be able to determine the weight of blocks resulting in no damage.

6) *Type of Block*: Tetrapods with a 1 : 4/3 slope.

2.4 New Stability Formula

Detailed analysis of the experimental data in Table 1 was carried out on the above mentioned basis and the resultant stability formula was expressed as follows.

$$Ns = H_{1/3}/(\Delta Dn) = 2.32(N_0/N^{0.5})^{0.2} + 1.33 \tag{6}$$

Figure 6 compares the results from Eq. (6) with the model test data employed, and good agreement is clearly indicated. Figure 7 also shows another evaluation where the proposed stability formula shows markedly better agreement with experimental data when compared with Figure 3.

Figure 6 Comparison of proposed new formula with experimental data

Figure 7 Comparison of proposed new formula with experimental data

Figure 8 compares the mass of the Tetrapod using the new formula having $N_0=0.1, 0.3, 0.6, 1.0$ and $N=1000$ with that using Hudson's formula using $K_D=8.3$ and $\cot\alpha=4/3$. As shown in the figure the new formula, using $N_0=0.3$ and $N=1000$, corresponds to conventional design using Hudson's formula. Figure 9 shows the mass variation against N_0 and N with the wave height of $H_{1/3}=8.0\text{m}$ fixed. As shown in the figure, the change in mass against N_0 up to 0.5 and N up to 1000 is significant.

Figure 9 Mass change with N_0 and N

3. APPROACH TO PROBABILISTIC DESIGN

3.1 General Method

Reliability based design is a design methods which incorporate uncertainty and statistical deviation of design parameters. It is considered to be requisite for port and coast related structures from the view point of economic design especially for wave-dissipating concrete blocks. For the design of wave-dissipating concrete blocks, damage level accumulated within the lifetime of the structure is considered to be necessary. Therefore the process of damage accumulation in structures within their lifetime should be taken into consideration.

Design for port related structures includes many parameters to be treated probabilistically such as offshore wave height, wave period, tide, wave deformation by refraction, diffraction, shoaling and breaking for wave calculation. After calculation of the waves, the statistical uncertainty of damage to blocks should be taken into account specifically for wave-dissipating concrete blocks.

In this study, the authors demonstrate a procedure for the estimation of the expected value of damage accumulated within the lifetime of horizontally composite breakwaters incorporating statistical deviation of the offshore wave height, tide, shoaling, wave breaking, and damage to wave-dissipating concrete blocks.

The Monte Carlo simulation is used in probabilistic treatment, because of the advantage in handling physical phenomena using many sequential steps like the design process mentioned here. The simulation is considered to be a useful tool well supported by the advance of personal computers in recent years.

3.2 Detailed Calculation Method

(1) Offshore Wave Height

Damage to wave-dissipating concrete blocks is generally considered to be caused by large waves comparable to design waves. Therefore the yearly maximum offshore wave height is considered sufficient to be incorporated into the calculation. This offshore wave height H_{0e} is sampled from an extreme distribution of offshore waves. The estimated value of the offshore wave height is considered to include a statistical deviation. An average value H_0 is considered to follow a normal distribution with a bias (mean shift) α_{H0} , a standard deviation σ_{H0} and a deviation coefficient γ_{H0} as expressed as follows (Takayama et. al., 1994)

$$H_0 = (1 + \alpha_{H0})H_{0e}, \quad \sigma_{H0} = \gamma_{H0}H_{0e} \quad (7)$$

The sample offshore wave height datum H_{0c} to be used in the calculation is determined by a normalized random number based on Eq.(7).

(2) Tide

The tide is assumed to change sinusoidally between the High Water Level and the Low Water Level. A sample of tide value η is determined based on this assumption using a uniformly distributed random number as a phase of the sinusoidal curve.

(3) Wave Transformation (Shoaling, Breaking)

The height of wave incident to the structure $H_{1/3e}$ is calculated by the Goda method (1975) and the average value $H_{1/3}$ is expressed in a way similar to the offshore wave height, i.e.

$$H_{1/3} = (1 + \alpha_{H1/3})H_{1/3e}, \quad \sigma_{H1/3} = \gamma_{H1/3}H_{1/3e} \quad (8)$$

where $\alpha_{H1/3}$ is the bias, $\sigma_{H1/3}$ the standard deviation and $\gamma_{H1/3}$ the deviation coefficient. The sample wave height $H_{1/3c}$ at the structure is determined by a normalized random number based on Eq.(8) similar to that used for the offshore wave height.

(4) Stability Formula and Damage

As described before, in the reliability based design for wave-dissipating concrete blocks, the total damage level should be taken into account. Therefore the following formula derived from Eq.(6) is employed in order to estimate the damage level.

$$N_0 = \left(\frac{H_{1/3}/\Delta Dn - 1.33}{2.32} \right)^5 N^{0.5} \quad (9)$$

As for the uncertainty of damage to wave-dissipating concrete blocks, a statistical deviation of the increment of damage is taken into consideration. Tanimoto et. al. (1985) carried out a model test for wave-dissipating blocks and duplicated tests against the same wave condition with 6 to 7 wave height levels providing statistical data for damage increment. Figure 10 shows a sample of the distribution histogram of damage increment ΔN_0 , while the solid line indicates the

normal distribution function. The increment of damage is considered to be roughly distributed as the normal distribution function. Analysis of the data from Tanimoto et. al. shows that the larger the damage increase, the larger the standard deviation. Figure 11 shows the relation between damage increase ΔN_0 and standard deviation $\sigma_{\Delta N_0}$. The solid line indicates their relation as shown below.

$$\sigma_{\Delta N_0} = 0.36\Delta N_0^{0.5} \quad (10)$$

Figure 10 Example of histogram of ΔN_0

Figure 11 Relation between ΔN_0 and $\sigma_{\Delta N_0}$

(5) Damage Accumulation

Damage to wave-dissipating concrete blocks is considered to occur under rough sea conditions with a range of wave height of design level or larger in a cumulative way within the lifetime of the structures. This accumulation of damage is calculated in the following manner. Supposing the wave height at the structure for the i -th year is $H_{1/3c}(i)$ and the total damage up to the $(i-1)$ -th year is $N_0(i-1)$, the equivalent wave number $N=N'$ is determined by the following equation derived from Eq.(6) by substituting $H_{1/3c}(i)$ and $N_0(i-1)$ into $H_{1/3}$ and N_0 respectively.

$$N = \left(\frac{H_{1/3c}/\Delta Dn - 1.33}{2.32} \right)^{-10} N_0^2 \quad (11)$$

The total damage up to the i -th year $N_0(i)$ is calculated by Eq.(9) with $N=N'+N(i)$. The first estimation of ΔN_0 is calculated as $N_0(i)-N_0(i-1)$ and the sample data of ΔN_{0c} , taking into consideration the uncertainty of damage increment, is determined by the normalized random number with the standard deviation defined by Eq.(10). The estimated damage up to the i -th year is finally calculated as $N_0(i)=N_0(i-1)+\Delta N_{0c}$.

(6) General Flow of Calculation

The method described above is the procedure for calculating damage up to a certain year and the sample data of total damage accumulated within one lifetime is calculated by repeating this process for corresponding years of the total lifetime. Figure 12 shows the schematic flow of calculation. After obtaining several thousand

samples, statistical values such as the expected mean of total damage can be calculated.

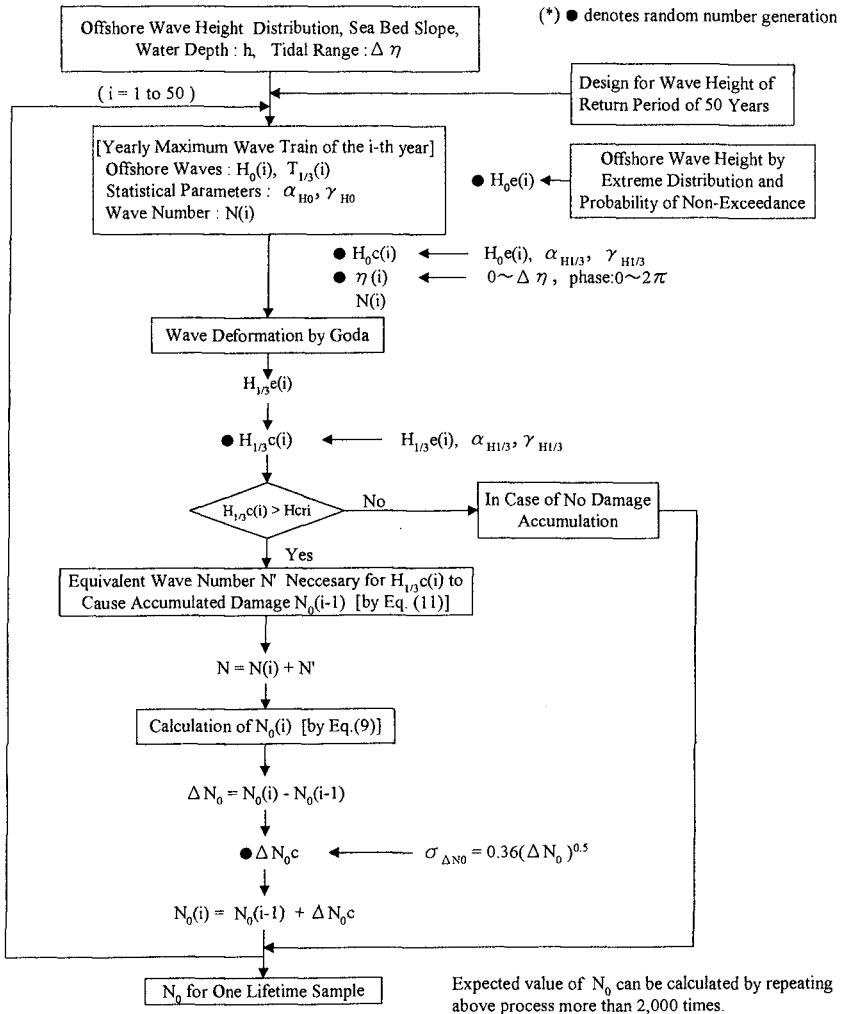

Figure 12 General calculation flow of one lifetime sample

(7) Calculation Sample of One Lifetime

Figure 13 shows an example of the offshore wave height, wave height at the structure and damage in chronological order. The design wave heights offshore and at the structure taken as a conventional manner with return period of 50 years for this example are $H_0=9.2\text{m}$ and $H_{1/3}=8.7\text{m}$ with a wave period $T_{1/3}=14.0\text{s}$. According to the figure, the offshore wave heights in the 33rd and 48th years exceeded the design

level. The wave height at the structure exceeds the design level in the 33rd year and the heaviest damage is accrued in the same year. Other smaller incidents of damages were recorded in the 2nd, 19th and 48th years resulting in a total damages of 0.45 accumulated within the lifetime of this one sample.

Figure 13 Example of lifetime sample

(8) Number of Lifetime Samples

In the example shown in the next sub-section, 5,000 samples of lifetime were computed for the statistical treatment for estimating total damage. Preliminary analysis, however, showed that 2,000 samples are considered to be enough to obtain a stable statistical result in this method from the practical view point.

3.3 Example of Estimation of Expected Value of Damage

In this sub-section, some examples of calculation based on the method mentioned previously are shown. The conditions of computation are as follows.

- a) *Wave Height* : A Weibull distribution with parameters $k=2.0$, $A=2.23$ and $B=4.78$ is assumed to be the extreme function for the offshore wave height ($H_0=9.2$ for return period of 50 years). The parameters expressing uncertainties for the offshore wave height and wave deformation mentioned in Eqs.(7), (8) were set as $\alpha_{H0} = 0$, $\gamma_{H0} = 0.1$, $\alpha_{H1/3} = -0.13$, $\gamma_{H1/3} = 0.09$ (Takayama et.al., 1994).
- b) *Wave Period and Number of Waves* : The wave periods for the examples here were determined so as to correspond to a wave steepness of 0.03 at the offshore. The wave period for the wave height $H_0=9.2$ m (50 year event) is $T_{1/3}=14.0$ s accordingly. The number of waves was set as 1,000 for all wave heights in these examples.
- c) *Tide* : The tide range of 1.0m (L.W.L. 0.0m, H.W.L. +1.0m) was assumed
- d) *Design of Wave-dissipating Concrete Blocks* : The mass of Tetrapods was calculated by Eq.(6) under the criteria of $N_0=0.3$ and $N=1,000$ against wave height for the 50 year event.
- e) *Sea Bed Slope* : Sea bed slopes of 1/50 and 1/10 were employed.
- f) *Water Depth* : Water depths of 7, 9, 11, 13 and 15m at low tide were examined.

Table 2 summarizes the parameters of the simulation such as the design wave heights and masses of the Tetrapods at each location based on the conditions above in a conventional design for a 50 year event.

Table 2 Design wave height and mass of Tetrapod

Case No.	1	2	3	4	5
Sea Bed Slopes	1/50	1/50	1/50	1/50	1/50
Water Depths (m)	7.0	9.0	11.0	13.0	15.0
Design Wave Heights (m)	5.57	6.64	7.59	8.34	8.81
Mass of Tetrapods (tf)	18.7	31.8	47.6	63.0	74.3
Case No.	6	7	8	9	10
Sea Bed Slopes	1/10	1/10	1/10	1/10	1/10
Water Depths (m)	7.0	9.0	11.0	13.0	15.0
Design Wave Heights (m)	8.16	9.41	10.18	10.31	10.13
Mass of Tetrapods(tf)	59.0	90.5	114.5	118.9	112.9

Figure 14 shows the variation of the expected value of $\max H/H_s$ with water depth, where $\max H$ is the maximum significant wave height at each location within the lifetime, H_s is the design wave height. As shown in Figure 13, the total damage to the wave-dissipating concrete blocks was significantly affected by the maximum wave height within the lifetime. The expected value of $\max H/H_s$ tended to decrease against the water depth in the case of the sea bed slope of 1/50. However, it had a minimum at around 11m for a 1/10 slope.

Figure 15 shows the calculated results of the expected accumulated damage at each location. The expected accumulated damages for these examples are estimated as larger than the design criteria of $N_0=0.3$. This is considered reasonable because of the possibility of occurrence of a wave height larger than the design level. The damage accumulation is accurately taken into account as shown in Figure 13.

From the conventional deterministic design view point, the masses shown in Table 2 are considered to equally assure the damage level of $N_0=0.3$ against each design wave height with a safety factor of 1.0. The present simulation shows that the expected total damage within the lifetime on the probabilistic basis depends on such parameters as the sea bed slope and water depth. It is also found that the expected value of total damage to wave-dissipating concrete blocks varies corresponding to the variation of $\max H/H_s$ shown in Figure 14.

Figure 15 also shows the effect of mass increase on the damage in the case of a 1/50 slope. It can be roughly said that a 10% to 20% mass increase caused a 30% to 50% decrease in total damage accumulated. This result means that the mass of the wave-dissipating concrete block might be adjusted to account for certain conditions by some percentage higher than that determined by the stability formula when based on the probabilistic design. This would assure the same level of total damage within the lifetime.

Figure 14 Expected values of $\max H/H_s$

Figure 15 Expected values of N_0

4. CONCLUSIONS

- 1) A new stability formula for wave-dissipating concrete blocks covering horizontally composite breakwaters was proposed and the applicability of this formula was verified by experimental data.
- 2) A probabilistic approach to the estimation of total damage to wave dissipating concrete blocks accumulated within a life time by Monte Carlo simulation was proposed and the applicability of this method for reliability based design of wave-dissipating concrete blocks was proved.

CHAPTER 131

Breakwater Stability under Regular and Irregular Wave Attack

Thomas Jensen^{*}, Henning Andersen^{*}, John Grønbech^{**}
Etienne P.D. Mansard^{***} and Michael H. Davies^{***}

Abstract

The main objective of the present study was to compare the damage to a rubble mound breakwater under regular and irregular wave attack, and thereby identify an irregular wave height parameter that corresponds to the wave height of a regular wave in terms of inducing a similar degree of damage to the structure. The 1984 edition of the Shore Protection Manual recommends this irregular wave height parameter to be $H_{1/10}$ (the average of the highest one-10th of the waves in a sea state), but other researchers recommend $H_{1/30}$ (e.g. Vidal et al., 1995). For the present study, $H_{1/20}$ is the irregular wave height parameter that yields the best correspondence between irregular and regular waves. However, this result is dependent on the length of the time series and on the number of times this time series is recycled to achieve a given damage level. The new wave height parameter H_n (the average of the n highest waves in a sea state) proposed by Vidal et al. (1995) takes into account the statistics of the large waves contained in the time series as well as the number of times this time series is recycled. The present study indicates that H_{250} (the average of the highest 250 waves in the sea state) is a suitable wave height parameter for characterizing breakwater stability under irregular waves.

1 Introduction

Over the years, several formulae have been proposed for predicting the hydraulic stability of armour layers; All of them are empirical and do not account for all of the parameters that affect the stability. One of these formulae is the well-known Hudson

* Danish Hydraulic Institute. Agern Allé 5, DK-2970 Hørsholm, Denmark.

** Department of Civil Engineering. Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

*** Canadian Hydraulics Centre, National Research Council of Canada, Ottawa, Ontario K1A 0R6, Canada.

formula, developed by R.Y. Hudson in 1958. Although this formula was developed on the basis of regular waves, it has been applied for irregular waves by replacing the regular wave height by the significant wave height H_s (i.e. $H_{1/3}$) of irregular waves.

The Shore Protection Manual (1984) recommends the use of $H_{1/10}$ instead of $H_{1/3}$. However, authors such as Vidal et al. (1995) claim that a wave height parameter such as $H_{1/10}$ or $H_{1/3}$ does not describe the large waves in a wave train sufficiently well. They argue that additional information is required on the length of the time series and the number of times it is recycled to achieve a given degree of damage. They also show that a new wave height concept H_n , based on the average of the n highest waves in a sea state, can account for the statistics of the large waves contained in the sea state as well as for the number of times it is recycled for achieving a certain degree of damage.

The main objective of the present study was to compare breakwater stability under regular and irregular waves in terms of measured damage. Whether or not H_n is a suitable wave height parameter for carrying out this comparison will also be established.

2 Experimental Set-up and Test Series

The experimental investigations were carried out in the Wave Research Flume at the Canadian Hydraulics Centre (CHC) of the National Research Council of Canada (NRC) at a Froude scale of 1:15 (Andersen et al., 1995). This flume is 97 m long, 2 m wide and 2.75 m deep. The wave generator in the flume uses active wave absorption, which allows the wave paddle to absorb reflected waves during wave generation thereby eliminating re-reflections (Davies et al., 1994a).

The tested structure was composed of a core, filter and an armour layer placed on a uniform slope of 1:1.8. The gradation of the armour stones was such that the ratio of $M_{max}/M_{min} \approx 2.5$. The median mass of the rocks, M_{50} was 2600 kg. A sketch of the tested structure is shown in Figure 1.

An array of five capacitance-type wave gauges was placed in front of the structure in order to separate the incident and reflected wave components. The applied reflection analysis was based on the least-squares technique described by Mansard et al. (1980). The incident sea state parameters obtained in the tests with regular and irregular waves are shown in Table 1 together with the number of repetitions of each sea state. For irregular waves the sea state was characterized by the incident significant wave height ($H_{s,i}$), derived from the incident wave spectrum and the spectral peak period, T_p . The incident sea state parameters for regular waves were also determined from reflection analysis.

Figure 1 - Sketch of the tested breakwater cross-section (prototype units).

Irregular Waves			Regular waves		
$H_{s,i}$ (m)	T_p (s)	Repetitions	H_i (m)	T (s)	Repetitions
1.0	4.1	1	1.3	3.8	1
1.5	5.0	1	1.7	4.7	1
2.0	6.0	4	2.3	5.6	1
2.3	6.4	4	2.7	5.9	1
2.6	6.6	4	2.9	6.4	1

-	-	-	4.5	7.7	2

Table 1 - Incident sea state parameters for regular and irregular waves.

For each irregular wave condition a time series was synthesized using the random phase spectrum method, which combines the amplitude spectrum derived from the JONSWAP spectrum with a random phase spectrum (Mansard et al., 1994b). The prototype length of the time series for irregular waves was chosen to be relatively long (i.e. 2 hours) in order to minimize any of the potential variability in wave parameters often associated with shorter time series. Thus the time series contained 1200 to 2100 waves depending on the peak period of the sea state.

In order to ensure that the damage had stabilized under each wave condition, each time series was recycled four times resulting in approximately 5000 waves. Damage patterns generally stabilized after about 5000 waves. Since damage patterns develop much more quickly for regular waves, the length of the regular wave time series was

chosen to contain approximately 300 to 600 waves (depending on the period). For incident waves with $H_i > 3.3$ m it was necessary to repeat the time series 2 or 3 times in order for the damage to stabilize. This illustrates a fundamental difficulty with the concept of damage stabilization. The tendency for breakwater damage to stabilize and the time-frame within which this stabilization occurs are in fact directly related to the stability number, N_s .

Table 1 shows the wave parameters that were used in this study. These are the incident waves that were determined from reflection analysis. When generating the regular waves, an appropriate wave period had to be chosen for each wave height. Based on earlier works suggesting that either $H_{1/10}$ or $H_{1/20}$ are appropriate parameters when comparing regular and irregular waves, the wave periods for the regular waves in this study were chosen to be equal to the average of the wave periods corresponding to $H_{1/10}$ and $H_{1/20}$ of the corresponding irregular wave trains (i.e. the bivariate statistics were used).

3 Damage Measurements

After each test series the damage to the breakwater was estimated by computing the eroded area (A_e) using an electro-mechanical profiler. The performance of this profiler has been found to be very reliable and it has also been compared with the estimates of eroded area derived by counting the number of displaced armour stones (Davies et al., 1994b).

Figure 2 - Damaged breakwater profile after 4th irregular test with $H_{s,i} = 2.8$ m.

The damaged profile is determined as the average of nine evenly spaced profiles across the flume. The cross-sectional area of erosion is calculated by integrating the vertical difference between the damaged profile and the initial profile. Integrating from the crest of the breakwater, the eroded area is defined as the maximum value of this integral as a function of the distance x (see Figure 2). The eroded area is interpreted as the eroded volume/metre breakwater length.

When analyzing damage on rubble mound breakwaters, a dimensionless damage parameter S is often introduced:

$$S = \frac{A_e}{D_{n50}^2}$$

where A_e is the eroded area and $D_{n50} = (M_{50}/\rho_r)^{1/3}$ is the nominal diameter of the armour stones. The damage parameter can be visualized as the number of cubic stones of dimension D_{n50} eroded within a D_{n50} wide strip of the breakwater. $S = 2$ corresponds to the initiation of damage and is equivalent to the 0-5% damage defined in Shore Protection Manual (1984). Failure is defined as exposure of the filter layer and for a two diameter thick armour layer, this occurs for S -values of approximately 8 (van der Meer, 1988).

4 Evolution of Damage under Irregular Waves

In Figure 3 the damage parameter S is shown as a function of the number of waves for each of the four test sequences carried out.

Figure 3 - Evolution of damage for irregular waves.

It can be seen from Figure 3 that the damage tends to stabilize in about 5000 waves. Based on approximately 50 tests with irregular waves, van der Meer (1988) proposed an equation for describing the damage evolution as a function of the number of waves. However, the results used to develop this equation were based on tests that started with zero-damage when the wave heights were changed. This means that the breakwater was rebuilt after each sea state. In this study the breakwater was not rebuilt after each severity of the sea state. Hence, the expression of van der Meer (1988) is not directly comparable to the evolution of damage shown in Figure 3. The evolution of damage is also seen in Figure 4 where the cumulative damage is plotted as a function of the cumulative number of waves.

Figure 4 - Damage versus the cumulative number of waves (irregular waves).

5 Evolution of Damage under Regular Waves

According to Vidal et al. (1995) it takes about 100 to 400 waves for the damage to attain its equilibrium under regular waves. Hence, a 10 minutes long time series containing approximately 300 to 600 waves (depending on the period) was used in regular wave tests.

In Figure 5 the damage parameter S is shown as a function of the cumulative number of waves for the tests with regular waves. For $H_i = 3.7$ m the time series had to be repeated three times before the damage patterns stabilized. This indicates that the number of waves required to reach a state of equilibrium is larger than the value suggested in Vidal et al. (1995). Further tests should be carried out to verify this observation. It is possible that the number of waves required to stabilize the damage patterns can also vary with the degree of breakwater damage.

Figure 5 - Damage versus the cumulative number of waves (regular waves).

The regular wave tests showed that a damage level of $S = 2$ corresponds to a regular wave height of $H_i = 3.3$ m. In Hudson's formula, this would correspond to a value of $K_D = 4$, which agrees well with published values.

6 Comparison between Regular and Irregular Waves

In Figure 6 the damage is plotted against the stability number, N_s given by:

$$N_s = \frac{H}{\Delta D_{n50}} \quad ; \quad \Delta = \frac{\rho_r}{\rho_w} - 1$$

where H is the wave height and ρ_w is the mass density of water.

Figure 6 compares the damage caused by irregular waves characterized using four different wave height parameters in the calculation of the N_s parameter: $H_{1/3}$ ($\approx H_s$), $H_{1/10}$, $H_{1/20}$ and the average of $H_{1/10}$ and $H_{1/20}$.

A time-domain reflection analysis recently developed by Mansard (1994) showed that the average ratio between $H_{1/10}$ and $H_{1/3}$ and the ratio between $H_{1/20}$ and $H_{1/3}$ were 1.28 and 1.42, respectively, in the irregular wave tests. Since the corresponding values from the theoretical Rayleigh distribution are 1.27 and 1.40 respectively, this suggests that the incident wave heights were Rayleigh distributed.

From Figure 6 it appears that the best correspondence between the damage levels for regular and irregular waves is obtained when the irregular waves are

characterized by $H_{1/20}$. A comparison of the results of the present study with results of previous tests with the same breakwater is shown in Figure 7.

Figure 6 - Comparison between damage for regular and irregular waves.

In terms of Hudson's stability formula it is seen from Figure 7 that there is a good agreement between the results of the present study and the results obtained previously. The K_D -factor for this study using $H_{1/3}$ as the wave height parameter and $S = 2$ as damage level is approximately 1.4. In similar tests undertaken at CHC (e.g. Laurich et al., 1995) with the same breakwater the K_D -factor was found to range between 1.2 and 1.7.

Shore Protection Manual (1977) recommends the use of $H_{1/3}$ in Hudson's stability formula for design of breakwaters. The K_D -values suggested for breaking and non-breaking waves for rough angular quarry stone were 3.5 and 4.0, respectively (note that these K_D -values were established using only regular wave tests). Shore Protection Manual (1984) recommends the use of $H_{1/10}$ instead of $H_{1/3}$, and also recommends that the K_D -values for breaking and non-breaking waves should be changed to 2.0 and 4.0, respectively. The recommendation of $H_{1/10}$ in Hudson's formula rather than $H_{1/3}$ was supported by hydraulic tests by Feuillet et al. (1980); However, tests by Tanimoto et al. (1982) suggested a design wave height of $H_{1/5}$ when comparing regular and irregular wave tests. Furthermore, Allsop (1993) suggests that the application of $H_{1/10}$ in Hudson's formula is overly conservative.

For irregular waves, van der Meer (1988) proposed the following general damage equation:

$$N_s = a(K_D \cot \theta)^{1/3} \cdot S^b$$

where N_s is determined using $H_{1/3}$, θ is the slope of the armour, and a and b are empirical coefficients ($a = 0.7$, $b = 0.15$) determined by regression analysis. The K_D -value corresponds to Shore Protection Manual (1984), here the use of $H_{1/10}$ in the Shore Protection Manual is taken into account by the value of the a -coefficient. If this formula is applied to the results of the present study the damage to the breakwater is underestimated. This may be attributable to the fact that $H_{1/20}$ is a better parameter than $H_{1/10}$ for comparing regular and irregular waves for this structure (see Figure 6).

Figure 7 - Comparison with previous studies. N_s is computed from $H_{1/3}$.

Based on the results of a number of laboratory tests performed to study damage mechanisms of riprap, Ben Belfadhel (1993) found $H_{1/10}$ to be an acceptable wave parameter for use in stability formulae developed from regular wave tests. However, based on CHC data for steep slopes (1:1.5) Ben Belfadhel* has found that $H_{1/20}$ may be a more suitable parameter.

A comparison between the results of Vidal et al. (1992) obtained under irregular waves and the results established by Givler et al. (1986) using regular waves was carried out by Vidal et al. (1995). They found a good correspondence between the damage of regular and irregular waves with $H_{1/30}$ as the wave height parameter in the stability expression. However, from Figure 5 in Vidal et al. (1995) it seems that an

* Personal communication between Dr. E.P.D. Mansard and Dr. B. Belfadhel.

even better correspondence could have been obtained if a wave height parameter closer to $H_{1/20}$ was applied.

7 Potential Sources of Inaccuracy

When dealing with irregular waves, the choice of an appropriate wave height parameter for use in the Hudson's formula is a continuous source of debate. Independent experiments by different researchers have failed to achieve consensus. Discrepancies between the findings of the various researchers could be partly due to different test methods used in different laboratories. Two potential sources of inaccuracies in experimental methods are described in the following.

Active Absorption of Waves

A commonly used technique for determining incident waves in flume tests is to calibrate sea states in the test flume with an efficient absorber in place before the breakwater is constructed, - thereby eliminating the need for sophisticated reflection analysis. During the breakwater stability tests, the damage is expressed as a function of the incident wave height obtained during this wave calibration procedure. Without active absorption, re-reflections can modify this incident wave height. This is discussed below:

Waves reflected by the breakwater propagate towards the wave generator and generally get re-reflected if the installation is not equipped with the capability for active absorption. These re-reflected components then propagate toward the breakwater as part of the incident waves. Depending on the differences between the phase angles of the original incident component and the re-reflected component, the net incident wave height attacking the breakwater could either be lower or higher than intended. Studies recently performed at CHC by Laurich et al. (1995) showed that active absorption can eliminate the inaccuracies introduced by these re-reflections.

The importance of using active wave absorption is shown in Figure 8, which shows the results of separate breakwater stability tests conducted with regular waves with periods of 2.0 and 1.94 s, respectively. No active absorption (position control) was used in these tests. For the test with $T = 1.94$ s, the phases of the re-reflected waves and the incident waves were such that they caused a higher than intended incident wave height at the structure (and correspondingly, a high degree of damage). The reverse was true when $T = 2.0$ s - the phasing of the re-reflected waves was such that incident wave energy (and damage levels) were reduced. If these test results were interpreted neglecting the effects of re-reflections, the damage levels seen in the two tests would have suggested two quite different conclusions. Using the results of the present study, the $T = 1.94$ s test would suggest that $H_{1/10}$ is the appropriate

wave parameter for comparison of irregular and regular waves, while the $T = 2.0$ s test would suggest that $H_{1/50}$ is more suitable.

This example shows that if active absorption is not used (or if the actual incident waves attacking the breakwater are not determined accurately), the interpretation of results could be quite different depending on the experimental installation.

Figure 8 - Comparison of damage between two regular and two irregular wave tests.

Stabilization of Damage

In order to perform a reliable comparison between the damage obtained under regular and irregular waves, the rate of damage progression must be considered. Ideally one should compare regular and irregular wave tests at some equilibrium damage level. This can be difficult because true equilibrium is rarely attained in breakwater testing, however the rate of damage progression does slow with time. Choosing an equivalent number of cycles for regular and irregular wave tests is thus somewhat arbitrary. It takes fewer waves (i.e. 300 to 600) for the damage to stabilize if these waves are regular. In the case of irregular waves, 5000 waves or more are required to approach stabilization. It is important to make damage comparisons after ensuring that the level of damage “equilibrium” in the regular and irregular wave tests is equivalent. Otherwise misleading conclusions can be drawn.

9 Suitable Wave Height Parameter

Although $H_{1/20}$ has been identified as the most appropriate irregular wave parameter in this study, it does not consider the role of storm duration. Since each of the four

tests was carried out by recycling the same time series, the value of the $H_{1/20}$ parameter remains the same (i.e. $1.42 \cdot H_{m0}$), whether one or four cycles were used. Vidal et al. (1995) suggest a technique to incorporate both the effects of wave height and the number of waves to which a structure is exposed. They introduce H_n , which is defined as the average of the n highest waves used in achieving a certain damage. To apply this concept to the present study, H_n would be computed based on all four cycles of the time series used in the experiments. For instance, since a total of nearly 5000 waves were used in this particular study, the average of the highest one 20th corresponds to a wave height parameter H_{250} . Vidal et al. (1995) report that the parameter H_{250} describes not only the damage that has attained its equilibrium but also the intermediate ones.

To illustrate the suitability of the H_n parameter, Vidal et al. (1995) assumed that damage is proportional to the 5th power of the H_n wave height as follows:

$$S_{nz} = K_1 \left(\frac{H_n}{H_{1/3}} \right)^5$$

where S_{nz} is the damage after n_z waves, and K_1 is a constant. The damage can also be predicted by applying the following equation of van der Meer (1988):

$$S_{nz} = S_{5000} 1.3 \left[1 - \exp(-3 \cdot 10^{-4} n_z) \right] = K_2 f(n_z)$$

Equating these two damage levels gives:

$$\frac{K_2}{K_1} = \frac{(H_n / H_{1/3})^5}{f(n_z)}$$

i.e., the right hand side of this equation should be constant for different n_z . Vidal et al. (1995) show that for Rayleigh distributed wave heights an appropriate value for n is approximately 100. It is presumed that this proportionality is applicable to a breakwater section that was tested if it had undergone no damage by previous wave heights. Since in this study, lower wave heights have already caused some initial damage, a somewhat different form of the relationship was anticipated. Consequently, both linear and parabolic relationships were considered in determining a suitable relationship, i.e.

$$S \propto H_n \quad \text{and} \quad S \propto H_n^2$$

For each cycle, the wave height parameter ($H_{1/m}$) is determined corresponding to the actual damage level (Rayleigh distribution of wave heights is assumed. This assumption has been verified in the wave analysis). Since $H_{1/20}$ was shown to be the best parameter in Figure 6, it is also used in the following illustration:

For example: after the 1st cycle of $H_{s,i} = 3.1$ m the damage level is 72% of the corresponding equilibrium damage level. Hence the wave height parameter is $0.72 H_{1/20}$ for the linear assumption and $\sqrt{0.72} H_{1/20}$ for the parabolic assumption, corresponding to $H_{1/3.0}$ and $H_{1/6.8}$, respectively, using the Rayleigh distribution. Based on the cumulative number of waves (determined from the mean period) the corresponding n -value can be determined for H_n .

Using this approach for the present study, the n -value can be determined for all the test series (i.e. including the intermediate damage levels). The average value of n was found to be 250 with a coefficient of variation of approximately 10 %. This indicates that the H_n parameter is a more suitable parameter to characterize breakwater damage than the conventional $H_{1/n}$ (e.g. $H_{1/10}$ or $H_{1/20}$) which does not take into account the number of waves.

10 Conclusions

The best correspondence between regular and irregular waves in terms of the damage is obtained when the irregular waves are characterized by $H_{1/20}$. Other researchers have proposed e.g. $H_{1/10}$ and $H_{1/30}$ to characterize irregular waves. These different results may be associated, to a certain extent, with variations in test methods.

Vidal et al. (1995) proposed the H_n concept to characterize irregular waves. This concept, defined as the average of the n highest waves, has the advantage of including the length of the time series, the number of times it is recycled, and the statistics of the highest waves. In this particular study, an n -value of approximately 250 was found to be suitable. Further research is necessary to verify the suitability of H_n to characterize breakwater damage under irregular waves and to determine a suitable n -value.

CHAPTER 132

Roundhead Stability of Berm Breakwaters

Jørgen Juhl¹, Amir Alikhani², Peter Sloth¹, Renata Archetti³

Abstract

Three-dimensional (3D) model tests were carried out for studying the stability of a berm breakwater roundhead and the adjacent trunk section. The present paper describes the influence of the wave incidence angle and wave steepness on the roundhead stability. The test results are described in terms of profile development, recession of the berm, eroded and deposited volumes and the transport of stones during reshaping. Results from analysis of the influence of wave obliquity on profile shape, initiation of longshore transport and longshore transport rate at the trunk section are presented in Alikhani et al (1996).

Introduction

For berm breakwaters as compared with traditional rubble mound breakwaters, special measures have to be taken for the breakwater roundhead. If stone displacements occur on a roundhead, the stones will be moved in the wave direction and will loose most of their stabilising effect. A point of special concern is whether, and under which conditions, a berm breakwater roundhead after some initial reshaping may develop into a stable shape that is not subject to continued erosion, or at least such slow erosion that it may be acceptable for a permanent structure.

The major part of the research on berm breakwaters has concentrated on the reshaping of the seaward side of the trunk under perpendicular wave attack. In 1988, van der Meer pre-

¹ Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark

² Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

³ University of Bologna, 2 Viale de Risorgimento, I-40136 Bologna, Italy

sented results from a series of flume model tests with gravel beaches and rock slopes which led to a set of parameters equations for assessing the profile development of berm breakwaters. Also Kao and Hall (1990) presented results on various aspects influencing the stability of berm breakwaters. Analysis of flume tests concentrating on the rear side stability was presented by Andersen et al (1992).

Only a little research has been made to study the stability of berm breakwater roundheads. Burcharth and Frigaard (1987) described results from model tests with reshaping breakwaters exposed to head on waves and waves having a wave incidence angle of 15° and 30° . The analysis concentrated on the stability of roundheads and trunk erosion in oblique waves, and some preliminary recommendations for berm breakwater trunks and heads were given.

Jensen and Sørensen (1992) presented results from a 3D model study of a berm breakwater including trunk and roundhead. Comparison of the profile development on the trunk and head was made.

Van der Meer and Veldman (1992) made a discussion on roundhead stability based on analysis of results from a series of wave basin tests.

Description of Model Tests

Model Set-Up

The model tests were carried out in a 22 x 30 m wave basin at the Danish Hydraulic Institute, see Figure 1, which also shows the various positions of the two 5.5 m wide movable wave generators for generating long-crested irregular waves. A stone absorber was placed along the basin boundary in order to minimise wave reflections. The berm breakwater profile used for the trunk section is shown in Figure 2. The roundhead was constructed by rotating the profile around the centreline.

The berm breakwater was constructed from two stone classes, ie one for the core and the scour protection and one for the berm, the crest and the rear side protection. The core material had a nominal diameter of $D_{n,50}=0.010$ m. A relative wide stone gradation was used for the berm, ie $D_{n,85}/D_{n,15}=1.80$ with a nominal diameter of $D_{n,50}=0.023$ m. The density of the stone material was $\rho_s=2.68$ t/m³ and the density of the water was $\rho_w=1.00$ t/m³.

Figure 1. Model plan, including positions of the wave generators.

Figure 2. Cross-section of the initial profile for the trunk.
The roundhead was made by rotating the profile around the centreline

Test Programme

A total of six test series were carried out with irregular waves, covering five angles of incident waves with a wave steepness of $S_m=0.05$ (45° , 30° , 15° , 0° and -30° ; where 0° is perpendicular to the trunk) and two wave steepnesses for -30° ($S_m=0.03$ and 0.05). The wave steepness, S_m , is given by $H_{m0}/L_{m0}=H_{m0}/(g/2\pi \cdot T_m^2)$, where H_{m0} is the wave height, L_{m0} is the deep water wave length, and T_m is the mean wave period.

Each test series consisted of five tests with a duration corresponding to 2,000 waves for reshaping of the berm breakwater ($H_0=H_{m0}/\Delta \cdot D_{n,50}=2.0, 2.5, 3.0, 3.5,$ and 4.0 ; where Δ is the relative density, and $D_{n,50}$ is the nominal stone diameter) followed by four tests with a duration of 1,000 waves for studying the stone movements on the reshaped profile ($H_0=2.5, 3.0, 3.5,$ and 4.0).

All waves were generated on basis of a Pierson-Moskowitz spectrum.

Measurements

The waves were measured in 14 positions in the wave basin by use of resistance type wave gauges. The incoming wave conditions were checked by five reference wave gauges placed in a way to minimise the effect of reflections. Spectral analysis and zero-crossing analysis were carried out.

A total of 38 profiles along the 8.5 m long breakwater were measured after construction of the breakwater (initial profile) and after each test run. The profiling was made with a laser running on a beam across the breakwater trunk. The horizontal position of the laser running on the beam was measured by another laser, whereas the position along the breakwater was fixed manually. The profiles were measured for each 0.5 m along the trunk and for each 0.1 m at the roundhead.

The data from the 38 profile measurements were interpolated into a 3D representation of the breakwater from which it was possible to extract profiles in arbitrary cross-sections and to make contour plots of the breakwater as shown in Figure 3.

Definitions and Analysis

Sections and Wave Directions

The 3D representation of the test results was used to calculate the results for 10° sections on the breakwater head and 10 cm sections on the trunk with the convention as shown in Figure 4, which also shows the wave direction convention. This means that

section 0 is the section covering 10° in continuation of the breakwater centreline and -90° is the section perpendicular to the centreline, where the trunk meets the roundhead.

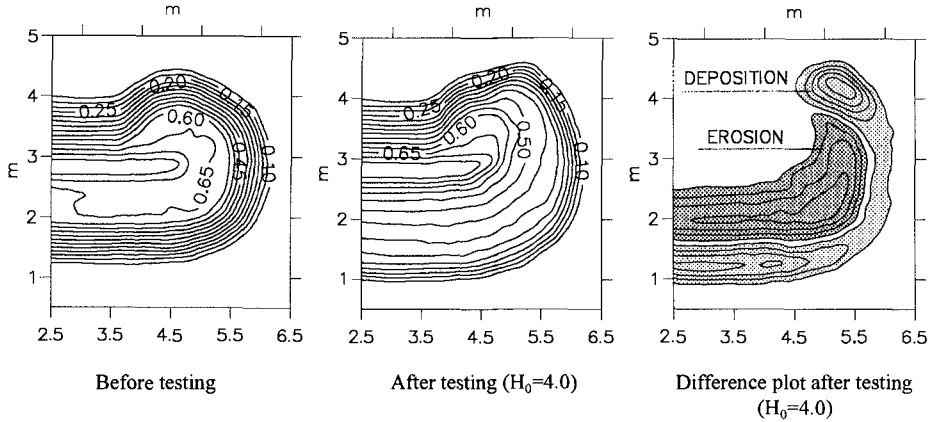

Figure 3. Contour (m) plots of breakwater. Wave direction 0°

Figure 4. Profile definition.

Definition of wave direction

Relative Angle

When comparing results at the roundhead for different wave directions, a relative angle is introduced, defined as the angle between the incident waves and the considered section on the head, see Figure 5. For example, a relative angle of 0° corresponds to the section pointing directly towards the waves, whereas a relative angle of 90° corresponds to the section perpendicular to the wave direction.

Figure 5. Definition of relative angle

Investigated Parameters

During the analysis, the following parameters have been investigated:

Recession

The recession is defined as the width of the berm eroded, see Figure 6. For the investigated breakwater profile with an initial berm width of 0.65 m, a recession of 0.65 m thus corresponds to a fully eroded berm with a directly exposed breakwater crest.

Figure 6. Definition of recession, erosion and deposition

Erosion

The erosion is defined as the volume eroded for the individual sections as shown in Figure 6. The erosion is presented as the eroded volume relative to the initial volume of berm material for the section. An erosion equal to 0.2 thus corresponds to the case where 20 per cent of the initial berm volume is eroded at the considered section. The erosion is presented as negative values.

Deposition

The deposition is defined as the deposited volume at the individual sections, as shown in Figure 6. As for the erosion, the deposition is presented as the deposited volume relative to the initial volume of berm material for each section. The deposition is presented as positive values.

Transported volume

This parameter is defined as the volume which has passed a given section since the start of the test series. The transport is defined positive in the anti-clockwise direction on the head (towards the rear of the head). On the trunk, the transport is positive towards the head. The volume is calculated directly from the measured profiles (ie including voids).

The transported volume is calculated by accumulating the volume changes from the rear of the roundhead - where no changes occur - clockwise around the head.

Stone transport

The stone transport is the estimated number of stones per wave passing a given section for a given H_0 . The number of stones is estimated by correcting the calculated transported volumes for porosity and dividing by the average stone weight.

Presentation of Results

This section presents the results of the analysis of the profile measurements and concentrates on recession, erosion and deposition, transported volume and finally stone transport during the reshaping process.

Recession

Figure 7 presents the recession at the head found for wave direction 45° , respectively 0° , for increasing H_0 .

It is seen that the recession for head on waves (wave direction 0°) is significantly higher than for 45° .

Plotting the recession measured after $H_0 = 4.0$ for all wave directions as function of the relative angle, see Figure 8, shows that the recession pattern follows the wave direction, and that maximum recession occurs at an area directly exposed to the waves. It is found that the maximum recession on the head occurs for wave direction 0° , where the recession reaches the initial berm width for H_0 between 3.5 and 4.

Figure 7. Recession of head and adjacent trunk

Figure 8. Recession. All wave directions. After $H_0 = 4.0$, $S_m = 0.05$

Comparing the maximum recession found at the head with the recession on the trunk, see Figure 9, it is found that only in the case with wave direction 45° the maximum recession on the head is equal to or less than the recession on the trunk section. In the case with wave direction -30° , the recession on the head is up to 75 per cent higher than for the trunk section. For head on waves, the maximum recession on the head is 50 per cent higher than the recession on the trunk.

Figure 9. Maximum recession on head, respectively trunk

When analysing the maximum recession as function of the wave direction, it can be seen that the maximum recession on the head is increased by a factor of up to 2 comparing the results for wave directions 45° and 0° , whereas the recession on the trunk is increased by a factor of about 1.4. The recession on the head is thus more sensitive to changes in the wave direction than the recession on the trunk. For comparison, a cosine (cos) and a cosine² (cos²) distribution of the recession found for wave direction 0° for $H_0=4$ were compared to the results, showing that the variation of the maximum recession with the wave direction, on the head, can be approximated by a cos² distribution for the higher H_0 's. At the trunk, the results show a distribution closer to a cos distribution.

The influence of the wave steepness was investigated for wave direction -30° . The results showed a strong influence by the wave steepness, as the maximum recession on the head for $S_m=0.03$ was almost twice the recession found for $S_m=0.05$. On the trunk, the influence was less pronounced. Analysis showed that a good agreement between the two data sets ($S_m=0.03$ respectively 0.05) was obtained when plotting the recession as function of H_0T_0 , especially for the trunk section. T_0 is given by $T_0=T_m \sqrt{g / D_{n,50}}$.

Erosion and Deposition

Figure 10 presents the erosion and deposition pattern around the breakwater head, after $H_0=4.0$ for all wave directions as function of the relative angle, again showing that the reshaping pattern follows the wave direction closely. A pronounced deposition area at the rear of the roundhead and a relative wide area of erosion is found.

Figure 10. Erosion and deposition after $H_0=4.0$. All wave directions

For an infinitely long trunk, the erosion and deposition areas are equal (disregarding compaction), whereas for a roundhead stones will be transported towards the rear side of the roundhead. At the directly exposed part of the head, the erosion will be larger than the deposition, whereas the opposite will be the case at the rear of the head. This can also be seen from the contour plots presented in Figure 3 showing the height contours of the breakwater before and after the test series with wave direction 0° together with a difference plot.

As seen from Figure 11, the erosion at the head accelerates for $H_0 > 2.5$. The influence of the wave steepness can be seen from Figure 12 presenting the maximum erosion and deposition as function of both H_0 and $H_0 T_0$ for the two wave steepnesses, $S_m=0.03$ and 0.05 , respectively (wave direction -30°). Plotting the maximum erosion and deposition as function of $H_0 T_0$ shows a better agreement between the two data sets than when plotting against the wave height parameter, H_0 .

Figure 11. Maximum erosion and deposition

Figure 12. Influence of wave steepness on erosion/deposition.
Wave direction -30°

Transported Volume

Figure 13 presents the transported volume at the roundhead for all wave directions as function of the relative angle after $H_0=4.0$ ($S_m=0.05$), showing that the section which experiences the heaviest traffic during the test series is located $110^\circ-130^\circ$ anti-clockwise from the angle of wave attack.

Figure 13. Transported volume on head after $H_0=4$. All wave directions

Figure 14 shows the maximum transported volume on the roundhead as function of H_0 revealing that the transport accelerates for $H_0 > 2.5$.

As for the recession on the head, the sensitivity to the wave direction can clearly be seen on the transport. The results indicate that the decrease in transported volume with the wave direction can be estimated by a \cos^3 distribution for the higher H_0 's comparing with the transport for wave direction 0° .

Figure 14. Maximum transported volume on head

Stone Transport

In Figure 15, the stone transport for $H_0=4.0$ is plotted for all wave directions as function of the relative angle, again showing that the maximum transport takes place at the sections 110° - 130° relative to the wave direction. The maximum stone transport on the head occurs with head on waves (0°), being up to three to four times higher than for wave direction 45° .

Figure 15. Stone transport for $H_0=4.0$. All wave directions

Conclusion

A total of six test series were carried out in a wave basin for studying the development of berm breakwater roundheads. Five wave incidence angles were tested together with two wave steepnesses. All tests were carried out with irregular long-crested waves, and each test series consisted of five tests for reshaping of the breakwater ($H_0=2.0, 2.5, 3.0, 3.5$ and 4.0).

The measurements included a total of 38 profiles along the breakwater which were interpolated into a 3D representation of the breakwater. This formed the basis for detailed calculations of the profile development, recession of the berm, eroded and deposited volumes and transport of stones in arbitrary sections of the breakwater.

The main findings of the work are summarised below :

- The maximum recession occurs at the area directly exposed to the waves.
- The recession/erosion pattern follows the wave direction.
- On the head, the maximum recession was observed for head-on waves (0°) being up to two times higher than for 45° . For the trunk section, the increase was less than 1.5. The recession on the head is thus more sensitive to changes in the wave direction than on the trunk.
- For 45° wave direction, the maximum recession on the trunk and on the head is of the same magnitude, whereas the maximum recession on the head is 75 per cent higher than on the trunk for wave direction -30° . For 0° , the maximum recession on the head is about 50 per cent higher than on the trunk.
- The results for the two wave steepnesses, $S_m = 0.03$ and 0.05 , showed that the wave steepness is of paramount importance, and that H_0T_0 is a good parameter when comparing the results - better than H_0 .
- The reshaping of the head accelerates for $H_0 > 80-100$.
- The maximum transport of stones takes place $100^\circ-130^\circ$ anti-clockwise from the angle of wave attack.
- The maximum stone transport rates were found for wave direction 0° , being up to three to four times higher than for wave direction 45° .

CHAPTER 133

Improvement of Composite Breakwater on Solid Bottom Against Severe Tsunamis

Yoshiaki KIMURA¹, Hideo KONDO², Shinji KUWABARA³ and Akira KAWAMORI⁴

1. Introduction

Recent diversification in the use of coastal areas has increased the importance of tsunami prevention measures in the areas. To prevent disasters, it is important to set up various facilities, including tsunami breakwaters and tide embankments, and to improve systems to ensure the safety of people escaping from tsunamis with larger waves than predicted when designing the facilities. Previous studies showed that coastal and port structures are effective to decrease damage caused by tsunamis. These structures are, however, easy to overturn or slide, since they are designed without considering tsunamis as external forces on them. The North Breakwater in Okushiri Port damaged by the tsunamis of the Hokkaido Nanseioki Earthquake in 1993 is an example of a damaged composite breakwater (Photo 1).

Recently, a composite breakwater has become popular as a port structure to cope with enlargement of ports and weak ground of coastal areas. It has two tiers: a caisson functioning as an upright breakwater on top, and a mound (rubble-mound foundation) functioning as a sloping breakwater on the bottom. Though a composite breakwater is frequently used as a tsunami breakwater, damage to it by wave forces larger than the external forces predicted for its design has not been sufficiently taken into account. In most cases, an incident wave of a tsunami on the composite breakwater is broken up due to the influence of the water depth, to become a tsunami. Tsunamis have the largest destructive force on a breakwater.

This study clarifies the features of damage by a surge tsunami to composite breakwaters designed without considering tsunamis as external forces by model experiments.

Photo 1 Damaged composite breakwater(1993 Okushiri Port)

2. Dimensional Analysis

A simple dimensional analysis was made to examine factors influencing the amount of damage to a breakwater Δ (horizontal displacement).

$$\Delta = F \left\{ \frac{W'}{\ell \rho g a (d + h_c)}, \frac{P_h}{\rho g a (d + h_c)}, \frac{P_u}{\rho g a b}, \frac{\ell_f}{a}, \frac{\ell_r}{a}, \frac{d}{a}, \frac{h}{a}, T \sqrt{\frac{a}{g}}, f, \dots \right\} \quad (1)$$

where W' = weight in water, P_h = horizontal wave force, P_u = uplift pressure, a = amplitude of a tsunami, T = period of a tsunami, f = friction coefficient. Fig. 1 shows other variables.

Fig-1 Variables

Fig-2 Relationship between Sf and h/a

Generally, Δ depends mainly upon a safety factor of the upright part against sliding. The first term of the right side F in equation (1) is almost equal to the safety factor. In Fig. 2 the axis of ordinates represents the safety factor against sliding and the axis of abscissas represents h/a . The parameters here are the water depth at the upright part (d) and the water depth (h). The wave force was calculated by the wave force formula of a surge tsunami by Tanimoto et al. This figure shows that the safety factor is proportional to h/a and is more influenced by the water depth (h) than the water depth at the upright part (d).

3. Experimental Equipments

3.1 Two-dimensional open channel

In this experiment, a steel two-dimensional open channel (Fig. 3) 15.0 m long, 0.6 m wide and 0.5 m deep was used. The gate was suddenly opened to produce a tsunami. Both sides of the channel were glass and the bottom was steel coated with paint. A gate to adjust the water depth was installed at one end. The breakwater model was placed with its front 3.5 m from the back of the channel. Pipes to adjust the water depth were installed along both side walls of the channel to level the water depths at the front and back of the breakwater. A tsunami was produced by a wave making gate, or a wave paddle, installed at 5.55 m from the breakwater.

Fig-3 Experimental channel and position of the experimental model

Fig-4 Wave form in the experiment

The difference in the water depths at the front and back of the gate was measured with a point gauge, and the gate was suddenly opened to produce a surge tsunami when the difference reached a specified amount. The installed gate was a wooden, hand-operated vertical lift gate. In this experiment, the difference in the water surfaces at two sides of gate almost corresponded to the amplitude of a surge tsunami. Six capacitance-type wave gauges were installed, and a video camera was installed at the side of the channel to confirm the wave form. Fig. 4 shows examples of wave form in the experiment.

3.2 Experimental model

The experimental model was made from the design of the North Breakwater in Okushiri Port (Photo 1). The North Breakwater in Okushiri Port was constructed recently to increase the calmness in the port located behind the island from the hypocenter. Tsunamis at the time of the earthquake caused foot-protection blocks at the back of the breakwater to drift away; the upright part, especially around the center, overturned and slid; and the mound deformed. The dimensions of a real-size breakwater were assumed from the central part of the North Breakwater which had slid so much. The assumed breakwater was scaled down to 1/40 for the experiments to make a model made of mortar. The dimensions of the assumed breakwater (1/40 figures for each is in brackets) were: height: 10.0 m (25.0 cm); width: 8.0 m (20.0 cm); length: 10.0 m (25.0 cm); height of the mound: 2.0 m (5.0 cm); water depth (h): 8.0 m (20.0 cm). We called the size of the 1/40 model the standard type in this study. The height, width and material of the mound and the water depth (h) were varied during the experiments. And also the weight of the model was varied as an experimental condition, a void of 10.0 cm × 10.0 cm × 15.0 cm (Fig. 5) was made inside the caisson model to make it lighter than reality.

Fig-5 Upright part model

3.3 Mound

The length of the mound was set at the same width of the channel (0.6 m). The standard size of the mound was 5.0 cm in height, 40.0 cm in width, and with the gradient of its slope was 1:2 (standard type). Rubble was used as the mound material, with the equivalent weight of 400 kg (6.0 g for each piece of rubble). Foot-protection blocks placed on the surface of the mound were ignored. By assuming that the mound was a sloping breakwater, the stability number and the Reynolds number of the surface layer of the sloping breakwater were calculated to investigate the mounds stability and scale effect. As a result, we found that the

scale effect need not to be considered and that the stability number was larger than that of the sloping breakwater, in spite of the low critical wave height for stability. From these findings, the weight and the size of the rubble seemed to be sufficient. Also, the experimental result that the rubble of the mound at the front of the breakwater did not move corresponded to the theory that rubble does not move. The reason why the rubble of the mound at the back of the breakwater moved seemed to be due to sliding of the upright part.

4. Experimental Procedure

The experiments were designed to investigate the behavior of the breakwater sliding (the sliding distance which is defined as the distance of the horizontal movement of its upright part), when receiving a surge tsunami produced at a specified water level difference. Tsunami amplitude was increased by 1.0cm, until all number of times became fatal damage. However the results varied much depending on the conditions of the mound and the breakwater. To understand the trend of the results of the experiments, a wave was produced 10 times for each amplitude. If a sliding distance of the caisson model exceeded 20.0 cm, the effect on the breakwater was different from the expected one. We called this effect on the breakwater fatal damage, and only the number of times was counted.

4.1 Effect of the water depth

Influenced by astronomical tides, storm surges and wind waves, the actual water level varies from the standard water level when an incident wave acts on a breakwater. In this experiment, therefore, we investigated the behavior of the upright part and the damage to the mound part, when the breakwater model and the mound had the standard type, and only the water depth (h) was varied from 16.0 cm to 24.0 cm.

4.2 Effect of the configuration of the mound

Composite breakwaters have varied shapes according to the design conditions, including the water depth (h), the design wave, and the purpose of the installment. This experiment, therefore, was designed to see how the damage of the breakwater was affected by changes in the height and width of the mound.

(1) Height

This experiment determined the behavior of the breakwater, when the water depth at the upright part (d) was constant(15cm) and the height of the mound was 5.0 cm, 7.0 cm, and 9.0 cm.

(2) Width

This experiment determined the changes in the behavior of the breakwater, when

the width of the mound was increased by 10.0 cm from the standard type.

4.3 Effect of the weight of breakwater

A general and popular way to increase the stability of the breakwater against wave forces is to increase its weight. This method is effective for waves smaller than the design waves. However, its effectiveness for tsunamis larger than the design waves has not been clarified. This experiment investigated changes in the damage, when a weight was placed on the breakwater.

4.4 Effect of W'

In the experiment where the water depth was changed, the results were difficult to interpret due to the changes in buoyancy and wave forces caused by the changing water depth. In this experiment, the weight offsetting the increased buoyancy caused by the changing water depth was placed on the breakwater to keep constant the underwater weight. The experiment aimed to understand the changes in the behavior due to changes in wave forces.

4.5 Effect of the restraining the settlement of breakwater

Previous experiments showed that fatal damage of the breakwater and its settlement often happened at the same time. We considered that a reinforced mound could be effective to prevent damage by tsunamis. Damage was investigated after installing supporting rods in the mound under the back of the breakwater to restraining the breakwater settlement (Fig. 6).

Fig-6 Effect of restraining the settlement of breakwater

5. Results and Discussion

5.1 Effect of the water depth (Fig. 7)

To understand the basic trend, the standard type for this experiment with the water depth at 20.0 cm (c) was investigated. As tsunami amplitude increased, the sliding distance and the number of cases of fatal damage increased, though the results were partly contradictory. When tsunami amplitude was 8.0 cm or less, the breakwater did not slide, and when it was 14.0 cm or more, the breakwater always underwent fatal damage. The sliding distances varied less when the amplitude was close to 7.0 cm or to 16.0 cm, and they varied more when the amplitude was halfway between these two distances. Such a wide variation in sliding distances halfway between 7.0 cm and 16.0 cm seemed to be caused by all

the manual operations, including molding the mound and installing the caisson model.

We found that, in general, the deeper was the water depth, the easier the breakwater slid. The number of cases of complete fatal damage increased almost in proportion to the increase in the water depth. It means that as the water depth increased, the influence from front wave pressure and buoyancy increase.

5.2 Effect of the configuration of the mound

(1) Height (Fig. 8)

Fig. 8 (a) shows the experimental results of the mound in the standard type with the water depth at 20.0 cm. As the mound height increased, the number of cases of fatal damage increased compared to the standard type. This trend was particularly obvious when the mound was 9.0 cm high, because the higher mounds seemed to have less stability and tended to fall down on a large scale when the breakwater began to slide. The critical point of sliding in terms of the tsunami amplitude was irrelevant to the height of the mound, because the constant water depth in front of the breakwater contributed to maintaining the same wave pressure on the breakwater front. The tendency for shorter sliding distances for the mound 7.0 cm high than those for the mound 5.0 cm high (standard type) was considered to be due to experimental errors from different experimental conditions.

(2) Width (Fig. 9)

Wider mounds brought better stability. No fatal damage was recorded especially when the mound was extended 10 cm toward the rear, though the sliding distance increased due to the shorter front side of the mound. This must be because more energy was required for the sliding while the mound at the rearside of the breakwater was settling.

5.3 Experiment of the weight of breakwater (Fig. 10)

Fig. 10 (a) is the standard type, with the weight of the breakwater of the standard weight +0.0 kg. When the tsunami amplitude was the same, as the weight increased the sliding distance decreased, because a larger horizontal wave force was required for sliding as the weight increased. However, when the weight was +3.0 kg, the breakwater had fatal damage at tsunami amplitude of 12.0 cm and the sliding distance was fairly large, because the bearing capacity of the mound did not sufficiently accommodate the increase in the vertical load. Therefore, once the mound starts to fall down, it falls down completely to the solid bottom of channel. The results of this experiment cannot be simply compared to the other results, since the installment conditions of the breakwater in this experiment were slightly different from those of the others.

Fig-7 Effect of the water depth

Fig-8 Effect of the mound height

Fig-9 Effect of the mound width

Fig-10 Effect of the weight of breakwater

5.4 Effect of W' (Fig. 11)

Fig. 11 (a) shows the standard type. Breakwater with a weight on top slid less, in the same way as in the experiment by changing the weight. The critical point of sliding for each case was mostly the same. Also, the trend towards fatal damage and the tsunami amplitude causing fatal damage were almost the same. As a result, we found that buoyancy change had a greater influence than the change in wave force caused by the water depth change.

5.5 Effect of restraining the settlement of breakwater (Fig. 12)

This experiment shows the least sliding distance and the least number of cases of fatal damage, compared to other experiments, because the falling down of the mound was restrained by supporting the breakwater. This means that the stability of the mound was dominant in influencing the sliding distance of the breakwater.

5.6 Features of Damage

Fig. 13 is from the data of the experiments on the water depth and the mound height. The axis of abscissas represents the water depth at the breakwater divided by the water depth, and the axis of ordinates represents the sliding distance divided by the water level difference producing a tsunami. Each figure is non-dimensional. Within the region of these experiments, the figures on the axis of ordinates did not exceed 2.0 unless the breakwater had fatal damage. This shows that the sliding distance was under twice the tsunami amplitude. The results corresponded to those of the experiment by changing the width of the mound, where the mound was moved toward the rearside. Moving toward both edges of the axis of d/h indicates the breakwater became less stable and easier to slide or have fatal damage, but near the axis center indicates the breakwater was most resistive to slide. As a result, the breakwater with d/h around 0.7 appears to be the most stable.

Fig-11 Effect of W'

Fig-12 Effect of the restraining settlement of breakwater

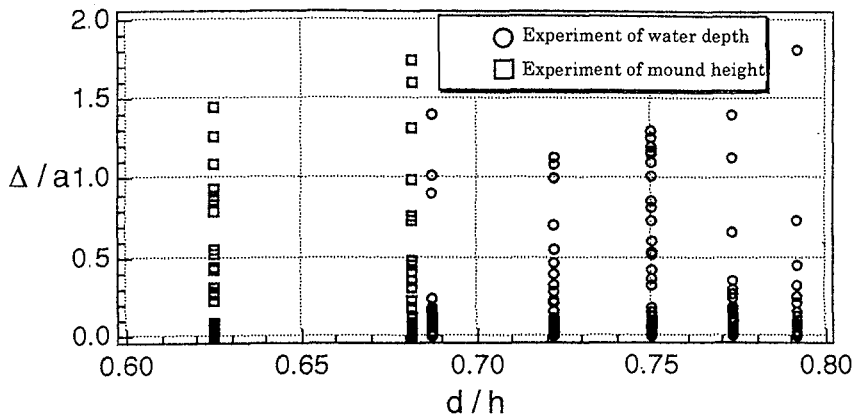

Fig-13 Features of damage

6. Conclusion

This study aimed to clarify the features of damage of a composite breakwater by tsunamis through experiments, and to find better damage prevention measures. As a result of this study, the following have been clarified.

6.1 Effect of breakwater configuration

- 1) An increase in buoyancy was more responsible for damage than an increase in wave pressure on the front of the breakwater due to the increase in the water depth.
- 2) Stability against sliding was remarkably influenced by the mound conditions. The stability increased, especially when the mound was prolonged toward the rear and when the mound was reinforced with body supporting rods.
- 3) A heavier weight of a breakwater for stabilizing the breakwater or an unnecessarily higher mound was not advisable, since it was easier to have fatal damage when exceeding the critical values.
- 4) For stability of a breakwater, the desirable ratio of the water depth (h) and the water depth at the upright part (d) was when the d/h ratio was around 0.7.

6.2 Proposed stability criteria

Stability criteria of composite breakwaters against tsunami wave action are deduced from the experimental result employing a dimensionless displacement, as,

$$\text{Heavy Damage } \Delta/a > 1.0 \text{ for } \mu W_u' / Ph \leq 1.0$$

$$\text{Slight Damage } \Delta/a < 0.1 \text{ for } \mu W_u' / Ph \geq 2.0$$

where a is tsunami amplitude, μ is the friction coefficient between the upright structure and the mound, W_u' ($=W' / \ell$) is weight of upper structure per unit length in water and Ph is the horizontal tsunami wave force per unit length. (Fig. 14)

6.3 Countermeasures

1) To increase simply the weight of upper structure is effective to the critical tsunami height, but Δ becomes abruptly greater for the tsunamis higher than it.

2) Prolongation of the rear shoulder ℓ_r is effective to lessen Δ to prevent the earlier falling down.

3) Most effective way to decrease Δ is to strengthen the mound surface around the heel of upright structure since Δ gradually becomes large as the stress concentration near the heel proceeds during the tsunami colliding on upright structure.

CHAPTER 134

Hydraulic Stability Analysis of Leaside Slopes of Overtopped Breakwaters

M. D. Kudale¹ and N. Kobayashi²

Abstract

The hydraulic stability of armor units on the leaside slope of an overtopped breakwater is analyzed using the velocity and depth of overtopping water on the crest computed by an existing numerical model. The stability analysis is carried out considering the hydrodynamic forces of the overtopping jet impinging on a leaside armor unit. A traditional force balance method is used to predict the stability number N_s for initiation of armor movement. The computed critical stability numbers N_{sc} for stones compare well with the observed stability numbers, provided that the hydrodynamic force coefficients are calibrated once for the stone stability on leaside slopes. The computed results indicate that the minimum stability of the leaside armor units occur at intermediate crest heights. The stability of leaside armor improves as the seaward slope is made flatter. The leaside slope of a breakwater in relatively deeper water is more stable. The leaside stability of a breakwater in shallower water with its crest height near still water level (SWL) can be improved by increasing the the back slope angle. A wider crest also improves the leaside stability.

Further studies are required to refine the developed stability model. The influence of tailwater in reducing the water velocity of overtopping jet needs to be included which has not been considered in the present analysis. The developed model would be very useful in designing the geometry of an overtopped breakwater and the size of leaside armor units because of a large number of design parameters.

Introduction

Low-crested breakwaters are usually constructed when only partial protection from waves is required landward of breakwaters. Low-crested breakwaters are more economical. Also, a significant amount of wave energy is transmitted due to overtopping, which results in the reduction of wave energy actually dissipated on the seaward slope of the breakwater. The weight of the armor units on the seaward slope can be reduced significantly by allowing overtopping. However, the armor units on the crest

¹Senior Research Officer, Central Water and Power Research Station, Pune-411 024, India

²Professor & Associate Director, Center for Applied Coastal Research, University of Delaware, Newark, Delaware 19711, USA

and leeside slope become vulnerable under overtopping waves. The weight of these armor units may need to be increased to withstand the forces of overtopping water.

The stability of a traditional non-overtopped rubble mound breakwater depends primarily upon the stability of individual armor units on its seaward slope. A major factor in the design of rubble mound breakwaters is hence the minimum weight of the armor units on the seaward slope, required to withstand the design waves. Many studies were carried out on the hydraulic stability of individual armor units on the seaward slope. Several empirical formulae such as Van der Meer formula (1988) are available for the estimation of the minimum weight. The present practices for the design of rubble mounds are based on hydraulic model tests and empirical formulae. A few numerical models have also been developed recently for the design of rubble mound structures. Kobayashi et al. (1989, 1994) developed a numerical model for the design of coastal rubble mound structures, which predicts wave reflection, runup and armor stability on the seaward slope.

For low-crested overtopped rubble mound breakwaters, the stability of leeside armor units also becomes an important design aspect. A few studies have been reported on this design aspect. Walker et al. (1975) indicated that the leeside slope was subjected to more damage than the seaward slope. Wave run-down on the seaward slope is reduced due to overtopping and the weight of the armor units may be significantly reduced as suggested empirically by Van der Meer (1988). However, armor units on the crest and leeside slope are more exposed to the wave forces and their weight may need to be increased. Ahrens and Cox (1990) suggested that the increased stability of the seaward slope and the decreased stability of the crest and leeside slope could lead to stability minimum of the entire structure at an intermediate crest elevation. Van der Meer and Veldman (1992) proposed simple empirical formulae for different damage levels for the design of leeside armor of berm breakwaters. Anderson et al. (1992) carried out a hydraulic stability analysis of leeside armor for berm breakwaters and suggested a semi-empirical formula for the size of leeside stone. In their analysis, the velocity of overtopping water on the crest was estimated using an empirical formula for wave runup and only the stability of armor units slightly above SWL was analyzed. Losada et al. (1992) used the velocity obtained from the numerical model of Kobayashi et al. (1987, 1989) and showed that the minimum armor stability on the crest occurred when the crest level of a submerged breakwater was at the mean water level. Vidal et al. (1992) carried out random wave tests in a three dimensional wave basin and presented the stability curves for different portions of a low-crested breakwater. The stability number plotted as a function of the normalized crest height showed that the minimum armor stability against the initiation of damage on the leeside slope occurred at an intermediate crest height.

In the present study, the stability of the leeside armor units is analyzed considering the drag, inertia and lift forces caused by the overtopping jet of water impinging on the leeside slope above or below the still water level. The structure with its crest at or above the SWL under the attack of normally incident wave trains has been considered. The numerical model RBREAK2 by Kobayashi and Poff (1994) is used to compute the temporal variations of the horizontal velocity and thickness of the overtopping jet on the crest. The jet of water issuing from the crest is treated as a free jet in a

quasi-steady manner. The stability of leeside armor units is expressed in terms of the stability number, N_s as a function of the impinging jet velocity and direction as well as the leeside slope. The computed stability number is shown to be in good agreement with the measured stability number for the initiation of damage presented by Vidal et al. (1992). The stability model is then used to perform sensitivity analyses to gain insight into the mechanisms of the leeside armor stability.

Armor Stability Model

Overtopping Flow on Crest

Kobayashi and Otta (1987) developed a numerical flow model to predict the flow characteristics on rough slopes for specified normally incident wave trains. The wave motion on the slope of a structure is described by the one-dimensional finite-amplitude, shallow water equations including the effect of bottom friction. An explicit dissipative Lax-Wendroff finite difference method is used to solve these equations. This numerical flow model was extended to predict the temporal variations of the velocity and depth of the overtopping flow on the crest of the structure by Kobayashi and Wurjanto (1989). The velocity and depth of the overtopping jet at the landward edge of the crest are the input to the stability analysis of leeside armor units presented in this paper. The numerical model called RBREAK2 (Kobayashi and Poff, 1994) for random waves is used for the computations made herein.

Free Jet Impinging on Leeside Slope

Walker et al. (1975) depicted three possible causes of the failure of the leeside of a low-crested breakwater: 1) pore pressure induced by waves striking the seaward slope; 2) overtopping jet of water impinging on the slope; and 3) toe scouring of the leeside slope by the impinging jet. Out of these causes the impinging jet on the leeside slope appears to be the most common. The wave-induced pore pressure would be significant only for a porous breakwater with a small width and porous material near the still water level. The toe scouring of the leeside slope may be important in very shallow water but is beyond the scope of this study. The breakwater is assumed to be essentially impermeable and only the stability of leeside armor units under the impinging jet is considered in the following.

The jet of overtopping water issuing from the landward edge of the crest impinges on the leeside slope. The jet may directly hit the leeside slope above SWL as shown in Figure 1 or it plunges into the tailwater and then attacks the leeside slope as shown in Figure 2. The properties of jet striking the leeside slope are analyzed using the following symbols shown in Figures 1 and 2:

- x_e = landward edge of the breakwater crest
- d_t = water depth below SWL at the seaward toe of the breakwater
which is assumed to be the same as the tailwater depth
- θ = seaward slope angle of the breakwater
- θ_l = leeside slope angle of the breakwater
- u = depth-averaged horizontal velocity of the overtopping water
at x_e computed by RBREAK2
- h = thickness of the overtopping jet at x_e computed by RBREAK2

Figure 1: Jet of Water Impinging on Leaside Slope Above Tailwater Surface

Figure 2: Jet of Water Impinging on Leaside Slope Below Tailwater Surface

- h_c = crest height of the breakwater above SWL
- x_s = impinging point of the jet on the leaside slope
- Δx = horizontal distance between the crest edge and the point x_s
- Δy = vertical distance between the center of the jet at x_e and the point x_s
- V_x = horizontal water velocity of the jet at x_s
- V_y = vertical water velocity of the jet at x_s
- V_R = resultant velocity of the jet striking the slope at x_s
- α = angle of V_R with the horizontal at x_s
- β = angle of V_R relative to the leaside slope given by $\beta = \alpha - \theta_l$

The jet of thickness h issuing from the crest with the computed horizontal velocity of u is assumed to fall freely due to gravity. The initial vertical velocity is zero. The horizontal velocity of the freely falling jet remains to be the initial value u if air friction is neglected. However, the vertical velocity accelerates under the influence of gravity and the vertical acceleration is assumed to be the same as the gravitational acceleration g until the jet impinges on the leaside slope above SWL or the tailwater surface. In the following the unknown values of V_R , α , Δx and Δy are expressed in terms of the known values of u , h , θ_l and h_c .

For the case of the jet impinging on the leaside slope above SWL, a simple analysis

of the quasi-steady jet falling freely due to the gravitational acceleration g yields the following expressions:

$$V_x = u \quad (1)$$

$$\Delta x = g^{-1} \left[u^2 \tan \theta_l + \left(u^4 \tan^2 \theta_l + gh u^2 \right)^{1/2} \right] \quad (2)$$

$$\Delta y = \Delta x \tan \theta_l + \frac{h}{2} \quad (3)$$

$$V_y = \frac{g \Delta x}{u} \quad (4)$$

$$V_R = \left(V_x^2 + V_y^2 \right)^{1/2} \quad (5)$$

$$\alpha = \tan^{-1} \left(\frac{V_y}{V_x} \right) \quad (6)$$

The impinging point x_s in Figure 1 can be found from the calculated values of Δx and Δy . If the point x_s is located below SWL, the jet plunges into the tailwater first and then strikes the leeside slope below SWL. For this case, the jet follows the path of a projectile up to the water surface only. After entering the tailwater, the jet is not falling freely due to gravity. It may be assumed as a first approximation that the jet penetrates straight with the same velocity as the jet velocity at the free surface. Blaisdell and Anderson (1988) made a similar assumption for their analysis of scour at cantilevered pipe outlets. The horizontal distance Δx from the crest edge to the impinging point on the leeside slope is the sum of the free-fall distance x_p to the entry point at the water surface and the horizontal distance of the straight jet penetration below the tailwater surface. The expression for Δx is obtained geometrically using Figure 2.

$$\Delta x = x_p + \frac{(x_p \tan \theta_l - h_c)}{\tan \alpha - \tan \theta_l} \quad (7)$$

where the horizontal distance x_p of the free fall is

$$x_p = u \sqrt{\frac{2(h_c + h/2)}{g}} \quad (8)$$

The vertical velocity V_y at the impinging point x_s in Figure 2 is assumed to be the same as the vertical velocity of the jet at the entry point at the free surface.

$$V_y = \frac{g x_p}{u} \quad (9)$$

The horizontal velocity V_x at the point x_s is assumed to be the same as u and given by (1). The values of Δy , V_R and α are given by (3), (5) and (6), respectively.

The assumption of the constant jet velocity below the tailwater surface may be reasonable for a short penetration distance and result in the overestimation of the jet velocity at the impinging point x_s for a long penetration distance. It is noted that if the horizontal distance Δx calculated by (7) exceeds the horizontal extent of the leeside slope, the jet will impinge on the seabed but the toe scour landward of the leeside slope is not analyzed herein.

Hydrodynamic Forces and Armor Stability

The hydrodynamic forces acting on an individual armor unit on the leeside slope are the drag, lift and inertia forces. These forces may be expressed by the following Morison-type equations:

$$\text{Drag Force; } F_D = \frac{1}{2} \rho C_D C_2 (d)^2 V_R^2 \tag{10}$$

$$\text{Lift Force; } F_L = \frac{1}{2} \rho C_L C_2 (d)^2 V_R^2 \tag{11}$$

$$\text{Inertia Force; } F_I = \rho C_M C_3 (d)^3 \left(\frac{dV_R}{dt} \right) \tag{12}$$

- where, ρ = fluid density which is assumed constant
- C_D, C_L and C_M = drag, lift and inertia coefficients
- C_2 and C_3 = area and volume coefficients of the armor unit
- d = characteristic length of the armor unit
- $\frac{dV_R}{dt}$ = acceleration of the impinging water

The drag force is assumed to act in the direction of the impinging jet as shown in Figure 3. The acceleration of the jet falling freely is vertically downward and its magnitude equals the gravitational acceleration g . The corresponding inertia force acting vertically downward is given by (12) with $dV_R/dt = g$. On the other hand, the inertia force is assumed to be zero where the impinging point x_s is located below SWL. This assumption is consistent with the assumption of the constant jet velocity below the tailwater surface. For simplicity, it may be assumed that the lift force acts upward normal to the slope.

Figure 3: Forces Acting on Armor Unit

In addition to these hydrodynamic forces, the submerged weight of the armor unit acts vertically downward.

$$\text{Submerged Weight; } W_s = \rho g (s - 1) C_3 (d)^3 \tag{13}$$

where s = specific density of the armor unit, which is assumed to be fully submerged.

These forces acting on the armor unit may be resolved in the directions parallel and normal to the slope as shown in Figure 3. The static stability condition against sliding or rolling may be given by

$$F_D \cos \beta + F_I \sin \theta_l + W_s \sin \theta_l \leq (F_D \sin \beta + F_I \cos \theta_l + W_s \cos \theta_l - F_L) \tan \phi \quad (14)$$

in which ϕ = angle of repose of the armor units.

The stability of armor units is traditionally expressed in terms of the stability number, N_s , defined as

$$N_s = \frac{H_s}{(s-1)D_{n50}} \quad ; \quad D_{n50} = C_3^{1/3}d \quad (15)$$

where D_{n50} is the nominal diameter defined as $D_{n50} = (M_{50}/\rho s)^{1/3}$ with M_{50} being the median (50% exceedance) mass of the stones. Accordingly, the characteristic armor length d is taken as the length corresponding to $M_{50} = C_3 \rho s d^3$. The wave height in (15) is generally taken as the significant wave height H_s .

Substitution of (10), (11), (12) and (15) with $dV_R/dt = g$ or 0 into (14) yields

$$N_s \leq N_R = \frac{2C_3^{2/3} \sin(\phi - \theta_l)}{C_2 V_*^2 [C_L \sin \phi + C_D \cos(\phi + \alpha - \theta_l)]} \left[\frac{C_M}{(s-1)} + 1 \right] \quad (16)$$

where $V_* = V_R/\sqrt{gH_s}$ is the impinging jet velocity normalized by the significant wave height. Eq. (16) corresponds to the case of $dV_R/dt = g$. For the case of $dV_R/dt = 0$ below the tailwater surface, N_R is given by (16) without the term $C_M/(s-1)$.

The temporal variations of u and h on the crest for the specified incident wave duration are computed using the numerical model RBREAK2 for the specified geometry of the seaward slope and crest as well as the specified incident wave train. For the specified geometry of the leeside slope, (1)-(9) are used to calculate the location of the jet impinging point x_s and the impinging velocity V_R and its direction α at each instant when the computed u and h are stored. The value of N_R at that instant is computed using (16). The critical stability number, N_{sc} , for the initiation of armor movement is defined as the minimum value of N_R during the entire duration of the incident wave action.

Assuming that C_2, C_3, ϕ, C_L, C_D , and s are constant and C_M is constant but zero if point x_s is below SWL, (16) clearly shows the increase of N_R and hence N_s with the increase of C_3 and C_M and the decrease of C_2, C_L and C_D . Also the leeside slope angle θ_l can be adjusted to increase N_R and hence N_s .

There are only two hydrodynamic variables in (16): i) $V_* = V_R/\sqrt{gH_s}$ with the jet impinging speed V_R at point x_s ; and ii) α = jet angle at point x_s . Eq. (16) clearly indicates the increase of N_R and hence N_s as V_* decreases and α increases. However, if $\alpha \leq \theta_l$, the jet will not strike the leeside slope. For the jet to strike the leeside slope, α should be greater than θ_l as shown in Figures 1 and 2. This implies that the increase of the leeside slope angle θ_l increases α and increase N_s . The increase of θ_l , however, will also decrease $\sin(\phi - \theta_l)$ and increase $\cos(\phi + \alpha - \theta_l)$ where $\phi > \theta_l$ for the

stone stability. In addition, V_R^2 is proportional to u^2 and can be reduced by reducing u^2 using a wider crest or a gentler seaward (front) slope.

The sensitivity of the stability criterion (16) to the force coefficients and the leeside slope is evaluated using the following basic values:

$$C_2 = 0.9, C_3 = 0.66, \phi = 50^\circ, s = 2.65, \cot \theta_l = 1.5, V_*^2 = 2.0, \alpha = 40^\circ \\ C_D = 0.1, C_L = 0.025, C_M = 0.1 \text{ (or zero if } x_s \text{ is below SWL)}$$

Figure 4(a) shows the variations of the stability function N_R with C_D , C_L and C_M where these coefficients are varied one by one from the above basic values. N_R increases with C_M and decreases with C_D and C_L as can also be seen in (16). C_M has a minor effect on the value of N_s . The value of N_s significantly depends upon C_D and C_L in the range of C_D and C_L less than about 0.1. Figure 4(b) shows the sensitivity of N_R to the leeside slope $\cot \theta_l$. For this example, N_R increases fairly rapidly as the leeside slope becomes gentler.

Figure 4: Sensitivity of Stability Function N_R to (a) Drag, Lift and Inertia Coefficients and (b) Leeside Slope $\cot \theta_l$

Comparison With Available Data

Vidal et al. (1992) carried out a series of tests in a three-dimensional wave basin for the stability of stones on the seaward slope, crest and leeside slope of a low-crested rubble mound breakwater. The present numerical model is compared with their test data for the initiation of damage on the leeside slope. The characteristics of the tested breakwater were as follows:

$$\begin{array}{ll} \text{seaward slope } \cot \theta & = 1.5 & ; & \text{leeside slope } \cot \theta_l & = 1.5 \\ \text{crest width} & = 15 \text{ cm} & ; & \text{water depth at toe } d_t & = 38 - 60 \text{ cm} \\ \text{stone diameter } D_{n50} & = 2.49 \text{ cm} & ; & \text{specific density } s & = 2.65 \end{array}$$

Some of the input parameters for the numerical model are based on those used for the armor stability on the seaward slope computed by Kobayashi and Otta (1987). The friction factor, f' , used in RBREAK2 is taken as 0.3 for the seaward slope and crest. The effect of permeability is neglected. The area coefficient, C_2 , and the volume coefficient, C_3 , of the stone are assumed as 0.9 and 0.66, respectively, and the angle of repose, ϕ , for the stone is assumed to be equal to 50° .

In the numerical model RBREAK2 the input time series of the incident wave train needs to be specified at the seaward toe of the structure. The one hour time series based on JONSWAP spectra with its peak period, $T_p = 1.4$ or 1.8 sec, and its peak enhancement factor, $\gamma = 3.3$, are used as the input to comply with the wave conditions used in their experiment. The zero-moment wave height H_{m0} was varied in their experiment to produce the different damage levels. Four tests in their experiment corresponded to the initiation of damage (ID) on the leeside slope of the low-crested breakwater. The corresponding significant wave height H_s for these four tests is calculated from the observed N_s using (15). Based on these values of H_s the time series of incident wave trains are then simulated numerically using the random phase method for the input to RBREAK2. The conditions of the four ID tests are listed in the rows of test 1-4 in Table 1.

Table 1: Test Conditions and Stability Numbers

Test No.	h_c (cm)	d_t (cm)	T_p (sec)	H_{m0} (cm)	H_s (cm)	h_c/H_s	N_s (data)	N_{sc} (computed)
1	0	40	1.4	11.5	11.1	0.00	2.70	2.56
		60	1.4	11.5	11.1	0.00		2.46
2	2	58	1.8	9.1	8.8	0.23	2.15	1.97
		58	1.4	9.1	8.8	0.23		2.20
		38	1.4	9.1	8.8	0.23		1.98
3	4	56	1.4	8.3	8.0	0.50	1.95	2.11
4	6	54	1.4	8.5	8.2	0.73	2.00	2.02
		54	1.8	8.5	8.2	0.73		1.91
5	8	54	1.4	8.5	8.2	0.98	-	2.00
6	10	54	1.4	8.5	8.2	1.22	-	2.02
7	12	54	1.4	8.5	8.2	1.46	-	2.25
8	14	54	1.4	8.5	8.2	1.71	-	2.53
9	16	54	1.4	8.5	8.2	1.95	-	2.80
10	18	54	1.4	8.5	8.2	2.20	-	3.47

Vidal et al. (1992) did not indicate the specific values of d_t and T_p for these four tests. As a result, all the values of d_t and T_p listed in their Table 2 are considered as indicated in the rows of test 1-4. It is noted that test 5-10 listed in Table 1 is hypothetical and used to examine the effect of the crest height h_c greater than the upper limit of $h_c = 6$ cm tested by Vidal et al. (1992). The computed time series of u and h at the landward edge of crest are stored at the rate of 40 points for each T_p .

The stability model was then calibrated to fit the computed values of N_{sc} with the observed values of N_s for initiation of damage for the leeside slope stones. A good agreement was obtained with the values of force coefficients as $C_D = 0.1$, $C_L = 0.025$, and $C_M = 0.1$. Figure 4(a) based on (16) suggests that a similar agreement might be obtained using different values of these coefficients. These values of the force

coefficients appear to be small as compared to the force coefficients for the stones on the seaward slope of the breakwater calibrated by Kobayashi and Otta (1987). Data on the values of C_D , C_L and C_M for the leeside slope stones will be required to resolve the different values of these coefficients for the seaward and leeside slope stones.

Figure 5 shows the comparison of the computed and observed stability numbers plotted against the normalized crest height, h_c/H_s , for test 1-4 listed in Table 1. It can be seen that by adopting the values of the force coefficients as mentioned above, the computed values of N_{sc} for all the four tests are in good agreement with the observed values of N_s .

Figure 5: Comparison of Computed N_{sc} with Measured N_s

Influence of Various Parameters

In order to study the effect of the increased crest height on the leeside stability above the range tested by Vidal et al. (1992), computations are carried out using the test conditions for test 4 with the crest height being increased in an increment of 2 cm as listed as test 5-10 in Table 1. The critical stability numbers for the leeside slopes $\cot \theta_l = 1.25$ and 2 are also calculated for all the tests listed in Table 1 where $\cot \theta_l = 1.5$ in Table 1. Figure 6 shows the variation of N_{sc} with the crest height normalized by H_s for $\cot \theta_l = 1.25$, 1.5 and 2 where the fitted curved line for each slope is added for clarity. For the leeside slope of 1:1.5 the minimum stability occurs at intermediate crest heights and the range of h_c/H_s for the minimum stability is wider. However, for the leeside slope of 1:2, the stability minimum moves towards zero crest height and N_{sc} increases monotonically with the increase of h_c/H_s . Figure 6 also shows that the stability increases rapidly as the crest height is increased beyond the minimum stability range. The stability at zero crest height shows the trend of increasing stability for the negative crest heights, consistent with the computed results by Losada et al. (1992). For this particular case with the normalized depth $d_t/H_s = 6.6$, the armor stability improves significantly as the leeside slope is made flatter.

Figure 6: Computed Variation of N_{sc} with Normalized Crest Height h_c/H_s for Leeside Slopes of 1:1.25, 1:1.5 and 1:2

Computations are also carried out to study the influence of the seaward slope, water depth, crest width and spectral peak period on the leeside armor stability. The basic characteristics of the breakwater and wave conditions chosen for the computations are as follows:

seaward slope $\cot \theta$	= 2.0	;	leeside slope $\cot \theta_l$	= 1.5
crest width	= 15 cm	;	crest height above SWL h_c	= 0 - 20 cm
water depth at toe d_t	= 60 cm	;	peak period T_p	= 1.4 sec
significant wave ht. H_s	= 10.0 cm	;	zero-moment wave ht. H_{m0}	= 10.1 cm

The seaward slope $\cot \theta$, the water depth d_t , the crest width and the peak period T_p are varied one by one from these basic values in the following sensitivity analyses. The values of the critical stability number are computed for different crest heights. However, the computations for the influence of the crest width and peak period are made only for the single crest height of 4 cm above SWL, that is, $h_c/H_s = 0.4$.

Figure 7 shows the influence of the seaward slope on the leeside armor stability where the seaward slope affects the depth-averaged velocity u and the water depth h at the landward edge of the crest computed by RBREAK2. The leeside stability improves as the seaward slope is made flatter. The range of h_c/H_s for the minimum stability becomes smaller and tends to move towards zero crest height for the flatter seaward slope. As the seaward slope becomes flatter, the velocity u of overtopping water is reduced and the stability of leeside armor is increased.

Figure 8 shows the variation of the computed stability number N_{sc} with the water depth at the toe, d_t , normalized by H_s . The stability of the leeside slope is generally larger for the deeper water. However, for the small crest heights at about zero, the leeside armor stability is greater for the shallower water. This is because the overtopping water with the higher velocity for the shallower water impinges beyond the toe of the leeside slope. The intense jet strikes the seabed instead of the leeside armor slope. For the shallower depth the leeside slope stability of a breakwater with a crest

near SWL could be increased by increasing the leeside slope angle. However, scour of the seabed landward of the leeside slope may become serious.

Figure 7: Variation of N_{sc} with Seaward (Front) Slope

Figure 8: Variation of N_{sc} with Normalized Water Depth d_t/H_s

Figure 9(a) shows the variation of the computed stability number N_{sc} with the crest width normalized by H_s . The increase of the crest width of the breakwater improves the stability of the leeside. This is obvious because the increased crest width provides additional friction to the overtopping water on the crest and reduces the velocity u at its landward edge. However, the stability number increases only slowly with the crest width increase and this option may not be very economical.

Figure 9: Computed Variation of N_{sc} with (a) Crest Width Normalized by H_s and (b) Iribarren Number by Varying T_p for $h_c/H_s = 0.4$

The peak period T_p of the incident wave spectrum has also a noticeable effect on the leeside armor stability. Figure 9(b) shows the variation of the computed stability number N_{sc} with the Iribarren number ξ defined as $\xi = \tan \theta / \sqrt{(2\pi H_s)/(gT_p^2)}$.

Figure 9(b) indicates that the stability of the leeside slope decreases with the increasing wave period for this case. The longer period waves increase the overtopping water velocity u for this geometry of the breakwater. A similar result was also observed experimentally by Van der Meer and Veldman (1992).

Conclusions and Recommendations

A hydraulic stability model for armor units on the leeside slopes of overtopped rubble mound breakwaters has been developed using the water velocity and depth of the overtopping flow computed by the existing time dependent numerical model RBREAK2. A good agreement has been obtained with available limited data. Some of the empirical coefficients used in the model have been calibrated using the same data. Consequently, more extensive data will be required to verify the developed model in a more rigorous manner. The limited computed results presented herein indicate the following qualitative conclusions:

- The flatter leeside slope increases the armor stability.
- The flatter seaward slope of a breakwater improves the leeside armor stability and the crest height for the minimum stability tends to approach zero at SWL for the flatter seaward slopes.
- The leeside slope of a breakwater is more stable in deeper water. Also, the crest height for the minimum stability approaches zero at SWL.
- For relatively shallow water depths the minimum armor stability on the leeside slope occurs for wide intermediate crest heights.
- For the shallower water depths the leeside slope stability of a breakwater with a crest near SWL could be increased by increasing the leeside slope angle.
- The stability of the leeside slope can be improved somewhat by increasing the crest width of a breakwater.

These conclusions are based on the specific computations made in this paper. It is difficult to obtain simple general conclusions because the number of parameters involved in this problem is large. The developed hydraulic model will allow one to examine the hydraulic stability of leeside armor units under various wave conditions and breakwater configurations. Consequently, the model is very useful in designing the geometry of an overtopped breakwater and the size of leeside armor units.

Acknowledgment

The study was carried out during the fellowship training of the first author at the University of Delaware. The fellowship was sponsored by the United Nations Development Programme (UNDP) under the Project IND/90/038 at the Central Water and Power Research Station, Pune, India.

CHAPTER 135

Influence of the core configuration on the stability of berm breakwaters

Nikolay Lissev¹
Alf Tørum²

Abstract

An experimental study has been carried out to investigate the concept of extending the core into the berm of a berm breakwater. Five different core configurations were tested. The reshaped profiles were not significantly influenced by the core configuration. The core configuration should be such that the core material is not directly exposed to the waves during the reshaping.

The concept of extending the core into the berm will lead to cheaper berm breakwater structures since the core material is cheaper than the armour stones.

Introduction

Berm breakwaters was introduced as a economical breakwater concept in the beginning of the 1980'ties. Baird and Hall (1987) discussed the main advantage of the concept. The main advantage of the berm breakwater concept is that smaller stone weights can be used in a berm breakwater than in a conventional rubble mound breakwater. Hence general contracting equipment can be used instead of more costly speciality equipment.

Several investigations have been carried out on the stability of berm breakwaters. van der Meer (1988) have carried out the most comprehensive study

¹ University of Architecture, Civil Engineering and Geodesy, 1421Sofia, Bulgaria

² Prof, SINTEF Civil and Environmental Engineering/Norwegian University of Science and Technology, 7034 Trondheim, Norway

on the stability of static and dynamic stable breakwaters, including the berm breakwater. Burchart et al (1988) carried out tests on berm breakwaters in which they concentrated mainly on 3-dimensional effects, i e transport of stones along the structure exposed to oblique waves and deformation of roundheads.

Much research on berm breakwaters was carried out during the EU MAST I (1992-1994) and MAST II (1994-1996) program. The present study was initiated by the second author when he participated in MAST I. Up to that time most of the systematic laboratory work had been carried on berm breakwaters as shown in Figure 1A. A cross section as shown in Figure 1B could be more economical since more of the (cheaper) core material can be used. The experimental study on the influence of the core configuration on the berm breakwater stability was reported in detail by Lissev (1993). This paper is a summary of the report.

Figure 1 Berm breakwater cross-sections

Test set-up

The model testing was carried out in a wave flume as shown in Figure 2. The width of the flume is 1.0 m.

Figure 2 Wave flume with berm breakwater model

Five different cross sections as shown in Figure 3 were tested.

The gradation curves for the berm stone material and the core material are shown in Figure 4. The nominal diameter is defined as $D = \sqrt[3]{W / \rho_s}$, where W = mass of the stone, ρ_s = specific mass of the stone.

Wave measurement

The surface elevations were measured with conductive type wave gauges. In order to be able to sort out the incoming and reflected waves the three gauges were placed with individual distances as recommended by Mansard and Funke (1980).

The group of three gauges were placed 8 m in front of the breakwater. This is more than one wave length, as recommended by Goda (1985).

To decompose the wave field into incoming and reflected waves a method based on linear wave theory and developed by Zelt and Skjelbreia (1992) was used.

Figure 5 shows reflection coefficients as obtained for profiles 1, 2 and 3 compared with coefficients obtained by Andersen et al (1992).

Test program

As mentioned five initial profiles with the same outer profile configuration were used, but with different configuration of the core, Figure 3. Two types of model tests were conducted for profiles 1, 2 and 3: Stability tests and tests for measuring some of the hydraulic responses of the developed profile of the breakwater after finishing the stability tests. For the initial profiles 4 and 5 only stability tests were conducted.

The tests were carried out with irregular waves with increasing peak period T_p with increasing significant wave height such that the wave steepness $s_{02} = 2\pi H_s / gT_{02}^2$ was kept approximately constant, $s_{02} = 0.045$. The lowest peak period was $T_p = 1.32$ s and the highest peak period $T_p = 2.8$ s. H_s = significant wave height, $T_{02} = 2\pi\sqrt{m_0 / m_2}$, m_0 = area under the wave spectrum, m_2 = second area moment of the wave spectrum.

The time duration of the different significant wave height steps are shown in Figure 6. Table 1 shows significant parameters for the tests.

3	1.75	1.36	13.0	0.046	2.26
4	2.00	1.51	15.6	0.044	2.72
5	2.20	1.65	18.4	0.044	3.20
6	2.40	1.74	21.4	0.046	3.72
7	2.60	1.87	24.7	0.046	4.30
8	2.80	2.00	27.6	0.046	4.80

Test results

Reshaped profiles after attacks of 1000 waves for each wave state between state 4 and state 8 and for every one of the five tested initial profiles are shown in Figure 7. The most significant changes for every wave state took place after the attack of the first two-three hundred waves for every wave state. For wave states 4, 5 and 6 only very small changes of the profile were observed after this time.

In Figure 8 are shown the reshaped breakwater profiles for all five initial profiles measured after finishing the tests with 1000 waves for every wave state 1-8. In Figure 9 are shown the final profiles after completing the tests with additional 5000 waves for wave state 8 for every of the five initial profiles.

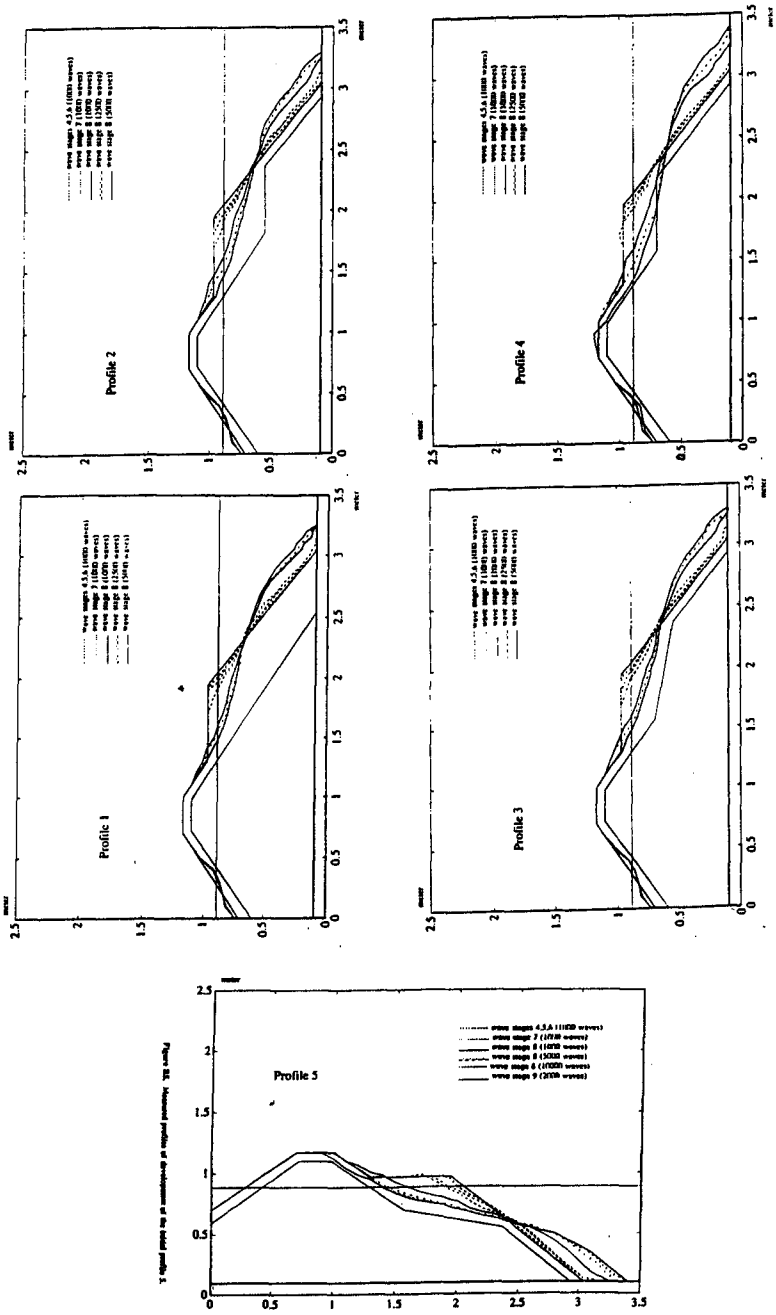

Figure 7 Reshaped profiles for the different initial profiles

Figure 8 shows that there are no significant differences for all five tested initial profiles after completing the sea wave states 1-8 with 1000 waves in each state. The profiles are almost identical with small deviations at the upper and lower berm slope. In this case the width of the berm was reduced from 0.65 m to 0.10 - 0.13 m. This means that for no one of the tested profiles seaward damage conditions are reached. The damage to the seaward side of the berm breakwater is defined to occur when the entire width of the top berm is eroded.

Figure 8 Reshaped profiles for every initial profiles 1-5 after completing every wave state 1-8 with 1000 waves for each state.

For profile 4 there was another critical point close to the dynamic stable profile. The berm stones were removed at this point and the core became directly exposed to the waves after completing the test with sea states 1-8 with 1000 waves in each sea state. Even though a critical condition was reached for profile 4 then it was decided to continue the experiments with the 5000 waves for wave state 8 for this profile to see if a complete failure would develop.

The experiments with additional 5000 waves for wave state 8 show almost the same reshaping for the initial profiles 1, 2 and 3. At the end of the tests for all these three profiles the width of the horizontal berm was reduced to zero. The results from the tests with the initial profiles 1, 2 and 3 gave the idea to use somewhat larger stones over the breakwater crest, Profile 5, Figure 3. Profile 5 is a modified

version of profile 3. The medium weight of the stones over the crest is $W_{50} = 0.24$ kgs, which is approximately twice the weight of the stones in the berm.

Figure 9 Reshaped profiles for every initial profiles 1-5 after completing every wave state 1-8 with 1000 waves for each state plus additional 5000 wave for wave state 8.

The development of Profile 5 up to 5000 waves is similar to the profiles 1, 2 and 3. For Profile 5 an additional 5000 waves of wave state 8 were run. During these 5000 waves there were only small changes in the upper and lower part of the profile. This means that the profile is dynamically stable for this wave state. Only some few stones were moved from the additional armour layer to the toe of the breakwater.

After completing the tests with wave state 8 for Profile 5, the wave height was increased to wave state 9, $H_s = 0.31$ m and $T_p = 2.8$ s. After 2000 waves with this wave state the armour layer was almost completely destroyed and the test was stopped. In this wave state the dynamic stable profile in the middle part was the same. The main development was in the upper and lower part of the berm slope. Bigger stones from the upper part of the profile were moved to the toe of the breakwater.

For Profile 4 the "failure" which started during the first 1000 waves with wave state 8 increased with the number of waves. Part of the core which was directly exposed to the wave action migrated gradually towards the crest of the breakwater. It is important to point out that this process developed gradually with time. Even without armour stones on the flat part, the profile was relatively stable because stone prism formed in the front part of the profile supporting finer core material. This is a good example that processes of destruction of the berm breakwaters are relatively slow in comparison with conventional mound breakwaters where failure is very fast after some critical stage has been reached.

The curves marked BREAKWAT in Figure 8 are results obtained with the computer program BREAKWAT developed by Delft Hydraulics (1990) based on the extensive tests by van der Meer (1988).

The curves in Figure 8 represented by the equations

$$y = a_4 x^{0.83}$$

$$y = p \cdot D^{0.22} x^{0.78}$$

comes from van der Meer (1988) and a modified version of Vellinga's (1986) equations for dune erosion during storm surges.

There is fair agreement between the results obtained in this study and previous studies.

Overtopping

Tests to determine irregular wave overtopping were carried out on the reshaped breakwater after the stability tests had been completed for Profiles 1 and 3. Figure 10 shows the test set-up to measure overtopping.

Figure 10 Scheme of measuring overtopping

We used the dimensionless freeboard parameter F' , Ahrens (1986):

$$F' = \frac{F}{(H_s^2 L_p)^{1/3}}$$

where F = freeboard, i.e. the vertical difference between the crest height of the berm breakwater and the still water line, SWL. L_p is the Airy wave length based on the peak period T_p and the water depth in front of the breakwater.

The overtopping rate Q is defined as the volume of water overtopping the breakwater per unit length of breakwater per unit time.

In Figure 11, Q is plotted versus F' . The curve shown in Figure 11 represents an equation of the general form due to Owen (1982):

$$Q = Q_o \exp(C_1 F')$$

The curve shown in Figure 11 is an eyefitted curve. The coefficients Q_o and C_1 leave in this case the values $Q_o = 4600 \text{ cm}^3/\text{cm s}$ and $C_1 = -21$.

Figure 11 Overtopping rate versus relative freeboard

Rear side damage

No special tests for rear side stability were included in this study. We only registered the beginning of the damage processes on the rear side. Some comparisons were made with Andersen et al (1992) on rear side damage. There was a fair agreement between the two test series.

Conclusion

Based on the results obtained in this study it can be concluded that the core can be extended into the berm of a berm breakwater. Since the core material is generally cheaper than the armour stones, the concept of extending the core material into the berm will give a cheaper berm breakwater structure.

Acknowledgement

This study was conducted by the first author under the supervision of the second author when the first author stayed for 9 months 1992/93 at the Norwegian University of Science and Technology on a scholarship from the Norwegian Research Council for Science and Humanities (NAVF). CHAPTER 136

Model Study of Reservoir Riprap Stability

Etienne P.D. Mansard¹, Michael H. Davies¹ and Octave Caron²

Abstract

A series of large scale (1:15) experiments have been undertaken to assist the Société d'Énergie de la Baie James (SEBJ) in the development of new design guidelines for riprap. The stability of revetments resting on 1:1.8 and 1:2.25 (V:H) slopes is considered. In an attempt to quantify the relative roles of stone size, gradation and armour layer thickness, these tests were undertaken with stone gradations varying from (M_{\max}/M_{\min} ranging from 1 to 10) and with armour layers both $2.2D_{n50}$ and $2.7D_{n50}$ thick.

Introduction

The La Grande Hydroelectric complex includes over 100 km of earth dykes. Over the past 15 years a small percentage of these dykes have suffered wave damage and have needed repair. (Caron et al, 1993, Levay et al, 1993 and 1994). The Société d'Énergie de la Baie James (SEBJ) was mandated to review the designs of these dykes and contracted the Canadian Hydraulics Centre (CHC) to undertake a physical model testing program. In the first phase of this study, repair schemes were developed for several dykes which have experienced damage (Mansard et al, 1994) The second phase of this study focused on improving riprap design techniques. This paper reviews some of the findings of this second phase.

In undertaking the original construction and the repair works, SEBJ has garnered extensive experience with riprap design and construction. Their experience suggests that riprap specifications based on a minimum acceptable stone size (M_{\min}), along with controls on stone gradation can provide an efficient and practical method for design, construction and quality control (Tournier et al., 1996).

2 Hydro-Québec, 75 Boul. René Lévesque Ouest, Montréal, Québec, H2Z 1A4.

Experimental configuration

The cross-sections studied in these experiments were typical designs for earth dykes in reservoirs exposed to wave action (see Figure 1). These are adaptations of the earth dyke designs used in the La Grande Hydroelectric Complex. A Froude-scaled model of these cross-sections (scale 1:15) was built in a 2m wide flume built within the Multidirectional Wave Basin (MWB) at the Canadian Hydraulics Centre. The basin configuration is shown in Figure 2. This layout allowed waves reflected by the structure to diffract and dissipate as they propagate towards the wave generator. This minimises the presence of re-reflected waves at the test section.

Figure 1 Cross-sections used in test program

Armour layer gradations for the model were obtained from crushed limestone from a local quarry. This rock was first mechanically sorted using the CHC's high capacity rock sizing facility. The tightly controlled gradations required for the armour layer were then obtained by individually weighing the stones from the mechanical sorting. Approximately 1 tonne of armour stone was required for each test configuration.

Test Conditions

Table 1 summarises the tests undertaken. The two slopes were both nominally designed to withstand a design storm of $H_s=2.5\text{m}$. This resulted in median stone masses (M_{50}) for the two slopes of 2600 and 2100kg for the 1:1.8 and 1:2.25 slopes, respectively. This typical design is listed at Tests 1 and 4 in Table 1. Tests were conducted with extremely uniform stone distributions where the median stone mass was set equal to the value of the minimum stone mass of the initial tests (see Tests 2, 3, 5 and 6 in Table 1). These uniform gradations of minimal stone size were tested with layers both $2.2D_{n50}$ and $2.7D_{n50}$ thick. Additional tests were also undertaken with two broader gradations $M_{\max}/M_{\min}=5$ (Test 7), and $M_{\max}/M_{\min}=10$ (Test 8) along with a final test (Test 9) with a uniform gradation ($M_{\max}/M_{\min}\approx 1$) in which the median stone mass was the same as in the original design. Tests on the typical designs were conducted at three water levels; high, medium and low, in order to establish any potential influence of overtopping and toe instability on the overall stability of the dyke.

Table 1 Test Program

<i>Test</i>	<i>Slope</i>	<i>M</i> ₅₀ [kg]	<i>D</i> _{n50} [m]	<i>Armour layer</i> <i>thickness, t_a</i> [m]	<i>Filter layer</i> <i>thickness [m]</i>	<i>Gradation</i> <i>M_{max}/M_{min}</i>	<i>Elevation of</i> <i>SWL [m]</i>

2	1:1.8	1500	0.82	2.2 (2.7) <i>D</i> _{n50}	1.9 (2.32 <i>D</i> _{n50})	1	91.5
3	1:1.8	1500	0.82	1.8 (2.2) <i>D</i> _{n50}	1.9 (2.32 <i>D</i> _{n50})	1	91.5
4	1:2.25	2100	0.92	2.0 (2.2) <i>D</i> _{n50}	1.5 (1.63 <i>D</i> _{n50})	2.5	95.8, 91.8 and 87.8 m
5	1:2.25	1200	0.76	2.0 (2.7) <i>D</i> _{n50}	1.5 (1.97 <i>D</i> _{n50})	1	91.8
6	1:2.25	1200	0.76	1.6 (2.2) <i>D</i> _{n50}	1.5 (1.97 <i>D</i> _{n50})	1	91.8
7	1:1.8	2600	0.99	2.2 (2.2) <i>D</i> _{n50}	1.9 (1.92 <i>D</i> _{n50})	5	91.5
8	1:1.8	2600	0.99	2.2 (2.2) <i>D</i> _{n50}	1.9 (1.92 <i>D</i> _{n50})	10	91.5
9	1:1.8	2600	0.99	2.2 (2.2) <i>D</i> _{n50}	1.9 (1.92 <i>D</i> _{n50})	1	91.5

Note: Tests were performed at a scale of 1:15, the structures had a crest elevation of 100.0m, and the basin floor was at elevation 59m. This table reflects target values for gradations and armour layer thickness.

Figure 1 shows the three water levels tested. Water depths and freeboard (the vertical distance between the still water level and the crest of the structure) were varied in the tests to cover the full range of likely operating conditions for the reservoirs. Table 1 lists the water depth for each test. The majority of the tests reported here were conducted at the medium water level, that is with a water depth of 32.5m and a freeboard of 8.5m. This represents a non-overtopping condition for the design wave height of $H_s=2.5\text{m}$, and the structure's behaviour approaches that

of a uniform, infinite slope. The milder 1:2.25 sloped structure required a slightly lower stone mass for stability and required less freeboard to minimise overtopping (i.e. 4.2m instead of 4.5m).

Wave conditions used in test program

All sea states used in this study were irregular waves based on the JONSWAP spectrum ($\gamma=3.3$). Waves were synthesised using the method of random phases as described in Funke et al (1988). The time series of each sea state was chosen to be rather long in order to minimise any statistical variability of wave parameters associated with short records. The length of time series corresponded therefore to two hours of storm duration at prototype scale, containing approximately 1100 to 2600 waves depending on wave period (see values of N in Table 2). This choice of long records also ensured that the wave heights fit a Rayleigh distribution. The ratio of H_{\max}/H_s was between 1.8 and 2.0 for all sea states. Table 2 summarises the wave conditions used in this study.

Wave Calibration

Generally, waves are calibrated in the basin (with an efficient absorber in place) prior to building the breakwater. During the testing program (with the breakwater in place) reflection analysis is performed on the measured wave records to separate the incident and reflected significant wave heights. Since the design of the 2 m section within the 30 m wide basin ensured a good diffraction zone for minimising the re-reflected components (see Figure 2), good agreement was obtained between the incident wave heights measured during calibration and those measured during the testing program. (This comparison can be found in Mansard et al, 1994). This good agreement, in conjunction with the CHC technique for dynamic wave machine calibration, allowed the use of the reflection analysis results (with the structure in place) for establishing incident wave conditions during the tests. Furthermore, during this testing program, CHC had developed and validated a new algorithm that can provide not only the significant wave heights but also the statistics of the incident wave train (Mansard, 1994).

Experimental Procedure

Testing involved the exposure of the structure to a sequence of wave conditions of increasing severity. Testing started at a 'no-damage' wave height and built in 0.5 m wave height increments to a wave height sufficient to cause major damage to the revetment (see Table 2). Each sea state that induced damage to the breakwater was run for approximately 5000 waves (corresponding to 8 hours of storm duration). For this test program, sea states with $H_s < 2.0$ m did not cause any significant damage to the structure.

The 5000 wave duration was chosen to represent relatively long-term exposure at each storm level. This is supported by the work of Thompson and Shuttler

(1975) and by van der Meer (1988) who both show damage evolution varying logarithmically with time and reaching roughly 80% of the maximum possible damage levels within 5000 waves.

Table 2 Wave conditions used in testing.

H_{m0} [m]	T_p [s]	Number of waves per cycle, N	Number of cycles tested	Total number of waves, N_{tot}
1.0	4.0	2600	1	2600
1.5	5.0	1750	1	1750
1.75	5.4	1613	1	1613

2.5	6.75	1328	4	5312
2.75	7.25	1239	4	4956
3.0	7.5	1162	4	4648

Figure 2 Test layout in Multidirectional Wave Basin

Measurement of damage

During construction of the underlayer and the armour layer the NRC electro-mechanical profiler was used to ensure model tolerances were met. This profiling system is described in Davies et al, 1994. This instrument uses a contact wheel on a pivot arm which is mounted to a traversing carriage. High-precision potentiometers

are used to measure the horizontal and vertical location of the contact wheel on the revetment slope. The slope is located using a counter-balanced mechanical contact wheel. This technique provides profiles of the structure accurate to within ± 2 mm and can be used either above or below the water line. This avoids the need for either draining or flooding the basin as is common with other techniques such as acoustic or electrical resistivity methods.

Profiles are analysed to determine the eroded cross-sectional area, A , by comparing the damaged profile at the end of each storm sequence to the original profile. The damage index, S , is then calculated as:

$$S = A/D_{n50}^2 \quad \text{where } D_{n50} = \sqrt[3]{M_{50}/\rho_s} \quad \text{Equation 1}$$

where ρ_s is the density of the armourstone [kg/m^3]. Damage was also measured by counting the number of stones displaced. For low damage levels these two methods provide comparable results (see Davies et al, 1994), while for high damage levels, the counting of stones become impractical.

Another damage index used in this study is the concept of depth of cover, d_c , presented in Davies et al (1994). This index provides a measure of the thickness of protection that remains on the breakwater section after every storm sequence rather than the area eroded from it. It is calculated as the minimum slope-normal armour layer thickness within the zone of wave action. This is based on the measured armour layer profile and the profile of the filter layer obtained during construction. Viewing damage in terms of the depth of cover remaining on the structure can facilitate the interpretation of the results, particularly if the breakwater sections is not a classical 2-layered section.

Test results for typical design revetment

Figure 3 shows typical damage progression for the 'typical revetment', with $M_{\max}/M_{\min}=2.5$ results are presented in terms of the damage level, S as a function of the cumulative number of waves to which the structure was exposed. Note that only the data at high and medium water levels are shown here since a different test protocol was followed for the low water level test. The low water level test was carried out only at the design wave height mainly to verify that there was no toe instability when the level of protection extends to 2 times the design significant wave height below the low water level.

Figure 3 shows that the damage progression curves for the 1:1.8 sloped structure are similar at the high and medium water levels. During the $H_s=3.0\text{m}$ test at the high water level, reduced damage levels were observed. This is possibly attributable to the high degree of overtopping observed during this test.

Figure 3 Damage progression for 1:1.8 slope - typical revetment (Test 1).

Figure 4 Damage progression for 1:2.25 slope - typical revetment (Test 4).

Similar damage evolution curves were observed for the mild sloped structure. Figure 4 shows the good agreement between the high and medium water level results for a 1:2.25 slope.

The Shore Protection Manual (SPM 1977, 1984) uses Hudson’s formula to evaluate riprap stability as a function of stone size, incident wave height, and structure slope. Using the stability number, $H_o = H_s / (\Delta D_{n50})$, Hudson’s relationship can be expressed as:

$$S = \varphi \left(\frac{H_o^3}{\cot \theta} \right)$$

The coefficient, K_d is the threshold for the onset of damage, commonly taken to be at $S=2$. K_d is the value of $H_o^3/\cot \theta$ at $S=2$. Figure 5 presents the S values, obtained after 5000 waves at each sea state, plotted as a function of $H_o^3/\cot \theta$. Through inclusion of the structure slope, θ , in the abscissa, both the steep and mild sloped structures can be viewed on the same plot. Results from the low water level test are also included in this figure. It can be seen from this figure that for a damage equivalent to $S = 2$, the K_d value ranges between 1.2 to 1.7. Note that this value of K_d is based on the significant wave height (H_s) of the sea states and not on the value of $H_{1/10}$ proposed in the Shore Protection Manual of 1984. Davies et al (1996) compared these experimental results with predictions using the formulae of van der Meer (1988). A good match between measured and predicted values exists for values of van der Meer's permeability factor P around 0.14. Here, the van der Meer formula was applied with $N=5000$ waves. For a more exact comparison, the cumulative effects of antecedent storm conditions should be included.

Overall results

The results discussed so far correspond only to the first test series where graded revetment with $M_{max}/M_{min} = 2.5$ was used. A similar comparison of the entire dataset in one figure is difficult because of differences in the stone masses, stone gradation and layer thicknesses listed in Table 1. Furthermore, the damage index S discussed above is the eroded area normalised by the square of the nominal diameter of the stone which is also different in the subsequent tests. It is possible, however, to review the ensemble of the results using simpler parameters such as eroded area, A , and significant wave height, H_s .

Figure 5 Damage S vs $H_o^3/\cot \theta$ - results for both Test 1 (1:1.8 slope) and for Test 4 (1:2.25 slope).

Figure 6 shows the values of A vs H_s for all the structures listed in Table 1. Note that for the graded revetment the averages of the values obtained during high and low water levels are presented here. This figure shows that the eroded area remains nearly the same for all configurations -- there is little difference in the values of the eroded area of the structures $2.2D_{n50}$ thick, whether they are made up of uniform or graded revetment. There is however a trend for the eroded area to be smaller when the layer thickness increases from 2.2 to $2.7D_{n50}$. The following sections provide different interpretations of the dataset which more clearly illustrate the effects of these various parameters.

Figure 6 Eroded area, A vs significant wave height, H_s .

Effect of uniform gradation

Figure 7 presents the results of the graded and uniform revetments $2.2D_{n50}$ thick in terms of S versus $H_o^3/cot \theta$ for the 1:1.8 slope. Here, we have not included test results performed with the reduced median mass (i.e. Tests 2 and 3). Tests 2 and 3 were performed using the same filter layer geometry as the rest of the tests, consequently, the relative permeability of these tests is higher (i.e. the ratio of filter layer thickness to D_{n50} is larger for these tests). This figure shows a trend for uniform revetments to provide higher stability. The influence of gradation is small, particularly at low damage levels. Values of M_{max}/M_{min} between 10 and 2.5 all show quite similar stability. For extremely narrow gradations (M_{max}/M_{min} approaching 1), stability is seen to increase.

Figure 8 shows the influence of gradation in terms of the value of $H_o^3/cot \theta$ required to cause a given damage level ($S=2$ and $S=8$). This figure shows that the extremely uniform gradation is more stable than the broader gradations. Similar analysis was undertaken by van der Meer (1988) – in considering two gradations

(equivalent to M_{max}/M_{min} of 11 and 2) he concluded that gradation had “no or minor influence on the stability and that, within this range, the armour layer can be described simply by the nominal diameter, D_{n50} ”. The present work is in general agreement with these findings, however, these results show that for extremely narrow gradations ($M_{max}/M_{min} < 2.5$) the gradation can significantly improve stability.

Figure 7 Influence of gradation, 1:1.8 slope (Tests 1, 7, 8 and 9)

Figure 8 $H_o^3/cot \theta$ to cause a given damage level as a function of gradation (Tests 1, 7, 8 and 9).

Figure 9 Effect of layer thickness for 1:1.8 slope (Tests 2 and 3).

Figure 10 Effect of layer thickness for 1:2.25 slope (Tests 5 and 6).

Figure 11 Response in terms of depth of cover, d_c

Effect of layer thickness

Figures 9 and 10 show the effects of layer thickness for the steep and mild slopes, respectively. All other test conditions were held constant for these tests so that layer thickness is the only variable. It can be seen that the thicker armour layer ($2.7D_{n50}$) provides better stability. This is as would be expected through the influence of permeability – as layer thickness increases, the ability of the slope to ‘absorb’ wave-induced flows increases.

The influence of layer thickness can also be viewed in terms of the depth of protection, d_c . Figure 11 presents the depth of protection normalised with respect to the nominal median diameter, d_c/D_{n50} as a function of $H_o^3/cot \theta$. As one would expect, the tests with greater layer thickness show a smaller loss in the depth of protection compared to its counterparts with two layers. Furthermore, the remaining protection on the structure is also higher – that is, not only are the damage levels lower (i.e. the amount of material removed is reduced) but, by virtue of the three-layer thickness, the structure can tolerate a higher damage level before the underlayers are endangered.

Conclusions

This study has led to the creation of a large-scale dataset on revetment stability. The parameters S and $H_o^3/cot \theta$ have been seen to accurately describe the revetment stability. The results for the typical revetment design lead to values of K_d ranging between 1.2 and 1.7 (for a damage level of $S=2$). In establishing these K_d values the median mass of the revetment and the significant wave heights of the sea states were used.

Uniform stone distributions have been shown to provide better stability than graded revetment. However, the influence of gradation is small for ratios of M_{\max}/M_{\min} between 2.5 and 10. For uniform stone distributions, increased layer thickness reduces actual damage levels and increases tolerable damage levels. This response is described well by the remaining depth of cover, d_c .

Application of these test results into practical design techniques for dam revetment have been undertaken by the Société d'énergie de la Baie James and are presented by Tournier et al (1996).

Acknowledgements

This study is the result of close cooperation between Hydro-Québec, the Société d'Énergie de la Baie James, and the Canadian Hydraulics Centre. In particular, the authors would like to thank J. Levay, J-P. Tournier and P. Dupuis of SEBJ for their support throughout this study and for their comments in reviewing this paper. The technical support of Dave Watson (CHC) was key to the successful completion of this study.

CHAPTER 137

PROTOTYPE MEASUREMENTS OF WAVE PRESSURES ON A WAVE SCREEN: COMPARISON TO PHYSICAL AND ANALYTICAL MODELS

Martin¹, F. L., Losada², M. A., Vidal³, C., Diaz Rato⁴, J.L.

ABSTRACT

The results of a field campaign of measurements of pressures on a prototype wave screen are analyzed and compared to the results of laboratory tests and to the calculation methods proposed by Jensen, 1984, Günbak et al., 1984, and Martin et al. 1995. Both the field campaign data and the lab tests results seem to fit quantitatively better to the method of Martin et al. than to other proposed formulae. Moreover, the proposed modelization and description of the process employed to develop the method of Martin et al., 1995, are consistent to the measured pressure profiles and time-pressure series.

INTRODUCTION

Most of the rubble-mound breakwaters have a crown wall on their top. These superstructures may help to control wave overtopping and to limit the height of the main layer. Moreover, they may provide access to the breakwater and give support and protection to wiring and pipelines along the breakwater crest. There are few methods to evaluate wave forces on wave screens: Iribarren et al., 1964, Günbak et al., 1984, Jensen, 1984, revisited by Bradbury et al., 1988, and Pedersen et al., 1992, Martin et al. 1995. However, others consider physical modelling as the unique reliable method. The Spanish experience is that the wave screens may withstand without failure higher waves than expected by using Engineering methods.

⁴ *Engineer in chief. Port Authority of Gijón. Claudio Alvargonzalez s/n. Gijón (Spain)*

The main objectives of the present paper are (1) to describe the instrumentation of the Gijón breakwater wave screen and (2) to compare the prototype measurements to model test and to several formulae being used in the engineering practice.

In this paper the reader will find a brief description of the field campaign, the lab tests and the engineering methods employed in the comparison, then a qualitative check of the hypothesis employed in the calculation methods by analyzing the measurements and finally a quantitative comparison of results.

PROTOTYPE INSTRUMENTATION AND MEASUREMENTS

Gijón is located at the Cantabrian Sea, in the north of Spain (fig. 1). It is exposed to sea states from N-NW, which are the most severe sea states in that zone. The 100-year return period significant wave is 10.5 m which can lead to wave heights greater than 18 m.

Fig. 1. Prototype location.

Three wave recorders (W1-W3) were installed in front of the breakwater to be able to separate the incident and the reflected wave trains. One directional wave recorder (W4) is placed at the leeside of the instrumented section to identify the transmitted energy across the breakwater and the diffracted energy around the breakwater head. Five specially designed pressure gages were placed in the wall front (P1-P5), while three pressure cells were drilled across the wall basement to record the uplift pressures (S1- S3) (fig. 2). Moreover, there are two wave riders installed close to the breakwater by Puertos del Estado (Ministry of Public Works) continuously recording wave heights and periods.

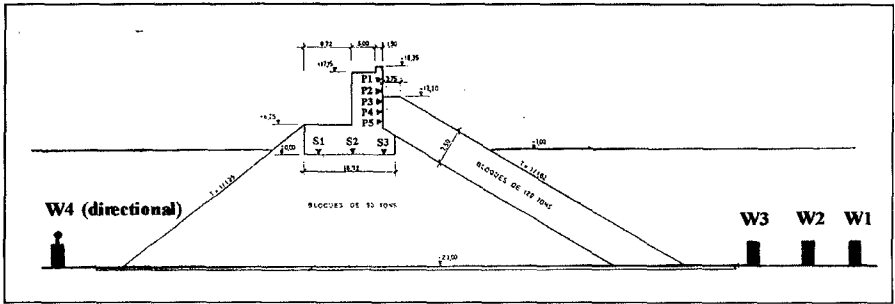

Fig. 2. Instrumentation setup.

The sampling rate of pressures in the wave screen is 20 Hz, which is enough to record the main characteristics of interest of the time-pressure series being researched. The system is continuously logging data in 45-min. bursts. After the burst is finished, the system checks if a given minimum level of pressures is exceeded. If so, the data is stored and if not, it is deleted.

The sampling rate for the wave recorders is 0.5 Hz. Notice that, for a 16-second wave period this data rate gives 8 data/wave period which is enough to define the wave shape. Waves shorter than 8 seconds will be underdefined, but their forces on the wave screen are not expected to be noticeable. Moreover, the wave recorders are fixed in 25 m water depth, and the information of short period waves in this depth will be strongly affected by the difficult-to-define pressure/free surface oscillation transfer function.

The system was set up in February 95 and is still working. During the February-April 1995 period, two storms of $H_s = 5.9$ m and 4.5 m respectively were recorded. In the second period (December-April, 1996) two more storms were measured corresponding to 6.0 m and 5.2 m significant wave height. Due to the tidal level at the instant of maximum wave height only three of these four storms produced significant pressures on the wave screen. The selected storms are described in Table 1. The tidal level is defined above the zero datum (minimum low tide level)

Date	Signif. wave height	Peak period	Tidal level
16/2/95	5.9 m	20 s	4.1 m
10/2/96	6.0 m	19 s	3.9 m
19/2/96	5.5 m	16 s	4.3 m

As the system is to exposed to the natural and port labour actions, some measuring problems appeared in different instants of the field campaign: some electrical noise in the signal and power outages in the initial months, lightning which hit the amplifiers and affected almost all of the system, etc. In figure 3, an abstract of the field work development and incidences is represented.

Figure 3. Field campaign schedule and incidences

LABORATORY EXPERIMENTAL SETUP

Model scale lab tests tests were conducted in the 70 m long, 2 m wide, 2 m high wave flume at the Oceanographical and Coastal Engineering Lab at the University of Cantabria. The test model consists of a 1/90 scale section of the Príncipe de Asturias breakwater at Port of Gijón (Spain) shown in figure 2. This breakwater has a wave screen based at low tide level (0.0) and crowned 18.3 m above. The main layer is built of 120-Ton parallelepipedical blocks, and the core is built of 90-Ton blocks. The water depth was set to correspond to high tide level in the prototype. Regular cnoidal waves were generated by a piston-type wavemaker. Wave heights ranging from 9 to 13.5 m and periods from 11 to 17 s were tested. Moreover, irregular wave series were generated. The irregular wave characteristics are represented in Table II.

Table II. Model scale 1/90. Irregular wave series.

Significant wave height	4 m	6 m	8 m	10 m	12 m
Peak period	12 s	14 s	16 s	18 s	20 s

Free surface in front of the structure was measured by three resistance gages and a reflection analysis of the free surface time series was done. By using this technique it is possible to obtain the incident and the reflected wave height. The transmitted wave height was measured by one free surface gage located 1 m from the lee side toe of the breakwater. Four strain-gage type pressure gages were installed in the wave screen basement while eight gages were fixed to the structure front.

One of the main targets of the tests was to identify and quantify the effect of the berm length on the resulting pressures. Three berm lengths were tested, corresponding to the length of 1 mound unit, 2 units and 3 units. Two types of parallelepipedic blocks were used corresponding to 90 and 120 tons.

ENGINEERING ANALYTICAL METHODS

There are few methods available for the calculation of forces on wave screens, some are mainly analytical: Iribarren et al., 1964, which largely overpredicts the resulting pressures, and Günbak et al., 1984; some are mainly experimental: Jensen, 1984, revisited by Bradbury et al., 1988, and Pedersen et al., 1992, which makes a probabilistic approach to the horizontal forces (not pressure distributions or uplift forces). The parametrization selected in Jensen, 1984, generates a relatively large dispersion in the results, and Bradbury et al., 1988, found that the influence of wave period on the resulting forces is not represented adequately.

Generally speaking, the response of the built wave screens reveals that the calculating methods available overpredict the wave induced forces, with the related influence on the construction costs. Therefore, it is clear that a deeper study of these forces was needed. The Ocean and Coastal Research Group of University of Cantabria has been working for several years in the conceptualization of the process and the study of the procedures of momentum transfer between a bore and a vertical surface. Finally, Martin et al. (1995) developed a new method for the calculation of the pressure profiles acting in the wave screen front and base due to bores hitting the superstructure in the run-up process.

From the results of the experimental study conducted at the Oceanographical Eng. lab at University of Cantabria (Losada et al. 1995, Martin, 1995) it can be concluded that two maxima of force occur due to each single wave; the former peak is generated during the abrupt change of direction of the bore front due to the wave screen (horizontal decelerations), while the latter maximum occurs after the instant of maximum run-up and is related to the vertical acceleration of the water mass piling in front of the wave screen (early Run-down movement).

The distinct nature of these force peaks is well revealed in the vertical distribution of pressures. In figure 4 an interval of the time-force curve obtained from lab tests is shown, and the two force maxima (A and B) are pointed out. The vertical distribution of pressures at the wall in the instants A and B are shown in the same figure. The pressures due to the first peak (A), hereafter denoted as Shock pressures (P_s), present an almost vertically uniform profile, where two zones are well distinguished: the upper zone, not protected by the rubble-mound layer, and the lower zone, protected by the rubble-mound layer. The pressure profile due to the second peak (B), hereafter denoted as Reflecting pressure (P_r), grows vertically with an almost constant increasing factor, always equal to or smaller than ρg . Martin et al., 1995, proposed a method to calculate the pressure profiles in the two instants of maximum force (P_s, P_r).

Figure 4. Force-time series and pressure profiles in instants A and B.

In this paper, the results from the lab and field campaigns are compared to the methods proposed by Jensen, 1984, Günbak et al., 1984 and Martin et al., 1995. The methods of Martin et al., 1995, and Günbak et al., 1984, are defined wave to wave and provide the pressure profiles in the maximum force instant, while the method of

Jensen provides the force of 0.1% of probability of occurrence under a given sea state defined by the significant wave height (H_s). As was said before, the method proposed by Jensen neither predicts the pressure profiles nor the uplift pressures and therefore, can not be used to predict the overturning momentum on the wave screen.

QUALITATIVE COMPARISON OF RESULTS

This comparison is done in order to achieve two main targets: 1) To make a qualitative check of some of the hypothesis in which the methods of Günbak et al., 1984 and Martín et al., 1995 are based and; 2) To identify any possible qualitative scale effects between lab and prototype results. To do that, comparison of force-time series and pressure profiles measured in the field campaign, in the lab and proposed by the methods, are done.

In figure 5, a brief interval of force-time series measured in the lab is presented. The wave train characteristics are $H_s = 9.0$ m and $T_p = 18$ s and the tests were done with a tidal elevation of 4.0 m above the zero datum. In this figure, two impinging wave forces are pointed up. The former (time 310-320 s) shows a double peak pattern while the latter (447-457 s) shows a single peak pattern. The only difference between the two impinging waves was the Run-up height. The former wave, slightly larger wave height and period, produced a Run-up tongue which overcame the main layer berm level (Ac) while the latter almost reached the level Ac.

Figure 5. Experimental time-force series.

If the main layer units can stand the rush-up wave action, most of the bore front horizontal momentum is transmitted to these units, in the region below A_c . If the bore does not overcome A_c level, the former peak of force (shock pressures) is smoothed, with only more or less noticeable pressure oscillations appearing, depending on the berm length and main layer porosity. The second peak (reflecting pressure) always occurs because it is generated by the water mass piled by the wall developing a pseudohydrostatic pressures profile.

In Günbak et al., 1984, only one maximum force situation obtained as the sum of the shock and reflecting pressures is defined. These two pressure maxima occur at different instants in the evolution of the bore and are due to different processes that must be analyzed separately.

From lab tests over regular shaped breakwaters (uniform slopes 1:1.5- 1:2, main layer porosity ranging 0.3-0.4) it can be estimated that shock pressure maximum of force is expected to appear in the cases when $H_s/A_c \geq 0.7$. Of course, this value heavily depends on the Run-up and thus, on the breakwater characteristics.

In the case of Gijón Breakwater, A_c level is 12 meters above the zero datum. In high tide situations (+4.0 m), the berm freeboard is 8.0 m. Thus, shock pressures are expected to occur for significant wave heights above $0.7 \times 8.0 = 5.60$ m. In figure 6, a pressure-time series corresponding to gages P3, P4 and P5 in the prototype front are represented. These series were measured during the storm on February 10, 1996. Recalling Table I, the characteristics of this storm were $H_s = 6.0$ m and $T_p = 19$ s. In the instant of the measurements shown in fig. 6, the tide level was 3.9 m.

Figure 6. Pressure-time series measured in the prototype front face.

Figure 6 shows that only three waves reached gage P3 (0.4 m below Ac level) in 45 minutes. This is consistent with the test results in 1/90 scale model under $H_s = 6.0$ m, where bores do not overcome Ac level.

One of the main hypotheses introduced in Martín et al., is the assumption that the basic run-up tongue characteristics (thickness, bore front velocity, etc...) on breakwaters with wave screens are similar than those in bores running-up on infinite slopes and, thus, the effect induced by the presence of the wave screen can be neglected. Under this assumption, the classical Run-up formulae can be employed. As an example, estimating $Ru \approx H$, the maximum run-up in a given sea state can be calculated. A sea state of $H_s = 6.0$ m and 150 waves (45 minutes of storm on 10/2/96) will lead in maximum waves about 8-9 meters. These waves would run-up 8-9 meters above the SWL (4.0 m tidal level) and merely reach the Ac level. This is consistent with the prototype measurements. Although this comparison is rough, it can be used as a engineering check of the hypothesis. The Run-up on rough permeable slopes is a process with high experimental variability, and all engineering formulae for Run-up are "best fit" methods. The hypothesis included in Martín et al., can not be experimentally distinguished from the experimental "noise".

In figure 7, a stretching of the previous fig. 6 is done in order to show three wave actions. It can be noticed that the shock pressure peak is not clear and only some pressure oscillations appear. These measurements are as expected because the ratio H_s/Ac in this storm is around the 0.7 limit. Once again, this is consistent with the lab results and the modeling of the double peak effect done in Martín et al., 1995.

Figure 7. Pressure-time series in prototype.

Finally, the vertical profiles of pressure due to a selected single wave of 8.3 m height and 16.2 s period measured in the prototype, measured in the lab and proposed by Martin et al., 1995 were compared. The results are shown in figure 8. It can be noted that the shock pressures profile is quite similar in the prototype and in the lab, and fits the homogeneous vertical distribution proposed for shock pressures in Martin et al., 1995, quite well. Generally speaking, the total force produced by the shock oscillations in the cases when $Ru < Ac$ are low and smaller than the reflecting force. In Martin et al., when $Ru < Ac$, it is assumed that the shock forces are always smaller than the reflecting forces and can be neglected.

In the reflecting pressures there are some differences between the quantitative values of the measuring points in the lab and in the prototype, but the overall trend of the pressure profile is quite similar. Notice that this comparison is done in qualitative terms. It is easy to understand the difficulty of make a deterministic comparison between the results in the prototype and the lab, trying to simulate exactly the same wave height, period, tidal condition, etc...

The dashed lines in Figure 8 show the proposed reflecting pressure by Günbak et al., 1984 and Martín et al., 1995. The overall trend is well simulated by both methods, but the profile proposed by Martín et al., 1995, fits better the actual quantitative values measured.

As a result of the quantitative comparison, it can be concluded that there are not large and noticeable qualitative scale effects between lab and prototype results, and that Martin et al., 1995, method adequately represents the main characteristics of the process.

Figure 8. Pressure profiles in prototype, lab tests and analytical methods

QUANTITATIVE COMPARISON OF RESULTS

As the method proposed by Jensen, 1984, provides the 0.1% probability force, this force has been selected as a comparison parameter. In figure 9 the net 0.1% horizontal force given by the lab tests, the methods from Jensen, Günbak et al. and Martin et al., and the three storms measured up to now in the prototype are given.

The method from Jensen is basically empirical and must be applied using some experimental parameters. In this case, it is applied using the experimental data collected by Pedersen and Burcharth, 1992. This data shows a wide spreading that makes it difficult for the engineer to define design values of the parameters. In this case, an upper and lower value of the parameters are selected and, thus, an upper and lower 0.1 % force is given for each wave height. These two lines define a region assigned as Jensen's results region in figure 9.

Figure 9. Quantitative comparison of results.

The 0.1 % force produced by the three storms are obtained by extrapolating the probability curve of forces in 45-min. burst, because in the next 45-min. burst the tidal range is different and the "test conditions" are not homogeneous. The maximum forces

are measured in the high tide situation (about 4.0 m in the three storms) and is equal to the tide level employed in the lab tests. Notice that in 45-min. burst, an average of 150 waves are measured and the 0.1% force requires 1,000 waves (about 6 hours).

The prototype results are 15% smaller than those of the lab results. Regarding the qualitative comparison done, it is clear that all the forces measured in the prototype under such storms are due to reflecting pressures. In the comparison of vertical pressure profiles, it was noticeable that the pressures measured in the lab were slightly larger than those measured in the prototype. This can be explained regarding the breakwater core. In the lab the core was built by small scale 90-T blocks, which can simulate the same porosity but not the same permeability. As the reflecting pressures are due to the water mass piled by the wall, larger wave transmission across the breakwater will produce less water accumulation by the wave screen.

Martin et al., 1995 and Günbak et al., 1984 methods are developed to be applied wave to wave. In this case the hypothesis of equivalence (Saville, 1962) is assumed and the methods are applied to a series of 3,000 synthetic simulated individual waves that represent a TMA spectrum. The fitting of Martín et al., 1995 to the lab results is not surprising as the parameters of the method were adjusted to this breakwater from the experimental results. The difference in the 12 m wave height is due to the breaking of waves in the wave flume, which occurs for breaking parameters (H_b/d , breaking wave height over depth) smaller than in the nature.

The results of Günbak et al., 1984, overpredicts the results (100% respect prototype, 60 %, respect experimental results) for smaller wave heights while for larger wave heights the results are smaller than the experimental. Perhaps the most important characteristic to point out is the different trend shown by Günbak et al. results (quasi linear) and Martín et al. results (quasi parabolic). It is clear that the shock forces on the wave screen front face depend on the pressure on the wall (horizontal momentum related to the water mass and the bore celerity) and on the area of wall exposed to the pressure (Run-up). Both of them are related to the wave height and, thus, the wave height must have an effect on the resulting forces at least in a quadratic form. It is clear that once the wall is overtopped ($H_s > 10$ m in fig. 9) the quadratic trend disappears.

Figure 10 represents the probability distribution of forces measured in the prototype on 19/2/96 ($H_s = 5.5$ m, $T_p = 16$ s) and the lab tests results for $H_s = 6$ m and $T_p = 14$ s which are the most similar cases available nowadays. The differences for smaller waves and the better fit for larger waves can be noticed.

Small scale effects are apparent by comparing the two probability curves. As no shock pressures occur for these wave heights these effects are not expected to be related to the water compressibility or aeration and perhaps more related to the core permeability

in the scale model or the differences in the wave trains between the lab and the prototype.

Figure 10. Force probability distributions.

CONCLUSIONS

- A field campaign is being developed as well as intensive lab tests over the 1/90 scale model of Príncipe de Asturias breakwater. The results of the field campaign and the lab tests are used to check the validity of some analytical methods employed in engineering practice to design wave screens. Moreover, the comparison of the results between the prototype and the 1/90 model allows to analyze the scale effects.
- The lab test results and the analytical methods seem to slightly overpredict the forces measured in the prototype.
- Maximum forces measured in the prototype up to now are due to reflecting pressures, where Froude scaling works properly, and the discrepancies must be explained by other modelling effects (core permeability, wave modeling, etc).
- No severe scale effects between lab results and prototype results are identified in a qualitative analysis.
- The method proposed by Martín et al., 1995 produces results which fit the lab test results well and 60% more accurately than Günbak et al., method. Jensen's method is difficult to apply by the designing engineers.

- The field campaign will provide more fruitful results when $H_s > 7$ m occur and shock pressures are measured.

ACKNOWLEDGEMENTS

This project is partially funded by the European Communities Research Programme, MAST III (Marine Science and Technology), Project PROVERBS (Probabilistic design tools for vertical breakwaters) under EU contract MAS3-CT95-0041. We appreciate this financial support very much.

The authors are grateful to the participants of PROVERBS for fruitful discussions and comments during workshops.

The authors wish to thank the Port Authority of Gijón for the unconditional technical and financial support to this project.

CHAPTER 138

Velocity Field Measurements over Breakwater Heads under 3D Waves

Yoshiharu Matsumi ¹, Akira Kimura ² and Kenichi Ohno ³

Abstract

The measurements of wave kinematics over the breakwater heads under uni and multidirectional waves attack were undertaken to achieve an improved understanding of the influence of wave directionality on the stability of heads. The characteristics of the magnitudes and directions of velocity vectors under 3D waves were assessed by comparing with those measured under 2D waves. The sensitive zones of the initial damage in the head sections were evaluated by linking the measurements of velocity components with a stability formula for armour stones on the heads, which was derived in this study.

Introduction

Breakwater designs have been generally evaluated using unidirectional waves, because they are widely considered to be conservative. This may be true for the trunk section of the breakwater where the directional spread associated with the multidirectional seas tends to reduce the wave loads imparted on the structure. However, for the breakwater heads, multidirectional waves could be expected to induce more loads on the structure due to their geometry.

The previous study which was carried out by Matsumi and Mansard et al. (1994), was the first step towards an experimental program achieving the realistic stability criteria for breakwater heads under multidirectional seas. It presented a comparison for the performance of breakwater heads under 2D and 3D waves attack. However, those experimental results could not draw general conclusion that the head sections were prone to more or less damage under 3D waves.

 - 3 Graduate Student, M. Eng., Dept. of Social Systems Eng., Tottori University

The objective of this study is, as a continuation of that program, to explore a better insight into the reasons for the damage results of the heads in previous study through the measurements of wave kinematics over the heads under uni and multidirectional waves. Furthermore, directly unexpected waves attack under 3D waves may lead to higher loads to armour stones at some local position in the heads. Namely, the locality in location of the sensitive zones of the initial damage in the heads for 3D waves is deemed to be stronger than the case of 2D waves. This initiation of damage is relevant to trigger of breakwater failure. Therefore, the second purpose is to investigate the locality in spatial occurrence of the initial damage over the heads for 2D and 3D waves, which is evaluated by linking the measurements of velocity components with a stability formula for the armour stone.

Experimental Setup

Layout of the basin

The physical model tests were carried out, at the Tottori university, in the multidirectional wave basin with a length of 14m and a wide of 8.4m. Figure 1 shows a plan view of the experimental set-up. A fourteen-segment generator of the snake type is located along one of the 8.4m sides of the basin. Expanded polystyrene absorbers with permeability, capable of limiting wave reflections to 20% for most frequencies of interest, are installed along the two sides of the basin. On the side opposite the wave generator, the slope with 1:10 is placed in order to ensure an efficient dissipation of wave energy.

Layout of current meters and wave gauges

The velocity field over the head was measured using 6 bi-axial electromagnetic current meters at 6 different locations indicated by dots in Figure 1. The positions of these probes were fixed before placing the structure. The initial deflection of the U and V components of each current meter, by placing against the coordinate system located in the basin, was established by means of the preliminary regular wave tests without the breakwater. In Figure 1, θ shows the directions of velocity vector, minus θ and V(-) velocity component indicate flow towards armour layer of the head. The water surface elevations of the sea states in the proximity of the model were measured using 8 wave gauges at 8 different locations.

Layout of breakwater model

The layout of the breakwater model had to be designed carefully to ensure homogeneous sea states on the breakwater. For this purpose, the numerical model which was based on the diffraction theory and boundary integral equation was used. This model, developed by Isaacson (1992), can predict the water surface elevation and kinematics of the sea states prevailing at different locations in the basin. A

sample output resulting from this numerical model is presented in Figure 2. It illustrates the spatial distribution of wave heights in the basin without the breakwater model in place, under a multidirectional sea state. The expected wave heights presented in this figure were normalized with respect to target wave height. Note that their maximum value is only 0.9. This is due to the diffraction processes and can be increased by applying an amplification factor. It can be seen from this figure that the useful test area, over which the sea state is homogeneous, is limited by a triangular boundary. According to this figure, the best location for the model would be close to the paddle. However, since this wave basin is not yet equipped with active absorption, in order to minimize re-reflections from the paddles, the model is placed with its longitudinal axis rotated 20° with respect to the paddles, as shown in Figure 1.

Figure 1 Plan view of the experimental set-up.

Figure 2 Spatial distribution of wave heights in the basin without the model.

Characteristics of the breakwater model

Figure 3 shows both plan and profile views of the breakwater model. The three dimensional rubble-mound breakwater with 2 layers of armour stones and a relatively porous core was built with a slope of 1:2. Its height was 50cm and it performed as a non-overtopping structure in a water depth of 30cm. Since this study was to focus on the wave velocity field over the heads without any damage, the whole surface of breakwater was covered with a hard nylon mesh to restrain armor stones. The reflection characteristics of the breakwater were estimated under unidirectional waves of normal incidence. The reflection coefficient was about 25%.

The characteristics of the armour and core stones used in the experiments are presented in Table 1. The weight of armour stones, W_{50} , was 42 grams, this value was 1.5 times the weight estimated by van der Meer's formula (1987) with damage parameter $S=2$ against the targeted significant wave height, $H_{m0}=6\text{cm}$, and peak wave period, $T_p=1.4\text{s}$. The gradations of armour stones were meticulously checked and the resulting D_{n85}/D_{n15} ratio for the armour was 1.1.

Figure 3 Plan and profile view of the breakwater model.

Table 1 Summary of the breakwater characteristics.

W_{50} weight of armour (g)	42
W_{a50} weight of core (g)	3.75
D_{n50} weight of armour (cm)	2.51
Porosity	0.45
D_L Length of head (cm)	205
T_L Length of trunk (cm)	250
Crest breadth (cm)	6
Height of breakwater (cm)	50

$$D_{n50} = (W_{50} / \rho_s)^{1/3} , \rho_s : \text{unit weight of armour stone}$$

Table 2 Characteristics of waves in experiments.

Spectrum	T_p (s)	γ	H_{m0} (cm)	α (deg.)	S_{max}	T_R (min.)	N	D_L/L	T_L/L
JONSWAP	1.0	3.3	6, 8.5	0, -15	10, 20, ∞	20	1440	1.49	1.82
JONSWAP	1.4	3.3	6, 8.5	0, -15	10, 20, ∞	20	1028	0.95	1.16

Test series

Table 2 indicates the characteristics of the waves adopted in the experiments. The spectra were the JONSWAP type with two different peak periods ($T_p=1.0s$ and $T_p=1.4s$). The peak enhancement factor γ was chosen to be equal to 3.3. The multidirectional waves were simulated by using the well known Single Summation Method in order to eliminate spatial variability of sea states. For the directional spreading function, the Mitsuyasu-type (1975) was chosen, the spreading parameter s was given by the following form (Goda 1985):

$$s = \begin{cases} S_{max} \cdot (f/f_p)^5 & : f \leq f_p \\ S_{max} \cdot (f/f_p)^{-2.5} & : f \geq f_p \end{cases}$$

Here f_p denotes the frequency at the spectral peak. Values of $S_{max}=10, 20$ and $S_{max}=\infty$ were applied to simulate multi and unidirectional waves respectively. In order to assess the influence of obliqueness, two different mean angles of incidence $\alpha = 0^\circ$ and $\alpha = -15^\circ$ were used, ensuring at the same time homogeneity of the sea state at the head sections.

In order to minimize statistical variability associated with short lengths of wave records, a recycling period of 20 minutes in model scale was used in the synthesis. This storm duration corresponded to about 1400 waves when $T_p=1.0s$ and 1000 for $T_p=1.4s$. The ratios of diameter of the head over wave length and length of trunk over wave length are indicated in Table 2.

Table 3 Significant wave heights in the experiments.

Wave Condition	H_{m0}	H_{s_no} ($T_p=1.0s$)	H_{s_no} ($T_p=1.4s$)	H_{m0}	H_{s_no} ($T_p=1.0s$)	H_{s_no} ($T_p=1.4s$)
Uni Normal ($S_{max}=\infty$)	6.0	6.01	6.17	8.5	8.68	8.42
Uni Oblique ($S_{max}=\infty$)	6.0	6.12	6.15	8.5	8.65	8.66
Multi Normal ($S_{max}=20$)	6.0	5.99	5.99	8.5	8.75	8.70
Multi Oblique ($S_{max}=20$)	6.0	6.16	6.16	8.5	8.77	8.49
Multi Normal ($S_{max}=10$)	6.0	6.01	6.05	8.5	8.63	8.40
Multi Oblique ($S_{max}=10$)	6.0	6.13	5.94	8.5	8.70	8.52

(Units : cm)

Twenty-four test series were carried out using different combinations of spreading index and mean angle of incidence. In each series, the spectrum-based

significant wave heights, H_{m0} , were 6cm and 8.5cm. These sea states were pre-calibrated in the basin without the structure in position, while keeping all wave gauges and current meters in place. The water depth was 30cm.

Table 3 provides a summary of wave heights measured under different experimental combinations without the breakwater model. The values of H_{s_no} are given by averaging the significant wave heights at every wave gauges. It can be found that there is not so much difference between values of H_{m0} and H_{s_no} of incident waves under uni and multidirectional waves.

Characteristics of Velocity Field over Breakwater Head

Armour stones of the breakwaters may be strongly prone to move under a condition of faster flow velocities. Therefore in this study, larger magnitudes of velocities in the time series data of the measurements were discussed. Figure 4 shows the comparison of the U and V component velocities at 4 different locations (CM-2, CM-3, CM-4, CM-5 shown in Figure 1) on the head under 3D waves and those under 2D waves, when H_{m0} is 6cm and Tp is 1.4s. The velocities employed in this figure are the average of the highest 1/3 of the time series data from each current meter. The ordinate in this figure indicates the ratio of the values of U, V for 3D waves to those under 2D waves. Therefore, when these values exceed one, velocities under 3D waves become larger than those under 2D waves. It can be seen that for 3D waves, the V(-) component which is towards the armour layer causing severe damage is larger than those for 2D waves. In even back head section, this value under 3D waves is nearly 1.2 to 1.3 times larger than the values measured under 2D waves.

Figure 4 Comparison between U, V component velocities under 3D and 2D waves.

Figure 5 shows the spatial characteristics in correlation of the magnitude of velocity vectors at every current meter. In these figures, the value of R indicates the coefficient of the correlation between measurements at every current meter and that at CM-1 current meter placed on the top of the front head section. It can be seen that in the case of multidirectional waves, the correlation in the middle and back head section is very poor regardless of the mean direction of waves and peak periods. From these results, the possibility of waves attacking directly the heads due to the directional spread associated with 3D waves may be supported.

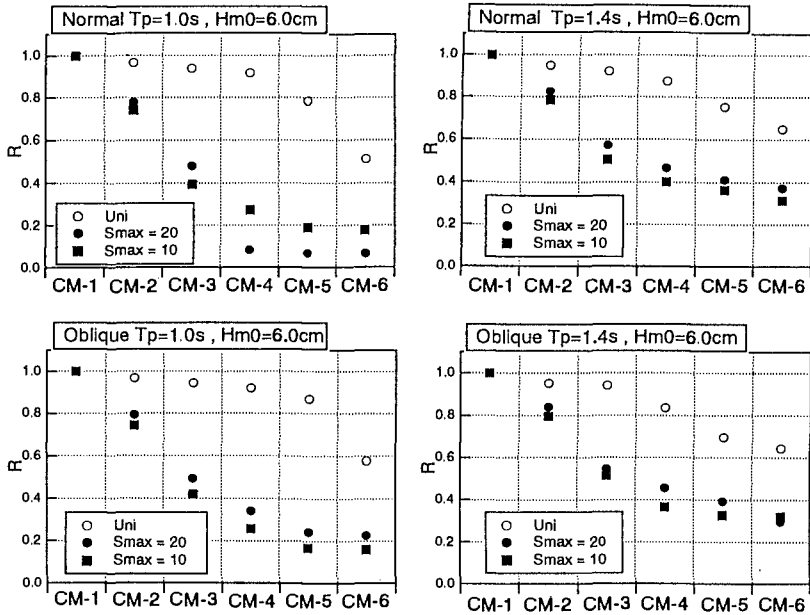

Figure 5 Spatial characteristics in correlation of velocities over the head.

In order to achieve a better understanding of these results, the directionality of velocity vectors on the heads was investigated. Figure 6 (a) and (b) show examples of the directionality of the highest 1/100 of the velocity vectors evaluated from the time series data of U and V at CM-3 (Middle section) and CM-5 (Back section) under 2D and 3D waves, respectively. Especially in the back head section, velocity vectors ($\theta < 0$) under 2D waves wrap around there. Conversely, in the case of 3D waves, the velocity vectors ($\theta > 0$) towards the down-slop of the head appear to be remarkable. The reason may be explained by the influence of the reflection of oblique waves directly attacking the front and middle head sections due to the directional spread in multidirectional waves. From these measurements, it is pointed out that in stability design for the heads, waves attacking directly the front and middle heads in 3D seas cannot be negligible.

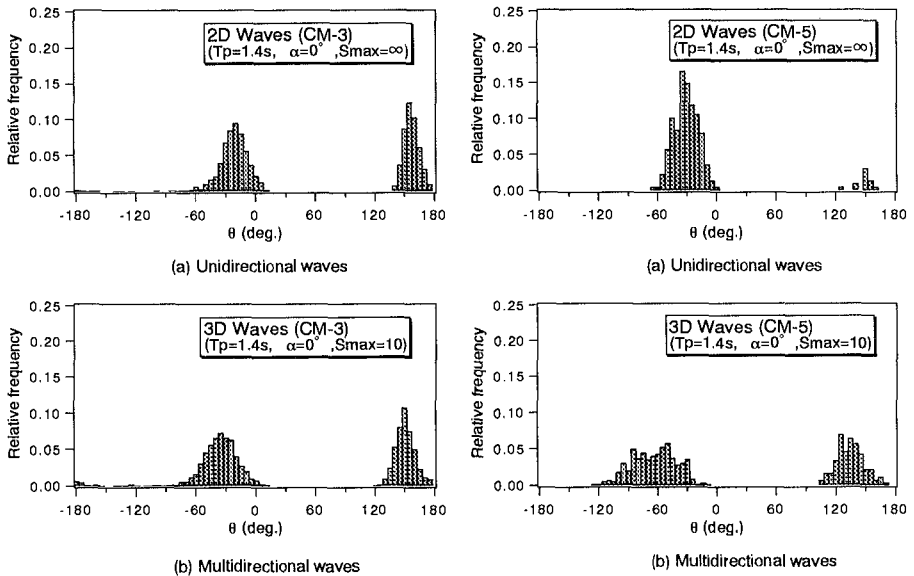

Figure 6 Directionality of velocities over the head.

Consideration on Stability of Armour Stones

The stability of armour stones on the heads is deeply concerned with the magnitudes and directions of the attacking velocity vectors, besides the slope of armour layer with respect to the velocity vectors (Jensen 1984). In this section, an equation about critical current velocity, when the armour stone movement in the heads is brought, is derived by taking account of tangential slope of the heads with respect to the direction of velocity vectors. The sensitive zones of initial damage in the heads will be evaluated by linking this stability formula for armour stones with the measurements of velocity components.

Critical velocity for stability of armour stones

The armour sphere (A) is placed on the head with the horizontal angle β for the velocity vector v_r with horizontal angle θ , as shown in Figure 7. By assuming the shape of the head as a circular cone, the curve of intersection between the vertical plane and the cone becomes a hyperbola. In this study, the only drag force was considered as hydrodynamic force. Then, the equilibrium equation between the armour weight and the drag force can be derived by balancing the moment about point O in this figure:

Figure 7 Attacking velocity and hydrodynamics force on armour stone.

$$\left(1 - \frac{\rho}{\rho_s}\right) W \left[\cos a_t + f \sin a_u \left\{ 1 + \cos(a_t - a_u) \right\} \right] = F \left(\sin a_t + \frac{b}{r} \right) \quad (1)$$

where W and r are weight and diameter of armour stone, ρ_s and ρ are unit weight of stone and water, F is drag force, f is friction coefficient between stones. The parameters a_u and a_t in Eq.(1) are respectively the angle of elevation of armour sphere (A) from (C), and (B) from (A) as shown in Figure 7. The drag force is described by the following formula:

$$F = m' \rho \pi r^2 v_r^2 \quad (2)$$

where m' is drag coefficient of armour stone, v_r is magnitude of attacking velocity vector. The velocity can be expressed by substituting Eq.(2) into Eq.(1) as:

$$\frac{v_r^2}{gr} = \frac{\left(1 - \frac{\rho}{\rho_s}\right) \left[\cos a_t + f \sin a_u \left\{ 1 + \cos(a_t - a_u) \right\} \right]}{\frac{3}{4} m' \frac{\rho}{\rho_s} \left(\sin a_t + \frac{b}{r} \right)} \quad (3)$$

where g is gravitational acceleration. In Eq.(3), f , m' , r and b are unknown parameters, a_u and a_t can be derived from tangential slope of the head with respect to the velocity vector as the following.

The cone is mathematically expressed by following formula in X-Y coordinate system shown in Figure 7:

$$Z = a - \frac{1}{2} \sqrt{X^2 + Y^2} \quad (4)$$

where a is the height of the cone, Z is distance from bottom. The coordinate (X, Y) of center of armour sphere (A) becomes $(R \cos(\beta - \theta), R \sin(\beta - \theta))$ in X-Y coordinate system. The tangential slope of the heads with respect to the velocity vector can be derived by partially differentiating Eq.(4) with respect to X , and inserting the (X, Y) of the point A:

$$\text{Tangential slope} = -\frac{1}{2} \cos(\beta - \theta) \tag{5}$$

Assuming that a_t is equal to a_u for simplicity in this study, they are given as:

$$a_t = a_u = \tan^{-1} \left\{ \frac{1}{2} \cos(\beta - \theta) \right\} \tag{6}$$

Finally, the critical velocity, v_{rc} , for armour stone movement in the heads is expressed by substituting Eq.(6) for a_t and a_u into Eq.(3):

$$\frac{v_{rc}^2}{gr} = \frac{\left(1 - \frac{\rho}{\rho_s}\right) \{1 + f \cos(\beta - \theta)\}}{\frac{3}{4} m' \left(\frac{\rho}{\rho_s}\right) \left[\frac{\cos(\beta - \theta)}{2} + \frac{b}{r} \sqrt{1 + \left\{ \frac{\cos(\beta - \theta)}{2} \right\}^2} \right]} \tag{7}$$

When the tangential slope with respect to attacking velocity vector becomes positive, in Eq.(7), the plus sign before the friction coefficient, f , is replaced by the minus sign. The unknown parameters m' , b and f in Eq.(7) were considered as $m'=1$, $b=0.5r$ and $f=0.4$, for simplicity in this paper.

Figure 8 Measuring points of velocity components over the head.

Influence of wave directionality on sensitive zone for initial damage

In this section, in order to investigate the influence of wave directionality on the stability of breakwater heads, the spatial occurrence frequencies for armour stone movement in the head sections were estimated by linking Eq.(7) and the velocity vectors which were newly measured at 76 points over the head shown in Figure 8.

Figure 9(a) and 9(b) show the spatial distribution of calculated occurrence frequencies for armour stone movement in the head under conditions of the normal 3D waves and 2D waves with $T_p=1.4s$ and $H_{m0}=6cm$ respectively, in which θ_p is the angle from the front head and R is the distance in the radial direction from the center of head as shown in Figure 8. In these figures, contour lines of relative occurrence frequencies which are normalized with respect to the total number of velocities measured for 20 minutes are indicated with interval every 0.002.

(a) Multidirectional waves ($S_{max} = 10$)

(b) Unidirectional waves ($S_{max} = \infty$)

Figure 9 Spatial distribution of occurrence frequencies for armour stone movement.

In order to investigate the reliability of those calculated results, the initial damage tests of armour stones in the head sections were carried out under the same incident wave conditions as those in the velocity measuring tests. The resulting initial damage zones in the head under 3D and 2D waves attack are shown in Figure 10(a) and 10(b), respectively. In these figures, the hatched parts mean that the second armour layer is clearly exposed due to the displacement of the first armour layer. By comparing these initial damage patterns with the spatial distributions of occurrence frequencies for armour stone movement shown in Figure 9, it can be seen that the results of the calculations evaluating the locations of the initial damage are fairly close to the experimental locations.

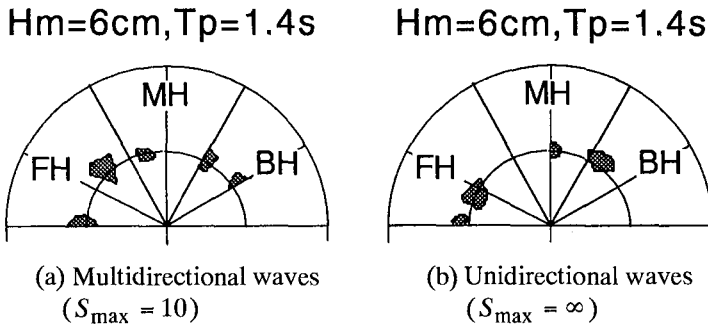

Figure 10 Initial damage zones in the head.

It can be found from Figure 9 that the sensitive zones for armour stone movement in the head sections are appeared at three locations; the front, middle and back head section respectively. Although there is not so much difference in these locations under 3D and 2D waves, there is obvious difference between the values of both occurrence frequencies, that is, in the case of the unidirectional waves, the back head section is more sensitive part for armour stone movement. Under unidirectional waves attack, it could be observed in the damage tests that the damage in the back head section was caused to plunge of the strong current with the high velocities generated by refraction, shoaling and diffraction processes. On the other hand, under multidirectional waves attack, the front and middle section are more sensitive part for the initial damage, because of the oblique waves attacking directly these sections due to the directional spread associated with the multidirectional seas. This consideration may be supported, since in the case of the multidirectional waves of Figure 6(b), the direction ($\theta > 0$) of velocity vectors outwards from the armour layer in the back head section is remarkably recognized in comparison with those under unidirectional waves.

Under oblique incidence, the multidirectional waves resulted in larger occurrence frequencies in the three sensitive zones (FH, MH and BH) for armour

stone movement than those under unidirectional waves. This is caused by the waves attacking directly the back head section due to the oblique incidence. When T_p was equal to 1.0s, the difference in calculated occurrence frequencies for armour movement in the head sections between uni and multidirectional waves was relatively small.

Conclusion

In this study, the characteristics of velocity field over the head under 2D and 3D waves were investigated. The V velocity component under multidirectional waves was larger than those under unidirectional waves. A noteworthy finding was that those on the back head section under 3D waves were larger by nearly 1.2 to 1.3 times the values measured under 2D waves, and that the direction of velocity vectors downing slope in the back section under 3D waves were remarkably recognized.

The presented equation of the critical velocity for armour stone movement in the heads could satisfactorily explain the initial damage zones in the damage tests. The front and middle head section were more sensitive zone for the initial damage under multidirectional waves attack. This result provided a better insight into previous study.

Further the unknown parameter in the presented equation will be investigated by physical experiments or theoretical techniques, the stability of breakwater heads will be evaluated by linking the equation of the critical velocity for armour stone movement with a numerical analysis of wave kinematics over the heads.

CHAPTER 139

WAVE CLIMATE SIMULATION AND BREAKWATER STABILITY

Josep R. Medina¹

Abstract

The nonstationarity of the sea waves is usually significant for periods longer than 3 hours (1,000 waves) with a correlation coefficient $r_{HH}(3)$ below 95% on most coasts of the world. Therefore, the actual engineering problem is to define an appropriate armor damage model applicable for nonstationary processes and not only for stationary sea states with a given storm duration. In deep water, five conditions are identified for any rational armor damage model to properly take into consideration the storm duration. A new exponential model applied on individual waves is shown to accomplish the five necessary conditions identified, and is compared with the Teisson's and Vidal's models based on totally different assumptions, but accomplishing most of the conditions. The three models provide similar results for a wide range of values if the parameters are $n_{63\%}=30$ and $N_w=50$ for the exponential and Vidal's models respectively. An example of the application of the exponential model to nonstationary processes is given, applying the new method to the case of the partial failure of the Zierbana breakwater (Port of Bilbao, Spain) under construction in February 1996.

Introduction

The duration of the storm and the wave groupiness are design factors not explicitly addressed by the Hudson formula. The storm duration obviously increases the expected damage on the armor layer because it increases both the number and the size of the individual waves above the corresponding damage threshold level. On the other hand, some characteristics of wave groups are related to the variability of variance and storm duration. A number of models and stability formulae considering storm duration have been

1) Professor, Departamento de Transportes, Univ. Politécnic de Valencia, Camino de Vera s/n, 46022 Valencia, SPAIN. // E-mail: jrmedina@tra.upv.es

developed during the last decade, introducing a variety of empirical relations based on different interpretations of test results up to 16,000 waves. The relationships between wave groupiness and extreme waves was considered by Vidal et al.(1995) to introduce a new discrete wave parameter to characterize design storms, instead of wave spectrum and storm duration. However, the problem of defining an appropriate and simple method to take into account storm duration and stochastic variability, is not solved.

The stationarity of the process is a basic assumption of most methods for analyzing breakwater stability; however, although the random sea waves were stationary, the significant wave height shows a natural variability that increases when spectral peakedness increases and record length decreases. Therefore, a larger storm duration increases the expected armor damage. Moreover, it is obvious that sea waves are never stationary and stationarity only should be considered a reasonable approximation for short periods of time. When long storm durations are considered for designing ($N > 1,000$ waves), the influence of nonstationarity on sea waves should be taken into consideration.

This paper compares first some of the most common methods and formulas proposed to analyze the influence of storm duration on the estimation of the armor damage. Secondly, the influence of the intrinsic variability of variance of the stationary processes related to wave groups on the expected armor damage is evaluated. Thirdly, the wave climate simulators and the need of multivariable stochastic models to describe the wave climate are justified. Fourthly, the necessary conditions are given to build up rational armor damage models for nonstationary processes. Fifthly, a new exponential model on individual waves are described and compared to the Teisson's and Vidal's models. Finally, an example of application is given to the case of the partial damages occurred at the Zierbana breakwater (Port of Bilbao, Spain) under construction during February 1996.

Armor Damage as Function of Storm Duration

Using SPM(1984) as the basic methodology for designing rubblemound breakwaters, the expected armor damage would not be dependent of the storm duration. However, it is obvious that given a design storm, the armor damage increases if the storm duration increases. There are significant discrepancies among different authors to quantify the relationship D versus N . Taking into consideration a reference storm duration of 1,000 waves, Fig. 1 shows the relative damage estimated by the models proposed by SPM(1984), Van der Meer(1988), Medina and McDougal(1990), Teisson(1990), Smith et al.(1992), and Vidal et al.(1995). Vidal's model has been applied considering a Rayleigh wave height distribution; therefore, the model may be considered an upper limit of the armor damage as function of the number of waves of a given sea state. The models compared in Fig. 1 have different variables and assumptions; the relative armor damages, $D(N)/D(1000)$, have been calculated referring the damage estimated by each model to the damage estimation for 1,000 waves in deep water conditions.

Figure 1.- Armor Damage as Function of Storm Duration.

Variability of Variance

The stationarity of the process is a basic assumption of most methods for analyzing breakwater stability; however, although the random sea waves were stationary, the significant wave height shows a natural variability that increases when spectral peakedness increases and record length decreases. Therefore, the storm duration affects not only the expected armor damage but also the variability. According to Medina and Hudspeth(1987), the coefficient of variation of H_{m0} is given by

$$CV(H_{m0}) \approx \sqrt{\frac{Q_e}{8 N}} \tag{1}$$

in which Q_e is the spectral peakedness parameter given by

$$Q_e = \frac{2m_1}{m_0^3} \int_{f_{min}}^{f_{max}} S_n^2(f) df \tag{2}$$

in which $S_n(f)$ is the variance spectrum, and m_0 and m_1 are the zeroeth and first spectral moments respectively. Assuming a perfect stationarity of the process, the variable H_{10} of finite records of 1,000 waves, $\{H_{10}\}_{1000}$, is a Gaussian random variable; therefore, the maximum $\{H_{10}\}_{1000}$ increases when the storm duration increases so do the corresponding armor damage (see Medina et al.,

1994) according to

$$\frac{H_{10}}{H_d} = \left[\frac{D}{1.6} \right]^{\frac{1}{5}} \quad (3)$$

in which $H_{10} = 1.27 H_{m0} > H_d$, H_d is the design wave height, and D is the armor damage. Eq. 3 fits the failure data given by the SPM(1984) and may be considered a reasonable good approximation for estimating damages of tests with wave runs around 1,000 waves. For very long wave runs, it may be reasonable to select the highest $\{H_{10}\}_{1000}$ to estimate the damage according to Eq. 3.

Fig. 2 shows the relative damage corresponding to the highest $\{H_{10}\}_{1000}$ when the storm duration increases up to $N=16,000$ waves; the values of the spectral peakedness parameter $Q_e = 2.3, 4.4,$ and 6.2 correspond to the JONSWAP spectral shapes $\gamma = 1, 5,$ and 10 and are related to different wave grouping characteristics (see Medina and Hudspeth, 1990). The variability of variance increases significantly the expected damage, but far below that observed in Fig. 1.

Figure 2.- Effect of Variability of Variance on Expected Armor Damage.

WAVE CLIMATE SIMULATION

The quantitative estimation of storm-induced beach change, as function of the time-dependent forcing conditions, has proved to be a powerful technique that may be applied in project designing of coastal structures. The basic input of the numerical models for simulating beach profile changes are the evolution in time of the wave climate variables. By analogy, it is reasonable to consider that reliable models for quantitative estimation of armor damage as function of the time-dependent forcing conditions will be developed in the near future. In this scenario, new wave climate models will be necessary to provide the appropriate input variables as do the wave climate simulators.

Fig. 3 shows a typical wave climate simulation corresponding to the first hours of the year on the coast of Oregon, according to Medina et al.(1991). The nonstationarity is significant for periods as short as 3 hours ($N < 1,000$ waves). The correlation coefficient of Oregon, $r_{HH}(3) = [r_{HH}(6)]^{1/2} = +0.92$, is similar to the $[r_{HH}(6)]^{1/2}$ given by Rossouw(1988) for the South African coast, slightly lower than the $r_{HH}(3) = +0.94$ given by Bettencourt et al.(1995) for the coast of Portugal, but higher than the $r_{HH}(3) = +0.89$ calculated for the coast of Valencia with shorter fetchs in the Western Mediterranean. Therefore, the actual problem is not to estimate the armor damage corresponding to a given design storm, $D[H_{m0}, T_{01}, N]$, but to estimate the evolution in time of damage for nonstationary processes, $D[\{H_{m0}, T_{01}\}(t)]$.

Figure 3.- Hourly Simulation of {Hs,Ts} Corresponding to January (Oregon)

Armor Damage Models for Nonstationary Processes

The armor damage models compared in Fig. 1 are based on different assumptions, some of them inappropriate for nonstationary processes. The design method proposed by SPM(1984) is based on a wide range of laboratory tests only with regular waves; the extrapolation to random waves has been changing in time with $H_{D=0}=H_s$, proposed by SPM(1975), and $H_{D=0}=H_{10}$ proposed ten years later by SPM(1984). In deep water conditions, the storm duration obviously affects the armor damage, because changes both the expected largest wave and the number of waves above any threshold level; therefore, armor damage must increase when storm duration increases, and no fixed equivalence independent of duration exists between regular waves and random waves.

The models proposed by Van der Meer(1988) and Smith et al.(1992) are based on laboratory tests only with random waves; both have an equilibrium limit for the armor damage under random wave attack in stationary conditions. However, armor damage must increase when storm duration increases for the reasons given above; therefore, no equilibrium limit is acceptable for random waves in deep water conditions. The empirical model of Medina and McDougal(1990) based on the Van der Meer's results avoid this problem but is difficult to be applied to nonstationary processes.

The method proposed by Teisson(1990), based on the test results with random waves given by Lepetit and Feuillet(1979) is directly applicable to nonstationary processes. The design wave height, H_D , producing similar damages with regular waves is

$$H_D = 1.18 H_{1/3} t^{0.085} \quad (4)$$

in which H_D and $H_{1/3}$ are given in meters and t in hours. For rubblemound breakwaters and nonstationary process the damage is calculated according to:

$$D(t) = 0.706 \left(\sum [H_{1/3}(\Delta t)]^{10.64} \Delta t \right)^{0.37} ; t = \sum \Delta t \quad (5)$$

in which Δt is small enough to admit the nonstationary process correctly composed by a succession of short stationary sea states characterized by $H_{1/3}$.

Vidal et al.(1995) proposed the use of the average height of the $N_w=100$ largest waves in a sea state, as the characteristic wave height which take into consideration both the intensity and duration of the sea state. Although these authors indicated that the most suitable value of N_w is still a subject of continuing research, their method may easily be applied to nonstationary processes. The armor damage would then be related to the average of the highest N_w waves in the storm, whatever was the evolution of the significant wave height in time during the storm.

Any rational model to estimate the evolution in time of the armor damage of rubblemound breakwaters in deep water conditions should fit reasonably well the existing test results with regular and random waves. Therefore, the following necessary conditions for acceptability of an armor damage model applicable to nonstationary processes are:

- (1) Under regular wave attack, the maximum damage must be limited by the existence of an equilibrium profile, $D(H,T,N) < D_0(H,T)$.
- (2) The maximum damage under regular waves may be approximated (if wave periods are not considered) by Eq. 3.
- (3) There is no equilibrium profile under random wave attack in deep waters; the damage must grow with the storm duration without any limit.
- (4) The armor damage should be insensitive to the waves below some threshold level related to the design wave height, $H_i < H_d$; only the large waves are relevant to the armor damage.
- (5) The characteristics of a few highest waves should have a significant effect on the armor damage.
- (6) The method must be applicable to nonstationary processes where the characteristics of the sea states are continuously changing in time.

Only Teisson's model, based on hypothesis of equivalence for damages, and Vidal's model, based on a parameter $N_w=100$ not well justified, may be applied to nonstationary processes and accomplish most of the necessary conditions given above. Laboratory test are rarely conducted considering nonstationarity; furthermore, long runs in wave flumes have a low reliability because of the difficulty in controlling the stochastic structure of random waves for a long time. As a result, the overall quality of data supporting the models compared in Fig. 1 has to be considered low, because observations are partially contaminated by assumptions not compatible with the necessary conditions given above.

Exponential Model on Individual Waves

A simple method that accomplish the six conditions given above is the exponential model applied on individual waves. The exponential model is normally used for describing events occurring at random time with a constant future lifetime, and in life-testing applications. The evolution of damage of the armor layer of a rubblemound breakwater in deep waters shows some of the characteristics suitable for the exponential model.

The exponential model for regular waves may be described by

$$D(H,T,N) = D_0(H,T) [1 - \exp(-kN)] \quad ; \quad k = \frac{1}{n_{63\%}} \quad (6)$$

in which $n_{63\%}$ is the number of waves that causes 63% of damage in a regular wave attack. Fig. 4 shows the evolution of damage in time, under regular waves, corresponding to the exponential model.

Figure 4.- Parameter n63% Controlling the Evolution of Damage in Time.

The exponential model for random waves requires first the identification of the individual waves, $\{H_i, T_i\}$, in a continuous record. In this paper, the orbital criterion proposed by Giménez et al.(1994) has been selected. The model could be extended to both wave heights and periods; a simplified version considering only wave heights may be described by

$$D_i = D_{i-1} + \left(\frac{1}{n63\%} \right) [D_0(H_i) - D_{i-1}] \quad \text{if } D_0(H_i) > D_{i-1} \quad (7a)$$

$$D_i = D_{i-1} \quad \text{if } D_0(H_i) < D_{i-1} \quad \text{or} \quad H_i < H_{min} \quad (7b)$$

in which $D_0(H_i) = 1.6 (H_i/H_d)^5$. Eqs.7 are the discrete derivative version of Eq. 6, if wave periods are not included in the armor damage model. The different armor damage models were compared on the basis of numerical simulations and the orbital criterion shown by Giménez et al.(1994). Fig. 5 shows the evolution of damage corresponding to the exponential model with n63% ranging from 10 to 40, compared to the estimations given by the models of Teisson(1990) and Smith et al.(1992). Teisson's model gives similar results to the exponential model with n63%=30; on the contrary, Smith's model shows radically different results. On the other hand, Fig. 6 compares the exponential model and the model of Vidal et al.(1995).

Figure 5.- Damage Estimations Compared to Teisson's and Smith's Models.

Figure 6.- Damage Estimations Compared to Vidal's Model.

The results provided by the exponential and Vidal's model for $N > 5,000$ waves suggest that only the largest waves in a record are relevant to estimate armor damages. Fig.7 shows the sensitivity of the armor damage estimated by the exponential model to the threshold level H_{min} of Eq. 7b. The significance of

damages caused by the lowest waves ($H_i < H_{min}$) in a storm decreases when the storm duration increases. Considering the exponential model with $n_{63\%}=30$, 95% of damage are produced by less than 1% of the highest waves in a random wave train of 10,000 waves.

Figure 7.- Sensitivity of the Exponential Model to H_{min}/H_s .

Example: Partial Damages on the Zierbana Breakwater in the Port of Bilbao (Spain) under Construction During February 1996.

The development of the Port of Bilbao in the outer Abra is described by Losada et al.(1996). The Zierbana Breakwater under construction in 1996 was partially damaged in February 1996. The part of the breakwater with the armor completed with the 100 tn concrete blocks was not damaged; on the contrary, the advanced part of the breakwater protected only with the secondary layer of 8 tn concrete blocks collapsed. Additionally, the crane used for installing the armor units was lost in the storm.

Uzcanga and González(1992) describe the technical and economic design criteria and laboratory tests conducted to justify the breakwater design under construction. Taking into consideration the technical information given by the above mentioned authors, the data provided by the waverider buoy operating during the peak of the storm (7-8 February 1996), and the observation of armor damages in different parts of the breakwater, the Zierbana case has been selected to show the possible applications of the exponential model to the analysis of the evolution of the armor damage.

Fig. 8 shows the evolution in time of the H_{m0} and T_{01} measured by the waverider buoy off Bilbao during the damaging storm in February 1996. The wave measurements were taken at one hour interval (about 300 waves/hour), the peak of the storm had about 1,000 waves with $H_{m0} \approx 8$ meters and $T_{01} \approx 12$ sec.; according to Fig. 7, more than 95% of damage is caused by $H_i > 1.2 H_{m0} \approx 9.6$ meters. The maximum individual wave height is expected to be $(H_{max}) \approx 1.7 H_{m0}$; therefore, the minimum H_{m0} significant for estimating the armor damage is $(H_{m0})_{min} \approx 9.6/1.7 = 5.6$ meters. Therefore, the damages are expected to be suffered between the 15:00 p.m. (7 Feb 96) and 7:00 a.m. (8 Feb 96) with a probable maximum wave height of 15 meters.

Figure 8.- Evolution of H_{m0} and T_{01} (7-8 February 1996).

Considering the evolution in time of H_{m0} and T_{01} given in Fig. 8, and the numerical simulations described by Giménez et al.(1994) used in Figs. 5 and 6, it is possible to estimate the evolution in time of the damage on the armor layer applying the exponential model described previously. The technical information provided by Uzcanga en González(1992) are used to link the waverider measurements and structural response to the wave characteristics. Fig. 9 shows the estimations of the armor damage evolution in time considering the exponential model on individual waves with $n_{63\%}=30$, and three different armor blocks ($W= 8$ tn, 16 tn and 100 tn). The model predicts only minor damages on the armor of 100 tn blocks, and total destruction of the armor of 8 tn, in agreement to what was observed in the Zierbana Breakwater. According to the exponential model, a secondary layer of more than 16 tn was

necessary to resist the wave storm measured during February 1996.

Figure 9.- Estimation of the Evolution in Time of the Armor Damage.

The damages caused in the Zierbana Breakwater suggest the need of re-analyzing the risk associated with the construction during winter months. Considering the measurements given by the Bilbao waverider buoy before 1991, ROM 0.3-91(1992) provides an estimation of $R=7$ years ($R=3$ years is the 90% confidence band limit) for a wave storm of $H_s=8$ meters. However, it is possible to apply the method given by Rossouw and Medina(1996) to estimate the risk associated with each month independently. Taking into consideration the wave measurements before 1994, and based only on the monthly average and standard deviations, it is possible to estimate the intensity of the storm having a 10% and 2% annual risk of being overpassed during a specific month. Fig. 10 describes the monthly average, $E[H_{m0}]$, the monthly standard deviation, $std[H_{m0}]$, and the H_{m0} (storm duration: $Dt = 3$ hours) having 10% and 2% annual risk ($R=10$ and $R=50$) of being overpassed during each month.

According to Fig. 10, during the months of December and February it is probable to suffer a wave storm of $H_{m0} \approx 8$ meters ($1/R \approx 10\%$ each month) while there is a low additional risk during January, March, April, October, and November ($1/R \approx 2\%$ each month). The total annual risk of the event ($H_{m0}=8$ meters, $Dt = 3$ hours) is approximately 30%; therefore, the damaging storm measured by the waverider buoy off Bilbao shown in Fig. 8 ($H_{m0} \approx 8$ meters, $Dt \approx 3$ hours) was likely to happen during the four year construction period of the Zierbana Breakwater. Furthermore, February is the most risky month to work

with partially protected breakwater during construction. The failure of the forecasting system used in Bilbao during construction may be responsible for losing the main crane, able to place the 100 tn blocks at 50 meters; however, from the climatic point of view, it is difficult to justify the work in February.

Figure 10.- Characteristics of the Wave Climate in the Coast of Bilbao.

CONCLUSIONS

New models for describing the armor damage evolution in time have to be developed. Existing $D(N)$ models are not appropriate to be applied for nonstationary stochastic models which are the most adequate for modelling real waves. The models must accomplish four basic conditions: (1)unlimited damage if unlimited duration, (2)unsensitive to characteristics of waves below a threshold level, (3)higher relative effect associated with the largest waves, and (4)simple to be applied to nonstationary stochastic models.

CHAPTER 140

INCIPIENT MOTION OF BREAKWATER ARMOR UNITS

J. A. Melby¹, M. ASCE, and N. Kobayashi², M. ASCE

ABSTRACT

This paper describes observations made of incipient motion on both stone and sphere armor layers. Velocity measurements were made during these experiments both inside and just outside the armor layer. It is shown that the vertical convective acceleration across the armor layer is proportional to the square of the vertical velocity. An incipient lifting motion criterion is derived based on Morison forcing for the dominant mode of motion: vertical lift under the steep breaking-wave face. The experimental observations and measurements are used to validate the incipient motion criterion for breakwater armor.

1 INTRODUCTION

Extensive research on breakwater armor stability has produced many empirical stability models. These models predict minor damage reasonably well. Many investigations have also quantified the wave forces on undamaged armor; and these force measurements have been used to compute more explicit stability criteria. But few studies have been done to observe and quantify the wave and structure conditions under which armor just begins to move, i.e. incipient armor motion.

The Iribarren (1938), Hudson (1958), and other empirical armor stability models are based on a free body analysis of an armor unit undergoing forcing due to breaking waves. Early stability models assumed the principle wave force was 1) due to down-or up-rush on an unsheltered and unrestrained unit, 2) drag dominance, and 3) that the drag force would be critical if the maximum horizontal fluid velocity was used, which was considered to be proportional to the incident wave celerity. But for an intact structure and prior to initiation of incipient motion, the armor units are typically partially hidden and restrained from up or down slope movement; so lift, inertia, and convection across the armor layer must be considered. Moreover, Sawaragi et. al. (1982) showed that the maximum fluid velocity on a rubble mound was not necessarily proportional to the wave celerity. Sigurdsson (1962) made force measurements on sphere armor at extremely steep slopes with an impermeable underlayer and with no underlayer and derived incipient equations of motion; but concluded by stating that the

² Professor, Center for Applied Coastal Research, University of Delaware, Newark, Delaware, 19716

dominant mechanism of initiation of armor motion was still unknown and required further investigation. Although many authors have discussed wave kinematics and dynamics on armor layers and the resulting forces, including Mizutani et. al (1992), Torum and van Gent (1992), Torum (1994), and Cornett and Mansard (1994), there have been few observations of incipient movement of armor units discussed in the literature. As such, the relationships between incipient motion, wave kinematics, and forces on armor units is still unknown.

Kobayashi et al. (1990) presented a numerical model for predicting the displacement of armor on a traditional rubble mound. The shallow water wave model interacted with a permeable flow model and hydrodynamic drag, inertia, and lift forces were computed using a Morison type of formulation (Morison et al. 1950). The model was limited to forces parallel to the structure because the hydrodynamics were one-dimensional vertically averaged. Torum and van Gent (1992) discussed a similar model and compared it to velocity measurements above a berm breakwater. Torum (1994) discussed the measurements further. Although two dimensional velocities were measured, vertical flow in the breaking wave was not modeled numerically. In addition, Torum noted that the inertial force was not well defined by the traditional inertia term of the Morison equation. Cornett and Mansard (1994) described an experiment where forces were measured on a panel of stones. This approach was unique and yielded insight into the average frictional force on sections of the armor layer. The results were used to develop a stability model for armor sliding.

The present article discusses a series of physical model experiments to identify and develop predictive models for breakwater armor incipient motion and to relate this motion to existing empirical stability relationships. The experiments were done in wave flumes at the Waterways Experiment Station in Vicksburg, Mississippi. The first experiment consisted of measuring wave-induced fluid velocities on and within the armor layer and runup/down. In addition, free surface oscillations were measured while observing armor motion on stone and Core-Loc armor. The observations from this early study led to an incipient motion experiment using a fixed-sphere armor layer with several loose spheres placed at various depths within the armor layer. A dominant incipient armor motion mode and predictive stability equation were verified.

EXPERIMENTAL SETUP

The initial experiments were conducted to determine the nature of armor incipient motion and surrounding flow. The instrumentation included a laser Doppler velocimeter (LDV), high resolution video, and runup and vertical free-surface-piercing gages near and within the armor layer. The experiments discussed herein were all carried out using regular monochromatic waves. The analysis techniques were done using short segments of between five and ten uniform waves to develop clear relationships between wave parameters and armor motion.

The primary study was done in a 46m long by 0.46m wide by 1m deep flume, with an offshore slope of 1V:30H. A conventional rubble mound cross section was constructed with various seaward slopes and armor types (Figure 1). Table 1 lists the different test plans. In this paper, only the sphere and stone armor plans will be discussed (Test Plans 3 and 4). Velocity measurements, sampled at 100 Hz, were made

throughout the water column from the toe to two armor dimensions above the still water level. The ranges of physical quantities and common dimensionless parameters for plans 3 and 4 are listed in Table 2.

Figure 1. Definition sketch for typical structure profile.

Table 1. Experimental Plans							
Plan	Armor Type	Armor Weight W, g	Nominal Armor Dia. $D_n = (V)^{1/3}$ cm	Structure Slope, cot θ	Off-shore Slope cot α	Runup down Meas.	Force Meas.
1	Core-Loc	220	4.6	1.33	100	no	no
2	Core-Loc	105	3.6	1.5	20	no	no
3	Stone	200	4.6	2.0	30	yes	no
4	Sphere	58	3.8	2.0	30	yes	no

Table 2. Ranges of Measured Physical Quantities and Common Dimensionless Parameters for Plans 3 and 4	
Parameter	Range
Wave height at toe, H_t	2.4 to 18 cm
Wave period, T	0.75 to 4.0 sec
Water depth at toe, d_t	15 to 24 cm
Wave steepness, $S_z = H_t / L_o$ L_o = deepwater wave length	0.007 to 0.1
Surf similarity parameter, $\xi = \tan \alpha / (H_t / L_o)^{1/2}$ $\tan \alpha = 1/30$ = beach slope	0.1 to 1.4
Surf similarity parameter, $\xi = \tan \theta / (H_t / L_o)^{1/2}$ $\tan \theta = 1/2$ = structure slope	1.5 to 21
Relative depth, d_t / L_o	0.009 to 0.28
Relative wave height, H_t / d_t	0.06 to 0.88

The LDV was a two-watt argon-ion two-component device assembled by the Dantec Corporation. The version used works in the back scatter mode using a non-intrusive probe which contains both the emission and receiving optics. The benefits of this device included nonintrusive measurements, small measurement volume, clean drop outs, high sampling rate, and no required calibration. The LDV is unique in that the probe can be pointed through the glass flume wall into the voids within the armor layer and allow measurements of the internal flow within the porous media. Many of the voids are more than a nominal armor diameter deep so the measurements can be made outside the flume wall boundary layer. One drawback to the LDV is it requires a full time operator with continuous attention to detail. Also, because of the small measurement volume, small changes in measurement location often yield large variations in measured velocities, especially near or within the breakwater armor layer. Therefore, the instrument requires many measurements to map the flow field. So data analysis requirements were substantial for this experiment.

The wave heights were determined using free surface measurements from a capacitance-type gage positioned at the location of the structure toe with no structure in place. Synthetic rubberized horse-hair mats were placed landward of the structure location to absorb the waves. The sampling rate for free surface measurements was 20 hz. The zero-downcrossing wave height was computed as the average height from a burst of approximately ten regular waves.

INCIPIENT MOTION OBSERVATIONS

Several dominant incipient motion modes were identified during the stone stability experiment in Plan 3, Table 1. The following descriptions pertain to initial armor

motion on an intact, as-built structure. Rolling was the only mode of motion for stones on the toe. Although both onshore and offshore motion was observed, the toe units always moved out of the layer in the onshore direction. For upslope armor, armor near the still water level was more likely to displace than armor in other areas. This appeared to be due to the fact that the armor was loosened in this area due to high velocities in the breaking wave jet. Once loosened, the motion would depend on the armor shape and its position. If the armor shape was flat, then the armor unit would flop back and forth until it rolled out of the armor layer, generally rolling upslope during uprush. If the armor shape was rounded, which was normally the case, the armor units would jump vertically under the steep wave face if the wave was severely plunging or collapsing. If the wave was surging, then loose units would only be displaced if they were exposed. There did not appear to be sufficient lift in downrush or uprush flows along the armor layer to displace the stones unless they were odd shaped (flat). The only displacement mechanism observed for rounded stones sufficiently hidden in the armor layer was uplift under the steep wave face.

These observations indicated that a fluid velocity or acceleration component in the vertical direction is normally required to initiate armor motion for hidden armor units. Additionally, this early qualitative study indicated that, for a wave of given energy, incipient motion was primarily influenced by wave shape, stone position, stone exposure, and stone looseness.

EXPERIMENTAL MEASUREMENTS

Throughout the experiments, vertical and horizontal wave velocities were measured in the vicinity of the armor layer. Figure 2 shows typical time series of the horizontal and vertical velocities on the structure. The sign convention was such that the horizontal velocity was positive seaward while the vertical velocity is positive upward. Note that the horizontal velocity amplitudes are very regular while the vertical velocity typically varies considerably. Figure 3 shows a velocity vector time series over one wave period, measured just above the armor layer one-third of the depth down from the still water level, and the wave profile at the point of maximum vertical velocity. The plot shows a large vertical velocity vector just below the steep wave front. Observed maximum stone movement for this wave profile position is also shown. Figure 4 shows an example of vertical velocities outside and inside the armor layer. The measurement locations for these time series are shown in Figure 5, where the structure slope is 1V:2H. Here it is clear that the velocities within the armor layer are highly irregular due to turbulence.

Figure 2. Velocity time series for one wave period, $H_t = 12\text{cm}$, $T = 1\text{ sec}$, $d_t = 24\text{ cm}$.

Figure 3. Velocity vector for one wave period for armor lifting.

Figure 4. Vertical velocity time series outside and inside the armor layer

Figure 5. Measurement locations for vertical velocities shown in Figure 4.

Figure 6 shows a typical plot of vertical velocity $v_{1/3}/(gH_t)^{1/2}$, measured just above the armor layer at various depths, versus the square root of wave steepness, where $v_{1/3}$ is the average of the highest one-third peak velocities, g the gravitational acceleration, H_t the toe wave height, structure slope = 1V:2H, and L_o the deep water wave length. For simplicity, v is used instead of $v_{1/3}$ in Figure 6 and hereafter. Relative laser depth, rd , is the ratio of the depth of the laser to the depth at the toe, measured from the still water level. As noted by Sawaragi et al. (1982), maximum non-dimensional velocities commonly occurred for collapsing to plunging breaking waves. The peak vertical velocities for given wave period decreased downward with increase of rd in this figure.

Figure 6. Maximum vertical velocity versus the square root of wave steepness for wave periods $T = 1$ and 2 s and relative depths $rd = 0.36, 0.5,$ and 0.7 .

INCIPIENT MOTION PREDICTION

The previous experimental results indicated that one of the dominant incipient motion modes was due to the vertical force occurring under the steep wave front. The balance of forces for vertical incipient armor motion with no external restraints yields the equality between the submerged armor weight and the vertical fluid force; $W' = F_v$. The vertical force at the steep wave front can be described by the Morison equation (Morison et al. 1950).

$$F_v = \frac{\rho}{2} A C_D v^2 + \rho V C_m \frac{dv}{dt} \quad (1)$$

where ρ = fluid density, A = cross sectional area of armor unit in direction of flow, C_D = drag coefficient, v = peak vertical velocity just above the armor layer as plotted in Figure 6, V = armor unit volume, C_m = inertia coefficient, and dv/dt = total fluid acceleration. The drag force can be expressed as a function of the armor nominal

diameter, D_n , by introducing an armor shape factor, K_A , as follows

$$A = K_A D_n^2 \tag{2}$$

The drag force in (1) is then given by

$$F_D = \rho D_n^2 C'_D v^2 ; \quad C'_D = \frac{K_A C_D}{2} \tag{3}$$

where the nominal diameter is defined as

$$D_n = V^{1/3} = \left(\frac{W}{\gamma_r} \right)^{1/3} \tag{4}$$

where W = armor weight, V = armor volume, and γ_r = armor specific weight.

At the point of maximum vertical fluid velocity, the local vertical fluid acceleration, $\partial v/\partial t$, and horizontal velocity, u , are negligible. As such, the total acceleration reduces to a convective term.

$$\left(\frac{dv}{dt} \right)_{\max} = \left(\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} \right)_{\max} \approx v \frac{\partial v}{\partial y} \tag{5}$$

where x = horizontal coordinate and y = vertical coordinate. If we assume the convective acceleration across the armor layer to vary linearly vertically, then the acceleration can be expressed as

$$\left(\frac{dv}{dt} \right)_{\max} \approx v \frac{\partial v}{\partial y} = K_c \frac{v^2}{D_n} \tag{6}$$

where K_c is an empirical coefficient on the order of unity. The maximum inertial fluid force in (1) can thus be reduced to

$$F_i = \rho D_n^2 C'_m v^2 \tag{7}$$

with

$$C'_m = K_c C_m \quad (8)$$

Substituting (3) and (7) into the stability criterion $W' = F_v$ with $W' = \rho g(S_r - 1)D_n^3$ yields a stability relation in form similar to Shields criterion for the initiation of motion of sediment particles

$$\frac{v_c^2}{D_n g(S_r - 1)} = (C'_D + C'_m)^{-1} \quad (9)$$

where S_r = armor specific gravity, g = acceleration of gravity, and v_c = critical vertical velocity at which armor just begins to lift. In terms of N_s = armor stability number, (9) becomes

$$N_s = \frac{H_c}{D_n(S_r - 1)} = \frac{gH_c}{v_c^2} (C'_D + C'_m)^{-1} \quad (10)$$

where H_c = critical wave height at toe. It is interesting to note that the stability number is primarily a function of the Froude number, $v_c / (gH_c)^{1/2}$. This formula ties the traditional stability relations to local vertical velocity measurements.

Based on results of detailed velocity measurements in the interior and just outside the armor layer, the vertical velocity gradient was found to be proportional to the ratio of the vertical velocity and the armor diameter, as assumed in (6). This is shown in Figure 7 for a typical case. The empirical convection coefficient is $K_c = 0.67$ for these tests.

The drag and inertia coefficients can be more accurately defined if we assume spherical armor. Based on previous studies of forces on armor by Mizutani et al. (1992) and Torum (1994), reasonable estimates for drag and inertia coefficients are $C_D = 0.8$ and $C_m = 0.4$ yielding

$$C'_D = \frac{K_A C_D}{2} \approx 0.5 \quad (K_A = 1.21) \quad (11)$$

$$C'_m = K_c C_m \approx 0.3 \quad (K_c = 0.67) \quad (12)$$

where $K_A = 1.21$ corresponds to a sphere. The critical vertical velocity, v_c , for the

incipient vertical armor movement reduces to

$$\frac{v_c^2}{D_n g(S_r - 1)} = 1.3 \tag{13}$$

where the critical vertical velocity, v_c , depends on the nominal diameter, D_n , and the specific gravity, S_r , only, for a loose armor unit.

Figure 7. Vertical variation of vertical velocity under steep wave front.

Plan 4 in Table 1 was designed to test the above criterion. For Plan 4, the armor layer was constructed using silicon rubber spheres which were glued together and attached to an inflexible yet porous metal mat. The metal mat was placed directly on the underlayer and fixed to the flume walls. Several loose concrete spheres were placed in the armor layer along a line from above the still water level down to the toe. Each two loose spheres were separated by two glued spheres so that there was no interaction between loose spheres. The sphere layer of Plan 4 was constructed to have the minimum porosity of 0.33.

For Plan 4, the loose spheres would not move under any conditions unless they were slightly raised in the armor layer. This was accomplished by placing a 0.5-cm-thick washer under each sphere. The primary effect of this was to raise the porosity surrounding the loose sphere slightly, providing a path for water motion under the sphere. The only motion observed for the raised loose spheres was vertical motion under the steep wave front, following a slightly elliptical path, and landing back in their hole after the wave front passed. For tests with vertical velocities corresponding to the critical value, the spheres were just lifting off. For the larger vertical velocities, the

spheres were lifting entirely out of their initial holes, but settling back into their holes. Spheres at a depth of one-third the toe depth were the most mobile while spheres at the still water level were somewhat less mobile. This movement corresponded to the variation of the vertical velocities in the water column as shown in Figure 6. Figure 8 shows the incipient motion criterion versus wave steepness for Plan 4 using a few representative points from each motion category. The dark horizontal line represents the theoretical incipient motion criteria while the velocity measurements are represented by the dark dots. Observed movement is noted for each data point. For the drag and inertia coefficients selected, the incipient motion criteria agrees quite well with the observed movement.

Figure 8. Incipient motion criterion versus wave steepness

CONCLUSIONS

Experiments on incipient motion of breakwater armor showed several modes of displacement. One dominant mode was due to vertical wave forces which are shown to occur at the point of maximum vertical velocity under the steep wave front. A simple relation was derived assuming a Morison-like wave force balanced by the armor unit submerged weight. The wave force model was composed of drag, due to the maximum vertical velocities, and inertia, due to the vertical convective accelerations. The maximum vertical convective acceleration is shown to be roughly linearly related to the square of the velocity, which puts the inertial force term into the same form as the drag term. The resulting incipient motion stability relation is similar in form to the Shields sediment motion criteria. Further, when expressed as a traditional stability number, incipient motion is shown to be a function of the Froude number, $v/(gH)^{1/2}$. The incipient motion criterion is shown to predict the incipient motion of spheres well for the conditions tested.

ACKNOWLEDGEMENT

This study was conducted and this article prepared with funding from the U.S. Army Engineer Coastal R&D Program. Permission to publish this article was granted by the Office, Chief of Engineers. Dr. Steven Hughes, U.S. Army Engineer Waterways Experiment Station, is acknowledged for his helpful suggestions regarding interpretation of data throughout the study.

CHAPTER 141

OVERTOPPING REDUCTION IN CROWNWALL DESIGN

José Luis Monsó ¹

Alfonso Vidoar ²

Cristina Cadevall, Cristina García ³

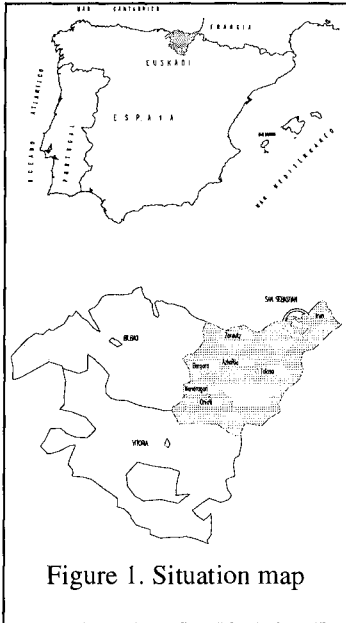

Figure 1. Situation map

1. ABSTRACT

This study for overtopping reduction in crownwall design presents several results of 2D (wave flume) and 3D (wave basin) tests on irregular wave overtopping of different configurations for breakwater sections were obtained by the Applied Hydrodynamics Institute (INHA) in order to improve the design of the small-craft harbour at San Sebastian in the North of Spain (fig.1).

San Sebastian is one of the most well-known and beautiful tourist cities in Europe and for that reason aesthetic as well as environmental aspects of construction had to be taken into account.

³ Research Engineers, Instituto de Hidrodinámica Aplicada (INHA), Parc Tecnològic del Vallès, 08290 Cerdanyola, Spain

2. INTRODUCTION

The San Sebastian harbour (fig.2) was designed by Europrincipia in 1995. The harbour would like to become a centre of attraction to citizens and tourists, not merely a berthing area for vessels. For this reason the creation of a new shopping and recreational area and urban integration with the city, which is extended to the end of the harbour by a promenade, are some of the issues that have to be dealt with.

Figure 2:Marina location

From an engineering stand point the most important issue is, however, the wave climate, which is very severe in that area. The design incident wave height is $H_s=10.5\text{m}$ at a depth of $h=-20\text{m}$ and the average wave period is $T_z=15\text{s}$. The tidal regime in this area is $\text{hw}l=+4.8\text{m}$ and $\text{lw}l=0\text{m}$. The water depth at the toe of the berm can reach -15m and therefore important non breaking waves can reach the structure. For this reason, and also because the visual impact of a very high crownwall to prevent overtopping would be of significant importance for the city, it was necessary to determine a freeboard height of the crownwall that agreed with both requirements.

Some strategies for improving the performance of the main breakwater of San Sebastian harbour were therefore tested.

The design of a recurved breakwater in plan view (Figure 3) resulted in a reduction of overtopping rates due to oblique wave attack as well as a reduction of wave induced forces in the crownwall. These results can be shown by comparing 2D tests (straight breakwater) and 3D tests (curved breakwater).

Figure 3: Final breakwater in plan view

3. PHYSICAL MODEL TESTS

The 3D model tests were conducted in a wave basin 28m long, 23m wide and 1.2 m high at scale 1/50 and the 2D model tests were performed at a scale of 1/30 in a wave flume with dimensions of 52m long, 1.8m wide and 2 m high.

In both facilities, tests of irregular waves with a Jonswap type spectrum were considered.

$$S_f = \alpha H_{1/3}^2 T_p^{-4} f^{-5} \exp[-1.25(T_p f)^{-4}] \gamma^{\exp[-(T_p f^{-1})^2 / 2\sigma^2]} \quad \text{with}$$

$$\alpha = \frac{0.0624}{0.230 + 0.0336\gamma - 0.185(1.9 + \gamma)^{-1}}$$

$$\sigma = \begin{cases} \sigma_a; f \leq f_p \\ \sigma_b; f \geq f_p \end{cases} \quad \sigma_a = 0.07 \quad \text{and} \quad \sigma_b = 0.09$$

$$\gamma = 1.9$$

The quantity f_p is the frequency at the spectral peak and T_p is the inverse of f_p

$$\text{with } T_z = 1.3T_p$$

The experiments were performed for 4 different water levels, and for 7 significant wave steps.

The section that was compared in 2D and 3D experiments is the one shown in fig.8. (fourth alternative) with a toe depth of 13m.

4. STRATEGIES TO REDUCE OVERTOPPING

The initial design (fig.4), almost a straight breakwater in plan view, was a stepped crownwall with height as reduced as possible in order to minimise visual impact. Rubble mound units were used instead of artificial blocks taking advantage of a nearby stone quarry which is able to provide parallelepipedic blocks of up to 70 Tn perfectly cut with explosives. The main features of this initial configuration are:

- Crownwall height : +14 m
- Weight of slope rubble mound units : 27 Tn
- Length of the berm: 45 m
- Depth of the berm : -5.5 m
- Weight of berm rubble mound units :17 Tn.

Figure 4: Initial configuration .Stepped crownwall

In order to analytically estimate the wave run-up and the overtopping rate several formulations were used. The initial configuration used the J.P. de Waal and J.W. van der Meer formula proposed in Coastal Engineering 1992. In this formula the expression that describes the average overtopping is an exponential function :

$$\frac{Q}{\sqrt{gH_s^3}} = 8 \cdot 10^{-5} \exp \left[3.1 \frac{Ru2\% - Rc}{H_s} \right]$$

where

$$\frac{Ru2\%}{H_s} = 1.5 \gamma_f \gamma_h \gamma_\beta \zeta_{p,eq} \quad \text{with a maximum of } 3.0 \gamma_f, \gamma_h, \gamma_\beta$$

The theoretical values obtained differed from the experimental ones. Some reasons for this can be : the stepped crownwall does not act like a rough slope and, moreover, the stepped crownwall design has a ramp effect, as was shown in the overtopping tests performed.

As soon as the experimental values did not reach the requirements, 4 strategies to reduce overtopping rates were evaluated:

- To raise the height of the berm
- Design a crownwall topped with a recurved wall
- Raise the freeboard of the crownwall
- Design a curved breakwater in plan view.

These strategies were implemented in 4 new design alternatives.

a) First alternative:

In this case, the strategy of raising the height of the berm up to the MWL has the effect of a reduction of the initial overtopping rate as can be seen in several experiments carried out recently by Van der Meer (1990).

Figure 5: First alternative. Stepped crownwall with fronting berm.

The average overtopping rates for the section described above were still unacceptable. The reasons for these high values of Q_r were the relatively low freeboard and the ramp effect induced by the stepped crownwall.

b) Second alternative:

The second design alternative (fig.6) combines three more strategies in order to improve the overtopping rates: raise the freeboard, construct a recurved crownwall and ,finally, design a curved breakwater in plan view.

Raising the freeboard of the crownwall has an immediate reductive effect as expected by theory. Considering the simplified theoretical model of Jensen and Juhl (1987) or Ahrens (1988), the overtopping rate Q is an exponential function of the dimensionless freeboard, $F' = F/H_s$, with F the freeboard of the structure and H_s the incident significant wave height. The limitation of this strategy is the visual impact of construction, which should be kept to a minimum.

The construction of a crownwall topped with a recurved wall has also a beneficial effect. Experimental tests showed that overtopping rates are considerably reduced due to the effectiveness of the recurved wall.

c) Third alternative:

The third design alternative (fig.7) consisted of reducing the long berm at MWL and constructing a short berm high up the crownwall instead. For this configuration, as can be seen in figure 9, the overtopping rates increased again

Figure 6: Second alternative. Raised freeboard and recurved crownwall

probably due to the fact that the recurved wall partially blocked by the berm is not effective enough from a hydraulic point of view. Therefore, the rubble mound berm in front of the recurved wall should not reach high up the wall, as in this case the small curve above would be ineffective. This means that the corresponding rubble mound slope produces a ramp effect on the waves, resulting in disappointing performance.

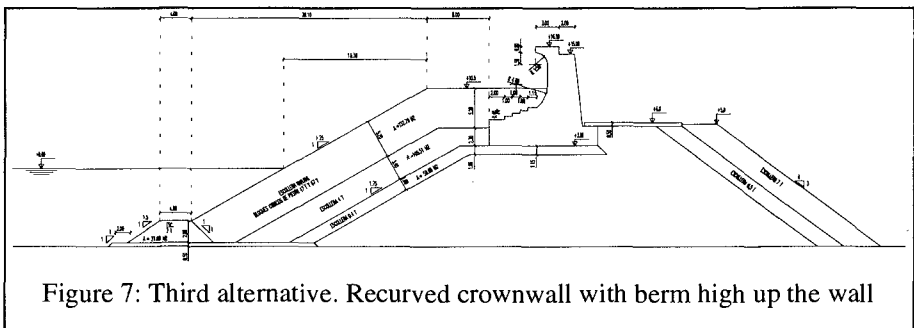

Figure 7: Third alternative. Recurved crownwall with berm high up the wall

d) Fourth alternative:

The final section proposed, corresponding to the fourth alternative (fig.8), has the following characteristics:

- Crownwall height : +16.5m
- Weight of slope rubble mound units : 27 and 47 Tn

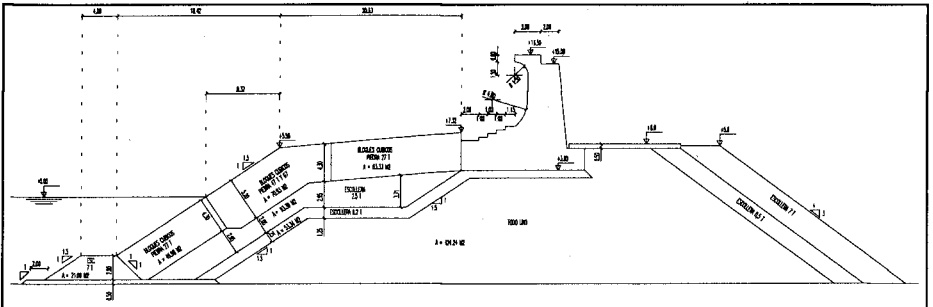

Figure 8: Fourth alternative. Final proposed section

- Length of the berm: 45 m
- Height of the berm : +7.5 m

Figure 9 shows the results of Q_r for the four alternatives.

Figure 9: Overtopping results for 3D experiments.

5. COMPARISON BETWEEN 2D AND 3D RESULTS

Up to now, nothing has been said about the effect of a curved breakwater in plan view on the reduction of overtopping.

Figure 10: 3D model tests

Figure 11: 2D model tests

In order to assess such an effect, 2D tests of alternative 4 were performed in a wave flume. Incidentally, stability tests of the crownwall were also performed in order to approve a final design of the breakwater.

Figure 11 shows the good performance of the curved breakwater making the wave return seaward.

Figure 12 shows the differences in overtopping reduction between a straight and a curved breakwater in plan view.

Apart from possible scale or laboratory effects that may somewhat reduce the difference in the overtopping rate, the tests performed confirm that the curved breakwater considerably improves the hydrodynamic performance of the water flowing along the crownwall, reducing wave overtopping.

All these results could be compared with some state of the art formulas for overtopping rates like for instance Van der Meer's. Unfortunately, the geometry did not meet the hypothesis or requirements to fit these formulas.

6. CONCLUSIONS

The laboratory tests conducted at INHA in Barcelona (Spain) with different configurations of the breakwater of San Sebastian have shown various alternatives as ways to reduce the overtopping rates. First of all, there is a more or less exponential relationship between dimensionless freeboard and overtopping. Moreover, the use of a rubble berm in front of the structure is also an improvement, as is the construction of a recurved crownwall of an appropriate shape. Finally, as determined by comparing wave flume tests with basin tests, the design of a curved breakwater in plan view instead of a straight one considerably

improves the hydrodynamic performance of the water flowing along the recurved wall and reduces wave overtopping. This series of strategies makes it possible to design an optimised breakwater compatible with the visual impact limitations of the site.

CHAPTER 142

Stable Profiles of Reshaping Breakwaters with a Berm Below the Water Level

C.I.Moutzouris¹

Abstract

An experimental study of breakwaters with an initially horizontal berm below the SWL was conducted in a wave flume. The study aimed at defining the shape and geometrical features of the adjusted stable profiles and at confirming the existence of a zone of non-significant profile adjustment below the initially flat and horizontal slope.

Indroduction

Berm breakwaters are increasingly recieving attention from researchers and practicing engineers (see f.i.van der Meer, 1988, Hall & Kao 1991, Tomasicchio et al., 1994, etc.), because they are considered to be economically attractive, to minimise rock movement and to reduce the time required for natural stability to be obtained. The concept of the berm is to pre-break incident waves further out and the stability is greatly enchanced due to waves breaking on a level surface instead of on a slope. As an almost general rule, the berm is placed slightly above the still water level(SWL), as it can be seen in Fig. 1.

Although the existence of a berm above the SWL facilitates the position of construction equipment

¹Professor, Laboratory of Harbour Works, Civil Engineering Department, National Technical University of Athens (NTUA), 5 Iroon Polytechniou Str., Zografou, 15773 Athens, Greece

from Lingteringen et al., 1992

Figure 1. Typical breakwaters with a berm above the SWL

physical evidence seems to indicate that in reshaping (or dynamically stable) breakwaters flat slopes form below the SWL. The model tests reported by Foster and Hall show that flatter slopes tend to develop in the area below the SWL, but above the level of the lowest wave rundown, which is an area of maximum hydrodynamic forces. It is, therefore, surprising that very little

data exist on the response of profiles with a berm built below the SWL.

An experimental study of breakwaters with an initially horizontal berm below the SWL was conducted in a wave flume of the Laboratory of Harbour Works, NTUA. The study aimed at defining the shape and geometrical features of the adjusted stable profiles and at confirming the existence of a zone of non-significant profile adjustment below the initially flat and horizontal slope.

Experimental Conditions and Procedure

The wave flume was 25m long and 0.6m wide. The wave generator was placed at one end of the flume and generated regular waves. Crushed stones with a density of $\rho_s = 2.6\text{t/m}^3$ were used for the armour layer of the breakwaters. Nominal armour diameter D_{n50} defined as $(W_{50}/\rho_s)^{1/3}$, where W_{50} is the 50% value of armour mass distribution, was equal to 3.5cm.

A total of 258 experiments were carried out. The seaward slope underwent reshaping under the wave action until a stable (or final) profile developed. The influence of numerous initial conditions were examined, namely (see Fig.2 and Table 1): initial berm height d_a and width b , water depth d , wave height and length H and L , respectively, initial slope of the armour layers in the upper and lower parts 1:n and 1:m, respectively. For comparison reasons numerous experiments with $b = 0$ (conventional breakwater or no berm conditions) were carried out. Some experiments with a berm built above the SWL ($d_a > d$) were also performed. Finally, a number of experiments with an initially sloping berm (1:k) were executed.

The stability (or mobility) number N_g defined as $H/\Delta D_{n50}$ ranged in all cases examined from 2 to 3.5, which indicates a conservative design of the initial profile. Δ is the boyant mass density. The ratio h/d ranged from 0.2 to 0.35 indicating rather shallow water conditions.

The following geometrical features of the final profiles were measured (see Fig.3): slopes of the fronts and the berm, the final berm height d_b , the height h_c of the adjusted profile above the SWL, the length l_c of the adjusted profile above the SWL and the height of the zone of non-significant profile

Figure 3. Initial and final profiles

Results

In the paper results from the experiments are presented on the following features of the reshaped and finally stable profile of the breakwaters: final slope of the initially horizontal berm, non-dimensional height of the zone of non-significant profile adjustment, non-dimensional height and length of the adjusted profile above and below the SWL, final berm height and finally shape of the profile above and below the SWL.

Berms initially built horizontal tend to become sloping as a result of wave action, as it can be seen in Fig.4. In the present experiments it was found that

from Montgomery et al., 1988

from van Gent, 1995

Figure 4. Sloping final berm

always the final (or stable) berm was curvilinear with a central part nearly rectilinear. This central part was found to be almost always sloping with slopes ranging from 1:8 to 1:1 (vertical : horizontal). Most frequent final slopes were from 1:6 to 1:3. Slopes as steep as 1:2 or 1:1 were rare. No influence of the initial berm slope was detected (see Fig. 5).

Figure 5. Slopes of the final berm

A considerable part of the profile remained always as it was built and did not deform under the wave action. The so-called "zone of non-significant profile adjustment" is the lower part of the seaward profile with a height above the flume bed equal to d_c . The values of d_c/d were found to range between 0.4 and 0.6 (see Fig.6). d_c/d was increasing when the initial slope was decreasing and this could be explained as follows: Changes in the breakwater profile are mainly due to wave breaking. As it is known, steeper breakwater slopes lead to a higher degree of wave reflection and to less pronounced wave breaking, which explains the experimental result. The initial height of the berm d_a was not found to influence the ratio d_c/d .

The conclusion that at least 40% of the height of the initial profile remains always stable and does not change is rather interesting.

Figure 6. Height of the zone of non-significant profile adjustment

The height of the adjusted profile above the SWL was found to be strongly influenced by the width of the berm (see Fig. 7). In the case of a conventional breakwater (no berm) h_c was of the order of the deforming wave height (0.7 to 1.2 H). When a berm 70cm wide was present, h_c decreased to less than half the wave height. This could be explained as follows: Waves break directly on the slope of a conventional breakwater and cause extensive deformation of the profile. A wide berm forces the waves to break further offshore and, therefore, the zone of deformation becomes smaller.

Similar conclusions were drawn from the experimental results on the length l_c of the adjusted profile above the SWL. l_c was decreasing as the berm width was increasing. The wave length was in most cases in the order of 10 to 20 times the length of the adjusted profile (see Fig.8). Van der Meer (1988) proposed an empirical expression for l_c . The present results concerning l_c were not always in good agreement with van der Meer's $l_{c,VM}$.

The seaward profile of a berm breakwater is often predicted by simple models (f.i. van der Meer, 1988) based on physical model tests of the following type:

$$y = ax^b \quad (1)$$

where a and b are empirical coefficients. The present experiments showed that both the sections below and above the SWL of the deformed profile could be represented by an equation of the same type as equ.(1), namely:

$$y = a_1 x^{b_1} \quad \text{for the section below the SWL}$$

and

$$y = a_2 (-x)^{b_2} \quad \text{for the section above the SWL}$$

The range of values of b_1 and b_2 were as follows:

$$b_1 = 0.70 \text{ to } 1.15$$

$$b_2 = 0.98 \text{ to } 1.12$$

Table 2 contains the values of b_1 and b_2 as found in the present experiments and as proposed by various authors. According to a PIANC report, for values of N_s lower than about 10 to 15 the prediction model of van der Meer seems to be less reliable than for larger values of N_s .

(f) 1:n=1:1.5, 1:m=1:2, 1:k=1:5 and 1:8 (8 exper.)	0.74	-

Table 2. Values of b₁ and b₂

The range of values of a_1 and a_2 was rather broad. No conclusion could be drawn.

The final height of the berm d_b is defined as the height above the flume bed of the center of the rectilinear part of the final sloping berm. d_b was always found to be in the order of 80% to 100% of the initial berm height d_a (see Fig.10). In many cases d_b was almost equal to d_a , which means that the final position of the berm did not change considerably in its central part.

Figure 10. Final berm height

Conclusions

Some rather interesting conclusions are drawn from the results. The adjusted berm height was found to be in the order of 80% to 100% of the initial height. The height of the zone of non-significant profile adjustment was in all cases in the order of 40% to 50% of the water height.

CHAPTER 143

Experiments on a non-wave overtopping type seawall

Keisuke Murakami,* I.Irie[†] and Y.Kamikubo[‡]

Abstract

A new type of seawall is proposed in this study. The seawall has a deep circular arc cross section and allows no wave overtopping any more. The critical crest elevation of the seawall, which defined as the minimum crest elevation on which the wave overtopping dose not occur at all, is investigated through the wave tank experiments. The wave pressures and wave forces acting on the seawall are also measured, and the characteristics of the wave pressure distribution and wave forces are examined.

1. Introduction

The landward area of a seawall provides an excellent space for various use so long as it is protected from the wave overtopping. Recently, the coastal areas are planned for land use which is very sensitive to the spray falls such as the electronic power plant and the airport, and the very small quantity of the wave overtopping rate is allowed. Furthermore the reduction of the seawall height is also required to afford unobstructed view as well as to save the cost. Though some types of seawall were proposed for the purposes of the reduction of the rate of wave overtopping and the height of seawall (Inoue, 1974; Takata, 1979; Kono, 1993), those could not release the land from hazard by the wave overtopping thoroughly.

In this study, a new type of seawall is proposed(referred as *Flaring Shaped Seawall (FSS)* ; see **Fig.-1**). The seawall has a deep circular arc cross section and no wave overtopping is allowed any more. The critical crest elevation of the *FSS*,

Fig.-1: Conceptual sketch of the *FSS*

which defined as the minimum crest elevation on which the wave overtopping dose not occur at all, was investigated through wave tank experiments, and the required crest elevation which satisfies the non-wave overtopping condition was examined. The wave pressures and uplift wave forces acting on the *FSS* were also measured through wave tank experiments and characteristics of the wave pressure were discussed by classifying the wave colliding patterns in front of the *FSS*.

2. Experimental conditions

2.1 Measurement of the critical crest elevation

As shown in **Fig.-2**, the experiments were conducted with two-dimensional wave tank of $28m$ in length, $0.5m$ in height and $0.3m$ in width. The water depth was maintained at $h_0 = 35cm$ and the impermeable slope with $1/20$ was installed at the end of the wave tank. Four types of seawall with the same seawall

Fig.-2: Schematic of wave tank facility

Table-1: Wave conditions for the measurement of the critical crest elevation

$B(cm)$	D/B	H_0/L_0	$H_0(cm)$
15	0	0.012	4,6,7,8,9
		0.036	
	0.5	0.012	
		0.036

		0.036	

height, $B = 15cm$, and the different arc depth, $D/B = 0, 0.5, 1.0$ and 2.0 , were tested. The tip of these seawall was made with a thin plate and its thickness did not affect to the wave overtopping. The critical crest elevation depends on the configurations of the wave dissipating works such as crest elevation, crown width, location and void content (e.g., Yamamoto, 1984, Takayama, 1988, Sasajima, 1993). In this study, the wave dissipating works with 50% void content was installed in front of the seawall and its crest elevation was coincide with the still water level. The wave dissipating works was made by using 1/25 scale model of 2t type blocks, and these blocks were piled one upon another in the layers.

Table-1 shows the incident wave conditions, where H_0 and L_0 indicate the incident wave height and wave length respectively. Two kinds of incident wave steepness of $H_0/L_0 = 0.012$ and 0.036 were used in this experiment, and the incident wave height, H_0 was changed in the range from $4cm$ to $9cm$. With changing the location of the seawall and incident wave height, the critical crest elevation, h_c for these incident wave condition was measured. The critical crest elevation was obtained by observing whether the wave overtopping occur or not.

2.2 Measurement of the wave pressure

The experiments were conducted with two-dimensional wave tank of $20m$ in length, $1.2m$ in height and $0.6m$ in width. The water depth was maintained at $h_0 = 85cm$. Four types of seawall with the combinations of the different seawall height, $B = 22.5cm$ and $36.4cm$, and the different relative arc depth, $D/B = 1.0$ and 0.5 were tested. The wave dissipating works with 50% void content and crest elevation in the still water level was installed in front of the seawall.

Table-2 shows the incident wave conditions. The incident wave steepness of $H_0/L_0 = 0.036$ was used in this experiment, and the incident wave height, H_0 was changed in the range from $4cm$ to $13cm$. With changing the location of the seawall and incident wave height, the wave pressure distributions on the seawall were measured by the pressure gauges of $8mm$ diameter attached on the face of

		18	4,6,8,9,10			34	3,4,5,6

the seawalls. The output signals were recorded in the digital data recorder with 1000Hz sampling frequency.

3. Characteristics of the critical crest elevation

Fig.-3 shows the characteristics of the critical crest elevation, h_c/H_0 for the incident wave steepness of $H_0/L_0 = 0.012$ on which the wave dissipating works are installed in front of the seawall. **Fig.-4** also shows the characteristics of h_c/H_0 for $H_0/L_0 = 0.036$. In these figures, the symbols \circ , \diamond , and \triangle show the results of the *FSS* with $D/B = 0.5$, 1.0 and 2.0 respectively. The symbol \bullet also shows the results of the conventional upright seawall which has the same seawall height as other *FSS*. The thick line in **Fig.-4** shows the relative crest elevation of the upright seawall with wave absorber proposed by Goda(1985) for $H_0 = 2\text{m}$ as a model scale of 1/20. The wave overtopping rate, $q = 2 \times 10^{-4}(\text{m}^3/\text{m} \cdot \text{sec.})$ was employed as a level where the wave overtopping rate can be considered negligible.

The critical crest elevation, h_c/H_0 of the conventional upright seawall increase linearly with increase of the relative water depth, h/H_0 . On the other hand, the critical crest elevation of the *FSS* decrease with increase of h/H_0 , and the differences of the critical crest elevation between *FSS* and conventional upright seawall become larger. The *FSS* checks the wave overtopping more effectively than the upright seawall, and the crest elevation, h_c of the *FSS* can be reduced to about a half of the offshore wave height even under the non-wave overtopping condition.

Fig.-5 and **Fig.-6** show the critical crest elevation for $H_0/L_0 = 0.012$ and 0.036 on which the wave dissipating works is not installed in front of the seawall. Though the characteristics of the critical crest elevation are similar to the results shown in **Fig.-3** and **Fig.-4**, the differences of the critical crest elevation between

Fig-3: Critical crest elevation for $H_0/L_0 = 0.012$ (with wave dissipating works)

Fig-4: Critical crest elevation for $H_0/L_0 = 0.036$ (with wave dissipating works)

the *FSS* and upright seawall become significant because h_c/H_0 of the upright seawall increase rapidly with increase of h/H_0 .

Comparing with the results of $D/B = 0.5, 1.0$ and 2.0 in **Fig.-3** and **Fig.-4**, the checking capability of the wave overtopping becomes higher along with the increase of the relative circular arc depth, D/B . **Fig.-7** shows the relationship between the critical crest elevation and relative arc depth, D/L_0 . h_c/H_0 decreases monotonously with increase of D/L_0 . So that, the *FSS* with deep arc depth relative to the incident wave length is effective for the prevention of the

Fig-5: Critical crest elevation for $H_0/L_0 = 0.012$ (without wave dissipating works)

Fig-6: Critical crest elevation for $H_0/L_0 = 0.036$ (without wave dissipating works)

wave overtopping.

The critical crest elevation, h_c/H_0 is deeply related to h/H_0 , D/B , H_0/L_0 , H_0/h_0 , $\tan \beta$ and f_D , where f_D means a wave damping rate by the wave dissipating works. The linear multiple regression analysis was carried out with using above factors to obtain the approximate equation for h_c/H_0 , and the equation was obtained as follows:

Fig.-7: Relationship between h_c/H_0 and D/L_0

Fig.-8: Results of the regression analysis

$$\frac{h_c}{H_0} = -0.24 \frac{h}{H_0} - 0.18 \frac{D}{B} - 11.59 \frac{H_0}{L_0} - 2.63 \frac{H_0}{h_0} + 2.17 \quad (1)$$

where $\tan \beta$ and f_D are constant in this study.

Fig.-8 shows a result of the regression analysis. The computed results show fairly good agreements with experimental ones, and h_c/H_0 is estimated with high correlation coefficient of $\gamma = 0.95$ by Eq.(1).

4. Wave pressure acting on FSS

Fig-9 and Fig-10 show the wave pressure distributions on the *FSS* of $D/B = 1.0$ and 0.5 at different water depth, h/h_0 , where the seawall height is $B = 22.5\text{cm}$. The lateral axis shows the location of the wave pressure gauges and coordinate z is taken upward from the still water surface. Each symbol in

Fig-9: Wave pressure distributions on *FSS* of $D/B = 1.0$

Fig-10: Wave pressure distributions on *FSS* of $D/B = 0.5$

the figures mean the difference of the incident wave height, H_0/h_0 .

The patterns of the wave pressure distribution are varied with the incident wave height, H_0/h_0 and the water depth, h/h_0 . The maximum wave pressure appears between $z/B = 0$ and 0.2 , and the pressure in the range from $P_{max}/\rho g H_0 = 1.2$ to 4.5 were observed. The values of the maximum wave pressure closely relate to the wave colliding patterns in front of the *FSS*.

Fig.-11 and Fig.-12 show the variation of the maximum wave pressure,

Fig.-11: Variation of the maximum wave pressure to the relative water depth, h/H_0 ($D/B = 1.0$)

Fig.-12: Variation of the maximum wave pressure to the relative water depth, h/H_0 ($D/B = 0.5$)

Fig-13: Variation of the vertical wave force to the relative water depth, h/H_0 ($D/B = 1.0$)

Fig-14: Variation of the horizontal wave force to the relative water depth, h/H_0 ($D/B = 1.0$)

$P_{max}/\rho g H_0$ to the relative water depth, h/H_0 for $D/B = 1.0$ and 0.5 . In the range of the small relative water depth, h/H_0 , the maximum wave pressure is relatively small, because the incident waves break on the offshore side of the wave dissipating works and fully dissipated waves attack the seawall. With increase of h/H_0 , the maximum wave pressure increases because the wave breaking point approaches to the seawall. The maximum value of $P_{max}/\rho g H_0$ appears when the waves break just in front of the seawall. After taking the maximum value, the maximum wave pressure decreases with increase of h/H_0 . In the range of the

large relative water depth, h/H_0 , the maximum wave pressure becomes small because the waves attack the seawall without wave breaking.

Fig.-13 and **Fig.-14** show the vertical and horizontal wave forces acting on the *FSS* of $D/B = 1.0$. The profiles of the wave pressure at each measuring point were assumed to be synchronized, and the wave forces were obtained by integrating the maximum wave pressures along the seawall face.

The variations of the vertical wave force are similar to that of the horizontal wave forces. The magnitude of the vertical wave force takes nearly the same value of the horizontal wave force, and the vertical force acting on the *FSS* is relatively larger than that on the upright seawall. The same tendencies were observed in the *FSS* of $D/B = 0.5$. In that case, the values of the vertical wave force took about 50%~60% of the horizontal wave force.

5. Conclusions

A new type of seawall (*FSS*) with deep circular arc cross section was proposed. The relative critical crest elevation of the *FSS* was extremely smaller than that of the conventional upright seawall, and the crest elevation could be reduced to about a half of the offshore wave height even under the non-wave overtopping condition. Further, the critical crest elevation of the *FSS* was estimated with fairly good correlation coefficient by using the approximate equation obtained from the experimental results.

The characteristics of the wave pressure were investigated. The values of the maximum wave pressure deeply related to the wave colliding patterns in front of the seawall, and those values change with the relative water depth, h/H_0 .

The maximum wave pressure appears near the still water surface and this pressure causes the large vertical wave force. The increase of the vertical wave force reduces the stability of the seawall, and a new type of wave dissipating works which could reduce the maximum wave pressure effectively must be investigated in further studies.

CHAPTER 144

A Condition and Performance Rating System For Breakwaters and Jetties

John Oliver¹, Don Plotkin²,
John Lesnik³, Douglas Pirie⁴

Abstract

This paper describes one aspect of a series of projects which the U. S. Army Corps of Engineers has undertaken to improve maintenance management of coastal and navigational structures. At the core of these projects is the development of procedures for more uniformly evaluating and describing the physical condition and functional performance of structures, and further, the development of methods where the condition and performance of structures, and their parts, can be expressed numerically to take best advantage of the benefits available from the use of microcomputers in maintenance management. These procedures are designed to allow the condition and performance of different structures to be more easily compared and more uniformly tracked over long time periods and to aid the repair budgeting prioritization process. This paper briefly

describes the performance-based assessment method for breakwaters and jetties, primarily of rubble construction.

System Philosophy

The most important analysis within this system is on structure performance, with physical condition taking a secondary role. In this performance-based system, the difference between current structure condition and as-built (or "like new") condition is not, in itself, a deciding factor on the need for repair. Rather, it is a structure's documented loss of function as a result of structural deterioration which is most important. When performance is judged unsatisfactory, then repairs are considered which would raise performance back to satisfactory levels. Evidence of near-term structural instability is also an important consideration, as it could adversely affect performance.

The Eight System Steps

Table 1 lists the eight steps in the implementation and use of the system. A brief description of these steps is given below. A more complete system description is contained in Oliver, Plotkin, Lesnik, and Pirie 1996. This document will be referred to as the "system manual" in the rest of the paper.

Assigning Functions and Defining Reaches

The first step is to determine which functions the structure is intended to perform, according to the four main functional areas and nine functional rating categories, as listed in Table 2. These are described in the system manual which also contains a spreadsheet to assist in performing the complete functional assessment.

Generally, Harbor Area and Navigation Channel cover how well the structure controls waves and currents with respect to the categories listed for those areas. To avoid confusion and duplication of defect reporting, all sediment control aspects are grouped together under Sediment Management. Structure Protection refers mainly to how well a structure protects adjacent structures against attack by waves and currents. This function may apply to an outer breakwater protecting an inner breakwater, or to one jetty protecting the one on the opposite side of the channel.

Table 1. Eight Steps in the Rating System

Step Number (1)	Description (2)
	Steps 1-5 are Initial (One Time Only):
1	Determine What Functions Structure Serves.
2	Divide Structure into Major Reaches - by Function.
3	Establish Functional Performance Criteria.
4	Establish Structural Requirements.
5	Further Divide Reaches into Subreaches - by Structural and Length Criteria
	Steps 6 - 8 are Repeated as Required:
6	Inspect Structure - Produce Structural Rating.
7	Assess Functional Performance - Produce Functional Rating.
8	Review Structural Requirements.

The Toe Erosion and Trunk Protection categories serve as a useful reference but are not included in the Condition Index calculations, as their effect is covered by the structural rating categories.

Next is the initial step in dividing the structure along its length into reaches. The functions provided by different portions of the structure are determined, using the categories listed within the four main functional areas. Initial reach limits are set where functional changes occur. The head of a structure is always considered to be a separate reach.

Performance Criteria and Structural Requirements

Step 3 is to determine, for each reach and for each functional category which applies to it, what level of performance is expected. This performance expectation is

Table 2. Functional and Structural Rating Categories.

Not included in Condition Index calculation.

indicated by the acceptable number of annual disruptions, or periods of disruption for each of the required navigation and related activities. The allowable disruption will vary not only with navigation activity, but also by size and type of vessel.

Performance is referenced to three levels of storm events:

1. Design Storm: This is the largest storm (or most adverse combination of storm conditions) which the structure (or project) is intended to withstand, without allowing disruption of navigation or harbor activities, or damage to the structure or shore facilities. The design storm is usually designated by frequency of occurrence or probability of occurrence.
2. Intermediate Storms (2X Design Storm Frequency): This level refers to storms (or combinations of adverse conditions) of intermediate intensity, which occur on the order of twice as often as the design storm. This level is intended to represent a midway point between the maximum storm levels (design storm) and small or minor intensity storms which may occur more frequently, especially during certain periods of the year.

3. Low Intensity Storm Conditions: This level refers to storms (or combinations of adverse conditions) of low intensity, which may occur frequently throughout the year, such as common rain storms or periods of above normal winds. This level is the next stage above normal non-storm conditions.

The design storm is the main reference point for establishing expected structure performance. Authorizing documents, design notes, project history, and current requirements are used to confirm the appropriate design storms for a project. For systems designed for seasonal use or for interrupted use, the expected non-use periods must be allowed for in arriving at a design storm. Design storm conditions include: wave height, direction, and period; water level; storm duration; and combinations of these factors.

The design storm typically varies from one project to another, and for different activities or areas within a single project. For example, disruption of cargo handling or limitations on channel entrance use might be tolerated more frequently than disruption in the harbor area. Thus the design storms for the navigation channel, damage to harbor facilities, vessel damage, and disruption of cargo handling are, or should be, at different return intervals.

For many harbor entrances, design depths and channel orientation are indications of design intent. For example, a 10 foot channel will have breaking waves at a wave height of 8 feet. At this wave height, about 4 feet of channel depth is lost at the wave trough and waves are steep enough to cause broaching of a craft with less than 5 feet of draft. Thus, with an 8-foot wave, the channel is impassable for all vessels due to either limited depth (for larger vessels) or excessive wave steepness (for smaller vessels). At this location, an 8-foot wave height can then be tied to a storm of a certain frequency or probability, and a tolerable frequency for closing the channel can then be determined. In a similar fashion, safety in the harbor berthing area and disruption to cargo handling could be analyzed.

When structure performance is rated later in the process, the ratings are based on storms of the greatest intensity which have occurred during the last rating period. Having three levels allows ratings to be produced during intervals when only storms of less than design intensity have occurred.

Once performance expectations are established for each function, it is then necessary to determine what structural requirements the structure must fulfill to allow performance requirements to be met. Seldom does a rubble coastal structure require full structural integrity to have continuity in function. In fact, most rubble structures are built with some allowance for damage before function is compromised, and many are overbuilt for constructability. Thus, structural damage does not automatically equate to loss of function.

Determining structural requirements involves estimating the minimum cross section dimensions, crest elevation, and level of structural integrity needed to meet functional performance requirements. Initial efforts in visualizing these dimensions can be aided by estimating the impact on functions if the reach under study were to be completely destroyed. Project history, authorizing documents, public input, and analysis may also be required to adequately determine these dimensions. As this is not an exact science, application of significant engineering judgment will be necessary to produce a reasonable estimate. Once this is done, these structural requirements are used to help identify sources of functional deficiencies in the existing structure.

Final Reach Division

At this point, the reaches which were initially divided according to function are now further divided according to the following two criteria:

1. By Construction: Further division is made based on changes in structural characteristics.
2. By Length: Where function and construction are uniform over a long length, divisions are made to keep reaches in the range of 60 to 150 meters (200 to 500 feet).

Divided in this fashion, the reaches now represent convenient-sized management units with similar properties. Reach definition is permanent, unless major changes are made to the structure.

At this point, all the initial steps in implementing the system are complete and need not be repeated. The following steps are then performed on a recurring basis, as needed.

Structural Inspection and Rating

Structural ratings are produced by comparing the current physical condition, alignment, and cross sectional dimensions of a structure to that of a "like new" structure which was built as intended and according to good practice, and with good quality materials.

For structural rating, each reach is divided into three cross sectional areas: the crest (or cap), the seaside, and channel or harborside. Each cross sectional area is given 0 to 100 ratings in five of six rating categories, as listed in the right-hand column on Table 2. (Slope Defects is not rated for the crest, and Breach is not rated for the two side slopes). These ratings are determined primarily from visual inspections of the structure, although additional information, such as hydrographic surveys, may also be used.

The system manual contains a rating table for each structural rating category. While these tables are specific to each category, they follow the basic format of the General Condition Index Scale shown in Table 3. Values are usually selected as multiples of 5 (60,65,70, etc). The system includes a field form for recording the ratings, inspector comments, and other information useful in producing a thorough inspection.

The ratings are then entered into the BREAKWATER computer program which calculates a composite structural index (SI) for each of the three cross sectional areas, a single SI for the whole reach, and finally an SI for the whole structure (Aguirre and Plotkin 1996). The SI value for a structure or structural component indicates its level of physical condition and structural integrity.

Functional Assessment and Rating

Functional assessment begins with a review of the functional performance criteria for the structure. Then, the environmental setting (wave and current energy, water level variability, sediment transport, etc.) is examined, followed by a review of the structural ratings, SI values, and comments made during the structural inspection. The intent is to determine the extent to which structural deterioration has adversely affected function.

As for structural rating, the system also contains rating tables for each functional rating category which likewise follow the general format of Table 3. After the

Table 3. General Condition Index Scale.

Observed Damage Level (1)	Zone (2)	Index Range (3)	Condition Level (4)	Description (5)
Minor	1	85 to 100	EXCELLENT	No noticeable defects. Some aging or wear may be visible.
		70 to 84	GOOD	Only minor deterioration or defects are evident.
Moderate	2	55 to 69	FAIR	Some deterioration or defects are evident, but function is not significantly affected.
		40 to 54	MARGINAL	Moderate deterioration. Function is still adequate.
Major	3	25 to 39	POOR	Serious deterioration in at least some portions of the structure. Function is inadequate.
		10 to 24	VERY POOR	Extensive deterioration. Barely Functional.
		0 to 9	FAILED	No longer functions. General Failure or complete failure of a major structural component.

ratings are chosen, a check is made to ensure that each rating is made based on how the structure itself (its presence or condition) has affected the rated functional categories.

The ratings are then entered into the BREAKWATER computer program which calculates a composite functional

index (FI) for the whole reach and then for the whole structure. The FI values for a structure or reach indicate how well it performs its intended functions. The FI values then lead to a condition index for the reach or whole structure.

Review of Structural Requirements

Finally, structural ratings and functional ratings are compared to the initial structural requirements. The intent is to perfect the relationship of performance to structural deterioration, which will occur over the long term through repeated analysis.

Budgeting for Repairs

Through use of the method outlined above, sufficient data and experience will be accumulated to track structure condition over time and properly relate physical condition with functional performance. At this point, general deterioration rates can be determined, along with minimum condition levels which will provide the required performance. From this information, the required repairs can be budgeted to the extent needed and at the appropriate timing.

While it is recognized that catastrophic effects of major storms can result in a clear need for immediate repair, these major events will not necessarily dictate the decision process or dominate a structure's overall long-term structural deterioration and accompanying loss of function. Even the repair of major storm damage is still appropriately assessed through the above method.

Conclusions

This system establishes a rational and systematic method for assessing the physical condition and performance of breakwaters and jetties. It emphasizes the need to establish performance expectations for coastal structures, and further, to relate the need for structural repairs to documented loss of function. The system for rubble breakwaters and jetties is currently being implemented throughout the U. S. Army Corps of Engineers. Similar procedures will also be developed for breakwaters and jetties of non rubble construction, and later, for seawalls, bulkheads, revetments, and groins.

Acknowledgements

Development of the system described here depended on the assistance of many within the Corps of Engineers' coastal community. Their efforts and ideas contributed greatly to the final product.

CHAPTER 145

Wave overtopping and stability of armor units under multidirectional waves

T.Sakakiyama¹ and R.Kajima²

Abstract

This paper describes the wave overtopping along a seawall of a man-made island where nuclear power plants are projected to construct and the stability of armor units at the concave section of seawall. Effects of the wave directionality on them were investigated by using multidirectional wave basin not only for a design wave but also larger waves than the design one to ascertain the durability and margin of the safety of seawall.

1 Introduction

To extend siting area for power plants, a synthetic project for new siting technologies has been undertaken by Central Research Institute of Electric Power Industries(CRIEPI). One of the most promising technologies is to site them in a man-made island instead of on coastal land. A new design method for very important coastal structure of the man-made island has been proposed by Kajima(1994).

Concerning the power plants on the man-made-land, the wave overtopping and the stability of armor units for the new design concept has been investigated mostly with two-dimensional physical model tests (Kajima *et al.*,1993; Kaijma, 1994; Sakakiyama *et al.*, 1994a; Sakakiyama *et al.*,1994b). Because the man-made island will be constructed offshore, effects of the wave directionality on the wave

¹ Central Research Institute of Electric Power Industry, 1646, Abiko, Abiko-city, Chiba, 270-11, Japan. e-mail:sakaki@criepi.denken.or.jp

² Ditto, e-mail:kajima@criepi.denken.or.jp

overtopping and the stability of armor units are of great importance for rational design of the seawall.

Works on the wave overtopping recently performed were aiming at design formula (de Waal and van der Meer, 1992; Herbert *et al.*, 1994). Although multidirectional wave basins are available nowadays, research on the overtopping rate was carried out for oblique waves (Juhl and Sloth, 1994) and for two-dimensional coastal structure due to multidirectional waves (Hiraishi *et al.*, 1995).

Effects of the wave directionality on the overtopping rate and the stability of armor units were investigated in the wave field where the diffracted waves were caused by three dimensional coastal structure. To ascertain the durability and margin of the safety of seawall of the man-made island, not only a design wave but also larger waves than the design one were applied for the structure.

2 Design concept

To guarantee the safety of man-made island where a nuclear power plant is supposed to be constructed, a new design method was proposed by Kajima (1994). That design concept is based on the following two-step design: At first step, according to the current design method, coastal structure should be stable for a "fundamental design wave". That wave condition is determined with 100-year return period.

In addition to the present design concept, functions of the seawall are confirmed for a severer wave than the fundamental design wave height, where it is named the "functional check wave".

In this research, to demonstrate this two-step design method, design wave conditions are supposed as shown in Table 1. The deep-water significant wave height $H_0=10\text{m}$ and wave period $T=16\text{s}$ are taken as the fundamental design wave with 100-year return period.

For second step, a wave condition to check up functions of the coastal structure is determined: The wave height is one and a half times larger than that of the fundamental design wave, $H_{F0}=1.5\times H_{0D}=15\text{m}$. Water depth of the man-made

Table 1 Design wave conditions

fundamental design wave		functional check wave
return period	100 years	roughly 1000 years
conditions in deep-water conditions		
wave height $H_0(\text{m})$	10m	15m(= $1.5\times H_0$)
wave period $T_0(\text{s})$	16s	16s
conditions at man-made island		
wave height $H_D(\text{m})$	10.3m	12.8m(= $1.24\times H_D$)
wave period $T_D(\text{s})$	16s	16s
armor units	stable	slight deformation
allowable overtopping rate	$0.05\text{m}^3/\text{s}/\text{m}$	$0.2\text{m}^3/\text{s}/\text{m}$

Fig.1 seawall covered with armor units

island is assumed as $h=22.5\text{m}$ including the high tidal range. An incident significant wave height at the water depth $h=22.5\text{m}$ applied in the tests ranges from the design wave height $H_D=10.3\text{m}$ to $H=1.24\times H_D=12.8\text{m}$.

Coastal structure should be stable for the fundamental design wave according to the current design method. However, it is allowed to get slight damage of the armor layer within keeping its functions.

Coastal structure to protect the man-made island consists of wave dissipating work and caisson on which drainage channel for overtopping water is constructed. Fig. 1 shows a cross section of the seawall and it is designed to be stable for the fundamental design wave condition with 100-year return period. The incident significant wave height for the fundamental design is $H_D=10.3\text{m}$ at the water depth $h=22.5\text{m}$ where the seawall is constructed. Armor units used in the present experiments is Tetrapod and its weight $W=80\text{tf}$ which is determined by Hudson formula ($K_D=8.2$). A crest elevation of the seawall was estimated as $h_c=14\text{m}$ above S.W.L. for an allowable overtopping rate, $q_{da}=0.05\text{m}^3/\text{s}/\text{m}$. For the functional check wave, the allowable overtopping rate was also given. But the crest elevation of the seawall is lower than that of the fundamental wave condition. For those given wave conditions, the relationship between the crest elevation and the overtopping rate was obtained by using the diagrams for wave overtopping proposed by Goda's (1985). Area inside the channel wall is site of the power plant. So extremely large amount of water due to the wave overtopping is not allowed in this area.

Coastal structure should keep its functions to protect the power plant inside of man-made island. Therefore, investigation was also performed in this research from this point of view. Dimensions of drainage channel was determined with two-dimensional wave flume tests including large- and small-scale test (Sakakiyama *et al.*, 1994b).

3 Experimental method

The experiments were carried out by using a multidirectional wave basin (35.0m long, 45.0m wide and 1.1m deep) equipped with a 48-segmented wave maker (19.2m

wide) as shown in Fig. 2. A scale factor of physical model test is $\lambda=1/88.1$. A model of man-made island is 5.7m long in the direction on-offshore and 11.4m wide in the direction alongshore(500m by 1000m in full-size). It is protected with seawalls consisting of caissons covered with armor units as shown in Fig. 1. The model of man-made island was located as shown in Fig. 2 to make center lines of the wave generator and of a half section of offshore-side seawall on the same line. Measurement of wave overtopping was done in a half section of seawall. Guide walls were settled during the tests for both normal and obliquely incident waves. Uniformity of wave heights at the water depth of offshore-side seawall was checked parallel to the shoreline

Table 2 shows the experimental conditions. Three kinds of wave directional conditions were selected, CASE A: multidirectional wave with normal incident($\theta=0$ deg.), CASE B: uni-directional irregular wave($\theta=0$ deg.) and CASE C: obliquely uni-directional irregular wave($\theta=30$ deg.). The wave directionality is expressed with the spreading parameter for wave energy S_{max} defined by Goda(1985). When S_{max} is small, e.g., waves with $S_{max}=10$ corresponds to wind waves. The wave of which S_{max} tends to the infinity is a uni-directional wave. Multidirectional wave used in the test has $S_{max}=25$ which corresponds to swell at short decay distance with relatively large wave steepness(Goda, 1985). The wave height ranges from the design wave height($H_D=11.7$ cm in model and $=10.3$ m in full-size) to the functional check wave height($1.24H_D=14.5$ cm in model and $=12.8$ m in full-size). The wave period is constant sa $T=1.71$ s(16s in full-size).

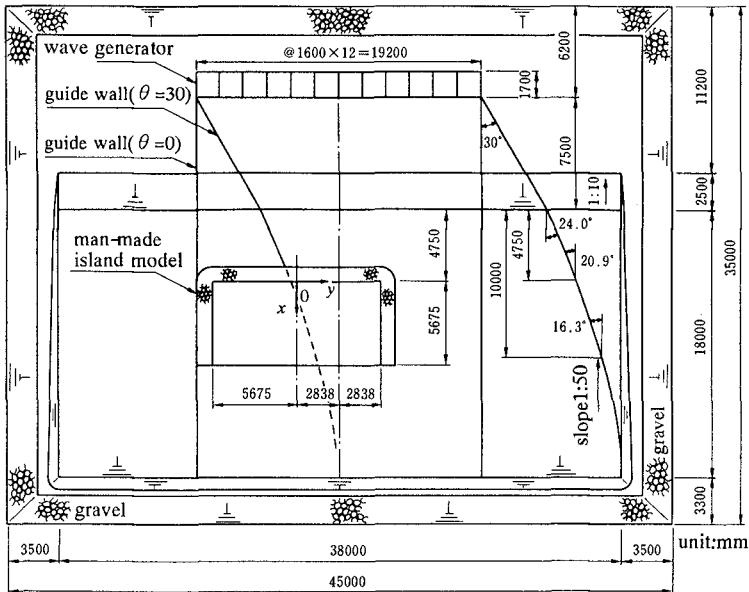

Fig.2 Multidirectional wave basin and man-made island model

Table 2 Experimental conditions(scale factor $\lambda=1/88.1$)

CASE	wave directionality	S_{max}	θ (deg.)	wave height	wave period(s)
A	multi-directional	25	0	H_D	1.71
B	uni-directional	∞	0	to	
C	obliquely uni-directional	∞	30	$1.24H_D$	

H_D is design wave height =11.7cm
water depth at seawall is 25.5cm.

Fig. 3 shows an experimental set-up for measurement of the overtopping volume. Local change of the wave overtopping was measured at a half of the offshore-side seawall alongshore for both in the drainage channel and onto the site of power plant. A half length of the test section is divided into ten parts to make tanks for water storage. Channel wall as shown in Fig. 3

Fig.3 tanks to measured overtopping volume

was scaled down to be 15.9cm high. To store the overtopping water beyond the channel wall and onto the site of the power plant, 50-cm high wall was set to the tanks in site of power plant. It was caused mainly by spray.

A number of wave trains was 250 in one test run. Because amount of water beyond the channel wall was very small, tests were repeated three or more times under the same wave condition to get sufficient volume of water. Mean overtopping rate was obtained from the measured volume and the wave duration time. Physical values are converted to full-sized ones in the following.

Fig.4 measuring sections of profiles

Fig. 4 shows the lines(No.1-1 to No.5-3) along which profiles of the armor layer were measured with depth-meters. Basically the armor units in two-dimensional section(Line No.1-1 in Fig. 4) are stable for the normal incident design waves. Interest in the stability of armor units is concentrated on critical part, that is, concave section. Profiles were measured at initial and several stages in the wave duration up to 3000 times the significant wave period($t/T=0, 250, 500, 1000$ and 3000). "Damage level S " defined by van der Meer(1987) is used to quantify the deformation of the armor layer. Fig. 5 shows its definition. The damage level physically means a number which is proportional to armor units number in an eroded area per width of the nominal diameter of the armor units D_n .

Fig.5 Definition of damage level

4 Overtopping rate

Fig. 6 shows distribution of the local overtopping rate along the seawall due to the multidirectional wave, where the local overtopping rate is defined as the discharge per unit length normal to the seawall. It was measured for several wave heights ranging from the design wave height (denoted by $H/H_D=1.0$) to the functional check wave height ($H/H_D=1.24$). Because the man-made island has finite length, diffracted waves were generated from ends of the structure. They cause the wave height change along the seawall. Consequently they results in change of the overtopping rate as shown in Fig. 6. The diffracted waves consist

Fig.6 Local overtopping rate along seawall due to multidirectional wave

Fig.7 Overtopping rate change along seawall on wave directionality

of plain waves and cylindrical scattered waves. The scattered wave propagates along the seawall not normal to that. Effect of the cylindrical scattered wave on the overtopping rate is smaller than that of the normal incident wave but not null. The diffracted wave causes an increase in the mean water level along the seawall as a function of wave height. A ratio of the maximum to minimum local overtopping rate is about four at the design wave height denoted with a hollow circle, $H/H_D=1.0$. The ratio decreases as the wave height increases. The ratio due to the functional check wave (with a diamond, $H/H_D=1.24$) is about two.

Dependency of the local overtopping rate on the wave directionality is shown in Fig. 7. The results of large waves show the overtopping rate of uni-directional wave denoted with solid triangle fluctuates most, the second is uni-directional wave and the smallest due to the obliquely uni-directional wave. This tendency agrees with the diffracted wave height distribution. Trend due to the design wave height slightly differs from the previous one. It is because that the overtopping rate is nonlinear to the wave height. The diffracted wave height due to the multidirectional waves is smoother than the uni-directional irregular wave ones.

Roughly speaking, the local overtopping rate fluctuates from a half to twice the mean value in space except the result of the obliquely incident wave with the design wave height. The diffracted wave from another corner of the model was not included from the experimental restriction. A ratio of the length of man-made island to the significant wave length is 4.5. It means that the man-made island is relatively long. Therefore, it is considered that the scattered wave from one corner dissipated at another. Experiments were also performed by capping the tanks in the drainage channel to investigate that the water can be drained through the channel. Outlets of the drainage channel were located at the landward ends of the side seawall. It was confirmed that most of water over the

Fig.8 Overtopping rate in drainage channel

parapet was drained through the channel on the caisson. Maximum water depth in the drainage channel was about 4m. Comparing with the height of channel wall 10.5m, the channel has sufficient capacity for draining. Dimensions of the drainage channel was determined mainly to reduce the overtopping water onto the site of power plant.

Overtopping water onto the site of power plant is caused by splash. Spray is not avoidable by the channel wall with reasonable height. Critical situation due to the wave overtopping is flood into the power plant. Therefore, it is required to estimate discharge in the site to design a drainage pumping system.

Fig. 8 shows the local overtopping rate onto the site. The right axis of ordinate shows the equivalent precipitation. A distance of drainage W_p is assumed as 40m from the channel wall which was estimated by observation in the experiments. Although the scale factor of this experiment is small and an accuracy for such small amount of water should be taken into account, the equivalent precipitation due to the design wave fluctuates from less than 10mm/h to 100mm/h. A mean equivalent precipitation over the seawall is O(10)mm/h. It is acceptable. Owing to the functional check wave, it will be about 500mm/h. It is equivalent to rainfall by a very strong typhoon. Drainage pumping system should be reinforced by double within this range of $W_p=40m$ for both the wave overtopping as well as the rainfall.

Fig. 9 shows an effect of the wave directionality on the overtopping rate which is averaged rate over the offshore-side seawall. The axis of abscissas indicates the incident significant wave height. The uni-directional wave with the principal wave direction $\theta=0deg$. causes the largest overtopping rate, the multi-directional wave with $\theta=0 deg$. medium and the oblique uni-directional wave with $\theta=30 deg$. the smallest. This results of the comparison between the multidirectional

and uni-directional waves agrees with that obtained by Hiraishi *et al.*(1995). The overtopping rate due to the multidirectional waves is smaller than that due to the uni-directional waves by about 30%. Results obtained with two-dimensional tests overestimates the overtopping rate when it will be applied for offshore structure in the multidirectional waves. The obliquely incident uni-directional waves produces the smallest overtopping rate among three wave directionality. Under such conditions, wave dissipating work becomes relatively long on wave run-up, although its slope becomes milder. This effect is valid for the multidirectional waves which come from the various directions.

Fig.9 Overtopping rate q dependent on wave directionality

5 Stability of armor units

Fig. 10 shows the profiles of deformed armor layers due to the multidirectional wave with the design wave height at $\alpha=67.5$ deg. of the concave section. Under the design wave conditions for three wave directionality, the multidirectional wave gives the largest damage to the profile change although the differences are small. It is seen from the difference between the initial($t/T=0$) and final($t/T=3000$) profiles that small area just below the still water level was eroded and accumulated close to by down the slope. This eroded area is quantified with the damage level $S \approx 4$. Although the area eroded is small, it is not allowed under the current design concept. The armor units used in the experiments correspond to the maximum one available in practice. So it is necessary to do further work to make alternative ways to satisfy the present design method, i.g., to use high density armor units or to use more stable armor units.

Fig. 11 shows the profiles due to the functional check wave at the same section. The armor units initially placed near the still water level were removed by much severer waves than the design wave. In this figure, an eroded area is seen but accumulated one is not. Change of area does not balance between the initial and final profiles. It is because the armor units were removed in the wave propagation direction, not down the slope. The damage level S at the final profile at $t/T=3000$ is about 11. For the functional check wave as well as the design wave, the damage does not reach the crest level of armor layer.

Figures 12 and 13 show the damage level change dependent on the time of wave duration. Deformation occurs at an early stage of the wave duration. This tendency is same as the previous results obtained using two dimensional tests(Kajima *et al.*, 1994). The damage level due to the design wave height reaches at most five at $\alpha=45(\text{deg.})$ denoted with the solid square as shown in Fig. 12. The damage level of $\alpha=67.5(\text{deg.})$ at $t/T=3000$ is four of which the profiles were shown in Fig. 10. It is considered that the damage level around five indicates small damage

Fig.10 Profiles deformed with design wave($H/H_D=1.0$)

Fig.11 Profiles deformed with functional check wave($H/H_D=1.24$)

from the geometrical point of view.

Fig. 13 shows the damage level change due to the functional wave. The most serious damage occurred at $\alpha=67.5(\text{deg.})$ of which profiles were given in Fig. 11. The damage due to the larger wave also occurred at the early stage of wave duration. The damage level does not increase significantly compared with the results of the design wave height. However, it was observed that more armor units were removed by the functional check wave than the design wave. They were carried away in the direction of wave propagation not down the slope. Some of the removed armor units might fill up the eroded part at the different sections. Consequently, the obtained damage levels are rather small compared with the results of the design wave height.

Fig.12 Time history of damage level (multidirectional wave, Case A1)

Fig.13 Time history of damage level (multidirectional wave, Case A5)

The hollow circle in Figures 12 and 13 shows the damage level at the offshore-side seawall where the wave motion is expected as two-dimensional. Its damage level is very small for the design wave height but somewhat large due to the functional check wave.

In this experiment, the wave was applied for 3000 times the significant wave period which is equivalent to more than 13-hour duration. It is expected that the extremely large wave does not last such long time. Therefore, the damage level will be reduced by taking account of the wave duration. It is required for estimation of the damage level in practical use that the duration time should be considered as a function of the wave height and period.

Fig. 14 shows the damage level at the final stage ($t/T=3000$) around the concave section, where the effect of the wave directionality is compared for the design wave height. The damage level around the center of the concave section has peaks for three different kinds of wave directionality. Although it is seen that the damage level due to the design wave height of multidirectional wave is the largest, which is up to five, it is not concluded that the effect of the wave directionality is significant by considering the magnitude of damage which are small. The damage level at the side seawall is invisible.

Fig.14 Damage level at concave section due to design wave

Fig.15 Damage level at concave section due to functional check wave

Fig. 15 shows the result by the functional check wave height. Larger waves than the design wave cause more serious damage as expected. The obliquely uni-directional irregular wave caused the most serious damage around the whole concave section and the damage level becomes 20. However, it is considered that such condition resulted in an overestimated one. The normal incident waves caused the maximum damage level about ten for both the multidirectional and uni-directional waves. As the results of two normal incident waves, the wave directionality does not influence the damage at the concave section.

Considering reparability of the damaged section, it have to be estimate an allowable damage level for the severer wave than the design wave. Under both the design and functional check conditions, the deformation of the armor layer does not reach the crest elevation. It is important that damage does not reach the crest elevation in order to keep functions of seawall. Otherwise seawall collapses in a short time like the result of the obliquely incident wave.

6 Conclusions

The effect of the wave directionality on the overtopping rate was confirmed by tests using the multidirectional wave basin. It is caused by the diffracted waves generating at the concave section of the man-made island. The durability of the armor layer is confirmed for both the design wave and the larger wave than it. The margin of the safety can be expected to a certain degree against the larger wave than the design wave. The following s are main conclusions obtained by the present work.

Conclusions:

- 1 The multidirectional waves give smaller overtopping rate than uni-directional waves for normal incident condition. Oblique wave gives the smallest.
- 2 The overtopping rate was estimated for both in the drainage channel and onto the site of power plan. The later case is important for the safety of power plant. The equivalent precipitation can us information to design the drainage pumping system in the site power plant.
- 3 No serious damage at the concave section of seawall was confirmed for keeping seawall's functions.

Future works:

- 1 To make a model to estimate the overtopping rate with a numerical model to simulate wave height around an man-made island.
- 2 To make no damage at concave section for the design wave. Alternative ways are to use high density armor units and to use more stable armor units.

CHAPTER 146

NUMERICAL MODELING OF BREACH GROWTH IN A SANDDIKE

by

Guus S.Stelling, Willem T.Bakker, Christine van Kuik and Christel Somers¹²

ABSTRACT.

On October 7, 1994 a full scale breach growth experiment has been carried out at the Dutch- Belgium border, in the Zwin at the west-end of the Dutch-Belgian border. A small breach was initiated in a sanddike with a height of 3.25 m and the breaching process was monitored. The present paper focusses on the numerical modeling (hindcasting) of the breach growth process.

1 INTRODUCTION; GOAL OF THE INVESTIGATIONS.

De Looff et al.(1996) give a summary of the current breach research in the Netherlands. The present paper reports on a part of these investigations, i.e.:

- . the full scale field experiments of 1994 (Zwin);
- . the present research, which should lead to a comprehensive numerical model for breaching processes.

On October 7, 1994 a full scale breach growth experiment has been carried out at the Dutch- Belgium border, in the Zwin [1], [2]. Fig. 1 shows the site of the experiment at the west-end of the Dutch-Belgian border.

A small breach was initiated in a sanddike with a height of 3.25 m and the breaching process was monitored. The experiment was carried out by Rijkswaterstaat and Delft University of Technology, with aid of Delft Hydraulics Laboratory.

Ultimate goal of the investigations, which are reported on is extrapolation of the behaviour of the Zwin breach to other circumstances:

- . Construction of the dike: use of other materials (clay instead of sand);
- . Larger areas of the submerged basin;
- . Other bottom level of the submerged basin.

The present paper focusses on the numerical modeling (hindcasting) of the breach growth process.

2 MEASUREMENTS.

The Zwin experiment has been reported before (Visser et al.,1995a,b): an experimental closure of a tidal basin near the Dutch-Belgian border, which is a historic residual of the former tidal entrance to the Belgian city of Brugge, called "the Zwin" (fig.1). Twice in 1994, on October 6 and 7, the inlet was closed off by a sanddam; breaching was simulated by digging a small trench in it at High Tide.

Fig. 1. Situation

Fig. 2. Site of measuring poles

Fig.2 shows the measuring site with the artificial dam. MP 2..6 are measuring poles in which the water level and the current velocities were measured. Maximum velocities were of the order of 4.2 to 4.4 m/s.

Fig. 3. Trillo's

An array of burglar alarms was placed in and underneath the dike in order to monitor the breaching process.

These alarms, specially developed for these tests were called: "Trillo". Fig.3 shows the instrument, with a PVC bar fixed to a watertight PVC cylinder (length 20 cm). The alarm consists of a piezo-electric element, reacting on the motion of a bolt, which is attached to it with a spring. When the PVC cylinder, buried in the sand, turns loose the bolt will tremble, which is monitored by an electrical signal in the piezo-electric element.

Fig.4 shows the sites, where the burglar alarms were placed in and underneath the dike and furthermore the dimensions of the dike.

¹Dutch: translated in English: "Tremblo".

It reaches up to a level of 3.30 m above NAP (which is about OD). The high water level at which the breach was initiated was NAP 2.75 m. An initial trench in the dike was dug to a level of NAP +2.50 m. Poles had been placed in a 5m-pattern underneath the dike. The Trillo's were attached on these poles at a mutual distance of 75 cm (4 Trillo's per pole). This paper reports on the second day of experiments. At that time the Trillo's in the body of the dike were not present any more because of the experiments of the first day. Also the Trillo's in the front of the dike disfunctioned the second day. Before looking to some results of the measurements it is useful to

Fig. 5. Phases

the experiment. The dip "a" in the water level on the seaside of the dike is caused by the Bernoulli term. Measuring gauges in deeper water show a convex curve in this hour. The thin lines (with the scales on the right) show the measured velocities in course of time on the seaward and landward side (maximum velocities 4.3 m/s).

remind to the various phases of breaching, as indicated by Visser (1995). Successively, one observes the steepening of the inner slope, backscour of the inner slope and removal of the sill at the seaside of the dike. After this happens, the breaching process reinforces itself and a quick growth of width takes place. Refer to fig.5 and the photo's 1 to 8. The thick lines in fig.6 show the water level at the seaside and the inner side of the dike as function of time. Indicated is the moment of initiation of the breach and the moment of the turning of the tide; furthermore the end of

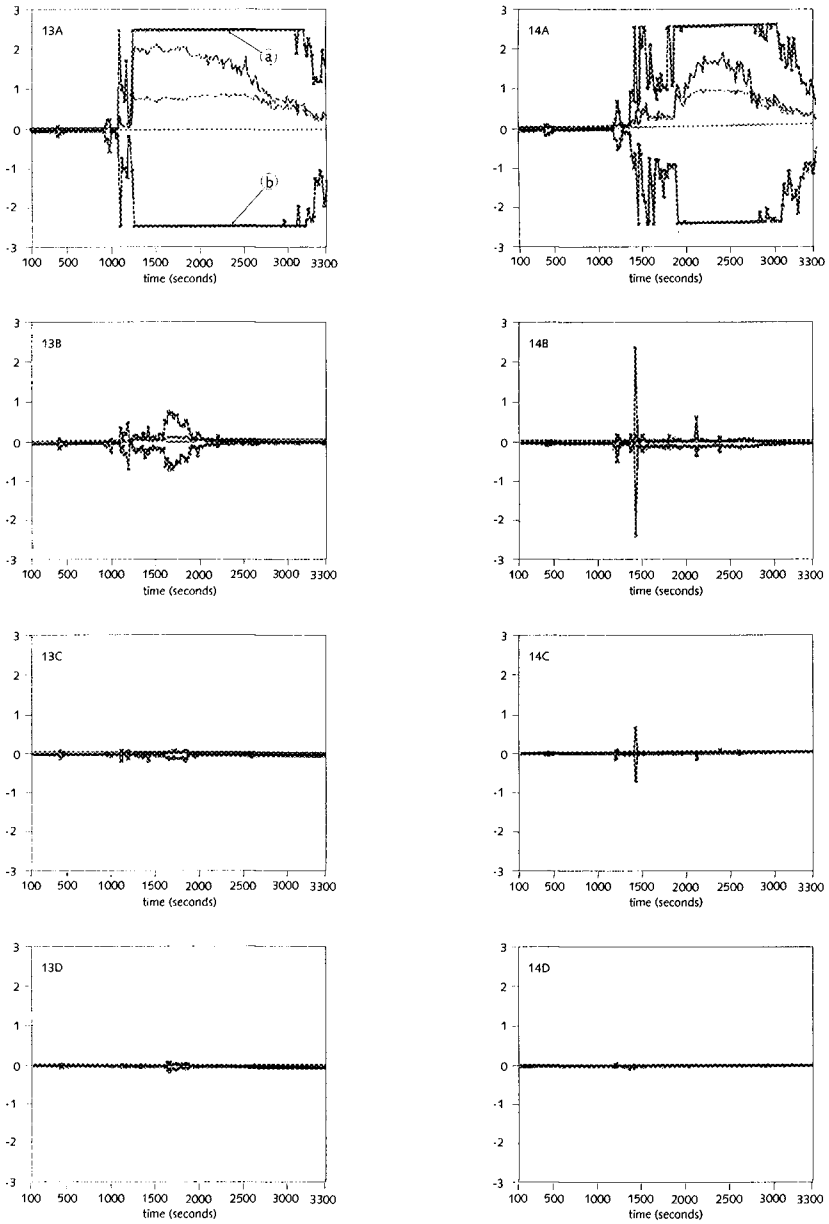

Fig.7 . Trillo registrations

Fig.7 shows the 8 registrations of two vertical rows of each 4 Trillo's, somewhat landward of the center of the dike. The larger the deviations between the lines "a" and "b", the larger the motion of the Trillo's.

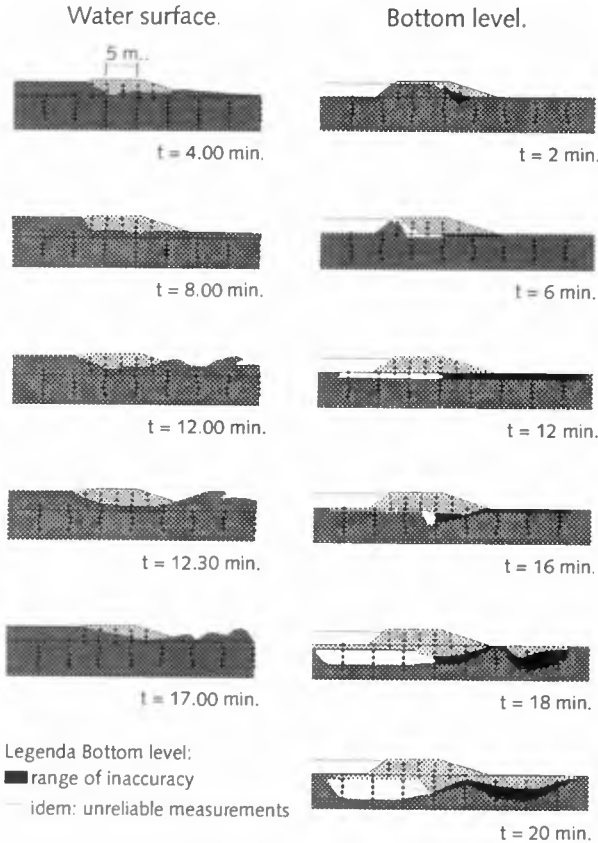

Fig. 8. Waterlevel and bottom depth

From visual analysis of the video's and slides and from the Trillo's figure 8 resulted concerning the relation between the water motion and the scour.

In the lefthand figures the dike and the watersurface at various times are indicated. No attention to the bottom is given. In the right-hand picture the bottom development is shown.

The black and white band show the rate of inaccuracy. The white band was caused by malfunctioning of the Trillo's; the black band by inaccuracy of interpretation. In both cases the upper side of the band is more likely than the lower extreme (in the white area this lower extreme is even very unlikely).

It doesnot seem likely, that much deeper scour holes occurred than 2m below the original bottom level. These scour holes were formed not before the phase of the breach, in which the sill at the seaside was removed.

COMPUTATIONS.

Numerical computations were made with the 3-D Trisula model of Rijks waterstaat and Delft Hydraulics. Fig.9 shows a 2DH-current pattern.

Fig.9 . Trisula model

With a flat sloping bottom (dotted line in fig.10), the water surface (in the center line of the breach) according to the line, indicated with diamonds was computed. The stars show the measured values after 12.5 minutes. If scour holes were introduced (lines with triangles; fig.10), the water surface as indicated by blocs was the result.

Fig.10. Water surface

Fig.11. Velocities

Current velocities (for the case with flat bottom) are as given in fig. 11. Maximum velocity found was 4.3 m/s.

IMPRESSIONS.

From the investigations, the following impressions resulted concerning the hydraulic aspects:

- . The maximum velocities occurred shortly after washout of the dike in the breach;
- . At that time the water level in the breach is mainly determined by the Bernoulli term;
- . The Froude number of the maximum velocity occurring in the breach was of the order of 1.5;
- . The current has a jet-like character; a Bernoulli-trough with a depth of ca. 1 m could be observed, ending in an undular jump.

Concerning morphology the following observations c.q. impressions seem relevant:

- . The dike washed away with a velocity of 2 m/minute; the sand consisted at some places of coarse sand, originating from a former artificial sand supply with a grain diameter of .315 mm and at other places of local sands with a diameter of .185 mm.
- . Scour started to develop at the landward side of the dike; this might have triggered an undular jump.
- . The bottom changes show some similarity with the dynamics of antidunes.

SEDIMENT TRANSPORT MODEL (under development).

A pick-up transport model (appendix B) is developed with the following characteristics. The acting forces are: self-weight; shear stress on the surface and the horizontal pressure gradient.

Hindered entrainment is implemented, caused by:

percolation resistance.

This is the resistance which occurs if a mass of grains is moved in vertical sense through a mass of ambient fluid.

Percolation resistance does not imply changes in the grain structure.

Suction forces in the contact points between the grains.

Additionally to the percolation resistance, there should be accounted for viscous suction forces, caused by opening of the grain structure, at the sites, where originally touching grains are quickly separated.

Fig.12. Zip-erosion.

Fig.13. Virtual reduction self-weight by horizontal pressure gradient.

The feature to be simulated is called: "zip-erosion" (fig.12).

In the course of the breaching process, the career of a grain is as follows. First it makes part of the soil, then of fluffy soil, then of dense slurry and it ends as suspension transport.

When the thick horizontal line in fig.12 is the bottom, the curved line shows the mutual distance between the grains, i.e.: an average gap width. The mutual distance between the grains is negative-exponential in downward direction.

During "Zip-erosion" the process of detaching propagates (as a zipper) with constant velocity in downward direction.

In the area just below the bottom line dilatation takes place. In the model, this process is simulated because the grains play leap-frog, triggered by gravity and pressure. Instability occurs, when the layers play leap-frog; this doesnot lead to infinite transports.

The model starts from the presumption of perfect spheres, which gives instability under an angle of repose of 30^0 in the case of a horizontal water surface, but 15^0 in case of a water level, parallel to the slope. This because of the effect of the horizontal water pressure.

Based upon hydrology and soil mechanics considerations, essentially the same mechanism was indicated by Edelman (1960).

Fig.14. Direction motion grains for horizontal water level and for water level parallel to slope.

6 ACKNOWLEDGEMENT.

The Zwin experiment and its elaborations were made possible by funding of the Technical Advisory Committee and the Road and Hydraulic Engineering Division of the Rijkswaterstaat. The Marine Survey Department of the Directorate of Zeeland of the Rijkswaterstaat carried out the current measurements and surveys; the Section Zeeuws Vlaanderen helped with the organization. Furthermore, collaboration is gratefully acknowledged of the Foundation "The Zeeland Landscape", the Belgian Service for Coastal Harbours, the Royal Dutch Army (the Corps of Military Engineers and the Military Command of Zeeland), the contractors Aertssen NV and Janson Bridging. Supervised by W.T.Bakker, P.J.Visser, A.W. Kraak, H.J.Steetzel and J.v.d.Graaff preparation of the experiment was carried out by M.J.Smit and D.W.Snip as part of their M.Sc.thesis work at Delft University of Technology. Many students of the Coastal Engineering Department assisted with the measurements. The authors acknowledge the contribution of P.J.Visser concerning fig.5 and photo 1,7 and 8 and of Mr.C.A.Pugh of the Bureau of Reclamation, who is the photographer of the other photos. Graphical assistance concerning the other figures by the Dept. for Visual Display of Rijkswaterstaat and by mr.M.Voorendt of Delft University should be gratefully acknowledged.

7 APPENDIX A. Hydraulic Model

MODEL EQUATIONS

The numerical model is based upon approximations for continuity, momentum, and transport equations for salinity, heat, turbulent kinetic energy k and its dissipation rate ϵ . The equations are based upon the hydrostatic pressure assumption. In cartesian coordinates they are given by:

continuity equation:

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (1.a)$$

momentum equations in the horizontal:

$$\frac{\partial u_i}{\partial t} + \frac{\partial u_i u_j}{\partial x_j} + \frac{1}{\rho_0} \frac{\partial p}{\partial x_i} + \frac{\partial R_{ij}}{\partial x_j} = f_i, \quad i=1, 2 \quad (1.b)$$

hydrostatic pressure assumption:

$$\frac{\partial p}{\partial x_3} = -\rho g \quad (1.c)$$

transport equations:

$$\frac{\partial c}{\partial t} + \frac{\partial F_i}{\partial x_i} = P \quad (1.d)$$

where u_i is the velocity in x_i direction, p is the pressure, ρ is the density, ρ_0 is a reference density, g is the acceleration due to gravity, c is the concentration, f is the external forcing, e.g. wind, F is the concentration flux due to convection and diffusion, R is the Reynolds stress tensor, and P is the dissipation and/or production function. The Reynolds stresses are modeled via the well-known eddy viscosity concept. The density ρ is supposed to be constant i.e. $\rho = \rho_0$.

The equations are transformed via a transformation given by:

$$\xi = \xi(x_1, x_2), \quad \eta = \eta(x_1, x_2), \quad \sigma = \frac{x_3 - \zeta}{h} \quad (2)$$

in which ζ is the free surface elevation, and h is the water depth. In the horizontal the transformations are orthogonal, in the vertical it is the well-known sigma transformation.

For the numerical approximation a "C grid", i.e. a fully staggered grid has been chosen. As far as the spatial derivatives are concerned the approximation method is based upon second order central differences for the continuity equation and for the pressure terms in the momentum equation. For the advection terms some weighted average is being used of second order upwind differencing and second order central differences. The integration in time is based upon a second order ADI and AOI (alternating operator implicit) type of factorization technique. Details are given by Leendertse (1989), Stelling and Leendertse (1992).

8 APPENDIX B. Sediment transport model

The principles of the sediment transport model, which will be used, are described in Bakker & van Kesteren (1986), Bakker, van Kesteren & Klomp (1990), Bakker & van Kesteren (1994) and Bakker & van Kesteren (1996). A comprehensive report concerning the theory will be published in 1997.

CHAPTER 147

AGING AND STABILITY OF PLACED BLOCK REVETMENTS

Theo Stoutjesdijk¹⁾, Hans Johanson²⁾ and Mark Klein Breteler³⁾

Abstract

Since the early 1980's fundamental research on the behaviour of placed block revetments has been carried out in the Netherlands. This research has focussed on understanding the physics of this particular revetment type, which has resulted in empirical (Pilarczyk, 1985), analytical (Burger et al, 1990) and numerical (Bezuijen et al, 1987) design methods. These methods have been tested extensively in large and small scale model tests (for instance Klein Breteler, 1988, den Boer et al, 1983).

During the last years extensive field research has been carried out (Stoutjesdijk, 1992). This research has shown that a large difference in physical behaviour can exist between newly placed revetments or large scale models, and older ('aged') revetments in the field. To investigate this phenomenon further, field work, laboratory tests and modelling efforts have been carried out. This paper describes the current state of affairs. Purpose of this research is to quantify the net effect of aging on the stability of placed block revetments. If the net effect proves to be positive, it may prove possible to upgrade the stability of revetments by artificial simulation of aging effects.

Historical development of placed block revetments

In the Netherlands dikes of clay have been built since approximately 1200 AC. Especially in the coastal and estuarian zone some type of revetment protecting the dike from erosion by waves has been necessary. Originally wooden pile

¹⁾ Delft Geotechnics, P.O. Box 69, 2600 AB Delft, the Netherlands

²⁾ Dutch Ministry of Transport and Public Works, Department of Road and Hydraulic Engineering, P.O. Box 5044, 2600 GA Delft, the Netherlands

³⁾ Delft Hydraulics, P.O. Box 177, 2600 MH Delft, the Netherlands

constructions were used for this purpose. Later, the soil was protected by stone. In the absence of rock quarries to provide sufficient amounts of stone, revetments were constructed by placing the stones manually in a closed pattern. Originally natural stone such as basalt was used, but in more recent years also concrete blocks are used at a large scale.

Beneath the blocks it was common practice to use reed mats to protect the soil. On top of this mat layers of bricks were placed to provide a smooth surface. To deal with the unequal sizes of the stones in the top layer rubble stone of smaller size was used. This rubble stone acts as a filter layer, but is relatively coarse for this purpose, and originally was not used knowingly for this purpose. Newer dikes were no longer exclusively built by using clay. With increased dredging capability sand became a cheap material. A large number of dikes have been constructed by placing quays of mine stone and placing sand in between them. These mine stone quays can also be identified as permeable sublayers of the placed blocks. Between the mine stone and the top layer a thin layer of filter material is present.

With the availability of concrete blocks, all of the same size, this rubble stone layer or filter layer is no longer absolutely necessary. It was thought advantageous to place the blocks directly on the clay layer. Because clay is a relatively impermeable material no uplift pressures beneath the blocks would be expected. In practice however, some problems with this type of revetment occur. In time, clay can be eroded from beneath the blocks, forming gaps between the blocks and the surface, thus causing a stability problem. Secondly, the clay dries out, cracks, becomes more permeable and if the top layer fails, the clay layer is more erodable by wave activity than thought earlier.

Figure 1 Example of a placed block revetment

Until the 1980's no design criteria on the stability of placed block revetments were available. Revetment design was based on experience. This experience was strongly damage-related, meaning that if blocks of a certain size at a certain location experienced too much damage during storms subsequently heavier blocks would be used. In the frequently loaded zones lower on the revetment this can work satisfactorily; waves can be depth-limited so that a revetment experiences waves that are almost design waves during its lifetime. In seldomly loaded areas of the revetment the design wave attack is more severe and there is no experience showing that heavier blocks are needed. Therefore, a lot of these revetments will not meet today's design standards and will have to be reinforced.

Figure 1 shows an example of a placed block revetment. As the term 'placed blocks' already indicates the top layer consists of blocks that are placed together in a closed pattern. The sublayer consists either of a filter layer of granular material or a clay layer, or in some cases both.

In time, and especially in the tidal zone, sand and other material from the foreshore is washed into the revetment. This causes the physical properties of the revetment to change quite dramatically (Stoutjesdijk et al., 1992).

The definition of aging, as used in this paper, is: "Aging is migration of sand from the foreshore into the top layer and/or filter layer."

The physical behaviour of a placed block revetment on a filter layer can be described by use of the so-called "leakage length":

$$\Lambda = \sqrt{\frac{b \cdot D \cdot k}{k'}}$$

with:

Λ	leakage length [m]
b	thickness of filter layer [m]
D	thickness of top layer [m]
k	permeability of filter layer [m/s]
k'	permeability of top layer [m/s]

By means of the leakage factor the hydraulic head (difference) over the top layer can be described analytically.

Background of research

In the 1980's a fundamental research program on the stability of placed block revetments was started. Design formulae based on model tests and descriptions of the physical behaviour of placed block revetments were developed.

In the 1990's attention has been paid to measuring field performance of existing revetments (Stoutjesdijk et al (1992)) and it was found that existing

revetments can show a different behaviour from that found in model tests. This was subscribed to the fact that, especially in the tidal zone, sand and other material from the foreshore had migrated into the filter layer and the top layer. Because the behaviour of the revetments was different from that of newly constructed revetments this was referred to as 'aging effects'.

The reason to research the effect of aging on stability is twofold. On the one hand, it is necessary to determine the actual strength of existing revetments, especially in the tidal zone. On the other hand, if aging proves to have a positive effect on revetment stability, it may be possible to upgrade the stability of existing revetments (above the tidal zone) by artificially filling them with sand.

Aging

Aging is defined as the migration of sand from the foreshore into the revetment. Both filter layer, which consists of coarse grains, and the cracks between the blocks can in time become completely filled with sand.

The most obvious way to see whether or not aging has taken place is to lift some blocks out of the revetment and inspect the filter layer and the cracks between the blocks. This has been done at several locations. Sieve analysis of samples of the filter layer has shown that weight percentages up to 30 % of sand can be present between the coarse filter material. The cracks between the blocks can be almost completely filled with sand, silt, shells and small stones. In one instance, when a bore hole was drilled through the top layer to place a pressure transducer in the filter layer, it was found that about 20 cm sand had sedimented into the bore hole during one single storm.

These extreme conditions are found in the tidal zone. More extensive investigations indicate that higher on the revetment less and less sand is found in the revetment.

In the tidal zone marine growth is common. Higher on the revetment, above the splash zone, grasses, wild plants and flowers are found.

Field measurements

To gain more insight into the actual behaviour of existing placed block revetments a field measurement campaign was initiated. A fairly simple method to measure the permeability of the top layer is to place a square box with no bottom on top of the revetment, fill this with water and monitor the speed with which the water level decreases. This can be supplemented by placing pressure transducers in the filter layer to check the pressure difference (hydraulic head) over the top layer. Usually no pressure built-up takes place in the filter layer, due to the limited permeability of the top layer.

Results of these tests indicate that permeability varies with the height at which the measurement takes place. One event showed a permeability 10.000 times less in the tidal zone compared to that high on the revetment.

Another type of test is the infiltration test. One or two blocks are lifted out of the top layer, and an infiltration box is placed directly on the filter layer. Water is pumped into this box until a more or less stationary situation is obtained. At several points around the infiltration point pressure transducers are placed in the filter layer. The pressure differences between the infiltration point and the pressure transducers can be used to estimate the leakage length.

This method has first been tried out in a large scale model. These results were encouraging. In the field problems were encountered with filters that consisted of more than one layer, and 'leakage' of pressure towards the sand core, whereas the model assumes a impermeable lower boundary. Also, it can occur that higher on the revetment, permeabilities are very high and that pumping capacity is inadequate to obtain sufficient pressure in the filter layer.

Measurements have also been performed during storm conditions. On the top layer a beam with several pressure transducers is fixed. Next to this beam bore holes are made in the top layer to place pressure transducers in the filter layer. In this way the reaction in the filter layer to wave pressures on the top layer are determined. These measurement can be numerically simulated to obtain the leakage length of the revetment. Because of practical reasons this type of measurement can only be performed in or just above the tidal zone, where moderate storms (several times per year) occur. In one instance, a leakage length of more than 10 m was found in the tidal zone. On another occasion the leakage length varied over a short distance: a leakage length of 6 m in the tidal zone was determined, while just above high water level the leakage length appeared to be 0.5 m.

During a third measurement a surprising new phenomenom was found. In expectation of a rather high water level the measurement beam was fixed higher on the revetment than usual. It appeared that, although the water level was high enough to record significant waves with the measurement beam, in the filter layer no pressures were recorded at all. As it appears, due to the limited permeability of the top layer and the filter layer, the rise in sea water level does not coincide with an equal rise in water level in the filter layer. There is both a phase lag and an amplitude damping. The water level in the filter layer never reached the level of the pore pressure transducers.

To see if this phenomenom could be measured and hindcasted several measurements of tides and corresponding water levels in the filter layer were carried out, all of which confirmed this theory. Due to the slow variation of water levels, it appears that if the subsoil consists of sand, this has a large influence on the flow of water to and from the filter layer. Also the permeability of the toe construction can have a large influence on the inflow of water into the filter layer. In some cases this has made interpretation difficult.

Pulling tests

As discussed in the previous paragraph, on several occasions decreased permeabilities led to larger values of the leakage length. This leads to an increase in load on the top layer during storms. If only the weight of the blocks is taken into account, severe damage in the tidal zone would be expected even during moderate storms. This is not the case. Even though in practice some damage occurs during 'once a year' storms, no major damage is found.

The presence of material in the cracks between the blocks appears to have a stabilizing effect. The interaction between blocks is improved, but also very important is the fact that the probability of very loose blocks is reduced.

At a number of locations pulling tests have been performed. To perform this test a specially designed pulling unit is manoeuvred into a position above a block, the pulling unit is attached to the block and then the block is pulled out perpendicular to the revetment. The pulling force and the corresponding movement of the block are registered.

Figure 2 Example of the results of pull out tests on square concrete blocks

One example of these pulling tests is shown in Figure 2. Shown are the results of tests on square, concrete blocks (size 0.5 x 0.5 m and 0.25 m thick) on different levels of the revetment. On the vertical axis the pull-out force is given in kN. The weight of one single block is about 1.35 kN. Only at the levels which are high above mean sea level a few 'very loose' blocks are found.

Not shown in Figure 2 is the fact that in the tidal zone no blocks could be pulled out at all, not even with a pulling force of six times the weight of one block.

Since then, a number of sites were visited with this equipment, and more insight into the strength of the top layer has been gained. To properly evaluate the strength it is necessary to statistically analyze these pulling tests. The approach aims at a lower boundary criterium of the strength that can be taken into account that is exceeded with a known, high reliability.

Application of these statistical methods to the results of pulling tests shows that, even though high pulling forces can be found for the majority of blocks, the net effect of this extra strength still is limited to factors 1.1 to 1.2 for large square concrete blocks. In the tidal zone higher factors can be found, and also polygon shaped blocks which have been washed in with gravel can have significant additional strength due to clamping forces.

Test location

The fact that in the tidal zone high pulling forces are found was subscribed to the fact that the revetment was entirely filled with sand at these lower levels. At a test location artificial filling of the top layer with sand was applied.

The test location consisted of six sections. The top layer in five of these sections was recently placed. The sixth section had been constructed in 1984, and had quite a lot of vegetation growing in the cracks between the blocks. The newer sections consisted of a reference section, where no special measures were taken, and four sections where coarse sand and fine sand, and different ways of filling the top layer (brushing in, washing in, densification) were tried. All of these attempts were succesfull.

In Figure 3 the results of pulling tests on this test location are shown. On the vertical axis the pulling force is expressed as 'Times blockweight'. On the horizontal axis the frequency or percentage of blocks that can be pulled at a certain pulling force is given. As an example, from the graph can be read that at a pulling force of 5 times the block weight only 1 % of the blocks in the old section can be pulled out. For the reference section this amounts to about 1.5 times the block weight and for the artificially filled sections a value of about 2 times the block weight is found.

In Figure 3 the symbols indicate the following sections:

- ∇ the old vegetated section
- the new reference section
- + new section, brushed in with coarse sand
- ⊗ new section, brushed in with fine sand
- △ new section, brushed in with fine sand and densified
- x new section, fine sand is washed in with water

As it appears two conclusions can be drawn from these results. Clearly the

strength of the older, vegetated top layer is much larger than the newer sections. This can be due to the influence of vegetation. Perhaps there is also some effect of cementing between the sand particles.

Secondly, the artificially filled sections perform slightly better than the reference section. The expected benefit lies in a range of 20 to 50 % increase in strength of the top layer.

In 1997 this location will be revisited to see if the sand is still present or that the sand has to be supplemented periodically. It would also be interesting to see whether the artificially filled sections can in time reach the same level of stability as is the case the old section.

Figure 3 Results of pull out tests on test section

Stability of sand in small cracks

One of the questions regarding the presence of sand in a revetment is whether the sand remains in the revetment during storm conditions or is washed out during wave attack. This was investigated in model tests using a set up as shown in Figure 4. The general idea is very simple: between two plates a small crack with a width of 1.5 to 6 mm is created. In this crack sand is placed. Then an upward hydraulic head is applied to the sand. The critical hydraulic head at which the sand is washed out is recorded.

Figure 4 Set up of model to test the stability of sand in small cracks

In Figure 5 some of the results from these tests are presented. A line has been fitted through the results of the tests with a static hydraulic head, using the equation:

$$i_{crit} = 6.2 \cdot D_r^{0.25} \cdot N^{-0.3} \cdot U^{0.4}$$

- with: i_{crit} the critical hydraulic head
 D_r the relative density of the sand $(n_{max} - n)/(n_{max} - n_{min})$
 n porosity (n_{max} , n_{min} are the maximum and minimum porosity)
 N the ratio between crack width and grain diameter
 U the uniformity of the sand (D_{60}/D_{10}) .

From Figure 5 it appears that some of the tests show high values for the critical head. It is assumed that the sand forms arches between the two walls of the

crack, and is thus able to withstand a considerable upward hydraulic head. As the ratio between crack width and grain diameter becomes larger this effect decreases, and eventually the critical hydraulic head will become close to 1.

There is some effect of density of the material. It is not entirely clear whether this has to do with material behaviour (dilatancy) of sand or with a more efficient way of forming arches in dense sand.

The uniformity of the material is demonstrated most clearly if a small layer of coarse material is placed upon a larger layer of fine material. Due to the higher permeability of the coarse material there is no built up of uplift pressure on this layer, and therefor the layer acts as a plug.

Figure 5 Results of static and cyclic head tests

The tests where a cyclic hydraulic head instead of a constant hydraulic head was used indicate that in general lower critical heads are found in the cyclic tests. The sand is washed out more easily. This can be subscribed to the fact that if arches are being formed by flow of water into one direction, these arches are continuously being formed and destroyed by a cyclic flow of water. Thus the sand is homogenized and washes out more easily than during tests with a constant hydraulic head.

In the cyclic tests there is a difference between 'start of movement' and 'wash out'. Once the sand is observed to start moving in one direction there is some time required to actually form a sand-water mixture that is washed out. During this time the flow can change direction.

In all cases however the critical head lies above the value of 1, which is the threshold value where the sand is supposed to liquefy and wash out.

Stability of sand in a filter layer

The stability of sand in a layer of granular material (gravel) has also been tested. Figure 6 shows the test set up. In a test cel with a diameter of 30 cm a gravel layer is placed. Then the sand is washed in and an upward hydraulic head is applied. Again the critical head at which the sand is washed out is recorded. Typical values for this critical head are 0.6 for loose sand and larger than 1 if the sand has been densified before the test is begun.

The mode of failure as observed during these tests is that at lower hydraulic heads small wells at the surface and pipes in the sand between the grains occur. At the critical value of the hydraulic head the entire sand mass is 'boiling' and can easily be transported away.

Figure 6 Set up for tests on sand-grain mixtures

The tests also permitted for the permeability of the sand-grain mixture to be measured. It was found that the permeability of these gap-graded mixtures was about equal to 0.3 times the permeability of the sand used in the tests. This seems a logical result, considering the fact that flow takes place through the sand and that the sand is present in the 30 % pore space between the gravel.

Modelling

Obviously, aging, in other words the presence of sand in the construction, causes permeabilities to decrease. This can lead to an increase in hydraulic load over the top layer.

On the other hand, due to the presence of sand, interaction between the blocks is improved, and if the cracks are completely filled with sand, the probability of loose blocks (blocks that do not interact with other blocks when loaded) is strongly reduced.

Figure 7 Hydraulic head difference (lower part) and corresponding displacement (upper part)

Modelling of different aspects has consisted of simple models, such as spreadsheet models or analytical, conceptual models, and more sophisticated modelling. Bezuijen (1994) is an example of an approach to describe hydraulic loads,

block movement and subsequent clamping forces in a revetment during oblique wave attack using the numerical STEENZET code.

In order to be able to simulate the complex event of block movement during wave-attack calculations have been made with the STEENZET-model to establish the hydraulic load on the top layer. The corresponding movement of the blocks in the top layer has been calculated with the Finite Element code DIANA. If the blocks are all touching each other the vertical movement causes large horizontal forces in the plane of the slope. These horizontal forces have to be counteracted by support (or stiffness) of the toe and top structure, and by friction between the blocks and the sublayer. An example of this procedure is shown in Figure 7. In the lower part of the figure the hydraulic head difference of a revetment at the moment of the impact of a breaking wave is shown. Above and below this point an upward hydraulic head is generated. The upper part of the figure represents the calculated response of the block revetment in terms of displacement. The movement is scaled up for presentation. Just to give an idea of the real dimensions it can be mentioned that this calculation gives an upward hydraulic head of about 1.75 m, which results in a movement of block 34 in the figure of about 7 cm. The upward water pressure is compensated by the weight of the blocks as due to clamping forces a lot more blocks are lifted than just block 34.

It is now thought that in the case of square concrete blocks the stability of a row of blocks parallel to the waterline is more critical for the stability of the top layer than the situation for blocks in a column parallel to the slope shown in Figure 7. This is because in the case of perpendicular wave attack an entire row of blocks is loaded with almost the same upward load. Theoretically all the blocks in this row would show the same upward movement and clamping can not take place. From calculations for this type of problem it appears that the presence and the stiffness of the material in the cracks is very important. Additional top layer strength is calculated to be 10 to 40 %, which is in reasonable agreement with the results of pull out tests on this type of revetment.

From the pull out tests a larger degree of additional strength is expected from polygon shaped blocks which are washed in with gravel. This is because the blocks do not spread the load into one direction (row or column) but in different directions. In the future 3D simulations will be performed to investigate this.

Conclusion

Finally, the balance between positive effects of aging, such as an increase in top layer stability by an improved interaction between blocks, and negative

effects, such as a possible increase of load on the top layer, has to be made up. Question marks in this process are the stability of sand in the revetment during storm conditions and the possibility to artificially fill filter layers with sand. The overall net effect of aging is, qualitatively, expected to be positive. There is a strong need for quantitative measures. This will take a lot more study of detail processes using for instance sophisticated models, large scale model tests but on the other hand also simple pragmatic tests, field research and test locations.

CHAPTER 148

Experimental Analysis of the Settlement Failure Mechanism Shown by Caisson-Type Seawalls

Shigeo TAKAHASHI¹,
Kojiro SUZUKI¹,
Katsumasa TOKUBUCHI²
Ken-ichiro SHIMOSAKO¹

ABSTRACT

We conducted a series of model in a wave flume measuring pore pressures in the reclaimed soil (sand) to investigate the settlement failure mechanisms of caisson type seawalls. Settlement of reclaimed soil was reproduced by considering that the geotextile sheet, which separates the backfill and reclaimed soil regions, had an opening ripped in it such that soil rapidly leaks out. Also reproduced were the phenomenon of sand boiling (liquefaction), the presence of saturated reclaimed soil above the backfill stones, seawall construction with no backfill stones, and impulsive pressures acting on the joint plate connecting two caissons. Experiment results further clarified the fundamental mechanisms of the settlement failures.

INTRODUCTION

The recent utilization of reclaimed land to provide large-area, man-made islands, e.g., those used for airports, has necessitated their construction in relatively deep seas, which naturally requires them to be surrounded by seawalls that are directly exposed to strong waves since no protective breakwaters are present. Consequently, failures frequently occur during and after construction. The settlement of reclaimed soil behind the seawalls is considered to be responsible for most, and while this type of failure *does not* result in complete failure of the seawall, it *does* lead to land-usage problems and expensive long-term maintenance requirements.

Photo 1(a) shows a typical seawall failure by settlement, occurring at S Port located along the Pacific Coast in Japan, where a large hole is formed behind the seawall. This type settlement failure occurred during construction, being the end result of wave actions from a strong storm. Figure 1 shows the cross section of the seawall, a relatively deepwater seawall protecting a large, man-made island; being particularly chosen due to a water depth of more than 10 m and a design significant wave height of about 8 m. The caisson is 12 m wide and covered by wave-dissipating concrete blocks. Backfill stones placed behind the caisson reduce the soil pressure acting on it. The large holes were formed in the reclaimed soil located above the backfill stones. A permeable geotextile sheet laid on the top of the backfill stones should prevent such soil leakage; thus, we surmise that it was damaged by waves either during and/or after placement of reclaimed soil.

The seawall failure in S Port is unique in that it also provided evidence of air blow, which can be seen in Photo 1(b), i.e., air is being blown out a gap between the caisson and reclaimed soil. Air blow occurs when wave motion inside the

Photo 1(a) A large hole formed behind a seawall.

Photo 1(b) Air blow occurring from a gap between the caisson and backfill stones.

Fig. 1 Cross section of a caisson type deepwater seawall.

Fig. 2 Cross section of a rubble mound type shallow water seawall.

backfill stones compresses the air within the stones such that it blows out through the gap; a phenomenon that occurs even at not-so-large wave heights.

Figure 2 shows another settlement failure, in this case for a rubble mound type seawall located in relatively shallow water. The apparent damage was caused by a winter storm, leaving numerous holes in the sidewalk. Note that the interlocking blocks in the sidewalk have been upturned/knocked out of place; a phenomenon thought to occur when the pore pressure in the backfill stones exceeds the overburden soil pressure in the overlying reclaimed soil.

Three years ago, a comprehensive study on the mechanisms of settlement failures was initiated at the Port and Harbour Research Institute (PHRI), Japan. The study is considered comprehensive due to the inclusion of hydraulic, geotechnical, and material aspects in conjunction with determining practical construction methods. Here, we report the results of hydraulic model experiments which further elucidate the mechanisms leading to settlement failures of seawalls.

EXPERIMENTAL PROCEDURES

Experiment series

Four series of model experiments were conducted. In series 1, the settlement failures of reclaimed soil were reproduced, and in series 2, pore pressures in the backfill stones and reclaimed soil were measured. Standard and special cross sections were tested along with a cross section in which the boiling type of failure can easily occur.

In the series 3 experiments, we measured the impulsive pressure acting on the joint plate connecting two caissons, as destruction of the plate is known to result in damage to the geotextile sheet and subsequent settlement of the reclaimed soil; while in series 4, a cross section with no backfill stones was tested to show the effect of the stones in preventing settlement failure. In this case, no reduction occurs in the ground pressure acting on the caisson, nor in the direct wave actions affecting the reclaimed soil. Pore pressures were also measured for this cross section.

Fig. 3 Cross section of the standard seawall model.

Seawall Model

Figure 3 shows a cross section of the standard seawall model in which the geotextile sheet is placed between the backfill stones and reclaimed sand (soil) in order to stop sand from leaking through the backfill. Although the surface of the reclaimed soil is usually paved, this was not simulated in the model.

Models at 1/16-scale were installed in a wave flume on top of a sand bed. The water depth and caisson width were both about 1 m, and crest elevation of the seawall was 88.9 cm, which is relatively high compared to the water depth. Equivalent water depth is about 16 m and crest elevation about 14 m. The locations of more than 40 wave pressure and pore pressure transducers are indicated.

We also tested a model cross section similar to one occurring during the construction period, where the reclaimed sand is filled just up to the top of the backfill stones. In this case, which was mainly considered in series 1 experiments, the crest height of the caisson is relatively low at 58.1 cm.

Waves

Regular and irregular waves were generated in the experiments, with wave height being varied from 25 to 61 cm and wave period from 2.1 to 3.5 s. The standard case uses a wave height of 52.4 cm and wave period of 3.04 s, i.e., equivalent to 8.4 m and 12.2 s for actual waves.

EXPERIMENTS REPRODUCING SETTLEMENT FAILURE

Soil leakage due to geotextile sheet damage

In series 1 experiments, under the assumption that the settlement of reclaimed soil was caused by an opening being

ripped in the geotextile sheet either during or after construction, we cut a relatively large, 10-cm diameter hole in the sheet, laying it between the backfill stones and reclaimed sand such that the hole was situated below the still water level.

Photo 2 shows the effect of sand leakage before applying wave action. After adding the overlying reclaimed sand, while slowly filling the wave flume with water, sand started leaking through the hole right after the water reached its level, with the end result being the formation of the large tunnel (cave) shown in the photo.

Upon commencing wave action after crushing the tunnel and refilling in the sand lost by leakage, the water surface in the backfill stones began moving up and down and gradually sand began leaking through the hole, in turn forming another tunnel. Some sand is trapped in the backfill stones, but most passes through them and piles up on the seabed.

Although larger waves led to a larger tunnel, when wave overtopping occurred, the water motion in the backfill region increased, leading to a higher leakage rate and rapid growth of the tunnel until the weight of the overlying sand suddenly collapsed it. Photo 2 also shows the resultant settlement of the reclaimed sand which is greatest just above the location of the hole.

Experiments to Reproduce the Settlement Failures

Generation of Cave before Wave Action

Generation of Cave by Wave Action

Collapsing of Soil by Overtopping Waves

Photo 2 Soil leakage through a 10-cm hole in the geotextile sheet at a location below the still water level.

Effect of hole size and location

To further investigate this behavior, we varied the size and location of the hole. Although the rate of sand leakage naturally increased with the size of the hole, for very small holes with a diameter of 1 cm, the leakage stopped due to the hole being blocked by sand that is trapped nearby between backfill stones. In addition, the rate of leakage is highest for holes located just below the still water level, being substantially increased by overtopping waves, or by rainfall which was also simulated.

Behavior of reclaimed sand without a geotextile sheet

Because some seawalls have been constructed in Japan without a geotextile sheet, under the premise that adding reclaimed soil to the backfill section during construction will prevent subsequent leakage upon completion, this case was also examined in the experiments.

As expected under this situation, the sand literally flowed into the backfill stone section during the filling process. Also, small wave actions promoted infiltration into the backfill section. In fact, even if reclaimed sand is added to fill all the void spaces in the backfill stones, the sand in the backfill stones located just behind the caisson is still carried away through the rubble mound. Such behavior indicates a good possibility that leakage will continue after construction, especially if large waves attack the seawall.

MEASUREMENT OF PORE PRESSURES

Pore pressure distribution

Figure 4 shows typical analogue data for the standard cross section measured at four channels, i.e., the front and bottom of the caisson (7, 10), in the backfill stones (23), and in the reclaimed sand (38). Channels 7 and 10 indicate ordinary standing wave pressure that is simultaneously transmitted to the backfill stones, where slight damping is apparent and negative pressures indicate higher damping than positive ones. Also, pore pressure in the reclaimed sand is highly damped and shows a very smooth pressure curve. Pore pressures in the backfill stones and reclaimed sand provide important data as settlement failure is more likely to occur at high positive and/or negative values.

Peak pore pressure for standard cross section

Figure 5 shows the corresponding pressure distribution for the standard cross section, where the size of the arrows indicates the relative magnitude of nondimensionalized positive peak pressure, while its inclination indicates the phase difference at peak pressure. Note that the pore pressure in the backfill stones is almost constant, being quite high at about 80% of the wave pressure at the front of the caisson. Pressure is not substantially reduced because the water and air in the backfill stones are enclosed relatively tightly by the reclaimed sand, i.e.,

the movement of pore water in the rubble mound and backfill stones is very limited by the reclaimed sand and the dissipation of pore pressure is low. This pore pressure, however, rapidly damps out as shown by the pore pressure in the reclaimed sand.

Fig. 4 Analogue data for the standard cross section indicating pore pressures measured at indicated channels.

Fig. 5 Distribution of positive peak pressures in the standard cross section in which reclaimed sand above the backfill region is not in a saturated condition.

Fig. 6 Distribution of positive peak pressures for a cross section in which the reclaimed sand above the backfill region is maintained in a saturated condition.

Fig. 7 Distribution of positive peak pressure using pressure relief opening.

Pressure increase due to saturation of reclaimed soil

Due to wave overtopping and rain, the reclaimed soil will normally be water saturated; thus, to simulate the strong effect of this condition on pore pressure in the backfill region, we added water as necessary to ensure the reclaimed sand stayed saturated during the experiments.

By comparing Figs. 5 and 6, which show the resultant pressure distribution of peak pressures with and without saturation, it is clear that much higher pore pressures are present when the reclaimed sand is saturated, being nearly equal to the wave pressure in front of the caisson. This phenomenon is a result of the backfill region being tightly enclosed by the saturated reclaimed sand above the still water level, i.e., pore pressure is transmitted without damping in the backfill stones.

Pressure relief measures

The transmission of pore pressure in the backfill region without damping can be prevented, however, by providing a vent path or opening in the backfill stones, which can be established if a portion of the upper surface of the stones is situated at or above the level of reclaimed soil. Figure 7 shows the resultant pressure distribution if such an opening is established, where the peak values are significantly reduced to about 10% of the wave pressure acting on the front of the caisson; and accordingly, the pressure in the reclaimed sand is reduced as well.

As another method for reducing pore pressure in the backfill stones, a pressure relief opening was made in the rear chamber of the caisson, with results indicating a substantial reduction in pressure, (although the data are not shown here).

Water level oscillation in backfill stones

Movement of pore water, especially that of the water level in the backfill stones, is another important factor affecting sand leakage. For the standard cross section, the level of water fluctuated between 10 and 20% of incident wave height as shown

in Fig. 8. Note that the magnitude of fluctuations decreases as wave height increases. Naturally the fluctuations in water level are smaller when the reclaimed sand is in a saturated condition, being less than 10% of the incident wave height. If, however, a pressure relief opening is established in the backfill region, the size of the fluctuations increases, ranging from 23 to 32% of the incident wave height.

Fig. 8 Water level oscillations in backfill region.

BOILING OF RECLAIMED SOIL

As boiling or liquefaction of sand is considered a major factor causing settlement failures of seawalls, we modified the cross section of the standard seawall to experimentally reproduce this behavior. That is, a 20-cm-thick layer of reclaimed sand was used to cover the backfill stones, and the level of water was maintained at the surface of the reclaimed sand in order to limit the overburden soil pressure acting on the stones.

Although no unusual behavior was observed at small wave heights, at a wave height of 42.8 cm, the entire layer of sand appears to lift up as shown in Fig. 9. This is the first indication of sand boiling (liquefaction), with increases in the wave height forcing the sand further upward until boiling occurs. The effect of boiling is disastrous as can destroy both the layer of reclaimed soil and any type of pavement covering this region. As another consequence, the geotextile sheet can be ripped such that an opening occurs.

Figure 10 shows the pore pressure distribution when boiling occurs, where the pore pressure in the backfill stones reaches about 17.8 gf/cm^2 (14.5 kN/m^2), approaching close to the overburden soil pressure. Note that the pore pressure stays at this level even though wave height is increased.

These experiments confirm that boiling of reclaimed soil occurs when the pore pressure in the backfill region increases close to the overburden soil pressure acting on the backfill region. Consequently, to withstand large wave heights, the layer of the reclaimed soil should be sufficiently thick such that the force produced by the weight of the soil counteracts that produced by the increase in pore pressure in the backfill region;

or alternatively, the backfill pore pressure should be reduced by establishing a pressure relief path.

Fig. 9 Boiling of reclaimed sand.

Fig. 10 Distribution of peak pore pressure in the case of sand boiling.

IMPULSIVE PRESSURE ON A JOINT PLATE

Caisson joint model

In series 3 experiments, the impulsive pressures acting on the joint plate connecting two caissons were measured, being done in response to learning that destruction of the joint plate leads to the damaging the geotextile sheet and settlement failure due to soil leakage.

Figure 11 shows the cross section and front view of the seawall model, where a 1.5-cm joint plate has been installed between the caisson and a glass observation window. Several pressure transducers were placed to measure impulsive pressures on the joint plate.

Wave action and impulsive pressure on the joint plate

Figure 12 shows typical analogue measurements indicating wave pressure on the caisson's front wall and joint plate

respectively. Channel 11 provides pressure on the joint plate at the still water level, while channel 4 provides the pressure on the caisson at the same level, and channel 14 on the plate near the caisson bottom. As shown, an impulsive pressure appeared near the water surface, having an intensity of more than $3 w_0H$. Also shown is the movement of the wave front which contains a layer of air such that it generates an impulsive pressure upon impact against the plate.

Fig. 11 Seawall model with a caisson joint plate.

Fig. 12 Generation of impulsive pressure on joint plates.

Peak impulsive pressure on the joint plate

Figure 13 shows nondimensionalized peak pressure acting on the joint plate near the still water level, where experimental values are plotted for four different wave periods as a function of wave height. Due to data scatter, the ranges and mean values are indicated, with pressure ranging from 1 to 4 w_0H and having an average value of about 2 w_0H .

The impulsive pressure acting on the joint plate above the still water level is very similar to the uplift pressure on the horizontal plate, e.g., the superstructure of a pillar quay or that

acting on the ceiling slab of a wave chamber in a perforated wall caisson. Based on this similarity, the methods used to determine these pressures can be applied here for determining the impulsive pressure.

Fig. 13 Impulsive pressure intensity on a joint plate.

Reduction of impulsive pressure by spacer plates

The impulsive pressure on the joint plate can be reduced by narrowing the gap (space) between two caissons using spacer plates. Figure 14 shows that two spacer plates installed in the gap between the caisson and observation window can substantially reduce impulsive pressure, although one spacer plate works almost as well.

Fig. 14 Spacer plates to reduce the impulsive pressure.

SEAWALLS WITHOUT BACKFILL STONES

Loss of reclaimed soil due to joint plate damage

The main purpose of using backfill stones is to reduce ground pressure acting on the caisson. If, however, the wave pressure is large compared to ground pressure, then backfill stones need not be used. This is commonly the case in Japan where the design wave height is large and the design acceleration produced by an earthquake is small. In addition, if backfill stones are not used construction costs will be lower.

Using backfill stones along with a geotextile sheet reduces the risk of the leakage of reclaimed soil through the joint plate should it be damaged. In fact, the stones function as a filter medium which reduces direct wave pressure acting on the

reclaimed soil. When a small hole was made in the joint plate, wave actions led to a continuous leakage of sand from the back region of seawall.

Pore pressure in the reclaimed sand

Figure 15 shows the pressure distribution for a cross section without backfill stones, where the high pressure in the reclaimed sand near the rubble mound should be noted, being almost 90% of the frontal wave pressure. Consequently, the pressure gradient in the sand near the rubble foundation will be large, which might easily lead to the adverse consequence of damaging the geotextile sheet placed between the sand and rubble mound.

The pore pressure in the reclaimed sand can be reduced using an opening in the caisson. Figure 16 shows the pressure distribution with an opening in the rear chamber of the caisson, which reduces the pressure near the sand and rubble mound to 10% of the frontal wave pressure. If the backfill stones are not used, then obviously measures such as this one must be taken in order reduce pore pressure in reclaimed soil.

Fig. 15 Distribution of peak pore pressure without backfill stones.

Fig. 16 Distribution of peak pore pressure with a pressure relief opening.

CONCLUDING REMARKS

By combining the present experimental results with those from field surveys various mechanisms were found to cause leakage of reclaimed soil, with the loss of this soil subsequently leading to seawall failure by settlement. Figure 17 shows the resultant settlement failure mechanisms using a failure path diagram. For example, failure occurs if the wave actions during and/or after construction breach the integrity of the geotextile sheet, where the soil can then leak into the backfill stone region due to wave actions. The occurrence of sand boiling and damage to the joint plate were also implicated as being important settlement failure mechanisms.

Although we have obtained a relatively sound qualitative understanding of settlement failure mechanisms, being an essential aspect towards realizing practical seawall designs, only with a sound quantitative understanding of the mechanisms can a full understanding be obtained.

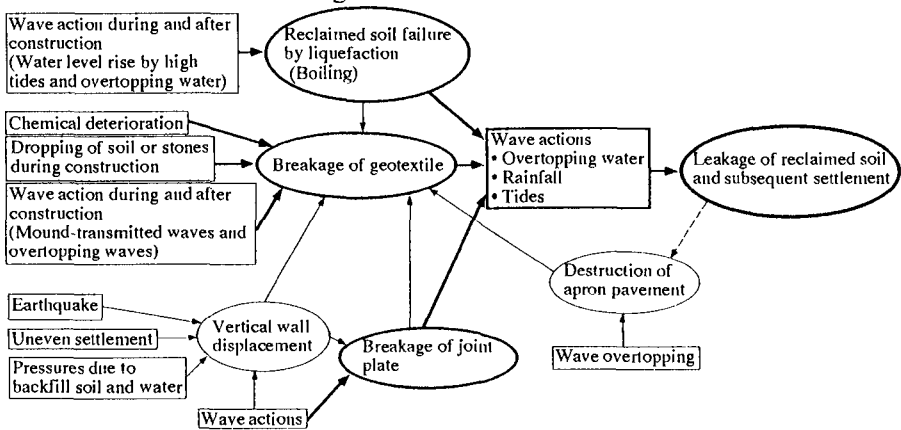

Figure 17 Diagram of mechanisms leading to seawall failure by settlement.

CHAPTER 149

FULL SCALE MEASUREMENTS OF WAVE ATTENUATION INSIDE A RUBBLE MOUND BREAKWATER

Peter TROCH¹, Marc DE SOMER¹, Julien DE ROUCK¹, Luc VAN DAMME²,
Dierik VERMEIR³, Jean-Pierre MARTENS⁴, Conan VAN HOVE⁴

ABSTRACT

At the Zeebrugge harbour (Belgium) a cross-section of the N.W.-breakwater has been instrumented for the study of physical processes related to the behaviour of a prototype rubble mound breakwater in random wave conditions. Within the EC MAST programme (project MAS02-CT92-0023) this monitoring system has been re-engineered and extended to a high-quality full scale data acquisition centre (Troch et al., 1995).

The development of the prototype monitoring system to a world-wide unique system with respect to the infrastructure available at Zeebrugge, the instrumentation installed on site, and the data management developed, is briefly summarised.

Filed measurements of wave attack in front of the breakwater, and pore pressure response inside the breakwater core, have been analysed in order to determine the hydraulic response of the full scale breakwater. Analysis results on wave run-up/run-down measurements, phreatic set-up calculations, and pore pressure wave attenuation are presented here in more detail.

INFRASTRUCTURE

The port of Zeebrugge is situated on the eastern part of the Belgian coastline, and is protected by two main breakwaters (Fig. 1). The Zeebrugge breakwater constitutes of a conventional rubble-mound breakwater with a low superstructure and an armour layer consisting of grooved cubes (25 ton). The breakwater core consists of quarry run 2-300 kg, the filter layer is made of rock 1-3 ton. On the breakwater crest, a service road enables easy access of the breakwater. The tidal range at spring tide is 4.3 m.

A measurement jetty of 60 m length supported by a steel tube pile at the breakwater toe and by concrete columns on top of the breakwater is situated on the NW-breakwater, Fig. 2. Six boreholes have been drilled in the core: four vertical boreholes and two oblique boreholes. Galvanised steel casings are placed in these boreholes. These casings are perforated in order not to disturb the overall permeability. Pressure sensors are mounted in these casings. Each pressure sensor cable is protected by a high density polyethylene tube provided with a perforated nylon head at the sensor end.

1) Civil Engineering Dept., University of Gent, Technologiepark 9, B-9052 Gent, Belgium.

2) Ministry of Flemish Community, Coastal Division, Vrijhavenstraat 3, B-8400 Ostend, Belgium.

3) Dept. Information Technology, HAECON, Deinssesteenweg 110, B-9031 Gent, Belgium.

4) ELIS, University of Gent, St-Pietersnieuwstraat 41, B-9000 Gent, Belgium.

In an air-conditioned container, placed on the landside of the breakwater, signal conditioning apparatuses and a data acquisition system (DAS) are installed. All electric cables from the measuring sensors are lead towards the container.

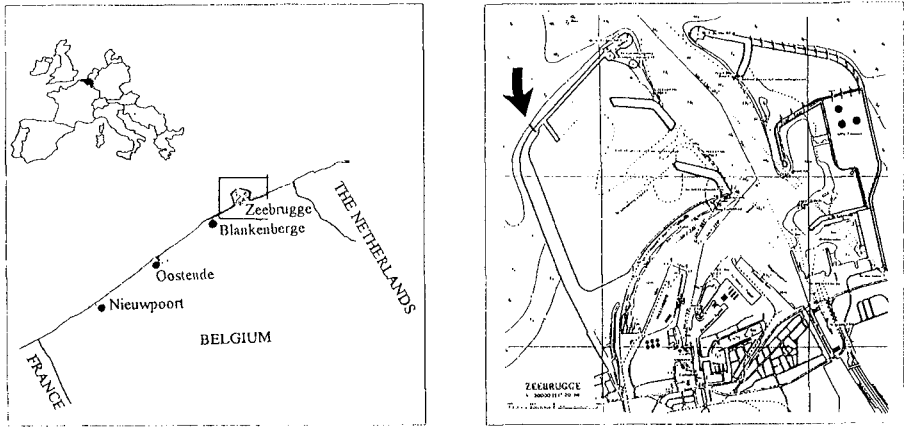

Fig. 1. Location of the prototype monitoring system on the NW breakwater at Zeebrugge harbour (Belgium).

Fig. 2. Cross-section of the Zeebrugge rubble mound breakwater.

INSTRUMENTATION

An overview of instrumentation installed on the measurement jetty is given in Fig. 3, and summarised in Table 1.

Full Scale Measurement Jetty at Zeebrugge Breakwater

Fig. 3. Zeebrugge breakwater: Location of instrumentation since 1994.

Wave rider buoys are located in front of the breakwater and measure the incident waves. The water level at the toe of the breakwater is measured by an infra-red wave height meter and by two submerged pressure sensors located in front of the steel tube pile.

A set of vertically placed stepgauges between the measurement jetty and the armour layer is able to registrate the wave run-up and run-down on the armour layer.

Inside the core 13 pressure sensors are installed in the six boreholes for the measurement of the internal pore pressures induced by the waves. Assembly of the sensors is conceived to allow flexible placement in the boreholes, ease of maintenance and ease of calibration.

A device called "integrating box" is designed for the measurement of wave forces, i.e. the integrated pressures on (a part of) an armour unit face. The solid steel box is filled with water under pressure. A pressure sensor mounted in the box measures the pressure variation in the enclosed box volume. The device has been calibrated extensively in the laboratory. The pressure inside the box is related to the wave force applied on the box membrane.

INSTRUMENTATION	LOCATION	AIM OF MEASUREMENT
2 waverider buoys	150 m and 215 m from breakwater	wave records
infra-red wave height meter	near steel tube pile	wave records, tide level
2 submerged pressure sensors	near steel tube pile	wave records, tide level
5 vertically placed stepgauges	between armour layer and jetty beam	run-up/run-down wave profiles
'integrating box'	on one face of armour unit	wave forces on an armour unit
13 pressure sensors	inside rubble core	pressure records

Table 1. Instrumentation of Zeebrugge breakwater.

DATA MANAGEMENT

A strategic data management plan is developed for acquisition, processing and distribution of all full scale data.

Each sensor has its dedicated signal conditioner providing individual isolated power supply and converting the current of the pressure sensor circuit to a voltage output -proportional to the physical input- which is galvanically isolated from the sensor circuit. The voltage outputs of all sensors are separately connected to an isolation amplifier followed by a lowpass-filter before being connected to the data acquisition system. Special care with regard to groundings and shielding of the electronic devices has been taken in order to prevent ground loops.

A scanner samples all analog data at 10 Hz. After analog-to-digital conversion raw data are stored as binary files on a hard disk of the computer. The data acquisition computer manages the hard disk as a ringbuffer.

An software package, written in ANSI C and portable on several systems, is included for presentation, evaluation and signal analysis. Software tools were written to read data from file, display data on screen, select pieces of data and analyse the selected

data. Routines for input and output have been implemented allowing the user to output measurements values and computational results and to input signals having a format different from the one of Zeebrugge data. Procedures have been developed for the quality control of raw data. This way an interface today is available for the input of external data from scale models and numerical models for comparison and research activities.

The acquired time series are edited for the elimination of errors in the signals. A very valuable technique, developed in speech analysis, and applied here to the signals, is the calculation of a spectrogram of a signal. The spectrogram (Fig. 4) consists of consecutive spectra, calculated for consecutive windows on the time series and placed vertically. The spectral energy information per frequency interval is converted towards a proportional line length. This way, errors in the signal, such as high frequency noise or sample gaps, are easily detected and edited.

Up to date about 16 storms with significant wave heights ranging between 1.00 m and 3.50 m, and wind directions from N.W. -allowing almost perpendicular wave attack- have been registrated. Continuously improvements and new instruments are prepared and installed, keeping the prototype monitoring system highly operational. For more detailed information and technical details of instrumentation and data acquisition, the reader is referred to (Troch et al., 1996-a; Troch et al., 1996-b).

FULL SCALE DATA ANALYSIS RESULTS

Wave run-up measurements

The wave run-up (run-down) derived from full scale measurements is defined as the vertical distance between Mean Water Level (MWL) and the highest (lowest) point attained by the wave up-rush (down-rush) on the slope. The run-up height R_u is one of the most important parameters associated with wave loading on rubble mound structures and their stability. It, along with the highest still water level, determines the necessary crest level of the breakwater.

At each stepgauge mounted along the breakwater slope, the instantaneous water surface level is measured. From these time series, the instantaneous wave profile on the slope is derived. At one instant, the wave profile is taken as the polygon connecting the water surface levels measured at all stepgauges. The instantaneous wave run-up height is defined here as the vertical distance between MWL, and the intersection of the breakwater slope with an extrapolated line, constructed through the two highest water surface levels measured at that instant. MWL is calculated as the mean of a water surface measurement using a submerged pressure sensor mounted in front of the steel tube pile. When the intersection is positioned below MWL, instantaneous wave run-down is identified.

The relevant run-up level of an irregular wave signal is taken as $R_{u,2\%}$. This is the level exceeded by only 2% of the waves running up the armour slope. The run-down level considered is the $R_{d,98\%}$ which is the level exceeded by 98% of the waves. The reference number of waves used for the computation of the exceedence level, is taken here as the total number of run-up waves on the slope. The non-dimensional run-up ratio $R_{u,2\%}/H_{mo}$, where H_{mo} is the significant incident wave height, and run-down ratio $R_{d,98\%}/H_{mo}$, are plotted versus the deep water Iribarren number of the wave form:

$$\xi = \frac{\tan \alpha}{\sqrt{\frac{H_{mo} 2\pi}{gT_{(0,2)}^2}}} \quad (1)$$

where α = slope angle ($^\circ$); significant wave height $H_{mo} = 4(m_0)^{1/2}$ (m); wave period $T_{(0,2)} = (m_0 / m_2)^{1/2}$ (s), where m_n is the n^{th} moment of spectral density.

Allsop et al. (1985) presented model test run-up results on a 1:1.5 Antifer cube slope with irregular waves, using Losada et al.'s (1982) relationship:

$$\frac{R}{H} = A[1 - \exp(B\xi)] \quad (2)$$

where R = run-up/run-down level, defined as: $R_{u,2\%}$ or $R_{d,98\%}$; $H = H_{mo}$; A , B = experimental coefficients; ξ = Iribarren number. Allsop reported:

$$\text{run-up: } A=1.52 \quad B=-0.34$$

From physical model tests on the identical Zeebrugge breakwater cross-section, carried out in the MAST II project (Kingston et al., 1996), it is found that for irregular waves the coefficients are:

$$\begin{array}{ll} \text{run-up:} & A=1.76 \quad B=-0.28 \\ \text{run-down:} & A=-1.05 \quad B=-0.43 \end{array}$$

Fig. 5. Comparison between prototype and scale model wave run-up results.

In Fig. 5 non-dimensional wave run-up heights and wave run-down heights obtained from Zeebrugge prototype measurements using the vertically placed stepgauges are plotted as a function of the Iribarren number ξ . Note that the range for ξ is small due to the occurred wave and breakwater characteristics. As a result, for $\xi \approx 3$ the wave run-up $R_{u,2\%}/H_{m0}$ has order of magnitude 1.50, and the wave run-down $R_{d,98\%}/H_{m0}$ has order of magnitude -0.75.

Comparing with the laboratory wave run-up measurements (Allsop et al., 1985; Kingston et al., 1996), it appears that from this analysis of prototype data the wave run-up is about 50% higher than the well-accepted wave run-up, based on laboratory results. Wave run-down agrees well with laboratory data. Due to the measurement technique, mainly the remaining distance between the gauge and the slope, the run-up measured in laboratory tests might be underestimated by up to 20 %.

This high run-up $R_{u,2\%}$ confirms the practical experience in Sines (Portugal) and Zeebrugge harbours that wave overtopping is higher than expected during design. As prototype results are only available for one storm within a narrow range of Iribarren numbers, they have to be confirmed by future measurements. It is clear that a better measurement accuracy is needed before final conclusions are drawn. However, this remarkable result, if confirmed, would have large impact on social, economic and environmental aspects of coastal protection works. As a conclusion, more detailed research and measurements on wave run-up are necessary in order to acquire a better understanding of prototype wave run-up.

Internal phreatic set-up

Due to the geometric non-linear effect on the slope subjected to waves, swell or tides, an internal phreatic set-up in a breakwater may occur. As the inflow section along the slope at the moment of a high water level is larger than the outflow section at the moment of a low water level, and as the average inflow path is shorter than the outflow path, more water will enter the breakwater than can leave during cyclic water level changes. Consequently, an average internal set-up of the water level inside will occur.

This internal maximum average set-up occurring after several cycles may be described by a simple theoretical formula (Barends, 1988):

$$\frac{s}{D} = \sqrt{I + \xi \cdot F} - 1 \quad (3)$$

with:

$$\xi = \frac{0.1cH^2}{n\lambda D \tan\alpha}, \quad \lambda = 0.5 \sqrt{\frac{DKt}{n}} \quad (4)$$

where s = maximum average set-up (m); D = depth at toe of slope (m); c = constant depending on effects of air entrainment and run-up ($c > 1$); H = wave height at slope (m); n = porosity (-); λ = penetration length of the cyclic water level into the porous structure (m); α = slope angle ($^\circ$); K = permeability coefficient (m/s); t = period of cyclic loading (s); F = function related to two cases (open or closed lee-side). For a closed lee-side the maximum set-up s is found at the lee-side.

As a practical example of the theoretical formula the Zeebrugge case is worked out. Barends (1983) assumed that the permeability $K \approx 0.50$ m/s and the porosity $n = 0.40$. The incident wave is characterised by $H = 6.50$ m and $T = 9$ s. The waterdepth D is 11 m. The penetration length is approximated by $\lambda = 5.56$ m. The situation corresponds to a closed lee-side and s occurs at lee-side. With $L \approx 85$ m and $L/\lambda = 85/5.56 = 15.3$ m, $F(\text{closed}) = 1$. With $\tan\alpha = 0.67$, $c = 1.25$ (according to Barends, 1988) and $H = 6.50$ m, ξ becomes 0.32. The maximum average set-up s derived from the theoretical formula (3) finally is 1.65 m. This theoretical result is in between the rule of thumb values proposed by Barends. With $D = 11$ m, $s = 0.15D$: the magnitude of the internal set-up is within 10-20 % of the waterdepth at the toe of the breakwater.

A permeability coefficient K with the same order of magnitude is found by (Gudehus, 1974) from tests on rock samples characterised by $d_{10} = 60$ mm, $d_{50} = 140$ mm, $d_{90} = 190$ mm. Dimensions of the test specimen are: height = 1.20 m, diameter = 1.22 m. The rock dimensions are clearly lower than the 2-300 kg rock used in the core. From this consideration, it may be assumed that the permeability of the core is higher than 0.50 m/s, however no measured values are available. Assuming that the permeability is 10 times higher, $K = 10 \times 0.50 = 5$ m/s, the set-up reduces to 0.50 m.

Thus, set-up is very sensitive to some of the parameters included, such as the permeability and the air entrainment factor. These are difficult to estimate. The results need to be treated with much care.

In order to study the stability of the filter layers of the Zeebrugge breakwater, a calculation with the mathematical model HADEER (Barends, 1983) was part of the study. Results from these calculations show similar set-up values as calculated from (3).

From full scale measurements, maximum average set-up values s , calculated at the position of the pressure sensor located closest to the leeside, are reported in Table 2. The Mean Water Level (MWL) is derived by calculating the mean of a wave record registrated by the infra-red meter. Inside the breakwater core pressure data (Pa) are converted into water level data (datum Z) by assuming a hydrostatic section where the density is constant. Those assumptions do not apply in the hydrodynamic area near the armour layer, but become more reasonable moving in the leeward direction. Internal phreatic set-up is calculated as the difference between mean values over a time interval of 180 s of the infra-red wave meter outside and the pressure sensors inside the core.

H_i [m]	s [m]	s/D [%]	s/H_i [%]
3.50	0.29	2.6	8.3
3.05	0.33	3.0	10.8
2.25	0.37	3.4	16.4
2.00	0.36	3.3	18.0

Table 2. Maximum average set-up s and rule of thumb ratios.

Comparison is made of calculated prototype set-up values with orders of magnitude proposed in literature: the results from prototype data are not within the range proposed by (Barends, 1988): $0.10D \leq s \leq 0.20D$, but the results have the same order of magnitude, as found by (Bürger et al., 1988) on large scale models: $0.10H_i \leq s \leq 0.20H_i$, where H_i = incident wave height $H_{1/3}$ (m). Ratios s/D and s/H_i used in the rules of thumb are summarised in Table 2.

Fig. 6. Comparison between theoretical and prototype set-up calculations.

Barends' theoretical formula (3), where depth at toe $D=11\text{m}$, wave height $H=3\text{m}$, wave period $T=7.2\text{ s}$ gives a setup value of $s=0.41\text{ m}$ at the landward side. This result is of the same order of magnitude of the full scale data, as extrapolating the pressure gradient towards the landward side yields $s=0.39$. Using $K=5\text{ m/s}$, set-up reduces to 0.12 m .

Fig. 6 shows the set-up for the Zeebrugge case as a function of wave height and period for $D=11\text{ m}$. Further to Barends' theoretical formula the setup increases with increasing wave height. Plotting prototype setup as a function of H_i on Fig. 6 shows no agreement with this suggested non-linear relationship between setup and H_i .

The set-up is evaluated as a function of the horizontal distance from the interface between the filter and the core. It is concluded from prototype measurements that the set-up increases with the distance to the outer face of the breakwater. This is in agreement with the Barends' formula, because the breakwater is backfilled.

Pore pressure wave attenuation

The main objective of a breakwater is to dissipate incident wave energy when waves propagate through the porous breakwater core. This points out the relevance of investigating the breakwater's capability in this respect. In this section, results of full scale wave attenuation are presented. It is not the wave heights which are measured in the core, but the pore pressures.

Theoretical work dealing with oscillatory flow in porous media was carried out by Biesel (1950) who identified the form of the spatial and temporal relationships which describe a linearly damped oscillatory flow. Le Méhauté (1957) applied this relationship to rubble mound breakwaters by introducing parameters accounting for porosity and inertia effects of the porous material. Oumeraci (1990) summarises Le Méhauté's theory on this topic and concludes that the height of the pore pressure oscillation $p(x)$ of a propagating pressure wave decreases exponentially with the distance to the breakwater interface according to the linear damping model:

$$p(x) = p(0) \exp(-\beta \frac{2\pi}{L'} x) \quad (5)$$

where x = co-ordinate across core (m); $p(x)$ = pore pressure at x (N/m^2); $p(0)$ = pore pressure at $x = 0$ (N/m^2), i.e. the first pressure sensor location, L' = wave length within breakwater (m), β = damping factor (-).

The wave length within breakwater L' is calculated by $L' = L/\sqrt{1.4}$, (Oumeraci, 1990). The wavelength L is calculated by the dispersion relationship using wave period $T_{(0,2)}$, and waterdepth in front of the breakwater toe D . The pore pressure height $p(x) = 4(m_0)^{1/2}$, is calculated from the energy content of the signal.

The magnitude of the damping factor β depends on the distance y_s of the horizontal level of the sensors to the MWL: the lower the location under MWL, the smaller the friction losses will become as the degree of turbulence decreases, and the smaller the damping factor β becomes.

In Fig. 7, a number of wave records of 15 minutes are considered for the horizontal level of sensors at $Z+2.30$. The ratio $p(x)/p(0)$ is plotted versus the relative distance x/L' . An exponential curve is fitted through the data, the resulting damping factor $\beta=0.68$. In Fig. 8 curves with damping factors 0.81 ($Z+3.00$), 0.53 ($Z+0.70$) are plotted as well. As seen from this Fig. 8 the damping factor β decreases with increasing distance

Fig. 7. Damping factor β from the three sensor levels for two MWL's.

Fig. 8. Prototype pore pressure wave attenuation inside breakwater core: prototype data and fitted linear damping model.

from the MWL (MWL at $Z+5.65$). In the same Fig. 8 the blank dotted lines have resulting damping factors β for a situation with lower MWL (at $Z+5.18$). Compared to the former β values at each level, the latter values are higher (e.g. 0.89 versus 0.68 at sensor level $Z+2.30$). Indeed there is more turbulence due to the lower MWL, and the damping factor β depends on the distance y_s .

Analysis of a comprehensive set of data (Troch et al., 1996-c) shows that the energy content of steeper waves decays much nearer to the front of the core, where $x=0$. In other words, the rate of attenuation within the core for a given wave period increases with increasing wave height. In contrast the opposite trend is evident for a constant incident wave height. Increasing the wave period resulted in a decrease in the rate of attenuation in the mound. Summarised, the damping factor β also depends on the incoming wave height and period.

It is assumed (Burcharth et al., 1995) that the extended Forchheimer equation models the flow resistance in porous media:

$$i = au + bu^2 + c \frac{\partial u}{\partial t} \quad (6)$$

where i = hydraulic gradient (-); u = bulk (or filter) velocity (m/s); a , b , and c = constants. However, the turbulent term (u^2) in equation (6) is normally predominant when considering internal flow in breakwaters, and this turbulent term does not occur in (5). Hence there is no evident purpose in relating the β -value in equation (5) to the coefficients in the Forchheimer equation. From the above it is suggested that the model derived by (Oumeraci et al., 1990) is too simple being a linear model compared with the non-linear Forchheimer model. Moreover a straight comparison between calculated β values, based on prototype results, and the value reported by (Oumeraci et al. 1990), $\beta=2$ is not possible because of the different geometrical shape factors, the different breakwater cross section and scaled core materials affecting the core permeability, and different position of the first pressure sensor (the first reference pressure sensor in Oumeraci's analysis is positioned in the filter layer between armour and core).

CONCLUSIONS

This paper briefly outlines the prototype monitoring system installed at the Zeebrugge rubble mound breakwater. To date a comprehensive set of full scale data have been acquired at this unique monitoring system during storm conditions with significant wave heights ranging between 1.00 m and 3.50 m, and are available for validation of physical and numerical models. Prototype measurements consisting of incident wave data, wave run-up data, and pore pressure data have been analysed in order to determine the hydraulic response of the full scale Zeebrugge breakwater. As hydraulic responses the following phenomena are included: wave run-up/run-down, internal phreatic set-up and pressure wave attenuation.

Comparing prototype wave run-up measurements with well-accepted laboratory results, it appears that the prototype wave run-up is about 50% higher than the wave run-up on armoured slopes of scale models. Wave run-down agrees well with laboratory data. This remarkable result, if confirmed, would have large impact on social, economic and environmental aspects of coastal protection works. As a

conclusion, more detailed research and measurements on wave run-up are necessary in order to acquire a better understanding of prototype wave run-up.

Prototype set-up measurements are compared with a simple theoretical formulation. For the range of wave heights available, there is good agreement between prototype and theoretical set-up. However no clear dependence of set-up on wave height, as suggested by the theoretical formulation (3), is found. The order of magnitude of calculated set-up from prototype measurements is between 10 and 20 % of the incident wave height.

Results show that the pore pressure height $p(x)$ of a wave travelling through a rubble mound breakwater in the horizontal direction decreases exponentially, and the magnitude of β depends on the distance from the horizontal plane to the mean water level. Finally some remarks on the applicability of the linear damping model, based on the Oumeraci formulation are made. There is a clear dependence of the damping factor on the incident wave height and period, which is neglected by the linear damping model. There is no non-linear Forchheimer term present in the linear damping model, although this term is predominant for internal porous flow.

CHAPTER 150

NUMERICAL MODELLING OF WAVE INTERACTION WITH DYNAMICALLY STABLE STRUCTURES

Marcel R.A. van Gent¹

ABSTRACT: Wave interaction with dynamically stable structures is simulated by means of a numerical model based on finite-amplitude shallow-water wave equations. The model can simulate wave motion on and inside permeable structures. For dynamically stable structures, including berm breakwaters, reef-type structures and gravel beaches, a procedure is developed to simulate the natural response to wave attack. This procedure is extended, for instance by implementing effects of grading and effects of seawalls, to increase the applicability for practical applications.

1. INTRODUCTION

Coastal structures that consist of rubble mound material and are designed to undergo reshaping under severe storm conditions, while their seaward slope is stable under normal wave conditions, are called here dynamically stable structures. These structures such as berm breakwaters and reef-type structures can be economically attractive since their natural response to hydrodynamic loads causes that smaller rock material can be used than with conventional statically stable coastal structures. On the other hand, the dynamic behaviour needs to be predicted to assess the performance of such structures. For berm breakwaters this dynamic behaviour of the seaward slope is very much depending on the hydrodynamic loads and vice versa. This interactive character of the hydrodynamics and the reshaping process are studied here by means of a numerical wave load-response model.

A verified wave model has been combined with a procedure to simulate the response of dynamic structures (Van Gent, 1995-c). Procedures for initiation of movement of individual stones and for the reshaping of the structure as a result of moving stones determine the response of the structure. Both the wave motion and the response of the structure are simulated in the time-domain which means that the response of a structure immediately effects the computed wave motion.

1) Delft Hydraulics, P.O.Box 177, 2600 MH Delft, The Netherlands.

2. MODELLING OF WAVE ATTACK

A numerical model for simulating wave motion on and inside permeable structures is described in Van Gent (1994, 1995-b,c). The wave dynamics of normally incident wave attack on various types of structures are approximated by the non-linear shallow-water wave equations with steep wave fronts represented by bores. The model is based on concepts by Hibberd and Peregrine (1979) who developed a numerical model with an explicit dissipative finite-difference scheme (Lax-Wendroff) for impermeable slopes without friction. Using this concept, many practical applications have been obtained, see for instance Kobayashi *et al.* (1987) for wave reflection and run-up on impermeable rough slopes. For the permeable part of a structure the same types of equations can be applied although the friction coefficients for porous media needed to be assessed, see Van Gent (1995-a,c). The coupling of the external flow to the internal flow is determinative for the accuracy of such a wave model, see Van Gent (1994, 1995-c).

The model is able to deal with waves either regular or irregular which attack various types of structures with arbitrary seaward slopes, smooth or rough, permeable or impermeable, overtopped or not. Although the model uses a one-dimensional description of the flow it can, however, give a useful impression of the flow field in two dimensions, see Figure 1 and Figure 2.

Fig.1 Computed flow-field for a berm breakwater with an impermeable core.

Fig.2 Computed flow-field for a permeable breakwater with crown-wall.

3. MODELLING OF RESHAPING OF STRUCTURES

3.1 APPROACH FOR SIMULATING PROFILE DEVELOPMENT

The stability of the stones is strongly dependent on the hydrodynamic properties. Several expressions for this stability have been developed. Although these design recommendations are rather accurate for many applications, more generally applicable results can be obtained by simulating the wave motion first and then using flow properties like the velocities and accelerations to predict forces on stones. This can be done numerically.

In the approach towards a numerical wave load-response model several model formulations are required. Firstly, the hydrodynamic flow, both outside and inside the structure, need to be known and modelled numerically. The mentioned one-dimensional model can be used as a first approximation. Secondly, information concerning the magnitude of forces on stones is necessary. Thirdly, relations between the forces on stones and the hydrodynamic behaviour are necessary. As mentioned before, the hydrodynamics can be represented by local velocities and local accelerations. As a first approximation, a Morison-type of expression (Morison *et al.*, 1950) can be used, see for instance Kobayashi and Otta (1987) or Tørum (1992). Fourthly, information concerning failure mechanisms and forces causing damage is needed. Often failure mechanisms referred to as *rolling*, *sliding* or *lifting* are distinguished. These mechanisms or other failure mechanisms need to be modelled. Finally, the new positions of unstable stones need to be known if the complete reshaping process is to be simulated. For most breakwaters no severe damage is allowed, so for those cases it is not of primary interest to study the new positions of the stones. However, for berm breakwaters and gravel beaches these new positions are of primary concern. Only the main aspects of the wave load-response model are mentioned in the following sections. A more detailed description, including the calibration and validation of the model, can be found in Van Gent (1995-c).

3.2 MODELLING OF FORCES ON STONES

The hydrodynamic loadings on a single stone can be modelled using a number of forces. For the relation between the hydrodynamics and the forces, local velocities and local accelerations are required. The numerical model provides these local properties although averaged over the depth. Differences between these properties at the position of the particles and the depth-averaged velocities naturally cause inaccuracies.

Three forces as a result of the hydrodynamic loadings have been distinguished; the drag force acting parallel to the slope in the direction of the velocity, the inertia force acting parallel to the slope and the lift force acting perpendicular to the slope:

$$F_D = \frac{1}{2} \rho c_D k_2 D^2 u |u| \quad (1)$$

$$F_I = \rho c_M k_1 D^3 \frac{Du}{Dt} \quad (2)$$

$$F_L = \frac{1}{2} \rho c_L k_2 D^2 u^2 \quad (3)$$

where the acceleration Du/Dt is approximated with $\partial u/\partial t$; c_D , c_M , c_L are the drag coefficient, the inertia coefficient and the lift coefficient respectively; k_1 and k_2 are the volume shape factor and the area shape factor respectively. With the area shape

factor k_2 the actual projected area in the flow direction can be incorporated. Since a cover particle is partially sheltered by other particles, the actual projected area is smaller than for a single particle in a flow. The sheltering effect has not been incorporated separately and therefore affects the values of the coefficients which are derived through calibration. In all computations $k_1=0.66$ and $k_2=0.9$ were used. For the stone diameter the equivalent sphere diameter D_{EQ} is taken as the characteristic stone size ($D_{EQ} \approx 1.24 \cdot D_{n50}$).

The submerged weight is taken as the counter-acting force. The submerged weight acts vertically and can be written as (ρ_s is the density of the stone material):

$$W_s = (\rho_s - \rho) g k_1 D^3 \quad (4)$$

Several concepts can be used for initiation of movement. Stability criteria for the phenomena referred to as *lifting* and *sliding* can respectively be expressed by:

$$F_L \leq W_s \cos \phi \quad (5)$$

$$|F_D + F_I - W_s \sin \phi| \leq \tan \mu (W_s \cos \phi - F_L) \quad (6)$$

where μ denotes the angle of internal friction and ϕ the local slope angle. The phenomenon *rolling* is assumed to occur if both stability conditions are not satisfied.

3.3 MODELLING OF STONE DISPLACEMENTS

If at a certain position a stone in the slope is unstable, the direction in which the stone will move has to be determined. It is assumed that the drag and inertia forces and the weight of the stone determine in which direction an unstable particle will move after one of the stability criteria is (Eq.5 and/or Eq.6) not satisfied:

$$(F_D + F_I - W_s \sin \phi) > 0 \Rightarrow \text{UPWARD} \quad (7)$$

$$(F_D + F_I - W_s \sin \phi) < 0 \Rightarrow \text{DOWNWARD} \quad (8)$$

In Van Gent (1995-c) erroneously an additional force (F_p) was taken into account in equations 7 and 8. Although this force did not have any effect on the computations, this force has been omitted in the new computations.

After determining the direction in which an unstable particle may move, the local hydrodynamic properties at a position one space-increment (Δx) away from the original position, are regarded. It is verified whether the particle would be stable or unstable in that neighbouring position. If the particle is stable at that position, the particle will stay at its original position. If the particle is also unstable at the

neighbouring position the particle is moved to this position. This is done without any time-delay which means that the particle is moved over a space-increment Δx within a period of Δt . The choice of Δt depends on the space-increment Δx and the wave celerity which means that the velocity of the stones is in fact related to the (average) wave celerity.

This response model for cross-structure transport is interactive with the hydraulic model. At each time-step (Δt) the hydraulic properties are determined at all positions. At each position and each time-step it is verified whether the particles are stable at their present position or not and whether they need to be displaced. The profile changes due to the movement of the particles while the new profile is immediately incorporated in the hydraulic model.

Fig.3 Comparison between measured and computed reshaped profiles of a prototype berm breakwater.

A few examples of performed computations are shown here. Figure 3 shows a comparison between measured (Montgomery *et al*, 1988) and computed reshaped slopes of a (prototype) berm breakwater. Computations for reef-type structures were performed after verification of wave transmission coefficients. Tests by Ahrens (1987) were used for comparisons of the dynamical response of reef-type structures, see Figure 4.

4. MODELLING OF EFFECTS OF GRADING

Besides a quantitative validation of the model also trends that have been observed in physical model tests have been studied. This concerns the effects of wave height, wave period, stone size and initial slopes. The wave load-response model has been extended to also include the effects of variations in stone size along the slope and stone size segregation.

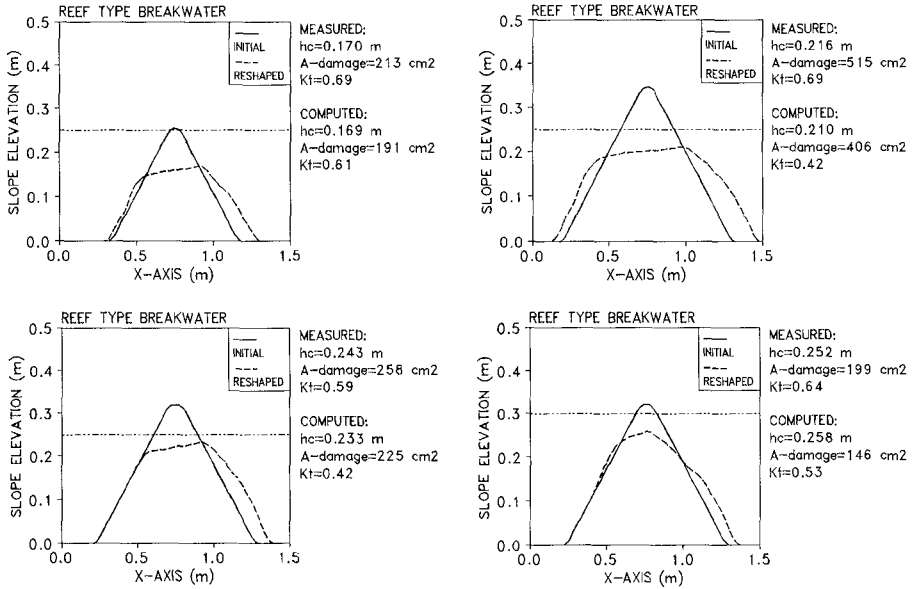

Fig.4 Computations with reef-type structures, initial profiles and reshaped profiles (stable).

To include these effects of the stone size distribution, the initial slope is made out of stones with at each position (each Δx) a stone with a different size. This is done randomly but such that the slope has a prescribed grading curve. At each position the forces are determined on the stone with its particular size. If a stone is unstable and moved in the upward or downward direction, the stone (size) in the second layer is treated as the exposed stone. At the position where the stone is moved to, this stone becomes the exposed stone while the originally exposed stone becomes the stone in the second layer. In this treatment the thickness of the layers is not equal to one stone diameter. Despite this simplification the effects of material with a range of sizes can be studied numerically.

The effect of grading on the reshaping process is not only determined by the size distribution of the stones. A wider stone size grading also has a lower permeability than a narrow grading. Grading might also affect the friction but since this phenomenon is not sufficiently quantified, the friction has not been varied in these computations ($f=0.10$).

The reshaping of gravel beaches with three different gradings are computed; $D_{n85}/D_{n15}=1.0, 1.33$ and 2.0 . For the grading curve a linear distribution is taken. Because the original wave load-response model was calibrated on a physical model test with material with a grading of $D_{n85}/D_{n15}=1.5$, while in the numerical model a grading of $D_{n85}/D_{n15}=1.0$ was used, the coefficients c_L , c_M and c_D should in fact

have been determined again after implementing the effect of grading. Since no recalibration was done, the analysis performed here is concentrated on the effects of grading itself and not into detail on the magnitude of the erosion and accretion on the reshaped profiles.

In Figure 5 reshaped profiles of three gravel beaches are shown. First only the effect of permeability is studied. For gradings of $D_{n85}/D_{n15}=1.0, 1.33$ and 2.0 the effect of decreasing permeability has been taken into account by simply reducing the porosity from $n=0.45$ for $D_{n85}/D_{n15}=1.0$ to $n=0.40$ for $D_{n85}/D_{n15}=1.33$ and $n=0.35$ for $D_{n85}/D_{n15}=2.0$. The results of this variation in permeability is shown in the upper graph of Figure 5. The second graph shows the effect of the variation in stone sizes along the slope while in the lower graph both effects are simultaneously taken into account. It is clear from the figures that reducing the permeability leads to more erosion of the slope. This seems reasonable since a increased permeability reduces the velocities along the slope. The variation in the size distribution shows a counteracting effect; a wider distribution shows a less affected profile. Apparently, after some reshaping the larger material of the distribution forms the toplayer and reduces further reshaping of the slope.

Combining the two effects shows (lower graph of Figure 5) that for the narrow grading the effect of lower permeability is slightly larger than the effect of the wider size distribution (slight increase in erosion from $D_{n85}/D_{n15}=1.0$ to 1.33). For wider gradings the effect of the wider size distribution becomes slightly more important (slight decrease in erosion from $D_{n85}/D_{n15}=1.33$ to 2.0). Similar conclusions were obtained by Kao and Hall (1990) who studied the effects of grading on a reshaping berm breakwater through physical modelling.

Figure 6 shows the computed effects of three different gradings for reshaped profiles with different material size (D_{n50}). As can be expected, larger material leads to less erosion of the initial slope; this also leads to a smaller effect of a wider gradation for larger material. Figure 7 shows the effects on reshaped profiles for different initial slopes; steeper initial slopes are much more affected than milder slopes. For slopes where considerable erosion of the initial slope occurs again the effects of a wider gradation is obvious. Apparently, the larger material of the distribution forms the exposed layer after some reshaping and reduces further reshaping of the slope. The computations also show that for wider gradings more material is moved upward; the forming of a beach crest is more substantial for wider gradings while the forming of a submerged bar is more apparent for narrow gradings.

Since the motion of material with different sizes within one slope is modelled, also the effect of stone segregation is simulated. Figure 8 shows the stone size distribution of material along the slope after reshaping. The stone size distribution is given for the exposed stones and also for the average of the ten upmost stones. In Figure 8 the stone size material is averaged over some sections of the slope in

which the variation in size is relatively small. Two examples for different initial slopes are shown in Figure 8. The general conclusion is that in the region around and just below the still-waterline the material in the toplayer is relatively large. More downward and more upward from this region around the still-waterline, the material is somewhat smaller. The main conclusion is that after reshaping relatively large material is located in the region where the largest velocities occur, i.e. just below the still-waterline.

5. MODELLING OF EFFECT OF TOP-LAYER WITH HIGHER WEIGHT

In practice sometimes the largest stones from a quarry are positioned on top of the primary armour layer of a berm breakwater. This causes that initial reshaping occurs for somewhat more severe wave conditions than without this measure. By using the numerical model it is studied whether positioning the largest stones on top has effect on the final reshaped profile. The computations shown in Figure 9 indicate that these largest stones are moved either upward or downward and do not remain in the section around the waterline where the largest velocities occur. This also causes that the final reshaped profile is almost not affected.

6. MODELLING OF EFFECTS OF A SEAWALL

Some computations are performed with a fully reflecting impermeable boundary landward from the gravel beach. If such a seawall is positioned in the region that is affected by reshaping under conditions without a seawall it is obvious that the seawall can change the reshaping process. Since a one-dimensional model is applied here for conditions where vertical accelerations cannot always be neglected, the results are affected by extra inaccuracies and must not be taken too seriously.

Figure 10 shows results for three different initial slopes. For each initial slope the first reshaped profile shows the situation without a seawall, the second profile the effect of a seawall located on the beach and the third profile the effect of a seawall at the initial waterline. In general the trend is that the seawall causes the submerged bar to develop more seaward, as can be expected since the reflected waves cause increased velocities in the seaward direction. The computations do not show a clear local effect on the reshaped profile near the seawall; in some computations the local erosion increases slightly but in some other computations some piling-up of stones against the seawall occurs.

CONCLUDING REMARKS

The reshaping of dynamic structures such as berm breakwaters, reef-type structures and gravel beaches has been simulated numerically. This approach

Fig.5 Influence of permeability, size distribution and combined effects of grading on reshaped profiles.

Fig.6 Influence of grading on reshaped profiles for different stone sizes.

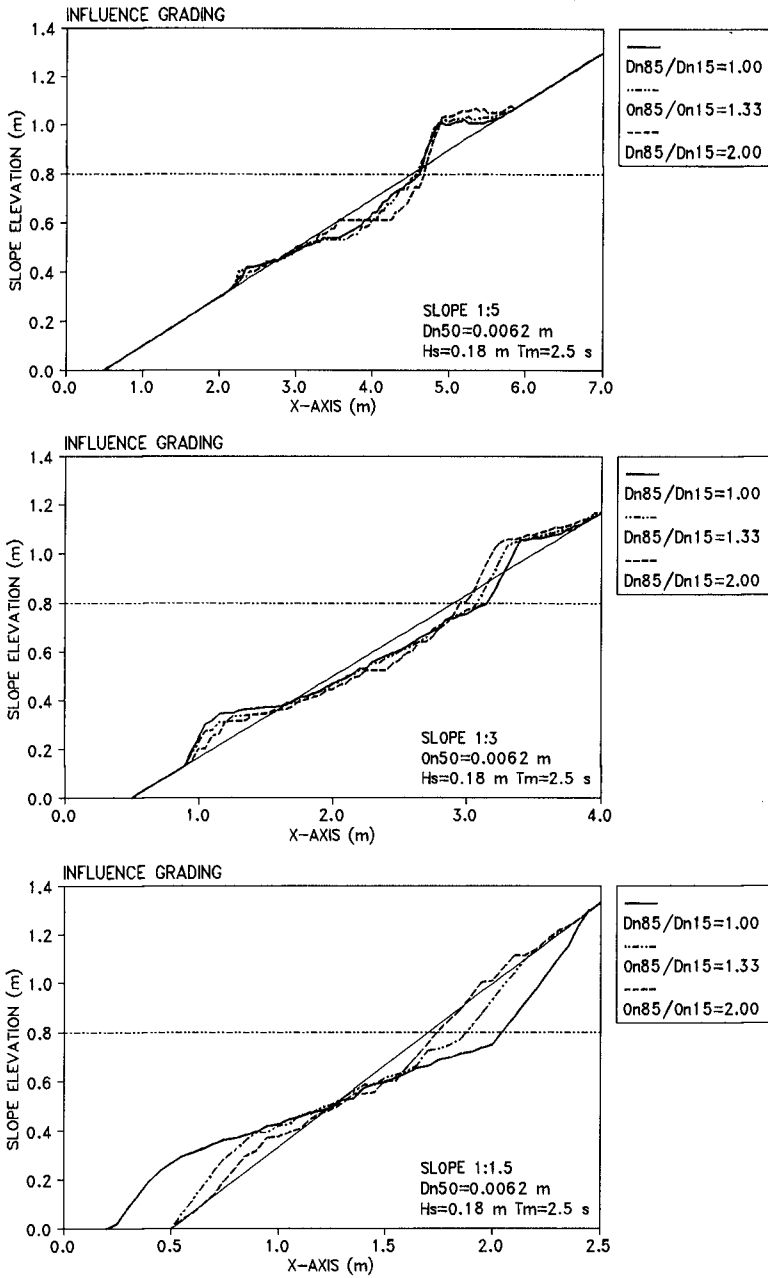

Fig. 7 Influence of grading on reshaped profiles for different slope angles.

appeared to be successful for predicting trends in the effects of variations of the wave height, wave period, stone material and initial slope. Although not validated, also effects of grading of stone material and effects of a seawall on a beach were incorporated. Further improvements to this wave load-response model might be obtained by applying a model which provides more detailed and more accurate information on the wave motion; the two-dimensional model (2DV) described in Van Gent *et al.* (1994, 1995-c), which includes detailed modelling of breaking waves, can be applied but this requires considerable computational efforts.

ACKNOWLEDGEMENTS

The financial support by the Commission of the European Communities by way of the MAST-Berm Breakwater project (contract MAS2-CT94-0087) is gratefully acknowledged. Thanks are also due to Prof. K. d'Angremond from the Delft University of Technology since a large part of the research concerning this paper is performed at this University.

CHAPTER 151

MONITORING OF ZEEBRUGGE BREAKWATERS

Luc VAN DAMME¹, Julien DE ROUCK²,

ABSTRACT

From the moment they are constructed, rubble-mound breakwaters are due to be damaged someday. Accepting damage is one of the basic principles of mound breakwaters design. Damage can take place either gradually in time or catastrophically after a major storm. Gradual deterioration of the armour layers or foundation may be unnoticed without the aid of a monitoring program and may ultimately result in the failure of the armour layer, in slope instability or in unacceptable large settlements. By comparison of measurements of the state of the structure at a number of points in time, a monitoring program allows these changes to be identified at an early stage, thus enabling the appropriate maintenance action to be carried out.

Several structural and environmental monitoring techniques are used in Zeebrugge. Three structural monitoring techniques are presented in more detail.

The emerged armour units of the Zeebrugge breakwaters are monitored using aerial remote sensing. An observation flight is made once a year. Each time, the position of over 15,000 armour units is very accurately retrieved by stereometric digitization. The coordinates are stored in a computer database. Several types of data visualization have been developed for a fast and efficient evaluation of the survey results.

For the underwater inspections of the breakwater two acoustic techniques are used. On the one hand, digital side-scan sonar recordings are used to produce high-resolution and contrasting images of the breakwaters' underwater armour layer. Such images allowed the detection of structure modifications in the breakwaters' toe protection.

On the other hand, high-frequent multibeam echosoundings, allow to exactly quantify the actual underwater armour unit movements in time.

THE MONITORING PROGRAMME OF ZEEBRUGGE

The monitoring programme of Zeebrugge breakwaters is composed of the following parts : visual control of the armour layer, the crest of the breakwater and the filter construction next to the road; topographic survey, bathymetric soundings of the different zones around and in the harbour; aerial remote sensing of the armour units ; side scan sonar recordings of the underwater part of the armour layer and the wave breaking carpet and berms coupled to multibeam recordings; evaluation of the hydraulic design conditions on the basis of data collected by five measurement stations and seven waverider buoys in the neighbourhood of the harbour. The monitoring programme is now running for more than 10 years.

Figure 1 - Cross-section NW breakwater

Two parts of the monitoring programme will be treated in detail : aerial remote sensing of the armour units and the underwater inspections. Figure 1 is a typical cross-section of the Zeebrugge breakwaters. The toe of the breakwater is protected by a berm in 3-6 ton stones. The armour layer of the breakwater consists of antifer cubes 20 to 30 ton.

AERIAL REMOTE SENSING OF THE ZEEBRUGGE BREAKWATER ARMOUR LAYER

Several techniques are used for the survey of armour units. Soon after the construction of the Zeebrugge outer harbour breakwaters, an attempt was made to determine the position of the individual armour units, using land-based photographic recordings. This method was labourintensive and time-consuming, and posed serious problems in the areas that cannot be accessed on foot. Indeed, the vast majority of the armour units are inaccessible, or even out of sight for a land-based surveyor. Therefore, the use of aerial photography was proposed.

A survey based on this method offers the advantages proper to aerial photography: high accuracy, rapid (instantaneous) coverage of the complete breakwater length, recorded documents (photographs) allowing objective interpretation and verification, highly automated data handling and preparation for interpretation.

Execution of the photoflight

The aerial photographic recordings are carried out at low water during spring tide, to ensure maximum coverage of the breakwaters, i.e. a maximal number of armour units is visible.

The flight axis is located above the seaward side of the breakwaters so that the breakwaters take a central position in the aerial photographs.

The flight altitude is a major key to the success and accuracy of the survey. First, the mean square error on height data, obtained by photogrammetric digitization, is directly proportional to flight altitude. As a rule of thumb, the error on altimetry is approximately 1/10,000 of the flight altitude. This clearly illustrates the advantage of low altitude recording.

Another advantage of very low flight altitudes is that recordings can be made under a cloud cover. The diffuse light favours the image quality of the objects surveyed (i.e. the individual armour units), as there are no deep shadows. This, however, is only possible using technical features to enhance the quality and contrast of pictures realized under such reduced light conditions. As a wide lens aperture ($f/4$) and a relatively long exposure time are needed, the use of forward-motion compensated (FMC) cameras is indispensable. The cameras are mounted in twin-prop aircraft of the STOL (short take off and landing) type, so as to realize the best stability at low flight altitude and low speeds.

At low-altitudes, the speed of the aircraft in relation to the reloading of the cameras determines the stereoscopic coverage of the area. As a minimum photographic overlap of 60 % in the flight direction is needed for adequate stereoscopic vision, a coupled system of two alternating photogrammetric cameras is used.

A first survey flight took place on 2 July 1988 ; a second flight was carried out on 18 October 1989. Each time, the flight altitude was situated between 150 and 200 m. About 7 km of the seaward sides of the breakwaters were covered. The recordings allowed the survey of over 15,000 concrete blocks from the upper layer of the breakwater armour layer.

Photogrammetric digitization of the armour units

The orientation of the photogrammetric couples in the stereoplotter poses a special problem. For the relative and absolute orientation of each stereocouple, use is normally made of six control points. The control points should be distributed equally over the area which is covered by the stereocouple. If the condition of aerial distribution is not met, inadmissible errors in the accuracy will occur as a result of the orientation procedure.

Aerial photographs of breakwaters, however, show large surfaces of water that do not allow the determination of fixed calibration points.

The breakwaters take up only the central portion of the aerial photographs, and so, no calibration points along the sides are available. The orientation problem was overcome by the use of a specially developed software orientation programme. After mounting the two aerial photographs that constitute a stereocouple into an analogous stereoplotter, the position is measured in stereoplotter coordinates of six arbitrarily chosen field points that can be recognized on both photographs and are sufficiently well distributed over the area. Also, the centre point of each photograph is determined. The computer program then calculates the parameters needed for the relative orientation of the stereocouple. The operator manually sets the stereoplotter using these parameters. Afterwards, use is made of field control points (situated on the breakwater), to perform the absolute orientation (i.e. relative to the known standard grid "Lambert"). This operation has to be performed on an analogous stereoplotter, because analytical stereoplotters have a built-in orientation program that continuously recalculates the orientation and repositions the photographs.

The digitization of the armour units is also performed using a non-standard procedure. Of every armour unit, a minimum of four well-defined points are digitized.

These points determine the exact position of each armour unit with sufficient redundancy. A computer program controls and corrects the digitization of the armour units, given that the exact dimensions of each type of armour unit are known. This operation minimizes operator-induced uncertainties. The high quality of the aerial photography recordings, the efficiency of the dedicated software and the skill and experience of the stereogrammetric digitization operators combined reduce the error on the altimetry of the armour units to below 5 cm. The accuracy was confirmed on a special occasion. In October 1989, some 20 armour units had to be displaced in order to improve the cover. Before the operation, their position was measured using classical, land-based methods. The position of those blocks that could be accessed was measured with high precision. Table 1 compares the centre point coordinates with those retrieved from the 1988 observation flight. It is clear that the differences in position are completely within the accuracy range stated above. Thus, the position of each armour unit is known with the utmost precision, as required to detect slight variations in position between consecutive flights.

Furthermore, if armour units are damaged, the entire cleavage area is digitized. The volume percent of the armour unit lost by breakage is calculated accordingly. If an armour block is broken up into several, almost equally large pieces, then these pieces are digitized separately.

The armour unit database

Each flight results in the creation of three data files, containing all the information for further data handling and visualization, which are incorporated in the overall breakwater database.

The main data file, the so-called master file, contains an identification number, the absolute position of the centre point of the upper plane and the relative coordinates of the corner points of all the armour units measured. The absolute position is specified by the planimetric coordinates (with respect to the national grid Lambert '72) and by the altimetric coordinate (with respect to the level datum "Z" of the Ministry of Public Works). A second data file, called pointer file, contains the armour unit type and links the block identification number of the current survey to the reference breakwater survey (i.e. the first survey, performed on 18 October 1989). In the third output file, called cleavage file the information regarding the damaged armour units is stored, i.e. the armour unit identification number, and the absolute coordinates of the cleavage line.

The displacement of the centre point of the armour units is calculated for each inspection flight. This data, together with the information on breakage, is represented in an updated report table.

In the table 1 the measurement some results of the 1989 and 1991 surveys of a selected area of the Westdam (between the P2810 and P2910 marks) are listed.

Block Number	Block Type	Top Plane Centre at Reference			Displacement (cm)			Breakage (%)
		X(Lambert)	Y	Z	dX	dY	dZ	
3925	25TP	66594,840	227772,352	10,181	0	-11	-21	1,1
3926	25TP	66590,628	227772,288	7,957	5	-1	-15	
3927	25TP	66592,556	227773,504	8,381	15	0	-2	
3928	25TP	66590,904	227774,560	6,774	2	1	-14	

Table 1 - Armour Unit Data table

This table consist of five primary columns, containing the following information:

1. The armour unit ID number : a unique number allotted to each armour unit at the photogrammetrical digitization of the 18 October 1989 reference survey. The position of the armour units can be found in the armour unit location plan.
2. The armour unit type : 20TP, 25TP, 25T or 30T.
3. The coordinates (respectively Lambert-72 X and Y (in metres), and Z (in metres as well) with respect to the Z datum of the Ministry of Public Work) of the centre of the armour unit's upper face, as measured at the 18 October 1989 survey.
4. The displacement of the armour unit's centre, in centimetres, i.e. the difference in position between the reference survey and the present survey.

The displacement is calculated by defining the difference between the reference survey coordinates and the present coordinates along each coordinate axis (X, Y, Z).

5. The breakage volume rate. The rate of volume loss due to breakage is calculated for each armour unit that has suffered breakage.

From the table (with armour unit identification numbers identical to those of the armour unit location plan) it can be quickly determined which armour units have undergone a displacement with respect to the reference survey, how large the displacement is, and in which direction it has occurred. This gives a quantitative overview of the displacements between the different surveys.

It can also be seen which armour units have suffered breakage, and how important the damage is. The armour unit displacement plans visualize the block's displacements.

VISUAL REPRESENTATION OF THE BREAKWATER SURVEYS

In order to allow a quick and accurate interpretation of the vast amount of data involved in the breakwater armour survey and several cartographic representations were developed. The definition and the main characteristics of the different ways of representation are briefly outlined below.

Armour unit location plan

The armour unit location plans show the position of each armour unit in the upper layer. The slope plane, as defined above, is taken as the projection plane. All upper surfaces are shown in projection.

It follows that the upper surfaces of all regularly-positioned blocks of the slope plane are shown as squares in an optimal projection.

Irregularly positioned or tilted units are represented by flat parallelograms.

Figure 2 - Unit location plan

The central part of Fig. 2 is an extract of the 1989 armour unit location plan corresponding to the part of the breakwater shown in the upper aerial photograph.

On the armour unit location plan, three digits identifying each block are indicated. Areas of tilted blocks or regularly-positioned blocks can immediately be recognized. Also, a qualitative picture is provided of the density of the breakwater cover. Furthermore, the blocks affected by breakage are hatched.

Armour unit occupation plans

Different ways of visualizing the positioning density of the armour units on the breakwater slopes have been established. Each method emphasizes one particular aspect with respect to the protective function of the armour layer:

- the mean occupation plan highlights the positioning density of the armour units as a function of their spacing and orientation. The plan shows the values of the "mean occupation density", calculated for each point of the slope plane. The mean occupation density assumes high values when armour unit spacing is smaller than originally designed (i.e. the units clump together), while low values indicate a poor block density.

Low values are also achieved when the armour units are irregularly oriented (i.e. the basal surface of the block is at angles to the slope plane). Therefore, a low mean occupation density always indicates a poorer protection of the breakwater at the location considered ; either the blocks make irregular angles with respect to the slope plane, or their spacing is too high ;

- the differential mean occupation plan compares the mean occupation density as calculated for a specific observation flight with the design mean occupation density. As different types of armour units and patterns of positioning were applied, part of the variation of the mean occupation density is due to the design. The differential mean occupation plan singles out this part of the variation and only shows discrepancies in occupation between the current survey and the design situation. Of course, this technique can be applied to any two surveys;
- the porosity plan regards the occupation density as an inverse function of the occurrence of hollows and spaces between the armour units of the upper layer. The plan represents the real porosity of the outer armour layer, such as calculated for a given observation flight. It does not conform with the design porosity, as the latter is calculated over the two armour layers, in which all armour units have the same orientation.

The values, represented in each type of plan are, respectively, the mean occupation density, the relative mean occupation density and the porosity.

These values are calculated for each point of the slope plane. For computational reasons, these points are positioned on a rectangular grid.

The unit spacing of the calculation grid can be chosen according to local conditions. For the Zeebrugge breakwaters, a 1-m spacing was adopted. All values determined are averages calculated over a unit surface, of which the centre is located successively in each grid point. In Zeebrugge, a unit surface of $6 \times 12 \text{ m}^2$ was found to provide the most relevant areal detail after some preliminary tests. The long axis of the unit surface is oriented parallel to the long axis of the breakwater. The rectangular shape of the unit surface provides a better sensitivity to density variations in the slope direction.

The dimensions of the unit surface were chosen so that it contains 15 to 20 armour units at a time. The values calculated in each grid point therefore represent the point itself and its immediate environment.

The armour unit occupation plans are produced in colour. In each of the three approaches, red corresponds to a poor condition, yellow represents the ideal or mean situation and green is used for a too close armour. The use of this colour representation of the occupation values described, enables a very precise and fast overview of the condition of the breakwater armour layer. The lower part of Fig. 3 is an extract of the porosity plan of the section shown above.

Though the figure is in black and white, the relation to the aerial photograph and the location plan above is still clear. Parts of the breakwater having a dense occupation of armour units are characterized by a low porosity, and vice versa.

Armour unit displacement plans

An essential indication of breakwater instability is the movement of the individual armour units. In order to detect such movements and their rate, inspection flights are carried out every year. As the aerial photography, the photogrammetric digitization and the subsequent computer processing are carried out with utmost care, absolute shifts in position of armour units can be traced once they exceed about 5 cm.

Therefore, a link is provided between the block coordinate lists of the reference flight and the last flight performed. Using a dedicated software program, the armour units of the last flight are automatically linked with the corresponding armour unit of the reference flight. The link method is based on the position of the centre of gravity of each block. Once this identification procedure has been carried out, the displacement of the individual armour units is readily established. The armour unit displacement plan represents, by the same projection method as the one used for the location plans, the displacement of all individual armour units between two surveys by means of colour coding.

DIGITAL SIDE-SCAN SONAR RECORDINGS

Side-scan sonar is basically an imaging technique whereby sound pulses are transmitted at both sides of a towed 'fish'. The pulses are sent perpendicular to the track of the vessel under approx. 90° , allowing a full coverage of the sea bottom on both sides of the vessel from the water surface to below the survey vessel. As the ship advances, a complete image of the seabottom along-track the survey vessel is created.

The strength and delay of the returned signals are measured and presented to the user on an analog thermal paper output. The returned signals are indicated by black dots on white thermal paper. As the initial sound pulse covers an angle of 90° , return signals from within this entire lookangle are received. The darkness of the dot corresponds to the strength of the returned signal. Usually, 16 or 64 discrete levels of black can be shown. The dot is positioned away from the centre of the paper roll proportional to the time delay of the returned signal. With each new emitted sound pulse, the time delays of the returned signals are measured with respect to the new trigger point (i.e. the new pulse). This provides information about the distance from the source the reflecting substance can be found, not however on the direction in which to search for this distance.

The maximum time allowed to wait for a returned pulse is a measure for and proportional with the distance the sidescan sonar is allowed to 'look' under the water. The thermal paper of the analog output is advanced at regular speed, which can be set manually or automatically to reflect, as much as possible, the speed of the survey vessel. By doing so, as one line of information is written with each emitted and returned pulse and consecutive pulses create consecutive lines in the output, an image of the seabottom is created.

However, because exact directional information (from where the return signal is coming) is missing, side-scan sonar measurements do not provide absolute positioning of the recorded features. This is the main difference with the other measuring technique used, multibeam (see below).

All objects under water, when hit by the sound pulse, will reflect part or whole of the incident energy back to the source. Some objects, such as stone, are much better reflectors than others, e.g. silt. The strength of the return signal, duly amplified because of the attenuation of the signal with distance from the source creates an image, that gives an impression of the kind of materials detected under water. Also, objects by returning the sound pulse create a shadow zone behind them, effectively hiding part of the seabottom or underwater part of the breakwaters from detection by the side-scan sonar.

Such shadow areas are normally indicated as white - blank areas on the visualisation output.

The description above applies to standard side-scan sonar. However in Zeebrugge the analog output of the side-scan sonar is systematically digitized, in real-time and this information is stored in digital form. That technique is therefore dubbed digital side-scan sonar.

The side scan sonar used is a dual-frequency instrument, with analog output and recording. The analog output is digitized in real-time and connected to a VME-computer for data logging. The VME-computer also records the GPS information as well as the information of the vessel's roll, pitch and heading, destined for geometric corrections later on.

The digital storage of the side-scan sonar output is in 12 bit, allowing 4096 distinct data values (or 'grey values' in terms of analog output), while normal analog output on thermal paper only allows 16 or 64 grey values. All subsequent data treatment is also performed digitally.

Processing of the digital side-scan recordings

Figure 3 - SSS-recordings

First, geometric corrections are applied, together with a straightening of the sounded track. Geometric corrections are needed because the sounding vessel's speed nor behaviour (roll, pitch) are constant during the recording.

Also, the followed path is not a perfect straight line parallel to the breakwater. Corrections are based on the continuously stored positioning, heading, roll and pitch data.

A further data treatment arranges the sonar recordings into a straight strip parallel to the breakwater.

Adequate along-track way-points ensure a uniform scale in this direction, to which the transversal scale is adapted. After the geometric corrections, a number of digital imaging techniques is applied to render the side-scan sonar image easy to read and interpret. This step is largely made possible by the great number of recorded grey levels. Figure 3 contains an example of enhanced side-scan sonar recordings, fit to aerial photographs showing the subaerial part of the breakwater. The armour units below and above water level are clearly detectable.

The aerial photographs are rectified grey-scale images of the breakwater, above the low-water line. Both types of recording are fitted together without transition break, so that a continuous image of the breakwaters is created, showing them from the breakwater crest till its toe. On the image, distance indications and other marks are added, so as to facilitate the interpretation.

MULTIBEAM RECORDINGS

With multibeam, as the name implies, a number of discrete sound pulses (or 'beams') are emitted and the returned signal is recorded within well specified angles. Basically the same information is thus collected as with side-scan sonar, only now because of the known direction of the returned signal, the exact distance and hence location of the underwater object can be determined. In multibeam, the output of the device is always in digital form, needing often not more than serial RS-232 connection to have access to the measured data. While, side-scan sonar can be considered an 'imaging' technique, multibeam is a real 'measuring' technique.

Multibeam principle and deployment geometry

Multibeam systems emit a number of discrete sound pulses and record the returned signal within well-specified angles. The system used in the Zeebrugge breakwater monitoring programme, emits 60 beams at a time in a profile, perpendicular to the track. The beams have an aperture angle of 1.5° so that a complete profile covers an angle of 90° . The basic geometry of the system deployment much resembles the one used in side-scan sonar surveying, only now, because both the delay time and the direction of the returned signal are known, the exact location of the reflecting underwater object with respect to the sensor head can be determined.

For the breakwater surveys, the sensor head is rigidly fixed to the vessel's starboard side in an angle of 45° from the vertical, so that the beams look sideward from the sea bottom over the toe protection and armour layer to the watersurface.

Contrary to the side-scan sonar measurements however, with the used multibeam, only on one side of the track are measurements possible at any one time. As the survey operation takes place in very shallow water, a high beam update frequency can be obtained.

A high frequency is advantageous to increase the number of measured profiles, so that a high data density is achieved. In the Zeebrugge breakwater surveys, update frequencies in the order of 13.5 Hz yielded the best results. This rate corresponds to 810 measured points per second, or, at a survey speed of 1 to 1.5 m/s at least 100 measured points per armour unit.

Processing and interpretation of the survey results

The output of multibeam echosoundings is typically a map showing all measured points (on their true location x,y), together with an indication of the measured depth (z , with reference to the chart datum).

Such a basic visualization poses some difficulties, especially when one is interested in comparing the results of successive surveys. Two different approaches to this problem can be used, depending on the type of breakwater material.

For quarry stone layers, such as the toe protection of the Zeebrugge breakwaters, a digital terrain model (DTM) can be fitted through the measured points that are located on the top of the rubble mound surface.

When a second survey has been completed, e.g. one year later, a new DTM of the rubble mound slope can be established. The difference of both DTMs can then be represented in a map, displaying areas where changes in the rubble mound topography have occurred.

If the breakwater is protected by armour units, such as in Zeebrugge (grooved cubes), this method no longer applies. Here, the exact location of the armour units is needed to assess the breakwater's safety, so that displacements per unit can be calculated. The determination of the exact location of the underwater units is possible, as sufficient points are measured per armour unit, with an absolute accuracy of approx. 20 cm in all three axes. This is less than 1/10 the dimensions of the armour unit. Comparison of the same unit, measured at a later stage, e.g. a year later, at the same accuracy, allows the production of differential maps of the submerged armour units with an approximate precision better than 40 cm, 1/5 the dimensions of armour units. Considering that only displacements equal to the unit length are significant in breakwater stability rules and equations, it is evident that the measuring technique effectively and quantitatively allows the assessment of breakwaters' stability.

CONCLUSION

The measurement of the position and displacement of individual armour units of a rubble mound breakwater is the most straightforward method for early detection of breakwater changes.

Due to the difficult and dangerous access, aerial remote sensing is one of the most appropriate ways to obtain the position of those blocks of the outer armour layer that are emerged at low tide.

Aerial photography moreover adds the advantages of high accuracy, fast speed of observation and automated data acquisition and processing.

Appropriate tools have been developed to obtain and evaluate the volume of information. The unit data tables, armour unit location plans, occupation plans and displacement plans provide an effective and accurate picture of the actual condition of the armour layer and the movement of the armour units since a reference situation.

The use of digital side-scan sonar recordings allow qualitative assessment of the stability of the underwater part of breakwaters. Multibeam recordings are very useful when quantitative data are needed.

Since 1993, the determination of the exact position of the Zeebrugge breakwaters underwater armour units, as well as of the exact underwater topography of the breakwaters' toe protection, is based on high-accuracy multibeam echosounding. Successive surveys allow the movements of the armour units and changes in the toe protection topography to be mapped and analyzed.

These three structural monitoring techniques are excellent tools to organize adequate maintenance and to keep the breakwaters in optimum condition.

CHAPTER 152

Influence of rock shape and grading on stability of low-crested structures

Jentsje W. van der Meer¹
W.H. Tutuarima²
G. Burger³

Abstract

The stability of low-crested rubble mound structures has been treated before by various researchers. In the first phase of this study two data sets from different laboratories were combined to one homogeneous data set. Re-analysis of these data resulted in a design diagramme for the stability of the seaward side, the crest, the rear and the total armour layer of the structure. Secondly, model tests were performed on carefully selected rock with different rock shapes (angular, flat and rounded) and different gradings, all for a low-crested structure. Results show that the differences between the various rock types were small, especially for the start of damage. The influence of the length/thickness ratio showed even no influence at all which means that the sometimes strict requirements in construction may be released.

Combination of existing results

Low-crested rubble mound structures were treated by Van der Meer and Pilarczyk (1990) and were divided into three types: reef type structures and conventional structures with, respectively, the crest above or below the still water level. For all three types design formulas were given, based on a limited number of tests. In fact the division between structures with the crest above or below still water is not really practical as both situations can happen for the same structure.

Vidal et al. (1992) treated low-crested structures in three parts: the front

¹ Delft Hydraulics, P.O. Box 177, 2600 MH Delft, The Netherlands

³ Delft University of Technology and Grabowsky & Poort Consulting Engineers, The Hague, The Netherlands

slope, the crest and the rear slope. Their tests were complementary to the available data of Van der Meer and Pilarczyk (1990). The first part of the present study was to analyse both data sets in the same way and bring them together. All data were submitted by Vidal.

Vidal et al. (1992) accounted for the development of damage onto the entire structure, where Van der Meer and Pilarczyk (1990) only looked at the stability of the front side including a small part of the crest. In addition, Vidal et al. divided the damage in three segments: the front, the crest and the rear. The division in these three segment, used for the present re-analysis, is given in Fig. 1.

Figure 1. Division of armour layer in three segments

The damages to the structures of Van der Meer and Pilarczyk (1990) and of Vidal et al, were re-established according to Fig. 1. All data and the analysis have been described in Burger (1995). The damage is defined according to Van der Meer (1988):

$$S = A_e / D_{n50}^2 \quad (1)$$

Where: S = damage; A_e = surface of eroded area; D_{n50} = nominal diameter (cubical size) of the rock. S -values between 1-3 mean start of damage and values higher than 8-12 give "failure", this means holes in the armour layer and visible underlayer or core. With steep slopes and small areas subjected to wave attack, the smaller S -values should be used.

Parameter	Van der Meer	Vidal
D_{n50} (m)	0.0344	0.0249
Δ (-)	1.61	1.65
H_s (m)	0.073-0.229	0.047-0.152
T_p (s)	1.96 and 2.56	1.4 and 1.8
s_p (-)	0.010-0.036	0.010-0.049
B/D_{n50} (-)	8	6
R_c/D_{n50} (-)	-2.9 to 3.0	-2.0 to 2.4

Table 1. Test conditions for Van der Meer and for Vidal

The stability number is given by $N_s = H_s / \Delta D_{n50}$, where H_s = the significant wave height and Δ = the relative buoyant density. The stability of low-crested structures will be dependent on the relative crest freeboard. This is defined by R_c / D_{n50} , the number of rock sizes that the crest is above (positive) or below (negative) the still water level. Other used parameters are the peak wave period T_p , the wave steepness s_p , and the crest width B . Table 1 gives the test conditions for both Van der Meer (1990) and Vidal et al. (1992).

Re-analysis of existing results

The parameters used by Vidal et al. are not fully the same as those by Van der Meer and Pilarczyk. Vidal et al. used a front slope with an angle of 1:1.5, whereas Van der Meer and Pilarczyk used 1:2. The comparison between the two test series was carried out as follows: from the damage curves various fixed damage levels S were chosen and the corresponding stability numbers were determined. Then figures were drawn of stability number against crest freeboard for the various damage levels. Fig. 2 gives an example of the front slope.

Figure 2. Stability at the front for fixed damage levels S

This figure shows that the two different data sets give a fairly good agreement, although some scatter is present. In order to make the analysis easier, in the following only start of damage will be considered. For the whole structure start of damage is given as $S = 2$. In order to remain consistent start of damage to the different segments separately should be lower, but in total again $S = 2$. The following distribution was chosen for start of damage: front 50% ($S = 1$), crest 25% ($S = 0.5$) and rear 25% ($S = 0.5$). The real distribution of the damage will vary with the freeboard. Fig. 3 gives the same data as Fig. 2 for the front, but now only for start of damage $S = 1$.

Figure 3. Stability front for start of damage

A curve is drawn through the data points and this curve is also extended beyond the range of test data. For positively increasing freeboard the value of the stability number can be determined easily. Because as the freeboard increases there will not be any more overtopping and the structure will behave according to the formulas by van der Meer (1988). The accompanying stability with the damage $S = 1$ is then $H_s/\Delta D_{n50} = 1.3$. For negatively decreasing freeboard the development is less easy to predict. However, it is evident that the stability will increase with a freeboard decreasing.

Figure 4. Stability of the crest for start of damage

Fig. 4 gives the data points for start of damage of the crest. Although some scatter is present, especially for the crest at the still water level, the trend is clear. The crest is most vulnerable for freeboards around the still water level. For high crest heights there will be hardly any or no overtopping and the curve will raise sharply. For negative freeboards the stability will increase with decreasing freeboards, more or less according to the front. Although the crest for large negative freeboards will show more damage than the front due to the wave attack directly on the crest for (very) low structures.

Figure 5. Stability rear for start of damage

Figure 6. Stability of entire structure

Fig. 5 gives the data points for start of damage ($S=0.5$) for the rear. Considerable scatter is present. For increasing positive freeboards stability should increase as soon as overtopping waves can hardly reach the rear. Therefore, the curve should go up quite steep. Again the stability of the rear should increase for very low structures, according to front and crest.

The total stability is shown in Fig. 6 where the curve is similar to the one for the front side. All four graphs together give a design graph for stability of low-crested rubble mound structures at start of damage. This design graph is given in Fig. 7. The crest and front slope are always normative in this figure. The crest is normative for a crest under water up to a crest height of 1 to 2 D_{n50} . Above that level the front is the least stable segment.

Figure 7. Design graph for low-crested rubble mound structures, for start of damage of various segments, front, crest, rear and entire structure

The design graph in Fig. 7 can be used in various ways. If the structure will be always under water it could be possible to use the armour layer only on the crest and to reduce the size at front side and rear. It is also possible to place the heaviest rock from the quarry at the least stable segment, which is determined from Fig. 7. Or one can design front, crest and rear with different rock gradings according to their required stability number. This may benefit the output yield curve of a quarry.

Tests on rock shape and grading

Requirements on rock shape and grading for construction of rubble mound structures are often fairly strict, see the CUR/CIRIA-manual (1991). The rock shape can roughly be determined by the L/D -ratio and by a description of the

shape (angular, round, etc.), see Figs. 8 and 9. Here L is the largest dimension and D the smallest. $L/D=1$ is a sphere or cube, $L/D=3$ is a fairly long and/or flat rock. In many cases values larger than 2 are not permitted, which in reality is difficult to obtain. Furthermore, such requirements are hardly based on testing. Also one is often strict as regards the demands for grading. The value of D_{85}/D_{15} may not exceed 2.0, implying that the quarry must produce uniform material.

Figure 8. Rock shape L/D

Figure 9. Round and angular rock

The above requirements give both delay as well as an increase of the costs of building the structure. It is remarkable, though, that none of these requirements have been tested sufficiently so as to substantiate them. However, a number of researchers have already determined (Van der Meer, 1988; Bradbury et al. 1990) for the grading that, within reasonable limits ($D_{85}/D_{15} < 2.5$), the grading has a negligible impact on the stability, but for low breakwaters this has not yet been investigated.

Tests were performed at Delft Hydraulics with six categories of rock which were very carefully prepared. Each individual rock was weighed and all three length dimensions were measured. These rocks were placed in fractions of 5 mm size difference (25-30 mm, 30-35 mm, etc.) and then further in three fractions with different shape: $L/D < 2$; $2 < L/D < 3$; and $L/D > 3$. These fractions were put together to form a predescribed grading and shape.

Table 2 shows the six different types of rock gradings and shapes. Three categories were used with angular rock, the same L/D -distribution, but with different gradings: $D_{85}/D_{15} = 1.25$ (uniform rock); 1.75 (normal grading); 2.5 (very wide grading). Two other categories were also made of angular rock, but had different L/D -ratio's. One of these categories had 40% rock with $L/D > 3$ (type 5). The sixth category was made of shingle which is very rounded rock. Fig. 10 shows a picture of each of the six different types of rock gradings.

Rock type	Shape	D_{85}/D_{15} (-)	$L/D > 2$ (%)	$L/D > 3$ (%)
1	angular	1.25	20	0
2	angular	1.75	20	0
3	angular	2.50	20	0
4	angular	1.75	50	15
5	angular/flat	1.75	80	40
6	rounded	1.75	50	15

Table 2. Rock types tested on a low-crested breakwater

Type 1. Angular; $D_{85} / D_{15} = 1.25$
 $L/D > 2$: 20% $L/D > 3$: 0%

Type 2. Angular; $D_{85} / D_{15} = 1.75$
 $L/D > 2$: 20% $L/D > 3$: 0%

Type 3. Angular; $D_{85} / D_{15} = 2.50$
 $L/D > 2$: 20% $L/D > 3$: 0%

Type 4. Angular; $D_{85} / D_{15} = 1.75$
 $L/D > 2$: 50% $L/D > 3$: 15%

Type 5. Angular/flat; $D_{85} / D_{15} = 1.75$
 $L/D > 2$: 80% $L/D > 3$: 40%

Type 6. Rounded; $D_{85} / D_{15} = 1.75$
 $L/D > 2$: 50% $L/D > 3$: 15%

Figure 10. Pictures of the six tested gradings

Tests were performed on a cross-section as given in Fig. 11. The prepared rock was placed on the upper sections only, as for the lower sections (shaded) no damage was expected. The seaward slope was 1:2, the rear 1:1.5. The water depth for all tests was 0.6 m, the structure height 0.67 m (crest freeboard of 0.07 m). The nominal diameter of the rock was around 0.035 m. Tests were performed with a Jonswap spectrum. The significant wave heights varied from 0.07 to 0.18 m. For each rock type two test series were done, one with a wave steepness of $s_p = 0.02$ (fairly long waves) and one with $s_p = 0.04$ (storm waves). A test series consisted of 6 to 7 test runs with different wave height in order to establish the damage curve (damage versus wave height). The structure was reconstructed after each test run (6 or 7 times during each test series). This procedure gives damage data that are independent and have no cumulative effect.

Figure 11. Tested cross-section

After each test run (of 1000 waves) the profile was sounded. Each time four cross-sections were measured with a sounding rod and a recording was taken every 0.039 m. Then the average profile was calculated and compared with the original profile. The final result was the damage area A_c and the damage S . The underside of the sounding rod had a circle shaped bulge with a radius of $0.5 D_{n50}$. The test data are given in Burger (1995).

For each test series a damage curve can be drawn. This gives two damage curves for each rock type, one for low and one for high wave steepness. With certain combinations of rock types in one graph the influence of rock shape and grading can be established. Figures 12 - 14 give all these combinations for the influence of:

- rock shape L/D
- rock shape angular/rounded
- rock grading D_{85}/D_{15}

Influence of rock shape L/D

Fig. 12 gives the results of rock types 2, 4 and 5, which have similar gradings, but have different shapes of L/D . Rock type 2 is almost cubical, where

rock type 5 has many long and flat stones (see also Fig. 10). The upper graph of Fig. 12 gives the results for a steepness of 0.02 and the lower graph for 0.04.

The influence of the rock shape L/D can hardly be traced in Fig. 12. In particular at the wave steepness of 0.04 the three rock types virtually overlap;

Figure 12. Influence of rock shape L/D on stability

results are virtually all on one line. With $s_p = 0.02$ there is no difference until a damage of $S = 4$; a little beyond that the more uniform material is more stable. At a yet higher stability number this is, remarkably enough, the least stable material.

Figure 13. Influence of angularity on stability

Figure 14. Influence of grading on stability

Influence of rock shape: angular/rounded

In Fig. 13 the results of the angular and rounded rock are given. Rock type 6 is composed of round shingle. For a wave steepness of $s_p = 0.02$ the data points up to a damage of $S = 4$ overlap one another exactly. The damage curves

for $s_p = 0.04$ are similar up to $S = 6$. Apparently the rounded material does not roll that easily as one would expect. However, when it does start rolling, the development of damage will occur progressively in comparison to the angular material.

Influence of grading D_{85}/D_{15}

Fig. 14 gives the damage curves for the first three rock types which all have the same shape, but different gradings. Up to start of damage, $S = 2$, there is hardly any difference between damage development. Beyond that and with a wave steepness of 0.02 one can recognise a difference in damage development. There is hardly difference for the wave steepness of 0.04. The scatter in results is largest for the widest grading with $D_{85}/D_{15} = 2.5$. This is similar to tests performed at HR Wallingford, for a very wide grading with $D_{85}/D_{15} = 4.0$ (CUR/C-IRIA-manual, 1991, page 271). There it is recommended not to use gradings with $D_{85}/D_{15} > 2.5$. The results in Fig. 14 show that upto this value the differences are small.

Conclusions

The existing test results of Vidal et al. (1992) and Van der Meer and Pilarczyk (1991) are reasonably in agreement, certainly if the differences in slope angle and crest width are considered. A design graph for start of damage was composed for stability of low-crested rubble mound structures (stability number versus relative crest freeboard). This design graph contains four curves: for the entire structure, the front slope, the crest and the rear.

Material factors of rock such as shape and grading appear to be of little influence on the stability of the armour layer of low-crested rubble mound structures. The length-width ratio L/D of the rock showed no influence at all on stability. A rock type with relatively many elongated/flat rocks is just as stable as a more uniformly shape rock type. There was hardly difference between the angular and rounded (shingle) shaped rock up to a damage of $S = 4-6$. After that the rounded rock showed a more progressive development of damage. Still the conclusion can be that also more rounded rock can be used for design of low-crested structures.

The grading has only little influence. It has no influence if the grading D_{85}/D_{15} is smaller than about 2. With $D_{85}/D_{15} = 2.5$ the stability can be the same, but the reliability of the results is smaller (the scatter is larger), probably due to unsorting of the grading, etc. It is recommended not to use gradings with $D_{85}/D_{15} > 2.5$.

The material factors as described above give hardly cause for the rejection of amounts of rock during construction. Hence, in future it is recommendable to be less strict as to the requirements for constructing (low) breakwaters than was

customary up to now. In particular, for the differences in length/width ratios of the rock this will yield gains in time and material to be used. This will benefit both principal and contractor.

CHAPTER 153

TOE STABILITY OF RUBBLE MOUND BREAKWATERS

Ton van der Meulen, Gerrit J. Schiereck, Kees d'Angremond¹

ABSTRACT

At the Congress on Coastal Structures and Breakwaters, a stability relation for toe structures of rubble mound breakwaters was presented, see Van der Meer et al., 1995. In that relation the relative stone density, Δ , was used in the stability parameter $H_s/\Delta D_{n50}$. In the tests on which the relation was based, however, Δ was not varied, so some uncertainty remained on the influence of this parameter. Additional tests were therefore carried out with different stone densities, leading to the conclusion that there is no influence of the stone density, other than represented in the stability parameter $H_s/\Delta D_{n50}$. Computations were done, coupling the orbital velocities in the waves in front of the breakwater to the stability of the stones of the toe structure leading to encouraging results. Both computations and tests show an influence of the waterdepth in front of the breakwater which is not yet included in the stability relation.

1. INTRODUCTION

Figure 1 shows a typical cross-section of a rubble mound breakwater, consisting of several layers, covered with an armour layer bordered by a toe structure. The function of the toe is mainly to support the armour layer, and to provide a transition to low(er) weight units in the base of the structure. Data about the stability of the toe are less in number than about the stability of armour layers. That is the reason to attach special attention to this part of the structure.

¹Delft University of Technology, Faculty of Civil Engineering,
P.O. Box 5046, 2600 GA Delft, The Netherlands

Figure 1 Cross-section rubble mound breakwater

Stability of the toe was traditionally related to the stability of the armour layer. For values of $h_t/H_s = 1.5$, a minimum weight of the units in the toe was given as $W/2$. For a greater submergence, with values of $h_t/H_s > 2$, toe unit weight could be reduced to $W/10$ to $W/15$ (Shore Protection Manual, 1984). These design rules were attractive because of their simplicity. They were, however, not based on extensive research or comprehensive theoretical considerations.

Figure 2 Existing relations for toe stability

Several other investigations on the stability of breakwater toes have been done. Van der Meer et al., 1995 presented the following expression, based on the MSc work of Gerding at Delft University of Technology (DUT):

$$\frac{H_s}{\Delta D_{n50}} = \left(0.24 \frac{h_t}{D_{n50}} + 1.6 \right) N_{od}^{0.15} \quad (1)$$

in which N_{od} is defined as the number of stones removed from the toe structure divided by the number of stones in a strip with a width of one D_{n50} and a length equal to the width of the test section (Van der Meer, 1993)

In this equation, the submergence of the toe is expressed as h_t/D_{n50} instead of h/H_s , since that gave a better fit with the experimental data. Figure 2 shows equation (1) for $N_{od} = 0.5$ (threshold of motion), together with the values from the Shore Protection Manual.

The stability parameter, $H_s/\Delta D_{n50}$, in equation (1) contains the relative density of the stones of which the toe structure consists. In the tests on which the equation is based, however, Δ was constant. The question therefore remains whether the influence of Δ is represented correctly in the equation. For another MSc-thesis, see Docters van Leeuwen, 1996, tests were done with a range of stone densities in order to check this.

The second item in this paper is an attempt to link the experimental results to the wave motion in front of the breakwater. Hydraulic engineering knows (too) many empirical relations. This makes application without sufficient knowledge of the backgrounds dangerous. The hydraulic engineering department at DUT has a policy, for reasons of didactics, to try to relate as much as possible stability of stones to the water motion.

2. EXPERIMENTS

Figure 3 Test set-up in wave flume

The tests were performed in a wave flume (length 40 m, width 0.8 m and depth 0.9 m) at the Laboratory of Fluid Mechanics at Delft University of Technology (DUT). An overview of the test set-up is given in Figure 3. In the flume a fixed bed foreshore with a slope of 1:50 was constructed. The length of the foreshore was 10 m. The rubble mound breakwater and toe structure were placed on a horizontal bed at a distance of 0.3 m from the end of the foreshore.

Irregular waves were generated according to a JONSWAP-spectrum. During a test the significant wave height was increased in 4 steps from about 0.1 m up till about 0.2 m. The peak period to match followed from the selected steepness s_{op} . In the research of Gerding the influence of the wave steepness on the stability of the stones in the toe appeared to be small (due to the selected steep front slope giving little variation in reflection with the wave steepness, hence in load on the toe). Therefore the steepness was kept constant at a value $s_{op} = 0.04$.

The wave heights used in the analysis are the measured wave heights at the beginning of the foreshore, reduced with the reflection and adapted for shoaling due to the sloped foreshore. The in this manner processed wave heights are indicated as incoming wave heights. The wave generator was provided with a reflection compensation. During the tests an average value of the reflection coefficient $C_r = 0.25$ was found with a minimum of 0.185 and a maximum of 0.315.

The breakwater was constructed with rubble according to Figure 4 to create a porous structure with a reflection coefficient similar to the one in prototype. The front slope was kept constant (2:3).

Figure 4 Cross-sections tested breakwater with toe

The tests by Gerding showed little to no influence of the width of the toe, therefore the toe structure width, b , (perpendicular to the length axis of the breakwater) was kept constant (0.12 m). Two toe heights were used in the tests, namely $z_t = 0.08$ m and 0.15 m. Each toe height was tested for two water depths $h_m = 0.30$ m and 0.45 m in front of the toe structure (0.50 m and 0.65 m at the beginning of the foreshore respectively). For the rubble of the toe structure three different materials with varying size were used:

Material	ρ (kg/m ³)	D_{n50} (mm)	D_{n85}/D_{n15}
basalt	2850	10.2	1.4
basalt	2850	15.1	1.2
porphyry	2550	9.8	1.34
porphyry	2550	14.4	1.31
porphyry	2550	21.0	1.26
brick	1900	23.1	1.45

The use of 6 stone types (ρ, D_{n50}), 2 waterdepth, 2 toe heights and 4 different wave heights led to a total number of 96 tests.

After each test the damage was determined by counting and weighing the total number of stones removed from the toe structure in the seaward direction. The damage is expressed with the damage number N_{od} .

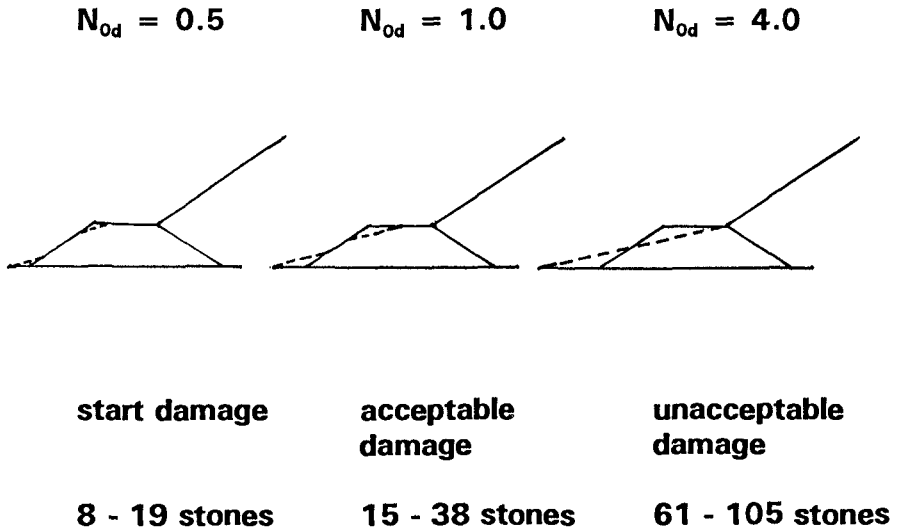

Figure 5 Sketch of damage for various values of N_{od}

Figure 5 shows various damage stages. $N_{od} = 0.5$ was chosen as the threshold of motion in this study.

N.B. Gerding found in his tests no influence of the berm width on the damage level. Of course, the acceptability of damage does depend on the berm width.

3. RESULTS

For the 96 tests, mentioned in the previous section, the damage results were plotted against the (incoming) wave height. Figure 6 shows an example of these results.

Figure 6 Example of damage as function of wave height

First, to check the influence of the density in the Gerding formula, $(H_s/\Delta D_{n50})/N_{0d}^{0.15}$ was plotted against h_t/D_{n50} . The results showed considerable scatter, making it difficult to draw a firm conclusion on the influence of Δ in the equation. Figure 7 shows the results limited to the threshold of motion, $N_{0d} = 0.5$. There is no clear distinction in this graph between the result points for the various densities. This justifies, for practical purposes, the use of $H_s/\Delta D_{n50}$ as a single stability parameter, indicating that there is no secondary effect of Δ on the stability (of course, there is a primary effect of Δ via the stability parameter).

In a more detailed investigation into the scatter of the results as presented in Figure 7, the data was also sorted out for toe height and waterdepth with the same horizontal and vertical axis. The toe height appeared to give no difference, but the waterdepth h_m shows definitely two different lines, see Figure 8. This makes that h_m should be involved, actually, in the stability relation, equation (1), although the differences are small.

Figure 7 Stability sorted out to stone density

Figure 8 Stability sorted out to water depth h_m

4. COMPUTATIONS

Empirical relations like equation (1) are only valid for the range of parameters that has been investigated. Application outside that range can be dangerous. Closely related to this drawback is the fact that empirical relations contribute very little to the understanding of the phenomena involved. In an attempt to understand more of the mechanisms behind the stability of toe structures and to extend the range of applicability of existing relations, computations were done, in which the orbital wave motion was linked to the stability of stones in the toe of a breakwater.

The orbital motion at the toe surface (at $h_m - h_t$) is derived from the linear wave theory:

$$\hat{u}_h = \frac{\omega H}{2} \frac{\cosh k(h_m - h_t)}{\sinh kh_m} \quad (2)$$

where the hat denotes the amplitude of the orbital velocity. The stone stability in orbital motion is approximated with the experimental results of Rance & Warren, 1968, see also Schiereck et al., 1994:

$$\frac{a_h}{T^2 \Delta g} = 0.025 \left[\frac{a_h}{D_{50}} \right]^{-\frac{2}{3}} \quad (3)$$

in which a_h is the orbital stroke at the breakwater toe, which is equivalent to \hat{u}_h/ω .

Both equations need some adjustment. The orbital motion at the toe is not only due to incoming waves, but is also influenced by reflection from the breakwater. Furthermore, incipient motion will not be caused by H_s , but by a larger wave in an irregular wave field, e.g. $H_{1\%}$. Equation (2) is therefore rewritten into:

$$\hat{u}_h = \frac{\omega (1 + C_r) F * H_s}{2} \frac{\cosh k(h_m - h_t)}{\sinh kh_m} \quad (4)$$

in which F is a "tuning" factor.

In the tests by Rance & Warren, the sieve diameter D is used, while in the investigations by the authors, the nominal diameter D_n is used, which is somewhat smaller. With $D_{n50} \approx 0.84 * D_{50}$ and $a_h = \hat{u}_h/\omega$, equation (3) becomes:

$$D_{n50} = \frac{2.15 * \hat{u}_h^{2.5}}{\sqrt{T_P} * (\Delta g)^{1.5}} \quad (5)$$

With these two equations the necessary stone size was computed for incipient motion in the experiments ($N_{od} = 0.5$). The accompanying, measured, incoming wave height H_s was used, together with the measured reflection, C_r . The resulting, computed, diameters, together with the other relevant parameters from the tests, were adapted to the same dimensionless parameters as used with the test results, $H_s/\Delta D_{n50}$ and h_t/D_{n50} . Figure 9 shows the results.

Figure 9 Results of computations

The tuning factor, necessary to give more or less equal results as the tests, appeared to be 1.7. This means that, assuming a Rayleigh distribution, $H_{0.5\%}$ is responsible for incipient motion, which seems reasonable. This, together with the trend of the computational results and the fact that the same influence of h_m is found in computations and experiments, is encouraging.

5. DISCUSSION

Stability of any structure is the relation between load and strength, in this case expressed as $H_s/\Delta D_{n50}$. The strength of a stone on the toe of a breakwater is expressed as ΔD_{n50} . This is, of course, a simplification of the strength mechanism in which e.g. also friction between the stones plays a role. The idea, however, exists that this is reasonably satisfying. The load is expressed as H_s which is a much more far-reaching simplification.

Stones in the toe of a breakwater move because of lift, drag and shear forces which again come from the velocity field in waves in front of the breakwater. This is a highly complex motion, even in a regular wave system, while, moreover, waves in nature are irregular. To this background it seems almost naive to try to catch the stability of stones in waves in simple formulas like equation (1).

Waves approaching a breakwater deform, mainly due to shoaling, bottom friction, reflection and breaking on the slope of the breakwater or the foreshore. All these processes can not be expressed by just including H_s as the single load parameter. The reflection, for example, plays definitely a role in the load on the toe, but is not used in equation (1), since the incoming wave is regarded as the load. This seems logically, since the incoming wave is the boundary condition as offered by nature. The reflection is a response of the structure, but any difference in this response is not expressed in the equation, so it will appear as scatter in the experimental results.

The only way to include these aspects, is a model in which the complete water motion is represented correctly. This is, however, not very practical. The procedure followed in this paper can be seen as a compromise between simplicity and correctly representing the physical processes involved. The path is promising enough to walk on. Results will not only be easier to understand and to explain, but there will also be a wider application. An example may be the design of a foundation sill under a vertical, caisson-type, breakwater, which is loaded in a very similar way.

6. CONCLUSIONS AND RECOMMENDATION

CONCLUSIONS

1. Tests in which the stone density is varied between $\rho = 1900$ and 2850 kg/m^3 show that there is no effect of the density on the stone stability in the relationship as proposed by Gerding:

$$\frac{H_s}{\Delta D_{n50}} = \left(0.24 \frac{h_t}{D_{n50}} + 1.6 \right) N_{od}^{0.15} \quad (6)$$

other than expressed in the stability parameter $H_s/\Delta D_{n50}$.

2. Simple computations, relating the orbital wave motion to the stone stability on the toe structure, give promising results.
3. Both computations and experiments show an influence of the waterdepth in front of the breakwater on the stability, which is not expressed in the Gerding's relationship.

RECOMMENDATION

It is worthwhile to put more effort into computations. Equations like Gerding's stability relationship have both the advantage and disadvantage of simplicity. The advantage is obvious, the disadvantage is that it is impossible to capture all aspects of the physical reality in one equation. Possibly a combination of hydrodynamic equations, describing the velocity field in the waves and experimental results, describing the relationship between the velocity field and the stone stability, leads to a relatively simple, but more comprehensive, model. Such a model, including the wave reflection caused by any structure, could be applied not only for toes of rubble mound breakwaters, but also for foundations of caisson type, vertical breakwaters.

SYMBOLS

b_t	width of the toe structure		m
D_{n50}	median nominal diameter of material	$(d_{n50} = (M_{50}/\rho_s)^{0.33})$	m

CHAPTER 154

SEAWALL EFFECTS ON HISTORICALLY RECEDING SHORELINES

Bryan N. Jones¹ and David R. Basco²

ABSTRACT

This paper presents the results of a study using 15 years of beach profile data to determine how the presence of seawalls influences the existing erosional trends of the beach at Sandbridge, Virginia (USA). Three analysis methods using historic and seasonal time scales were used to answer three questions about the possible effects seawalls may have on adjacent nonwalled beaches. The results show that, statistically, there is no difference in the erosion rates of walled and nonwalled beaches. Seasonal variability of volume is greater for walled profiles. Seasonal recovery rates for both profile types are similar. Finally, the claim that the erosion of landward volumes at nonwalled beaches is increasing due to the presence of nearby seawalls is not supported by the evidence at Sandbridge beach.

INTRODUCTION

Great debate has arisen over the long term impacts seawalls may or may not have on the erosion rate of an historically receding shoreline. An obstacle to the formation of definite conclusions about seawall and beach interaction is the lack of long term physical data, which must be collected prior to and following seawall construction. Kraus (1988), and Kraus and McDougal (1996), summarize the state of knowledge on seawall and beach interaction.

Sandbridge is a coastal residential and commercial community within the City of Virginia Beach, Virginia. Sandbridge is located 25 km south of Cape Henry at the entrance to the Chesapeake Bay and 25 km north of the Virginia-North Carolina border. The historical shoreline recession rate over the past 140 years varies linearly from -1.1 m/yr on the north end to -2.9 m/yr at the south end of the study area (Everts, et al., 1983; Dolan, 1985). The first seawalls were built at Sandbridge around 1978, with a peak construction period between 1987 and 1989. At present, about 62 percent of the study

¹Project Engineer, Collins Engineers Inc., 745 Bluecrab Road, Newport News, VA 23606.

²Professor, Coastal Engineering Program, Old Dominion University, Norfolk, VA 23529.

area is walled and 38 percent is nonwalled. The length of the study area is 7.7 km.

This paper presents a statistical analysis of subaerial beach profile data collected over the past 15 years in an effort to determine how the seawalls influence the existing erosional trends of the beach at Sandbridge, Virginia (USA). To achieve this goal, this study addresses the following three questions:

Question 1: Is the sand volume seaward of walled profiles disappearing at a faster rate than a similar volume defined at adjacent nonwalled profiles?

This question can be answered by analyzing the long term and seasonal trends for the volume of sand located seaward of the walls at walled and nonwalled profiles. A statistical analysis of profile data was performed to show any differences between the rate of change of these volumes. If the seawalls are responsible for increasing beach erosion, the trends should show that the volume seaward rate of change for the walls is greater than that for the nonwalled profiles.

Question 2: Are the seawalls responsible for delaying beach recovery during the seasonal transitions?

Another way in which seawalls may detrimentally affect beaches is by interfering with the processes responsible for the natural recovery of sand volumes with the change in seasons. This question can be answered by looking at when the walled and nonwalled profiles make their seasonal transitions.

Question 3: Following seawall construction, does the volume landward of an adjacent nonwalled profile erode at a faster rate than was previously recorded before the construction?

Because upland sand trapped by the seawalls is essentially removed from the littoral system, less sand is available to replace that removed by natural long-term erosion processes. If seawalls are increasing the erosion rate of the beach, then there should be evidence of an increase in the erosion rate of sand for the nonwalled profiles after the seawalls were built. This question is addressed by using 15 years of profile data divided into time intervals before and after construction of nearby walls.

DATA COLLECTION AND ARCHIVES

In August 1990, Old Dominion University began collecting subaerial beach profile data at 28 locations along a 7.7 km study area at Sandbridge. Surveys were made at these locations monthly and following significant coastal storms. Other agencies, including the City of Virginia Beach, have contributed profile data collected over the past 15 years at Sandbridge. At present, 13 of the ODU profiles are located at walled sections and 15 are located at nonwalled (dune) sections. The current data set contains more than 2700 profiles taken at 53 different locations over 15 years (October 1980 to September 1995). The 15 year data set includes several years before and after a boom in seawall

construction during the late 1980's.

Volumetric beach parameters were defined to quantify changes in space and time, as shown in Figure 1. For profiles at walled locations, the volume of sand located seaward of the wall and above MLW is called the volume seaward (V_S). Volume landward (V_L), therefore, is the volume of sand located behind the wall, down to the MLW elevation. For profiles at nonwalled locations, an imaginary partition is extended from adjacent walls parallel to the shoreline. This imaginary partition becomes the boundary separating V_S and V_L for the nonwalled profiles. The volumetric parameters (V_S and V_L) are the best indicators of long-term beach erosion trends for this study, using volume loss with time as the key variable of interest (Basco, et al., 1996).

Figure 1. Beach Parameter Definitions.

The measured volumetric beach parameters are known to vary with the seasons. In general, subaerial beach sand is dragged offshore onto bars during frequent storms in the winter months (October to March), and is pushed back onto the beach by the long swells of the summer (April to September). The seasonal variability was modeled as a sinusoidal wave with a period of one year. The seasonal amplitude of the sinusoidal wave was found using the value that produced the least variance between the measured parameter and the calculated seasonal signal. A linear regression analysis using the method of least squares was performed to estimate the annual rate of change for each profile parameter and each profile type. The null hypothesis test was performed to determine if one parameter's slope was statistically greater than the other.

ANALYSIS METHODS

Over the five-year ODU monitoring study, three methods were developed to analyze the observed changes in V_s and V_L . These methods included the Weighted Average Method (WAM), the Sectional Weighted Average Method (WAMSECT), and the Individual Profile Method (IPM).

The WAM method used only the 28 ODU profile locations surveyed since October 1990, and was useful to characterize generalized beach change for the entire study area. The 28 profiles were grouped into two sets by type, walled or nonwalled (dune). Each profile was assigned a representative length of beach which was assumed to represent the walled or nonwalled conditions along that particular length of shore. For each profile, the volumetric parameters were multiplied by that profile's representative length. All of the wall profile products were then summed for each parameter, then divided by the total wall length. The result was a set of weighted averaged parameters (V_s and V_L) for each survey that singularly represented the walled profiles at Sandbridge. A set of weighted average nonwalled profile parameters were found in the same manner, using different representative lengths of nonwalled beach.

The Sectional Weighted Average Method (WAMSECT) divided the Sandbridge study area into three distinct reaches (North End, Middle Section, South End) to recognize differences in barrier island elevation and historic shoreline erosion rates. As with the WAM, weighted averages were employed for each type (walled or nonwalled) based on the lengths of walled and nonwalled beach in each section.

Differences in the parameter change rates before and after seawall construction were studied using the individual profile method (IPM). Beach profiles taken prior to October 1990 varied in location, and were not sufficient in number to permit accurate use of the WAM or WAMSECT averaging methods. The volumetric beach parameters were calculated for all surveys dating back to October 1980 for each profile, thus permitting the profile history to be analyzed beyond the five years of ODU monitoring. Parameter rates of change could then be compared for the periods of time before and after wall construction, but only for each individual profile location. The results of this analysis could then be used to form conclusions regarding Question No. 3.

RESULTS

Seasonal trends are best identified by plotting the WAM and WAMSECT results for the volume seaward difference (ΔV_s) for the five full wave years of ODU profile data. The initial value of each parameter is taken as the regression line intercept for October 1, 1990. The differences, therefore, represent the change in time over five years. Comparisons of the trends between walled and nonwalled profiles were made in an attempt to find supporting evidence for Questions No. 1 and No. 2. Transition from winter to summer was defined by when the ΔV_s parameter passed from below to above the regression line for each profile type. Likewise, the summer to winter transition was said to occur once the ΔV_s parameter moved below the regression line.

WAM Results

Using the WAM, Figures 2 and 3 show the long term change in ΔV_s for the walled and nonwalled profiles, respectively. The negative regression slopes in these figures demonstrate the imbalance of the seasonal cycle, which is caused by the chronic long term erosion rates at Sandbridge. Volume seaward from the walled and nonwalled profiles is disappearing at yearly rates of $1.58 \text{ m}^3/\text{m}$ and $1.80 \text{ m}^3/\text{m}$, respectively. This difference in the change rates of the two profile types is not statistically significant, as determined from the null-hypothesis test.

It is apparent from Figures 2 and 3 that the winters of 1992-1993 and 1994-1995 were the most severe. Volumes seaward in each of these years were below the mean decreasing value for each profile type. By comparison, the winters of 1990, 1991 and 1993-1994 were very mild. The summer beach rebuilding periods also demonstrate variability from year to year. With the exception of the 1994-1995 wave year, the walled profiles recovered to about $\Delta V_s = +7 \text{ m}^3/\text{m}$ during each summer, which was the summer value prior to October 1990. In contrast, the nonwalled sections continued to fall below the seaward volume present during the summer of 1990.

A comparison of seasonal transition times showed that the walled profiles recovered in the summer of 1991 first. The dunes made the summer transition first in 1992. Both profile types recovered simultaneously in 1993 and 1994. In 1995, the severely eroded beach never quite recovered in front of the walls while the dunes eventually did recover near the end of the summer season. The summer to winter transitions occurred at the same time for both types in 1990, 1992, 1993, and 1994. In 1991 and 1995, the winter transition was observed earlier for the dune sections.

WAMSECT Results

Figures 4 and 5 show the trends in the North End seaward volumes for walls and dunes, respectively. Similar plots were generated for walled and nonwalled profiles in the Middle Section and South End. Differences in the rates of change and seasonal variation amplitudes between each WAMSECT subsection are apparent. The results of the WAMSECT linear regression analysis of volumetric change rates are summarized in Table 1.

At the North End, the linear regression analysis showed that the ΔV_s rates of change for dunes and walls are negative and statistically equivalent. In addition, the amplitudes of the calculated seasonal variation are also equivalent. Beach recovery following the winter season occurred simultaneously for both profile types from 1990 to 1993. The walled profiles recovered first in the 1993-1994 wave year. Wave year 1994-1995 was characterized by two hurricanes along the mid-atlantic coast (Gordon, Nov. 1994 and Felix, Aug. 1995) in addition to a stronger wave climate generated by hurricane activity in the Caribbean. While the nonwalled profiles eventually recovered, the data shows ΔV_s for the walled profiles never recovered above the regression line for this section. Both profile types made the transition from "summer" to "winter" characteristics (seasonal erosion) around the same time for the first four years of the

ODU study. During the stormy 1994-1995 season, the dunes made the transition first.

The results for the Middle Section showed the rates of change for ΔV_s were statistically equivalent for both walled and nonwalled profiles. Seasonal amplitudes in ΔV_s were greater for the walled profiles in this region. Beach recovery occurred simultaneously for both profile types in the first three years (1990-1993). The walled profiles recovered before the nonwalled profiles in the 1993-1994 summer season. Like the North End, the walled profiles never recovered above the regression line following the stormy 1994-1995 season. Transition from summer to winter levels occurred first for the walled profiles in 1990-1991. Both profile types changed at the same time in the three years between 1991-1994. The nonwalled profiles eroded to winter levels before the walls in the turbulent 1994-1995 wave year.

As in the North End and Middle Section, the rates of change for ΔV_s in the South End are statistically equivalent for both walled and nonwalled profile types. The greater historic erosion rates for the South End are clearly demonstrated by the greater change rates in Table 1. The walled profiles recovered first during the summer beach rebuilding season for the first two years of the study (1990-1992). In the 1990-1991 season, however, the nonwalled profiles did not recover above the ΔV_s regression line. In the remaining three years of the study, both profile types recovered simultaneously. Seasonal transition from summer to winter occurred at the same time for walled and nonwalled profiles for 1990-1994. The 1994-1995 season showed that the walls eroded to winter levels before the dunes, conflicting the trends observed for this wave year in the North and Middle regions.

IPM Long-Term Rates of Change

Comparisons of the volume rates of change for each of the profiles used in the IPM were made in three groups (North End, Middle Section, and South End) to recognize the regional differences in physical characteristics. The key variable is V_L of

the seawall or partition. A large decrease in the V_L after adjacent wall construction meant that Question No. 3 was supported, i.e., at one profile location, the volume of sand retained behind nearby walls is unavailable, causing adjacent, nonwalled locations to erode at a faster rate. Profile 1 is a good example as shown in Figure 6. For eight years (October 1980 - July 1988) and for 24 surveys, V_L "before" nearby wall construction was $+0.8 \text{ m}^3/\text{m}/\text{yr}$. Seawalls were built during the spring of 1989 about 30m south of Profile No. 1 so that for five years (July 1989 - June 1994) with 54 surveys the rate became $-9.0 \text{ m}^3/\text{m}/\text{yr}$. Unfortunately, the lot owner at Profile No. 1 leveled the dune in June 1994, so that some question remains as to how much affect the adjacent wall really has at this location.

By this same method of comparison for other profiles in the North End, supporting evidence does exist for Question No. 3. However, this is not true for the Middle Section or South End. A conflicting example in the Middle section lies at Profile 161. Figure 7 shows a similar eight year period (October 1980 - October 1988) for this profile. After 50 surveys, V_L "before" nearby construction was $-2.2 \text{ m}^3/\text{m}/\text{yr}$. Seawalls were built during 1989 starting 30m south so that after 5 years and 70 surveys, the "after" rate became $-0.8 \text{ m}^3/\text{m}/\text{yr}$. This evidence, and many other examples in the Middle section does not support Question No. 3. The South End includes both supporting, nonsupporting and inconclusive results so that it must be concluded that the evidence is inconclusive for this region.

Non-Wall Profile No. 1 Sand Volume

SUMMARY

The three basic methods (WAM, WAMSECT, and IPM) used in this study consider seawall and beach interaction on an increasingly more focused spatial scale. The WAM model provides trends for the Sandbridge area as a whole. The WAMSECT model concentrates on the effects of seawalls on a more localized level, and the IPM method considers each profile separately. Long-term effects are obtained from the results of all three methods using the five year ODU data set (15 years for profiles in the IPM). Seasonal variations are seen using both the WAM and WAMSECT methods.

Question No. 1: Does the sand volume seaward of the walls erode faster than a similar volume defined at adjacent nonwalled profiles?

Statistical comparison of parameter change rates (ΔV_s) using the null-hypothesis test revealed that the erosional trends are *statistically equal* for walled and nonwalled profiles. The results are the same for the WAM analysis and for each section in the WAMSECT analysis. Using five years of statistical data, there is no evidence to support the conclusion that the seaward volumes in front of seawalls is disappearing any faster than the seaward volumes in front of nonwalled profiles.

Seasonal variations in seaward volume were modeled using the five-year WAM and WAMSECT data. The WAM results show the amplitude of the seasonal variation

in V_s is greater for walled profiles. Because seawalls provide an impermeable barrier for cross-shore transport, sand is piled up against the walls by long period swells during seasonal recovery, resulting in larger relative seaward volumes for walled profiles during the summer. Likewise, winter erosion removes more sand from in front of the walls, since sand located landward of the partition is readily available to replenish sand removed seaward at the nonwalled profiles.

In the North End, the seasonal amplitudes for V_s were found to be the same for both profile types. Seasonal amplitudes in V_s were highest for walls in the Middle Section. The results indicate that the five-year seasonal variations in V_s are greater for the nonwalled profiles in the South End. Because not as much sand is available to replace that removed from in front of the walls during seasonal transitions, we might expect the walled profile variations to be less for the South End than in the North End and Middle Section.

Question No. 2: Do seawalls delay beach recovery during seasonal transitions?

Seasonal beach recovery was studied using the WAM and WAMSECT results over the five-year ODU monitoring period. Using the WAM, seasonal transitions generally occurred about the same time for both walled and nonwalled profiles. During the abnormally high erosion experienced by storm activity in the 1994-1995 wave year, the nonwalled sections eventually recovered while the walled sections did not. Continued monitoring for 1995-1996, however, shows that the walled profiles have recovered.

The North End WAMSECT trends indicate that seasonal beach recovery occurred simultaneously for both profile types in three of the five years studied. In 1995, the walled profiles never recovered above the regression line. In the Middle Section, seasonal recovery also occurred simultaneously for both profile types in three of five years. As in the North End, the walled profiles did not recover above the regression line in 1995. As for the South End, seasonal beach recovery for walls and dunes occurred at the same time for the last three years of this study.

Question No. 3: Does seawall construction increase the natural erosion rate of the sand volume landward of the walls at adjacent nonwalled locations?

After a seawall has been built, the sand trapped behind the wall is no longer available for transport to adjacent beaches during storms. This reduction in sediment supply is thought to place additional erosional pressure on beaches adjacent to walls. The IPM was the only method which provided enough long term data to form conclusions regarding Question No. 3. Linear regression was used to determine trends in the nonwalled V_L parameter before and after seawall construction. The individual profile results were compared according to region (North End, Middle Section, South End).

In the North End, evidence exists to support Question No. 3. None of the Middle Section profiles demonstrated an increase erosion rates, in fact, each of the profiles compared showed evidence to argue that erosion rates *decreased* following the

nearly addition of seawalls. The IPM results for the South End are inconclusive and include two instances where no significant change was noted, one instance where the change rate decreased, and one where the rate increased.

CONCLUSIONS

Seawalls are not responsible for the erosion problem at Sandbridge, they are a result of it. Three different spatial and time scales have been used to analyze fifteen years of subaerial beach profile data. While the results clearly show differences in short term coastal processes between walled and nonwalled beaches, the long-term and seasonal effects are very nearly the same.

With regard to Question No. 1, the results from the five-year WAM and WAMSECT trends clearly indicate that volumes seaward of walls *are not* eroding faster than volumes in front of nonwalled profiles. These results are consistent with the conclusions made by other researchers reviewed in Kraus (1988), and Kraus and McDougal (1996). The results do show that seasonal variation in volume is greater for walled profiles, however, these variations are temporary.

The results for Question No. 2 show that seawalls *do not* inhibit seasonal recovery for either profile type. The five-year seasonal recovery trends using both the WAM and WAMSECT methods yielded the same results.

Despite the use of over 15 years of profile data, no clear conclusions can yet be made regarding Question No. 3. Comparison of change rates before and after seawall construction yielded supporting evidence in the North End, nonsupporting evidence in the Middle Section, and inconclusive results for the South End. The results for the study area as a whole, therefore, must be considered inconclusive for Question No. 3.

The study at Sandbridge is continuing. As the ratio of volume trapped behind the seawalls to that remaining on the subaerial beach increases, some evidence to support Question No. 3 may be found in the future.

ACKNOWLEDGMENTS

Special thanks are due to the following graduate students who participated in the ODU beach monitoring program at Sandbridge over the course of this five year study: Tim Blankenship, Maolong Cai, Quin Chen, Gary Hobson, Bruce Husselbee, C.S. Shin, Murat Utku, Greg Ward and Rob Webb. The initial project engineer was Doug Bellomo, who was followed by John Hazelton.

This study was supported by the "Impacts of Coastal Armoring on Beaches" Work Unit (32747) of the USAE, Waterways Experiment Station (CERC), Vicksburg, MS. The conclusions are not necessarily those supported by the Army Corps of Engineers.

CHAPTER 155

CONTROL OF WAVE PROPAGATION ANGLE BY TAPERED-SUBMERGED BREAKWATER

Satoshi TAKEWAKA¹ and Isao IRIE²

ABSTRACT

A new type of submerged breakwater with a triangular plane form which modifies the wave propagation angle is proposed. Its performance is demonstrated and assessed analytically. Preliminary movable bed experiments were conducted. The breakwater was installed in front of the beach to modify the wave propagation angle in the offshore zone. Longshore current and littoral drift were driven through the effect of wave angle modification.

INTRODUCTION

A beach remains stable in the long term when supply and loss of sediment are equally balanced. Offshore structures often break this equilibrium state and the beach profile as well as the shoreline configuration change to a new state, which resulting in erosion problems in most cases. The deformation of the shore may be suppressed when sediment movement of the original state is preserved by regulating the wave height and propagation angle by some offshore structures.

In this context, a new type of submerged breakwater with triangular plane-form, Tapered-Submerged Breakwater (hereafter referred as TSB), is proposed. Its functions are reduction of wave height by reflection and wave breaking, and modification of wave propagation angle on downwave side as shown in Fig. 1.

This study describes and evaluates the performance of TSB in controlling wave propagation angle. Then results of preliminary movable bed experiments are demonstrated, which were conducted to test out the applicability of TSB in regulating wave field, current system and sediment transport of a beach.

Figure 1 The concept of Tapered-Submerged Breakwater

Figure 2 Normalized wave height distribution on downwave side of the breakwater. Wave height is normalized with the incident wave height. Experimental conditions : $T = 0.76s$, $h = 0.14m$, incident wave height = $0.015m$, $W = 1.8m$, $D = 0.9m$, (a) $h_T = 0.07m$, $h_T/h = 0.5$, (b) $h_T = 0.11m$, $h_T/h = 0.8$.

MODIFICATION OF WAVE PROPAGATION ANGLE

The shape of a TSB is characterized with three parameters, height of breakwater h_T , plane depth D and plane width W , as shown in Fig. 1. All these parameters were varied in a wide range in this study to find out an optimum configuration of TSB in wave angle modification.

Wave field around TSB subjected to regular incident waves was computed with *Collocation Method of Matched Eigenfunction Expansions* which was developed by Yoshida et al.(1992). This method provides linear potential solution of wave field over a submerged structure with an arbitrary plane form. Prior to the analytical work, experiments in a wave tank were made to examine the validity of the potential solutions. Figure 2(a) and (b) show the comparison of measured and computed wave height distribution normalized with the incident wave height on the downwave side of the TSB.

A fairly good agreement is observed in Fig. 2(a), while discrepancy becomes

Figure 3 Wave pattern and trajectories of water particles. $T = 0.76s$, $h = 0.14m$, $W = 1.8m$, $D = 0.9m$, $h_T = 0.11m$, incident wave height = $0.01m$. Incident wave travels from bottom to top in the figure.

apparent in Fig. 2(b) where wave breaking above the TSB was observed in the experiment. Since the potential solution fails to describe the wave field when wave breaking occurs, this study concentrates on non-breaking cases.

The wave height distribution shown in Fig. 2(a) oscillates remarkably which is a typical feature of wave diffraction from submerged a structure. Since the plane form of the submerged body is asymmetric in this study, the most energetic part appears aside from the center of the wave height distribution. This is an indication that the TSB modifies the direction of wave energy propagation.

The distribution of instantaneous water surface elevation and the horizontal trajectories of the water particle motion around the TSB is shown in Fig. 3. The incident wave travels from bottom to top of the figure. The water surface are shaded in this figure with the highest levels being white and trajectories of water particles are depicted with solid lines. Declined crest lines are apparent on the downwave side of the TSB. The main semiaxes of the water particle trajectory are almost perpendicular to the crest line which assures that the waves travel obliquely to the incident.

EVALUATION OF THE WAVE ANGLE CONTROL PERFORMANCE

The performance of the wave propagation angle modification is assessed by analyzing the character of the potential solution provided from the Collocation Method. The Collocation Method gives the complex amplitude potential Φ for the wave field by superposing two solutions : (i) known incident wave solution

Figure 4 Collocation Method of Matched Eigenfunction Expansions

Figure 5 Definition of the symbols and integral path

Φ_I and (ii) unknown scattered wave solution Φ_S which is determined so that the whole solution ($\Phi = \Phi_I + \Phi_S$) satisfies the boundary conditions on the submerged body and Sommerfeld's radiation condition at far field (see Fig. 4).

The scattered wave solution Φ_S is expressed in terms of Green's law :

$$\Phi_S(r, \theta) = \oint_B \left\{ \phi_B(s) \frac{\partial}{\partial n} - \frac{\partial \phi_B(s)}{\partial n} \right\} G(R, \theta) ds. \tag{1}$$

Here, ϕ_B and $\frac{\partial \phi_B(s)}{\partial n}$ are the potential of the scattered waves and its derivatives on the path B above the breakwater as indicated in Fig. 5, and G is the Green function. Further definitions of the symbols are depicted in the same figure.

The scattered wave solution ϕ_B consists of evanescent wave mode ϕ_E and progressive wave mode ϕ_P . The former (ϕ_E) is apparent only in the close vicinity of the structure and the latter (ϕ_P) is the wave which travels to the infinity by decaying its amplitude. Neglecting the evanescent wave, following equation for the scattered wave solution is obtained which is valid except in the vicinity of the structure :

$$\Phi_S(r, \theta) = \frac{i}{4} \oint_B \left\{ \phi_P(s) \frac{\partial}{\partial n} - \frac{\partial \phi_P(s)}{\partial n} \right\} H_0^{(1)}(kR) ds \tag{2}$$

where $H_0^{(1)}$ is the Hankel function of the first kind of the 0th order and k is the wave number of the incident wave.

A further approximation is adapted to Eq.(2) to split it into radial part r and directional part θ . Following relationships of R for $r \gg r_b$ and Hankel function

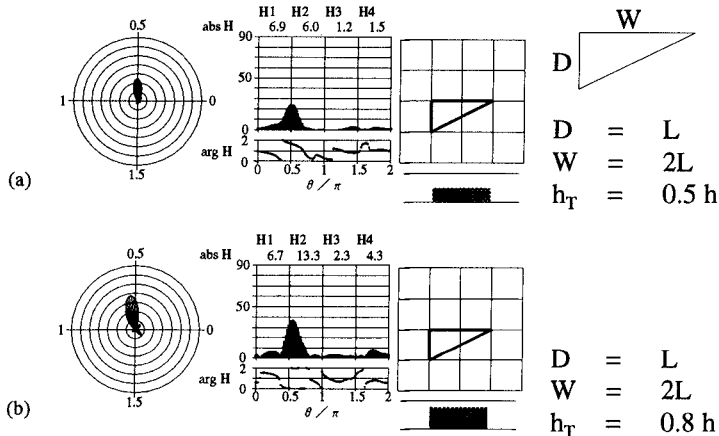

Figure 6 Distribution of Kochin function $H(\theta)$. L = incident wave length ($kh = 1.18$).

with large argument are substituted :

$$R = |\vec{x} - \vec{x}_b| \approx r - r_b \cos(\theta - \theta_b) \tag{3}$$

$$H_0^{(1)}(z) \approx \sqrt{\frac{2}{\pi z}} e^{i(z - \pi/4)} \tag{4}$$

$$\frac{dH_0^{(1)}(z)}{dz} = -H_1^{(1)}(z) \approx -\sqrt{\frac{2}{\pi z}} e^{i(z - 3\pi/4)}. \tag{5}$$

The result of the substitution is

$$\Phi_S(r, \theta) \approx -\frac{i}{4} \sqrt{\frac{2}{\pi kr}} e^{i(kr - \pi/4)} \times \oint_B \left\{ ik \cos(\theta - \theta_n(s)) \phi_P(s) + \frac{\partial \phi_P(s)}{\partial n} \right\} ds \tag{6}$$

where θ_n the angle of the integral path s to the y axis.

The scattered wave solution $\Phi_S(r, \theta)$ is now separated into radial part which expresses the decay of the scattered waves travelling to the infinity, and directional part which stands for the complex amplitude of the scattered waves. The directional part is termed as *Kochin function* $H(\theta)$ (Mei, 1983).

The wave angle modification performance is estimated by comparing the characteristics of the Kochin function distribution of different TSBs. The idea is to evaluate the directional amplitude of scattered waves from Kochin function and use it as a measure of the performance. Figure 6 shows the distributions of Kochin function for TSBs with the same plane form, but of different heights. The directional distribution of $H(\theta)$ is displayed in different expressions in the figure : left diagram displays magnitude of $H(\theta)$ as a radar chart and center diagram displays magnitude and phase of $H(\theta)$. Since the incident wave travels into $\theta = 0.5\pi$, scattered waves must have wave components which travel into

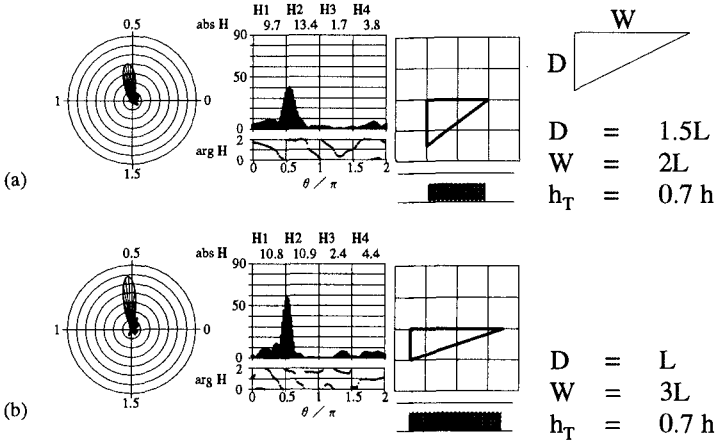

Figure 7 Distribution of Kochin function $H(\theta)$. L = incident wave length ($kh = 1.18$).

$0.5\pi < \theta < \pi$ if the wave angle modification is achieved properly. The comparison of the Kochin function distributions suggests that the TSB with larger height h_T is effective in wave angle modification.

Figure 7 shows the distributions of Kochin function for TSBs with the same height, but of different plane forms. It is hard to rate the efficiency of the two breakwaters from simple comparison of the Kochin function distributions. In this case, the integral of $H(\theta)$ in $0.5\pi < \theta < \pi$ (H_2) was estimated and used as a measure of the wave angle modification effect. The value of the integrals of different ranges is depicted in the top of the center diagram (H_1, H_2, H_3, H_4). The TSB with larger plane depth D is judged superior in wave angle modification, since it possesses a larger value.

A large number of tests for TSBs with different shapes were conducted to seek optimum configuration. It was found that heightening the height h_T and broadening the plane depth D of the breakwater enhance the effect of wave angle modification in general. It was also found that the plane depth D and the plane width W must be at least as large as incident wave length L , which means that the breakwater needs to a large structure to work well.

APPLICATION TO BED PROFILE MODIFICATION

Preliminary experiments on movable bed were conducted to test out the applicability of the TSB in topography modification. The experimental setup is shown in Fig. 8. The experiment is designed to observe the effect of wave angle modification in the offshore region on bottom topography variation and does not imply any realistic situation. The experiment started from a 1:10 slope beach made from fine glass beads with $0.08 \mu m$ mean diameter and 2.6 specific gravity.

Figure 8 Experimental setup of the movable bed experiment

Regular waves with 0.76s period and 0.02m wave height were acted for 2 hours without installing the TSB to excite the initial off-onshore sediment movement. Then the TSB was installed in front of the slope and the experiment was proceeded further for 8 hours. Bed elevations were measured for several times during the experiment.

Figure 9(a) and (b) show the depth contour lines of the bed form at $t = 2hrs.$ and $t = 10hrs.$ for the run with single TSB. No wave breaking above the breakwater was observed. In the region of $1.7 < x < 2.8m$, the shoreline and the depth contour lines in front of it inclined remarkably at $t = 10hrs.$ which were almost straight and parallel at $t = 2hrs.$ This region was affected by the waves whose propagation angle was modified by the TSB. The distribution of total longshore sediment rate (Fig. 9(c)) estimated from the results of bed profile measurements shows that the sediment was transported unidirectional as a whole.

The wave angle modification accompanies wave concentration on the down-wave side of the breakwater which results in the alongshore variation of the wave breaking point. Accordant with this breaking point variation, several circulations cells along the shore were observed which transported sediments alongshore.

Numerical computations of the wave and current field were conducted to give insight of the sediment transport. The wave field was computed with parabolic mild slope equation starting from the initial value given by the potential solution described in the previous chapter. Flow field was computed with the conventional ADI method inputting the radiation stress derived from the wave field computation. Bed profile data measured in the experiment was entered for wave and current computations.

Figure 10(a) and (b) show the computed wave height distribution and flow field at $t = 2hrs.$ The effect of wave angle modification concentrates the waves. This is shown in the figure of wave height distribution as strips of contour lines of high and low wave region. Since the high waves break at an earlier stage, the distribution of the breaking points varies alongshore. Accordant with this variation, the distribution of radiation stresses becomes complicated, and several

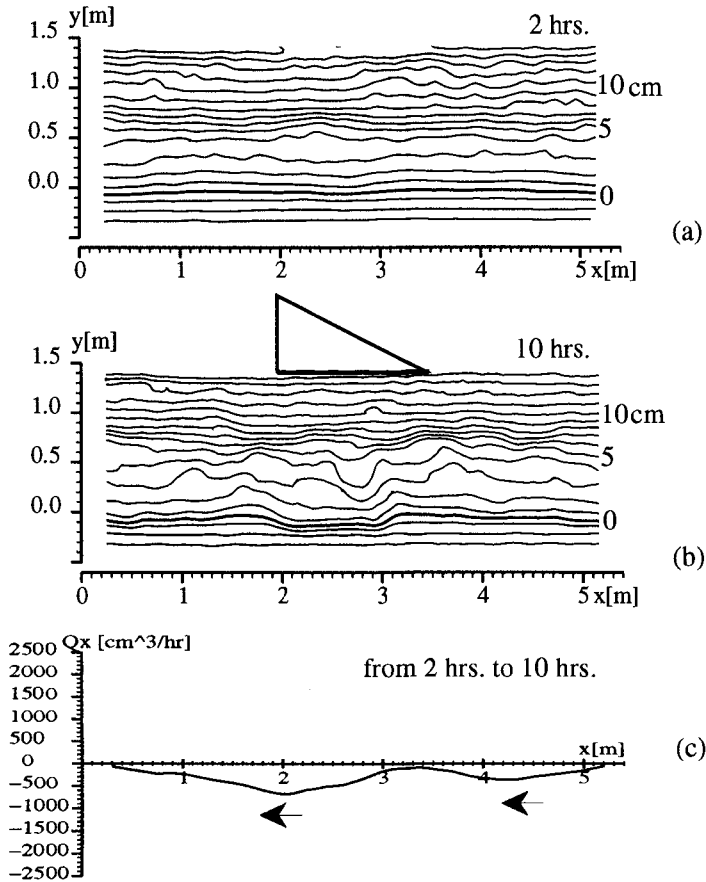

Figure 9 Resultant bed form and total longshore sediment rate, (a) $t = 2$ hrs., (b) $t = 10$ hrs., (c) Total longshore sediment rate (from $t = 2$ hrs. to $t = 10$ hrs.). $W = 1.5$ m, $D = 0.75$ m, $h_T = 0.084$ m.

circulation cells including two major counter-rotating cells are reproduced in the flow computation. Their number, position and scale agreed fairly with the experiment. It is supposed that the sediment is mainly transported by the current system. Bottom material is eroded where high waves attack. The current system then transports it as suspended sediment and deposits it finally where wave motion becomes calm.

Figure 11 shows the resultant bed form in case of two TSBs were installed in sequence. With this arrangement, it is expected that the effect of the wave angle modification extends to a wider range. The bed form at $t = 10$ hrs. shows that

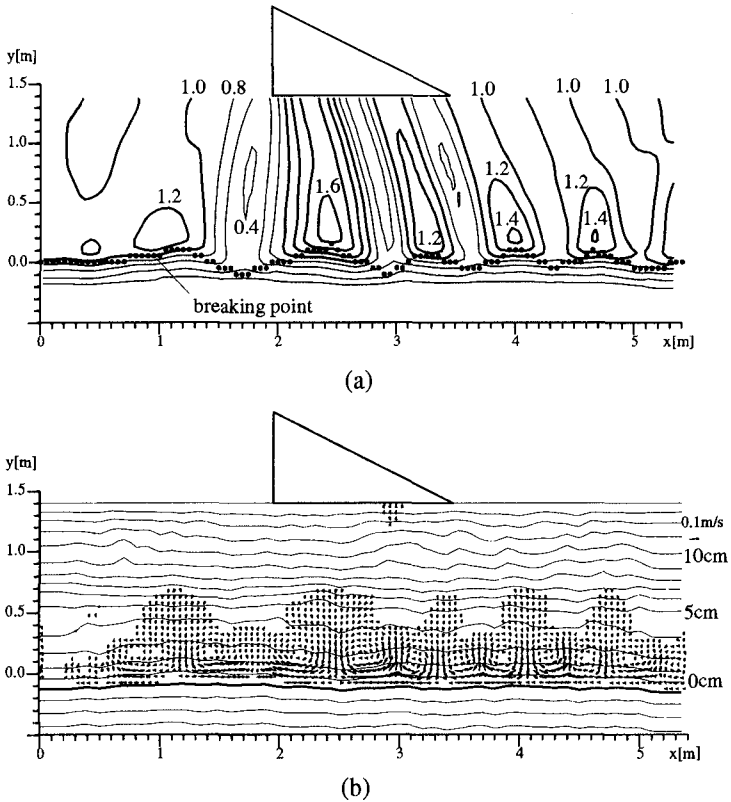

Figure 10 Computational result of wave and current system at $t = 2$ hrs., (a) Normalized wave height distribution and breaking points, (b) Current field and bed form. $W = 1.5m$, $D = 0.75m$, $h_T = 0.084m$.

each breakwater affected the sediment process individually. The distribution of total longshore sediment rate (not listed) indicates that the sediment is transported generally in the aimed direction in a wide range. It is, however, hard to conclude that the attempt is a full success. The shoreline, or depth contour lines become highly irregular and the beauty of the coast with gentle-curved or straight shoreline is lost. Further studies on this point, how to obtain a smoother shore line, are required.

CONCLUSIONS

A new type of submerged breakwater (Tapered submerged breakwater) which modifies the wave propagation angle is proposed. Its ability and performance were demonstrated and assessed analytically. TSBs with different shapes were

Figure 11 Resultant bed form at $t = 10\text{hrs.}$ for two TSBs run. $W = 1.5\text{m}$, $D = 0.75\text{m}$, $h_T = 0.084\text{m}$.

tested and it was found that broadening of the plane depth D and heightening the breakwater height h_T enhances the wave angle modification performance. It was also found that D and the plane width W of the TSB must be at least as large as incident wave length L to be effective. This means that the TSB needs to be a large structure to work well.

Preliminary movable bed experiments were conducted. The TSB was installed in front of the beach to modify the wave propagation angle in the offshore zone. The alongshore wave height distribution varied in the nearshore zone due to the effect of wave angle modification. Several flow circulations appeared subsequently which transported longshore sediment. The total longshore sediment rate indicates that the sediment moved unidirectional as a whole. The resultant bottom configuration, however, was highly irregular, even when two TSBs were installed in sequence. Further studies are required on this point to refine the conception acceptable.

ACKNOWLEDGMENT

Authors are indebted to Hiroshi Yamaguchi, graduate student of Kyushu University, for his collaboration in movable bed experiment.

CHAPTER 156

MULTIDIRECTIONAL WAVE LOADS ON VERTICAL BREAKWATERS

Claudio Franco¹, Jentsie W. Van der Meer², Leopoldo Franco³

Abstract

An extensive 3-D model test program has been performed to study the effects of wave obliquity and multidirectionality on the hydraulic response of vertical (caisson) breakwaters. In this paper the results of the wave forces and pressures are shown. The measurements are compared with the Goda's formula with some divergences. The tests show that multidirectional wave loads do not reduce with increasing obliquity of the mean direction, whereas a reduction occurs for oblique long-crested waves. Three-dimensional effects on the uplift forces are better described by Goda formulations and smaller scatter is observed when comparing with measurements. The analysis of the longitudinal distribution of the horizontal pressures confirmed that the global wave load decays with increasing multidirectionality and obliquity, with clear advantages for the design of long monolithic breakwaters.

Introduction

The design of coastal structures has been typically based on formulae developed for head-on long crested waves. After the development of 3D basins in hydraulics laboratories, the effect of wave three-dimensionality on structure loading has been considered mainly for the design of offshore platforms. More recently 3-D waves were found to have influence also on the long period wave components associated to the short period waves which induce harbour oscillations (Bowers, 1987) or on the stability of rubble mound breakwaters (Galland, 1994). Very little attention has been addressed so far to the influence of wave multidirectionality on the response of vertical face structures in intermediate or shallow water .

A 3-D model investigation has been carried out at Delft Hydraulics, within a joint European research project, in order to assess the effects of the obliquity and “multidirectionality” of wave attack on the hydraulic performance of caisson breakwaters. Tests have been performed with attack angles up to 60° to the normal and directional spreadings up to 30° on different structure geometries such as caissons with vertical plain wall, with perforated front wall, with an additional curved parapet and with a high impermeable slope and berm, measuring wave forces, horizontal and uplift pressures, reflection coefficients and overtopping.

Only the results of the analysis on horizontal and uplift forces on the plain wall vertical caisson are here presented in order to provide useful guidance for the design of caisson breakwaters. Comparisons are made with the more abundant results obtained by Goda (1985) on the simple vertical face structure under long-crested wave attacks.

Model setup and test conditions

The hydraulic model tests were carried out in the 26.4 m wide and 23 m long multidirectional-wave “Vinjè basin” at DH - De Voorst during summer 1994. The structure (Fig.1 and 2), consisting of 13 caissons, each 0.9 m wide, with curved roundheads at the two ends, was placed on a flat concrete bottom, and linked to the floor through a permeable two layer rock basement.

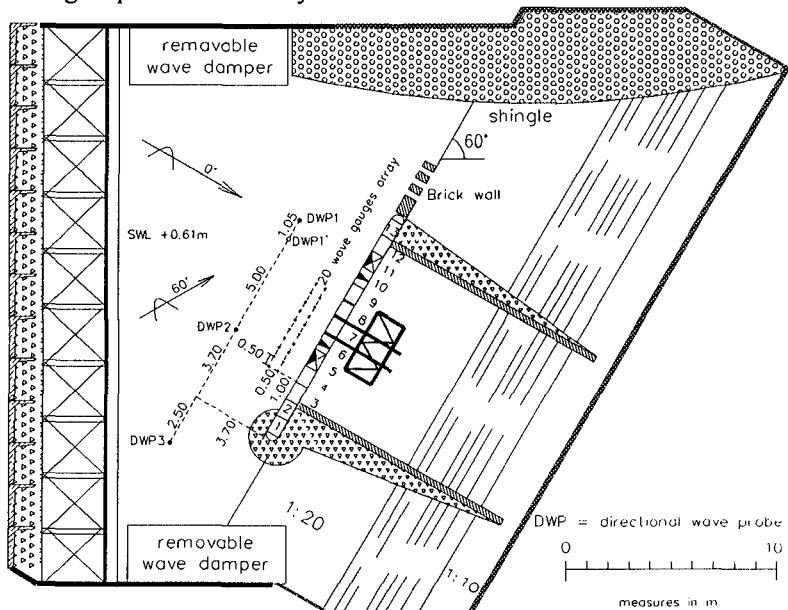

Figure 1.: Plan view of the basin and model layout

Figure 2 Plan and front view of the model caisson breakwater with location of measuring devices

Being a research model, there is no actual reference to particular prototype conditions, but a Froude scaling of 1:30 could be considered as an approximate scaling ratio for typical real structures. Crest elements were made removable in order to adjust the relative crest height (freeboard $R_c/H_s = 1.18, 1.50$ and 1.63).

The target significant wave height was kept fixed to 0.14 m throughout all tests, but the actual H_s was a little bit lower due to technical wave generation limits for the most angled wave conditions. The constant water depth in front of the caissons was 0.61 m in all tests, giving a relative water depth $h/H_s=4.3$. Peak periods (T_p) of standard ($\gamma=3.3$) JONSWAP spectra were 1.5 s and 2.12 s to give theoretical peak wave steepnesses $s_{op}=2\pi H_{os}/gT_p^2$ of 0.04 and 0.02 respectively. The minimum number of waves per test was 1000. Mean wave attack angles β varied with 10° steps from 0° (orthogonal to the structure axis) to the most oblique 60° . Energy dispersion around the mean direction was Gaussian with target standard deviations σ set equal to $0^\circ, 15^\circ$ and 30° (the latter two were actually 22° and 28°).

Wave conditions in front of the model have been analysed through a set of 20 gauges placed in two rows at 1.0 m distance offshore of the structure. The methods of analysis used to separate incident and reflected wave energy are the Maximum Likelihood and the Bayesian approach as explained by Frigaard et al. (1994).

A total of 84 tests with non-breaking wave conditions were performed. Of course wave breaking actually occurred before the wall when testing the caisson configuration with the frontal slope and berm. An extensive set of tests was performed for the simplest case of a straight vertical plain wall, whereas a more limited number of tests were conducted for the alternative structure geometries.

The selection of the structural configurations was based on the similarity with typical prototype conditions and with previous 2-D model studies. The basic caisson geometry (Fig. 3) was in fact designed in close agreement with a model structure

Figure 3 : Cross-section of the caisson with the simple plain vertical wall

tested in Milan for overtopping (Franco et al., 1994), while perforated walls were also designed in order to be comparable with a similar 2-D model investigation simultaneously going on at HR Wallingford, within the same MAST project. In one alternative configuration a small additional “nose” (with the same geometry tested in Milan) was placed at the top of the parapet wall, which is useful for reducing overtopping rates.

Two different types of devices have been used in the model to measure the wave-induced loads on the model structure. One central caisson (N.7 in Fig.2) was suspended above the floor of the basin by rigid metal plates attached to the inner section of the laboratory force metering frame. The inner section of the metering frame was supported by a rigidly mounted external frame section through six suspensions with strain gauges, three in the horizontal and three in the vertical planes to derive the total horizontal force F_h , the total uplift force F_u and the total overturning moment M . A clearance of approximately 2.5 mm was left around the front and sides of the measuring caisson to ensure complete freedom of movement during the force measuring tests. Two brick walls placed behind the caisson row (Fig. 1) avoided wave disturbances behind the force measuring caisson.

Wave loads were also obtained by integrating data from a set of 21 pressure transducers, which were positioned on the outer vertical face (8 cells on caisson n.5), on the bottom slab (5 on caisson n.4) and along the longitudinal direction of the caisson structure (Fig.2). All pressure signals have been combined into a total horizontal force and a total uplift force by multiplying each cell output with different factors, representing the respective influence area. The uplift force was therefore achieved only from the pressure cells measurements. The output signals from both the strain gauges of the measuring frame and from the set of pressure cells were sampled at 25 Hz and filtered analogically in real-time at 12.5 Hz. This means that only the “pulsating forces” and no wave impacts would have been recorded.

Horizontal forces

The comparison between the measurements obtained with the two systems (applied on different caissons) could be performed only in the four tests with long-crested (or unidirectional) waves approaching the structure perpendicularly ($\beta=0^\circ$). The total force over the two different longitudinal influence areas (a vertical line for the pressure transducers and a band-width of 0.9 m for the force-metering caisson) is in fact influenced by wave obliquity and multi-directionality.

With the longer period waves ($s_{op}=0.02$) the horizontal force obtained with the pressure cells showed values 8-9% higher than those derived with the force metering frame, thus revealing a standing wave pattern along the structure length with consequent non-homogeneity of the incident wave field (Fig.4a). Other reasons that can partially explain this divergences may be the dynamic response of the free caisson (n^o7) with consequent inclusion of additional inertia forces, or the different force application area which can have a small effect even under head-on wave conditions which are never perfectly two-dimensional. With the shorter waves ($s_{op}=0.04$) the comparison between the two measurements revealed an exact coincidence of the total force series, exception made for the highest two or three higher values (Fig.4b). In such case the pressure transducers were able to record also the faster transients that, acting only on a local scale, are not represented by the whole caisson metering system.

The general good matching of the force series confirmed the overall homogeneity of the incident wave field and thus the data reliability.

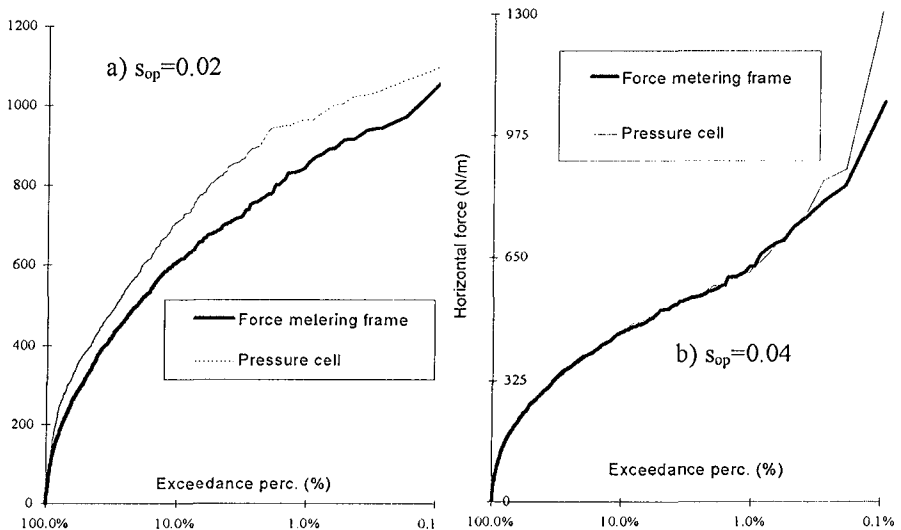

Figure 4 : Comparison between the force measurements of the pressure cells and the caisson frame outputs

The analysis has been mainly addressed to the pressure cell records, also to be consistent with the uplift force measurements which have been recorded only through the set of pressure cells. The analysis, however, demonstrated that the effects of the different wave conditions are similarly represented by both types of recordings.

The most commonly adopted prediction formula for determining the pulsating loads on vertical face structures, under long-crested attacks, is the Goda formula (1985). Design wave parameters are the maximum wave height in front of the structure H_{max} and the significant wave period T_s , which is close to the peak period T_p . Goda suggests to use as H_{max} the mean of the highest 1/250 part of the total number of waves. If Rayleigh is assumed as the probability distribution of wave heights in deep water, then $H_{max} = H_{1/250} = 1.8 H_{si}$. Thus, the analysis has been concentrated on the $F_{h,1/250}$ statistical value, which is the average of the four highest recorded forces in each of the 1000 waves-long tests. Other statistical values such as $F_{h,95\%}$, $F_{h,99\%}$, $F_{h,99.6\%}$, $F_{h,99.8\%}$, $F_{h,99.9\%}$ (the latter being the actual maximum measured force) have been used for further verification.

The little variations of the incident wave heights are taken into account when comparing forces of different tests by using the dimensionless force $F_{h,1/250}/\rho g h H_{si}$ as proposed by Goda (1985). h is the water depth in front of the structure, $\rho g = w_0$ is the specific weight of the water and H_{si} is the significant wave height measured at the structure. The graph of figure 5 clearly shows the change of this dimensionless parameter with the angle of wave attack β only for the tests with high crest. At perpendicular wave attacks, short-crestedness produces horizontal loads that are about 30% less than those acting under long-crested seas.

Figure 5: Horizontal forces: comparison of measurements with Goda's prediction. "h" on the y-axis is the water depth in front of the structure

Figure 6 : Horizontal forces: reliability of the Goda formula.

This applies also for the $s_p=0.02$ data set, for which such comparison can be performed at $\beta=0^\circ$ only.

The most direct way to present the measured forces compared with the Goda prediction is to plot $r=F_{h,1/250} / F_{h,Goda}$ versus the angle of attack as shown in Figure 6 in which the 3-D effects are described. A general increase of r with increasing wave obliquity is clearly noted, which is due to the fact that Goda assumes a load decay with obliquity proportional to a cosine function which is not confirmed by these tests.

The average ratios between the measured $F_{h,1/250}$ and the calculated horizontal forces $F_{h,Goda}$, together with the relative standard deviations, are given in Table 1.

Table 1: r factor and shape parameter b for different wave conditions

	s_{op}	$r = F_{h,1/250} / F_{h,Goda}$		Shape parameter b	
		Mean	St.dev.	Mean	St.dev.
Long-crested waves	both	1.11	0.12	2.15	1.08
Short-crested waves (3-D)	0.04	0.96	0.14	2.00	0.47
Short-crested waves (3-D)	0.02	0.96	0.20	1.86	0.28
ALL WAVE CONDITIONS		0.99	0.14	1.95	0.67

Variation coefficients, σ/μ , amount to 10-15% . Other conclusions can be drawn from the analysis of Figures 5 and 6:

- Generally for the long-crested case, a load reduction due to the obliquity of wave attack is observed. Goda predicts this reduction fairly well ($\pm 10-12\%$) up to attack

angles $\beta=40^\circ$. At $\beta=60^\circ$ however, the measured force is more than 25% higher than predicted by Goda.

- With long-crested head-on waves, Goda formula slightly (7%) underestimates the force for both wave conditions with $s_{op}=0.04$ and $s_{op}=0.02$.
- With short-crested seas, the force shows no reduction with increasing angle of attack. Then it appears that Goda formula underestimates loads with large wave obliquities ($\beta>40^\circ$), so it may not be suitable for representing the effect of wave obliquity in short-crested seas.
- With head-on short-crested seas, Goda prediction tends to overestimate the total horizontal force by 20% on average.

When short-crested wave conditions dominate, Goda’s formulation may be modified to take into account wave multi-directionality, by including a reduction factor $r_{3D} \approx 0.8 \sim 0.85$ on the total load and disregarding all the effects related due to wave obliquity β .

As far as the response of the alternative geometry with recurved parapet top (“nose”), little differences of the total F_h have been observed when comparing with the case of a simple plain wall, despite the effectiveness in reducing overtopping.

The loads acting on the tested structures have been analysed statistically. A two-parameter Weibull distribution, which is often used in extreme value problems, has been fitted to the measured horizontal forces with exceedance probability of 5%, 2%, 1%, 0.4%, 0.2% and 0.1% (the latter is the actual maximum measured force) as:

$$P(F_h) = \exp -(F_h/a)^b \tag{1}$$

where a is the scale parameter, b is the shape parameter and $P(F_h)$ the exceedance probability. Fig.7 shows an example of force data fitting with a two-parameter Weibull. The calculated shape parameters b are presented in Table 1 for different incident wave conditions.

Figure 7 : Example of data fitting with the Weibull distribution.
 ($\beta=20^\circ, \sigma=22^\circ, s_{op}=0.04$)

Even though variation coefficients, σ/μ , are quite large (25-50%), the mean values of “b” are found to be close to 2.0, which correspond to a Rayleigh distribution.

A design formula (Van der Meer et al., 1995) may thus be derived from equation (1) for the exceedance probability of the highest forces, based on Goda’s method:

$$P(F_h) = \exp -(2.547 F_h / (r F_{h,Goda}))^b \tag{2}$$

where some “indicative” values of the shape parameters b and of the factors r are given in Table 1 for various 2-D and 3-D seastates. The coefficient 2.547 (=1/a) is obtained by substituting $P(F_{h,1/250})=0.00152$ into equation (1).

Uplift forces

The uplift force measurements are shown in Figure 8 by using the dimensionless uplift force $F_{u1/250} / \rho g B H_{si}$, as proposed by Goda (1985), where B is the bottom width of the caisson. A consistent decay of the uplift force with increasing wave obliquity for the steeper sea-state is shown, as also described by the Goda formula. A little difference (7-8%) is found at perpendicular wave attacks between the long and short-crested wave loads, but not as large as found for the horizontal force measurements. When waves are oblique the two seastates give similar results up to $\beta=60^\circ$, where a reduction of 30-35% on the total load is observed if compared to the head-on case. The crest “nose”, as expected, was found to have a marginal influence on the uplift forces. The force decay with wave obliquity matches that of the simple wall without nose for both long and short-crested wave attack.

Figure 8 : Uplift forces: comparison of measurements with Goda’s prediction. “B” on the y-axis is the caisson width.

The Table 2 shows the mean values and the standard deviations of $r = F_{u,1/250} / F_{u,Goda}$ obtained for different wave steepnesses and multidirectionality indices. Standard deviations are generally lower than those of the horizontal forces and the mean values show a little reduction with short-crested waves. It is observed however, that wave obliquity effects on the uplift load are substantially well described by Goda's prediction. Some inaccuracy is noticed for angles up to $\beta = 20^\circ$ for which the measured $F_{u,1/250}$ can be on average $\pm 15\%$ of $F_{u,Goda}$. In the range $\beta = 30^\circ$ up to $\beta = 60^\circ$ the discrepancy reduces down to $\pm 10\%$.

Table 2: Uplift forces: r factor and shape parameter b for different wave conditions

	s_{op}	$r = F_{u,1/250} / F_{u,Goda}$		Shape parameter b	
		Mean	St.dev.	Mean	St.dev.
Long-crested waves	both	1.04	0.08	2.47	0.95
Short-crested waves (3-D)	0.04	1.03	0.10	2.29	0.74
Short-crested waves (3-D)	0.02	0.93	0.10	2.15	0.22
ALL WAVE CONDITIONS		0.99	0.10	2.30	0.70

Measured uplift force series have been fitted by a Weibull distribution, enabling the derivation of the scale and shape parameters for each test. Generally, the mean values of the shape parameter "b" were found to be higher than those relative to the horizontal forces, thus confirming a similar result obtained by Bruining (1994). For wave attack angles greater than 20° the shape parameter was found to be consistently higher than 2.0 (Rayleigh). For design applications the factors in Table 2 may be used as input for relation (1) with reference to F_u .

Wave pressure diagram shape

The analysis of the pressure distributions underneath and in front of the caisson revealed that few significant changes in the diagram shape occur with increasing obliquity of wave attack. When the 0.1%, 0.4%, 1%, 2%, 10% exceedance values of the total horizontal load were reached, the concurrent pressure values at the various locations have been recorded. The resulting instantaneous pressure distributions have been plotted in Fig.9 and 10 together with the calculated distribution of Goda. In the figures, attention is only focused on the diagram "shape" since comparisons in absolute terms cannot be performed, given the difference of the incident wave height in each data set and being the pressures not dimensionless.

The horizontal pressure distribution along the vertical wall, is fairly well predicted by the Goda's formula for both two and three-dimensional sea states, although the concave shape between the S.W.L and the sea bed differs from the simply linearized one by Goda. In Figure 9 the influence of wave obliquity is shown for long-crested seastate with $s_p = 0.04$: it can be observed that the vertical distribution of the horizontal pressures is not affected by the variability of the incidence angle.

Figure 9 : Wave pressure diagram: effect of wave obliquity

Figure 10: Wave pressure diagram: effect of wave spreading

For the uplift pressures, on the contrary, considerable changes in the diagram shape occur with increasing angle of wave attack. For large obliquity the uplift pressure distribution is not triangular (as predicted by Goda and as found in the head-on wave cases), but shows a slight concavity that shifts the centre of gravity to the seaward toe of the caisson, thus increasing the overturning moment M_u . However, the absolute value of the uplift force reduces with obliquity (not properly shown in the figure given the non-dimensionless force), so that the overall moment reduces,

even with larger arm. For most tests, the uplift distribution is fairly well in agreement with the Goda's prediction.

The effect of wave directional spreading on the uplift pressure diagram is similar to that induced by wave obliquity (Fig.10), whereas the influence of the pressure exceedance level on both the horizontal and uplift pressure distributions was found to be negligible.

Longitudinal distribution of the horizontal loads

Additional analysis has been addressed to the longitudinal distribution of the horizontal loads by coupling pressure signal time histories from adjacent caissons in various multiple combinations. Under oblique wave attack, in fact, long structures are not simultaneously subjected to the peak loads. Moreover, in short-crested seas, in which wave crests are characterised by a finite length, the correlation between the wave motion at distinct locations is lower than that achieved with long-crested waves. A global load reduction on long monolithic structures can thus be expected.

In this study, the total load decay with increasing longitudinal caisson lengths (L), as a function of peak wave length (L_p), attack angle and spreading, has been compared with the theoretically derived Battjes (1982) formula: as shown in the example of Figure 11, the agreement is reasonable for both long-crested and short-crested sea-states. Even under unidirectional head-on attack the 3-D tests showed a small load reduction, due to the finite wave width. With oblique and short-crested wave attacks the actual global load is underestimated by the theory for about $L/L_p > 0.5$.

Figure 11 : Longitudinal load decay for head-on long and short-crested waves

Real 3-D waves can produce substantially reduced total loads on a vertical structure even with length as short as $0.25 L_p$. Therefore the construction of new longer caissons may allow valuable savings. Various graphs from this new data set provide useful guidance for caisson breakwaters design (Franco C., 1996).

Conclusions

The results of an extensive model study on the three-dimensional wave loads on simple vertical face caissons (with and without an additional nose) has lead to the following conclusions:

- The current practice for the evaluation of design wave loads on monolithic vertical breakwaters subjected to pulsating wave loads may not be adequate in three-dimensional sea-states. The total horizontal force acting on a whole caisson should be calculated first by considering the pressure integral along a vertical section of infinitesimal width and afterwards by applying a reduction factor proportional to the caisson relative length. This reduction can be significant even for the structures commonly constructed in the practice ($l=20-40$ m) and it is even larger in case of impact loads, which are typically applied only on limited areas. In fact the analysis of 3-D model tests showed the coincidence of the total horizontal force measurement on a whole free caisson and the reduced averaged pressure integral of two adjacent caissons.
- The Goda formula gives a good prediction of the horizontal forces for long-crested waves approaching the breakwater at angles less than $\beta=40^\circ$ with respect to the normal. However, in short-crested sea-states it should include a correction factor of 0.8-0.85 and disregard all effects of wave obliquity.
- Three-dimensional effects on the uplift forces are better described by Goda formulations and smaller scatter is observed when comparing with measurements. However, minor changes in the shape of the pressure diagram are observed for the most oblique wave attacks.
- Even though the Weibull shape parameter b of the fitted probability distribution presents a large scatter, the highest horizontal forces can be described with Rayleigh ($b=2.0$), whereas slightly higher b values are found for the uplift force series.
- The global wave load on monolithic caissons with lengths as short as $0.25L_p$ are substantially reduced, as predicted fairly well by Battjes theory.

Additional analysis on the longitudinal decay of 3-D wave loads and on the distribution of the mean and individual wave overtopping for the various tested geometries are extensively presented in other papers (Franco et al., 1995) and in the final internal report of the research project team.

Acknowledgements

This 3-D model investigation has been financed by the UE under the Large Installation Programme (LIP) and the MAST II-MCS project and partly by Dutch Rijkswaterstaat (TAW committee). The research program was proposed and coordinated by L.Franco and J.Van der Meer; model testing was directed by J. Wouters; data analysis and interpretation was mainly conducted by C.Franco. The authors wish to thank J.P.de Waal and P.Pasterkamp (Delft Hydraulics) and C.Restano (Politecnico Milano) for their productive cooperation and advice. The good collaboration of the LIP-MAST partners, H.Burcharth, P.Frigaard and J.H.Petersen (Aalborg University, DK), of the other European MAST partners H. Oumeraci (LWI,D), W.Allsop (HR, UK), J.Juhl (DHI, DK), M.Canel (SOG, F) and P.Tonjes (RWS, NL) is also acknowledged .

CHAPTER 157

MODELLING THE IMPACT OF DETACHED BREAKWATERS ON THE COAST

K.J. Bos¹, J.A. Roelvink¹ and M.W. Dingenans¹

1. Introduction

Detached breakwaters alter the nearshore wave climate and hence the wave-driven current and sediment transport patterns. They obstruct a part or all of the longshore sediment transport and because of this they play a role in the large-scale sediment budget of the coasts where they are applied. Their local effect on the coast is to form single or double salients or tombolos. Which of these beach shapes will develop may be important for the attractiveness of the beach, in terms of visual aspects and water quality.

Besides having a function as part of a coastal management scheme, detached breakwaters with a jetty to the shore may be designed as a low-maintenance port. Obviously, one hopes that in such cases a salient rather than a tombolo will develop.

Clearly, engineers need to have means to assess the bypass-characteristics and the local impact of detached breakwaters if they want to apply them in a responsible manner. Several methods are at their disposal.

First, there are rules-of-thumb, based on field and lab experience. These are quite useful to get a first rough idea of the possible impacts, but generally do not give answers that are conclusive enough: a typical result is of the form that two design rules say you'll get a salient and three say you'll get a tombolo.

The most common tools applied at present are coastline models. They assume that the coastal profile is more or less constant in shape, and that the longshore sediment transport is related to the local angle of incidence of the waves. Several commercially available packages have special options to assess the local wave climate behind detached breakwaters. Effects that are not included in the current and transport models, such as circulations induced by set-up gradients, can be simulated by adjusting transport parameters locally. Generally, a lot of calibration is required, and the predictive capability is often uncertain. The calibrated models often show nice comparisons with data, especially for the initial stages. The development towards equilibrium is generally not represented at all.

Recently, more sophisticated "area models" have matured to the point that fully dynamic wave, current, transport and bed evolution simulations can be carried out over a period which is long enough to approach equilibrium conditions (see for instance Johnson et al., 1994). The advantages are obvious: these models explicitly take into account the most important processes, and therefore the amount of heuristic modelling is reduced substantially.

In the light of the ongoing efforts of devising coastal area morphological models, the performance of DELFT HYDRAULICS morphological model is tested on the simple situation of a detached breakwater in a coastal area with parallel iso-baths. This also furnishes a test for the DELFT3D system and has proven an opportunity of improving the model.

Netherlands Centre for Coastal Research (NCK), Delft University of Technology, c/o DELFT HYDRAULICS, PO Box 177, 2600 MH Delft, the Netherlands.

2. The model

The model system which is tested is DELFT HYDRAULICS morphological model DELFT3D. This model allows a flexible integration of the models for currents, waves, sediment transport, bottom changes, water quality and ecology (Roelvink and Van Banning, 1994; Roelvink et al., 1995). The morphological system contains the first four models and a control model. This control model allows the user to prescribe any combination of processes and arranges the time-progress of each model and possible iterations between models. The models relevant to morphological simulations are outlined below:

waves

Stationary multi-directional (short-crested) wave model HISWA (Holthuijsen et al., 1989). The model solves the spectral wave action balance equation assuming a frequency spectrum of fixed shape. The model includes directional spreading, wave shoaling, refraction, dissipation by bottom friction and wave breaking, current refraction and wave blocking.

Hydrodynamics

2D or 3D flow model DELFT3D-FLOW (formulae TRISULA) based on the shallow water equations, including effects of tides, wind, density currents, waves, spiral motion and turbulence models up to k- ϵ ; for morphodynamic computations, a quasi-3D option to account for wave-driven cross-shore currents is available.

Sediment transport

The sediment transport can be calculated according to several formulae, including bed-load and suspended load transport. Typical cross-shore effects such as return flow and wave asymmetry can be accounted for. The model includes a quasi-three-dimensional advection diffusion solver for suspended sediment, including temporal and spatial lag effects.

Bottom change

The bottom changes are computed from the sediment mass continuity equation. This equation is solved with a forward-time, central space (FTCS) explicit numerical scheme. The model contains a built-in time step optimization procedure.

The flow diagram for the combination of models applied in this study is given in Figure 1. Starting from an initial bathymetry, a wave computation is carried out followed by a run of the flow model. The wave and current computation can be iterated to account for full wave-current interaction. Sediment transport computations are carried out for a number of steps. After each step the bathymetry is updated based on the residual transport pattern. A very important branch in this scheme is denoted by B. Here, the discharge pattern is kept constant and (small) bottom changes are assumed to affect the current only locally: at a constant discharge rate, the current velocity increases if depth decreases. This is a reasonable assumption as long as the bottom changes are small and lead to an enormous reduction in computational cost. Typically, 20-40 so-called continuity correction steps can be taken in between full hydrodynamic runs (branch A).

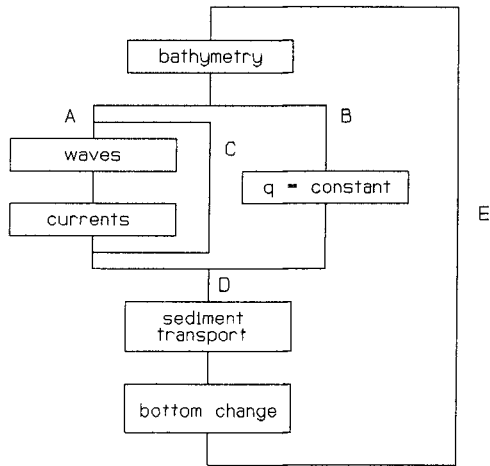

Figure 1 Flow diagram of morphological model system.

3. Test case

The breakwater lay-out to be simulated exists of a single offshore breakwater placed on a plane sloping 1:50 beach profile. The breakwater has a length of 300 m and is subjected to the action of normal or oblique incident storm waves, $H_{rms} = 2.00$ m. The relevant parameters are summarized below:

breakwater lay-out

beach slope	= 1:50	
L_b	= 300 m	breakwater length
X_b	= 220 m	breakwater axis-to-shore distance
h_b	= 4.6 m	depth at the seaward side of the breakwater

wave data

H_{rms}	= 2.0 m	root mean square wave height
T_p	= 8.0 s	peak wave period
θ	= 0° or 30°	mean wave direction

hydrodynamic data

tide = absent

sediment data

ρ	= 2650 kg/m ³	mass density of sediment
d_{50}	= 250 μ m	median diameter
ϵ	= 0.4	porosity of sediment

4. 2DH results

Within the 2DH computations the transport formula of Bijker is used.

Figure 2 Left: Initial bathymetry; right: Bathymetry after 200 hours.

Normal incident waves

In the left part of Figure 2 the initial bathymetry is shown. In Figure 3 the initial wave pattern, water level and flow field are presented for normal incident waves.

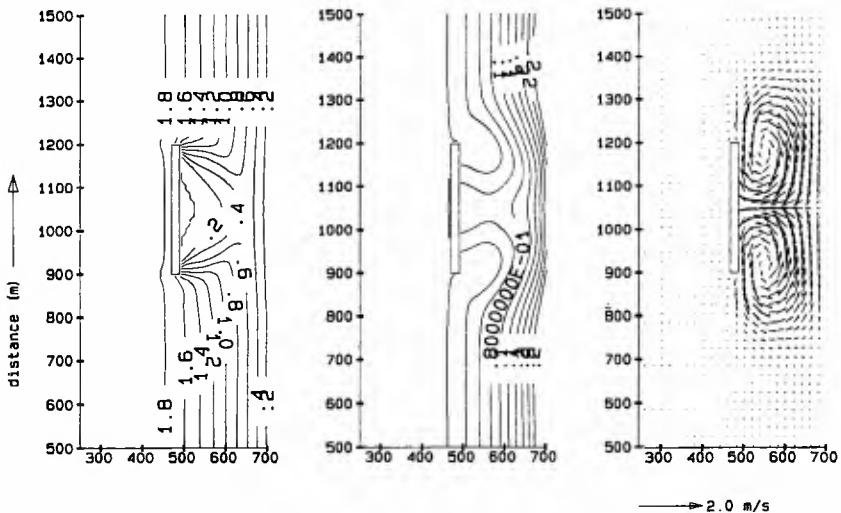

Figure 3 Left: Initial wave pattern; middle: Initial water level; right: Initial flow pattern.

The waves penetrate into the sheltered area as a result of diffraction. Although wave diffraction is not accounted for in HISWA its effect is limited in view of the wide directional

spreading used. Comparison of HISWA and a parabolic model by DHI (Johnson et al., 1994) showed that HISWA yields less wave activity and induced current behind the breakwater. However, these differences are partly due to the directional spreading accounted for in HISWA (and not in the parabolic model) since directional spreading has a smoothing effect on the wave and current field.

The isolines plot of the wave height shows that the breakwater is placed in the breaker zone which extends over about 300 m. As a result of the difference in wave height in longshore direction a water level gradient is present which generates two circulatory cells in the lee of the breakwater. These gyres have high current velocities up to 0.88 m/s at the breakwater tips which are able to transport sediment towards the lee of the breakwater (Figure 4).

Figure 4 Left: Initial sediment transport pattern; right: Sediment transport pattern after 200 hours.

The situation after 200 hours of wave action is shown in the right part of Figure 2. From this Figure it can be expected that a tombolo will be formed in the lee of the breakwater. At each breakwater tip a large scour hole develops. The sediment transport pattern after 200 hours is shown in the right part of Figure 4. Due to the formed tombolo in the lee of the breakwater the gyres are migrated towards the exposed area. The same happens to the sediment transport field which in the Bijker formula depends strongly on the flow pattern.

Oblique incident waves

If the waves are arriving at an angle to the shore a wave driven longshore current is present. In the left part of Figure 5 the initial flow field is shown. The longshore current reaches values up to 0.5 m/s. In the lee of the breakwater two gyres are generated but at the up-stream side this gyres is very much smaller and weaker compared to the down-stream gyre. The sediment transport related to this flow field is shown in the middle part of Figure 5. Sediment is trapped into the lee of the breakwater at the up-stream side by the longshore current while erosion occurs at the down-stream breakwater tip due to the strong current velocity of combined gyre and longshore current.

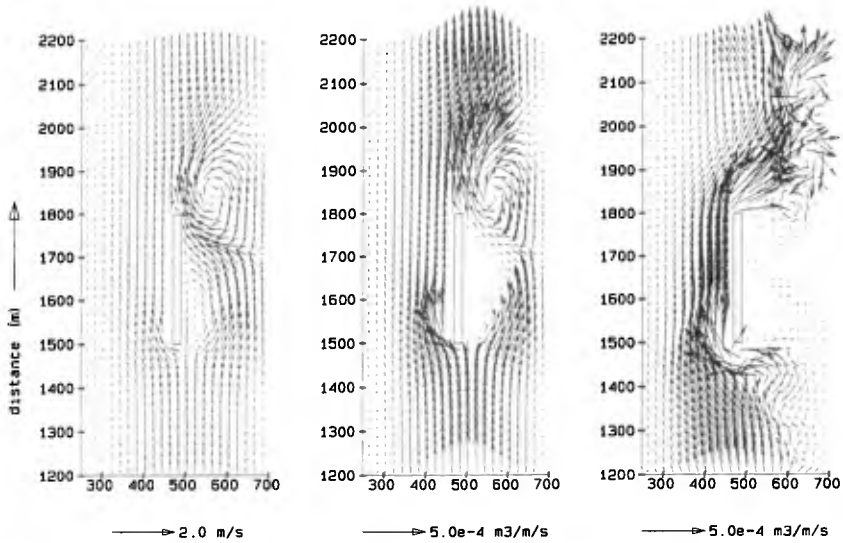

Figure 5 Left: Initial flow pattern; middle: Initial sediment transport pattern; right: Sediment transport pattern after 40 days.

Figure 6 shows the bathymetry after 200 hours and after 40 days respectively. Sediment is trapped into the lee of the breakwater forming a tombolo while a scour hole is generated at the down-stream breakwater tip. However, after some time the up-stream bathymetry is reshaped by the blocking of the sediment transport resulting in natural by-passing. This is shown in the right part of Figure 5. Almost all sediment passes the breakwater at the seaward side of the breakwater filling the scourhole at the down-stream side which result in a migrating scour hole in down-stream direction.

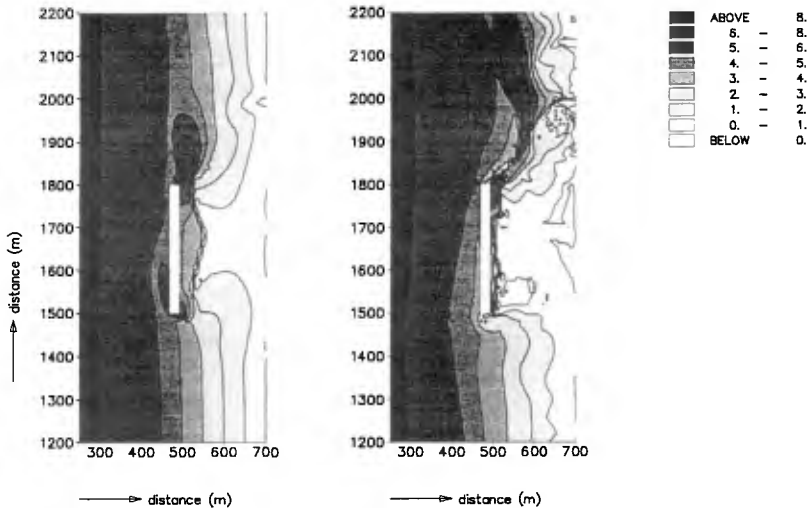

Figure 6 Left: Bathymetry after 200 hours; right: Bathymetry after 40 days.

Finally, the deposition in the lee of the breakwater is shown in Figure 7 for both normal and oblique incident waves.

Figure 7 Deposition behind the breakwater.

5. Q3D model

Within the DELFT3D model the transport formula of Van Rijn/Ribberink is used. The transport formula of van Rijn/Ribberink contains a Q3D approach of the nearshore flow pattern. The depth-averaged flow being the result of the TRISULA computation serves as input for a Vertical Structure Model (VSM). This VSM computes the vertical distribution of the horizontal flow velocity components including wind and wave effects and the orbital velocity. The local flow and orbital velocity as computed by the VSM are subsequently used for the prediction of the sediment transport.

Mean current profile
